[1]Dept. of Chem., Keio Univ. Sch. of Med., Yokohama-shi, Japan; [2]Dept. of Physiol., Keio Univ. Sch. of Med., Shinjuku-ku, Tokyo, Japan; [3]Keio Girls Senior High Sch., Minato-ku, Tokyo, Japan; [4]Dept. of Immunol., Kanazawa Univ. Grad. Sch. of Med., Kanazawa-shi, Japan

**Abstract:** Musashi is an evolutionarily conserved family of RNA-binding proteins that is expressed in the nervous system. In *Drosophila*, this protein plays an essential role in regulating the asymmetric cell division of sensory organ precursor cells through the translational regulation of target mRNA. Its mammalian homologue, Musashi-1, is a neural RNA-binding protein that is expressed in fetal and adult neural stem/progenitor cells (NS/PCs). Transcripts of *m-numb* and *p21$^{waf1}$* were identified as target of Musashi-1, and were repressed their translation by Musashi-1. Previously we reported Musahi1 also interacts with Lin-28 and down-regulates mir98 miRNA processing. Recently, we found that Musashi1 directly and specifically bound to mature *let-7* microRNA *in vitro* and *in vivo*. Their sequences are highly conserved among many species from *Drosophila*, *C. elegans* to human. The *let-7* function is known as translational repression of downstream target gene through Ago2-containing RISC (RNA induced silencing complex). In mammalian cells, *myc*, *ras*, and *hmga2* are known as targets of *let-7* miRNA. We measured *let-7* activities in various cells by using combinatorial Luciferase reporter containing *let-7* complementary sites. As a result, in Msi1-positive human NS/PCs and mouse P19 EC cells, *let-7* activities were relatively low. However, they were relatively high in Msi1-negative cell or the cell that Msi1 content was low. Interestingly, ectopic Msi1 expression in the Msi1-negative cells reduced *let-7* activity. Collectively, in NS/PCs, Msi1 co-existing with Ago2 complex is likely to regulate the activity of *let-7* miRNA at both *let-7* biogenesis and post processing level.

**Abstract:** Nutritional deficiency during pregnancy leads to intra-uterine growth deficiency, affecting the development of fetal cells especially those of the central nervous system. Myelination defect is a common feature of fetal growth restriction in maternal undernourishment, due to a deficit of myelination and a disturbance of oligodendroglial maturation induced by: arrested maturation of the oligodendroglial lineage, increased apoptosis of immature oligodendrocytes, and decreased proliferation of oligodendrocyte progenitors. However, the molecular mechanisms that underlie these phenotypes remain unknown. The mirnome and chemotactic transcriptome of white and grey matter of male pups with intrauterine undernourishment was analysed by qPCR using TLDA technology and individual Taqman probes, the differences were compared to intrauterine well nourished male pups. We found that intrauterine undernourishment decreased the expression of: rno-miR-31a-3p ($p = 0.043$), rno-miR-30d-3p ($p = 0.04$), rno-miR-27a-5p ($p = 0.04$), rno-miR-34b-3p ($p = 0.036$), rno-miR-34c-3p ($p = 0.037$), rno-miR-219a-3p ($p = 0.033$), rno-miR-224 ($p = 0.0224$) and rno-miR-449a-5p ($p = 0.006$) and increased rno-miR-1274a ($p = 0.008$) and rno-miR-10a# ($p = 0.005$) in the white matter, these changes correlate with the gene transcription increase of: IGF-1, BDNF, CXCL13, CXCL12, CCL4, CXCR4, CCR2, NOS1, NOS3, SOD1, SOD3 and decreased of the CXCR5, NOS2 and CCR8 transcription. While in the gray matter the transcription of: GDNF, CCR8, SOD3, NOS2 and SOD3, increased, and the transcription of: NFκB, NGF, IGF1, FGF2, VEGF, CCL4, CXCL13, CCR2, CXCL3, CXCL2, CXCR5, SOD1 and SOD2 decreased. These results show that the mirnome dysregulation is the main target of intrauterine undernourishment causing the development of myelination defects. This study highlights the role of mirnome in the regulation of proliferation, development and chemotaxis of the oligodendrocytes.

**Abstract:** Neurogenesis is a basic process occurring during embryonic development that proceeds throughout the adult life in the neurogenic areas, such as subventricular zone and the subgranular zone of the dentate gyrus in the hippocampus. Similar with neurogenesis, the vascular system develops during embryogenesis and continues in the adult dentate gyrus. In addition, neurogenesis and angiogenesis share molecular signals and are mutually promotive. These parallel and depending processes support the concept of neurogenic niche in the brain which proposes a functional unit between the precursor cells and their local microenvironment. Neural stem cells (NSCs) in the neurogenic areas proliferate in groups close to the perivascular space where their self-renewal and differentiation is regulated. Hippocampal neurovascular regulatory system include both diffusible signals and direct contact with endothelial cells and pericytes.,These microenvironmental niche signals include a number of growth factors such as

vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF, also called FGF2). Previous studies suggested that both vascular cells and glial cells may serve as a niche for NSCs. Since both cell types express VEGF and bFGF, these two growth factors may serve as niche signals for NSCs. In the hippocampus, VEGF stimulates the expansion of NSCs and neurogenesis. There are a number of observations suggesting that bFGF may also modulate neurogenesis. It has been reported that knocking out bFGF during critical periods of brain development produces a decrease of neural proliferation and subsequent neuronal differentiation. Interestingly, hippocampal neural precursors express Fgfr1, the major receptor for bFGF and its absence leads to a decrease in neurogenesis accompanied by a severe impairment of long-term potentiation and memory consolidation. We propose to describe the neurogenesis and angiogenesis crosstalk in the dentate gyrus of Fgfr1 mutant mice. In order to address it, we focused on pericytes and endothelial cells to detect vascular abnormalities due to decrease of neural proliferation in this mouse model. We are interested in asses of the potential role of VEGF and bFGF to test the hypothesis that these molecules coordinately regulate the hippocampal neurovascular niche.

**Title:** An embryonically expressed 40kD Carboxypeptidase E variant regulates gene expression and neuronal proliferation

**Authors: *L. XIAO**, X. YANG, Y. LOH
Section On Cell. Neurobiology, NICHD, NIH, Bethesda, MD

**Abstract:** Carboxypeptidase E (CPE), first identified as a prohormone processing exopeptidase, exerts its function by cleaving C-terminal basic residues from peptide hormones. In addition to its enzymatic function, CPE also known as neurotrophic factor-α1, plays an important role in neurodevelopment as a stem cell differentiating factor (Selvaraj et al,2017) and has neuroprotection activity, independent of its enzymatic activity (Cheng et al, 2013). Previous studies have reported a N-terminally truncated 40KD CPE variant, CPE-ΔN, which is highly expressed in embryonic mouse brain, and has neuroprotective activity in embryonic cortical neurons through up-regulation of FGF2 expression (Qin et al,2014). To determine the structure

of 40KD CPE-ΔN mRNA, Northern blotting, RACE assay and DNA sequencing were carried out. Surprisingly, we found that in addition to WT-CPE, there were three CPE-ΔN transcript variants in embryonic mouse brain. By DNA sequencing analysis the mRNA structure of these transcripts were determined, to be 2.0kb, 1.85kb and 1.54kb in size, of which the 1.85kb was the most abundant. Bioinformatics analysis revealed that the 1.85kb CPE-ΔN has a 1092bp open reading frame (ORF), encoding the 40KD CPE-ΔN protein (364 amino acid). The 1.85kb CPE-ΔN transcript was mainly expressed in the embryonic mouse brain with a peak of expression in E10.5 and then decreased after P1; in contrast, in adult organs such as liver, lung, heart and hippocampus, only WT-CPE was observed. Western blot showed similar pattern of changes of 40KD CPE-ΔN protein during embryonic development. To study whether 40KD CPE-ΔN has effects on regulating genes that are critical for embryonic neurodevelopment, we carried out a microarray analysis on HCC cells, a cancer cell line transfected with mouse CPE-ΔN plasmid. Death associated protein (DAP), Ephrin A1 (Efna1), insulin-like growth factor binding protein 2 (IGFBP2), and Eukaryotic translation initiation factor 4 G (ELF4G) mRNA were up-regulated and they were selected for further study. qRT-PCR results confirmed that transfection of 40KD CPE-ΔN into HT22 cells, a hippocampal cell line induced an increase in DAP, EFNA1, IGFBP2 and ELF4G transcription significantly. MTT assay showed 40 KD CPE-ΔN enhanced the proliferation of HT22 cells. These findings indicate a function of 40KD CPE-ΔN on gene regulation and neuronal proliferation and hence an important player in embryonic neurodevelopment.

**Abstract:** Exposure to prenatal stress (PS) and mutations in *Gad1*, which encodes the GABA synthesizing enzyme glutamate decarboxylase (GAD) 67, are both risk factors for psychiatric disorders. In addition, disturbance of PV-positive GABAergic interneurons in the medial prefrontal cortex (mPFC) and hippocampus (HIP) has often been observed in schizophrenia and autistic patients. To elucidate their relationship, we examined GAD67-GFP knock-in mice ($GAD67^{+/GFP}$) that underwent PS from embryonic day 15.0 to 17.5. Administration of BrdU revealed that neurogenesis of GABAergic neurons was significantly diminished in fetal brains during PS. Postnatally, the density of PV-positive, but not PV-negative, GABAergic neurons was significantly decreased in the mPFC, HIP and somatosensory cortex of $GAD67^{+/GFP}$ mice. By contrast, neither wild type (WT) litter mates underwent PS nor naive $GAD67^{+/GFP}$ offspring showed these finding, suggesting that PS in addition to *Gad1* anomaly could specifically disturb the proliferation of neurons destined to be PV-positive (Uchida et al., *Transl. Psychiatry* 2014). Interestingly, comparison of behavioral tests in 4 groups (i.e., WT-PS, WT-naive, $GAD67^{+/GFP}$-PS, $GAD67^{+/GFP}$-naive) indicated anomalous phenotypes only in $GAD67^{+/GFP}$-PS, supporting above hypothesis. Then we are interested in how the double hits by PS and *Gad1* heterologous deletion affected neurogenesis and behavior. We found multiple genes related to neurogenesis and/or neural migration were either hyper-methylated or hypo-methylated in $GAD67^{+/GFP}$-PS. So we have examined expressional alterations of those genes by means of microarray analysis. We also found expression of fukutin (*Fktn*) responsible for Fukuyama type congenital muscular dystrophy was suppressed. Since fukutin glycosylates α-dystroglycan (α-DG) which is associated with GABAergic synapses, we examined glycosylation of α-DG and found it decreased. α-DG is reported to promotes plasticity of GABAergic synapses, so that we examined GABAergic IPSCs. We found that frequency of miniature IPSCs were significantly decreased in the mPFC. These findings may provide new insights into underlying mechanisms of the pathogenesis of psychiatric disorders.

**Title:** Tissue-specific regulation of gene expression by Pax6 in the developing mouse forebrain

**Authors: *Z. KOZIC**, I. QUINTANA-URZAINQUI, D. J. PRICE
Ctr. for Integrative Physiol., Univ. of Edinburgh, Edinburgh, United Kingdom

**Abstract:** The development of complex forebrain structures is under the strict regulation of multiple molecular networks, which are controlled by a relatively small group of transcription factors. During embryonic development, the forebrain vesicle expands to form two telencephalic vesicles which surround the inner structure, the diencephalon. In later stages the telencephalon will form the cerebral cortex and basal ganglia, while the most notable diencephalic structure is the thalamic complex.
Pax6 is a high-ranking, pleiotropic transcription factor with an important role in the development of the neural system. It is a member of the Paired-box (Pax) family of transcription factors, known for containing both a paired domain and a homeodomain. Because of its key role in multiple processes in neural development, Pax6 has become one of the most studied members of the Pax family. Such processes include neurogenesis, neural patterning and differentiation, cell migration and axon growth and guidance. Pax6 mutations are known to cause aniridia in humans and the small eye phenotype in mice, where defects in forebrain structures and failure in forming thalamocortical connections have been observed. Therefore, its activity is well studied in the eye and the cortex, but little is known about its exact regulatory role in the diencephalon, where high levels of Pax6 expression have also been reported, especially in the prethalamus.
We performed a series of RNA-sequencing experiments coupled with computational analysis to detect genome-wide changes in gene expression in the developing cortex and diencephalic tissues after acute, tamoxifen-induced deletion of Pax6, and we identified a large number of genes with significantly altered expression levels after Pax6 deletion. Comparison of these effects across the cortex, prethalamus and thalamus has shown a major contrast in the direction of differential expression between the cortex and diencephalic tissues. The enrichment analysis of functional terms and pathways has shown a similar pattern, with groups of genes involved in certain processes being regulated in opposite directions between the cortex and the diencephalon. One example is the cell cycle where, after deletion of Pax6, many genes are upregulated in the cortex while a significant number of genes experience downregulation in the diencephalon. We present our findings, providing insight on how highly conserved transcription factors can exert their regulation in different, context-specific ways.

**Title:** The sole role of PRPS-1 in the regenerative processes after experimental stroke

**Authors: *K. DANIELYAN**[1], R. D. VARDANYAN[2], A. SIMONYAN[3], A. S. SAGYAN[2]
[1]H. Buniatian Inst. of Biochem., Yerevan, Armenia; [2]YSU, Yerevan, Armenia; [3]H Buniatian Inst. of Biochem., Yerevan, Armenia

**Abstract: Background.** Phosphoribosylpyrophosphate synthetase-1 (PRPS; EC 2.7.6.1) is the widely distributed in the human tissues and servs as a regulative key enzyme for purine metabolism (Becker and Kim, 1987), whereas Xanthine Oxidase (XO; EC 1.1.3.22) is the enzyme responsible for the catabolism of purine nucleotides and might coordinate by feed-back mechanism this entire biochemical pathway (Danielyan, K.E., 2011). We proposed, activation of PRPS-1 and simultaneous inhibition of XO might initiate regenerative processes after stroke. **Methods.** We have used hydrogen peroxide intracranial injection (3%) as the model for the ROS generation phase of stroke development. XO activity was measured by evaluation of uric acid formation. PRPS-1 was measured by the kit (Novocib, France). BBB (Blood Brain Barrier) integrity was evaluated by utility of Evans Blue. ANOVA one way analysis was used for evaluation of statistical significance of the results. KI-67 was used for detection of cells proliferation in the specific areas. **Results.** PRPS-1 activity after stroke in rats was stimulated by phosphates (control; 1.9145±0.0400 vs phosphates treatment 6.6304±0.0500 vs allopurinol treatment 1.6921±0.0359, $p<0.05$). In phosphate treated group in comparison with the control XO activity was lower (control; blank - 0.6406±0.0378; substrate - 0.8513±0.1527; phosphate treatment group blank - 0.2500±7.5758e-3 vs substrate 0.3314±0.0625; allopurinol treated group: blank - 0.5549 ±8.1301e-3 vs substrate 0.5786±0.017). Ki-67 incorporation was more pronounced in phosphate treated group in comparison with the control. BBB disruption was less in experimental vs control group. **Conclusion.** Phosphates are proposed to be used as the poststroke regenerative agents.

**Title:** Enhanced Nrf2 expression improves neural stem cell function during a critical aging period

**Authors: *A. ANNADURAI**[1], M. J. CORENBLUM[1], S. RAY[2], K. KIRWAN[2], A. REED[2], C. A. BARNES[3], L. MADHAVAN[1]
[1]Dept. of Neurol., [2]Neurosci. and Cognitive Sci. Undergraduate Program, [3]Departments of Psychology and Neurosci., Univ. of Arizona, Tucson, AZ

**Abstract:** Our recent studies have examined the function of rat subventricular zone (SVZ) neural stem and progenitor cells (NSPCs) during aging. This work indicates that although NSPC function continuously declines with advancing age, there is a critical time period during middle-age (13-15 mos) when a prominent reduction in NSPC survival, regeneration, and associated behavioral function (fine olfactory discrimination), occurs. We also find that this specific temporal pattern of NSPC deterioration is mediated via the reduced expression of the redox-sensitive transcription factor nuclear factor (erythroid-derived 2)-like 2 (Nrf2). Based on these data, in this study, we investigated whether increasing Nrf2 expression could potentially mitigate the decline in NSPC function across the identified critical middle-age period. First, we generated recombinant adeno-associated viral (rAAV2/1) vectors, to overexpress Nrf2 within endogenous NSPCs in the aging SVZ niche, and characterized their efficiency. Subsequently the Nrf2 vectors (or eGFP vectors as controls) were administered into the SVZs of aging rats, at time-points either before or after the critical period. Results indicate that animals that had received rAAV2/1-Nrf2-eGFP, before the advent of the critical middle-age period (at 12 mos), exhibited substantially improved fine olfactory discrimination abilities in comparison to animals receiving the control rAAV2/1-eGFP virus. Striatal function, measured via a beam task, was also enhanced in the Nrf2 overexpressing animals compared to controls. Additionally, histological analysis revealed that NSPC survival, proliferation, and neurogenesis in the SVZ had significantly increased upon Nrf2 overexpression. Early data also show greater NSPC migration through the rostral migratory stream, and their subsequent integration into the olfactory bulb, in Nrf2 overexpressing rats. On the other hand, Nrf2 overexpression in SVZ NSPCs after the completion of the critical period (at 21 mos) did not result in a significant improvement of NSPC activity at either cellular or behavioral levels. In summary, these data support Nrf2 pathway modulation as a potential

approach to enhance aging NSPC function, and have important implications towards developing stem cell-based therapeutics for age-related neurological disorders.

**Title:** Microglial cells intimately interact with multiple cell types in the proliferative zones of the fetal primate cerebral cortex

**Authors: *S. C. NOCTOR**[1], A. F. TARANTAL[2], N. BARGER[3]
[1]Psych & Behavioral Sci., UC Davis, Sacramento, CA; [2]California Natl. Primate Res. Center, Departments of Pediatrics, Cell Biol. and Human Anat., UC Davis, Davis, CA; [3]Univ. of California, Davis - MIND Inst., Sacramento, CA

**Abstract:** Microglia, the brain's immune cells, participate in normal developmental processes in the brain, in addition to immune functions. We have shown that microglia phagocytose neural precursor cells (NPCs), including radial glia and intermediate progenitor cells, in the fetal cerebral cortex. Our previous work identified microglia and NPCs by immunolabeling microglia with the Iba1 antibody, and NPCs with the cell specific antibodies Pax6 and Tbr2. Iba1 immunostaining labels the soma and processes of microglial cells, but Pax6 and Tbr2 label only the nuclei of NPCs. To better understand cellular interactions between microglia and fetal cortical cells, we labeled the entire cell body and cellular processes of fetal cortical cells with EGFP. We performed ultrasound guided *in utero* intracerebral injections of a lentiviral vector in fetal rhesus macaque on gestation day 85. Tissue was harvested 5 days later, brains sectioned at 100 microns, stained with cell specific antibodies (Radial glia: Pax6 and GFAP; Intermediate progenitor cells: Tbr2; Microglia: Iba1; Mitotic cells: 4A4; Cell nuclei: DAPI), and imaged with epifluorescent and confocal microscopes. In addition to phagocytosis, we find that microglial cells intimately contact radial glia. A single radial glial cell and its cellular processes are contacted by and enveloped by multiple microglia at several points between the ventricle and the pia. Microglia contact the soma and cellular processes of radial glia in all phases of the cell cycle, and make similar contacts with intermediate progenitor cells and migrating neurons. We

also show that individual microglia interact with more than one cell at a time: we observed single microglial cells phagocytosing and interacting with multiple cortical cells simultaneously. In addition, microglia exhibit unique morphological features that indicate a correlation with function. For example, microglial cells extend reticulated processes toward NPCs near the surface of the ventricle. The reticulated microglia appear to represent a specific subset of phagocytic cells. Given the multiple roles microglia play in both the immune response and postnatal neuronal development, our current findings expand the repertoire of microglial cells in monitoring, maintaining, and remodeling the neurogenic niche of the fetal primate cerebral cortex.

**Title:** A multimodal single-cell approach identifies intercellular signaling networks in the developing human neocortex

**Authors: *S. MAYER**, J. CHEN, D. VELMESHEV, U. EZE, B. ALVARADO, M. PAREDES, C. E. CUNHA, A. R. KRIEGSTEIN
Regeneration Med., Univ. of California, San Francisco, San Francisco, CA

**Abstract:** We have only just begun to understand the diversity of neural progenitor cells and the differentiation trajectories of postmitotic cells during human neocortical development. Recent advances in single-cell transcriptomics have identified novel molecular markers defining distinct cell types in the developing and adult neocortex. The combination of single-cell transcriptomics with the physiological firing patterns of neurons has revealed a larger diversity of neuronal cell types than previously appreciated. Even though classical synaptic signaling is absent during early stages of brain development, neurotransmitters nonetheless modulate critical aspects of neural progenitor cell proliferation and differentiation, as well as the migration and maturation of newborn neurons. Here we combine single-cell transcriptomics with physiological response characteristics of dissociated cells from the developing human cortex, to achieve a high dimensional characterization of the diverse cell types. We use a high-throughput method to

measure intracellular calcium dynamics in response to a range of neurotransmitters in single cells captured on microfluidic chips. Subsequently, the same single cells are processed for single-cell RNA sequencing. This novel approach enables us to link a cell's physiological response pattern to its molecular profile. We find that different molecularly identified cell types display differential responses to a panel of neurotransmitter receptor agonists and thereby uncover how response patterns change with cellular maturation and differentiation. Interestingly, progenitor cells in the germinal zone respond preferentially to the application of purinergic and serotonergic agonists, while postmitotic neurons in the cortical plate respond to the neurotransmitter receptor agonists that target glutamate and gamma amino butyric acid (GABA) receptors. Moreover, serotonergic receptor activation promotes the proliferation of progenitor cells in the late second trimester. The synthesis of the transcriptomic and physiological fingerprints of a cell allows us to start to decipher the signaling pathways that control the cell biology of different cell types in the developing human neocortex.

**Title:** JNK signaling is required for the directed migration of cortical interneurons

**Authors: *S. E. HICKLING**[1,2], A. K. MYERS[2], M. P. WILSON[2], E. S. TUCKER[2]

**Abstract:** During corticogenesis, inhibitory interneurons must migrate into the developing cortical plate, deposit in the correct cortical layer, and establish connections with their appropriate synaptic partners. Aberrant migration of inhibitory interneurons can alter the formation and function of cortical circuitry and lead to severe neurological disorders including epilepsy, autism and schizophrenia. Cortical interneurons travel tangentially in migratory streams to reach the cerebral cortex and then turn radially to exit migratory streams and invade the cortical plate. Our lab previously found that disruption of the c-Jun N-terminal kinase (JNK) signaling pathway results in a delayed entry of cortical interneurons into the cortex, as well as the premature departure of cortical interneurons from migratory streams. In the current study, we are using live-cell confocal microscopy to explore the mechanisms by which JNK activity

coordinates two cell biological processes that are essential for the guided migration of cortical interneurons: nucleokinesis and leading process branching. Nucleokinesis is a cyclical process whereby the cell bodies of migrating cortical interneurons translocate into a cytoplasmic swelling formed in their leading process. Our data shows that cortical interneurons treated with JNK inhibitor exhibit major deficiencies in nucleokinesis with smaller nuclear translocation distances, as well as shorter extensions of cytoplasmic swellings. These findings suggest that JNK plays a major role in the cellular control of migration through nuclear movement. On the other end of the cell, the leading process is a highly dynamic structure that extends and retracts branches in order to sense and respond to extracellular guidance cues that are located in the environment. Our preliminary data also suggest that JNK-inhibited cortical interneurons display longer leading processes, as well as fewer leading process branches. Together, these data indicate that JNK may be controlling nucleokinesis and branching dynamics to direct the migration of cortical interneurons. In future experiments, we will investigate upstream activators and downstream targets of JNK signaling that enable the guided migration of cortical interneurons. Ultimately, our results will improve our understanding of cortical development and hopefully provide novel insight into the etiology of cortical circuit disorders.

**Abstract:** The human cerebral cortex functions in a balance between excitation and inhibition. This balance is first established during embryonic development through proper generation, migration, and differentiation of both cortical excitatory neurons and inhibitory interneurons. Disruptions to these key developmental processes can impair cortical function and lead to diseases such as autism, epilepsy, and schizophrenia. During development, interneurons navigate their way through the cortical rudiment by integrating both intracellular and extracellular cues to direct their migration. Our lab has shown a role for the c-Jun N-terminal Kinase (JNK) signaling pathway in cortical interneuron migration. One of the three JNK genes, *Jnk1*, is required for

interneuron entry into the cortex and correct formation of migratory streams. In addition to *Jnk1*, we hypothesize that the *Jnk2* and *Jnk3* genes also play a crucial role in cerebral cortex formation. Accordingly, we developed a conditional triple knockout (cTKO) mouse model where *Jnk1* is deleted from interneurons in mice lacking both *Jnk2* and *Jnk3*. In the current study, we have analyzed *in vivo* cortices ranging from Embryonic Day 13.5 (E13.5) to Postnatal Day 0 (P0). At E13.5, cTKO interneurons are markedly delayed in their entrance into the cortex, have non-tangentially aligned processes, and have large gaps in their migratory streams. At E15.5, interneuron streams are dispersed, and interneurons form clusters in the intermediate zone and nascent cortical plate. In addition, disruptions to cortical excitatory neurons and radial glial scaffolding have also been observed. Cortical excitatory neurons are incorrectly positioned in the developing cortex. Nestin labeling indicates that radial glial end feet are often detached from the pial surface, and their basal processes are frequently misaligned. At P0, disruptions are seen to both interneurons and excitatory neurons. cTKO interneurons have migratory morphologies with radially aligned processes and do not appear to laminate correctly. Additionally, cTKO brains have enlarged ventricles, and a more compact layering of lower-level excitatory neurons. Through further characterization of the cTKO cortex, we will further define the roles of the three JNK genes in excitatory and inhibitory neuron development. Deciphering the genetic regulation of cortical development will help uncover potential causes of neurodevelopmental disorders that impact the assembly and function of cortical circuitry, and can ultimately lead to better treatment of these devastating diseases.

**Abstract:** We recently described that meningeal cells are able to migrate to the posterior cortex in the postnatal period, and differentiate into functional neurons that express the marker Satb2. These meningeal neurogenic cells belong to the PDGFRβ$^+$ lineage. By single-cell RNA sequencing analysis, we found in meninges the presence of radial glia-like cells and neuronal cells, and a cell type with an intermediate phenotype representing radial glia-like meningeal cells in their differentiation process (Bifari et al., 2015; Bifari, Decimo et al., 2017). However, whether neurogenic radial glia-like meningeal cells and newly added meningeal-derived postnatal neurons are maintained during aging is not known.With this work, we aimed to investigate the presence of radial glia-like cells in meninges in aging mice and the long-term survival of migrated meningeal cells in the upper layers of the brain cortex. We analysed the expression of the radial glia marker Glast in the meninges of 8, 24 and 40 weeks old mouse brains. We found Glast$^+$ cells in meninges of all analysed stages. At 8 and 24 weeks, Glast$^+$ cells represent ~15-17% of the meningeal cells, while their expression slightly decrease during aging (~12% at 40 weeks).Moreover, meningeal-derived cells in the brain cortex survived up to 1 year after meningeal labelling at P0, showed a similar phenotype compared to meningeal derived neurons in young mice and expressed the neuronal marker Satb2 (~52%). This study underlines the importance of meningeal-derived neurons in aging brain cortex, opening new questions about their role and their functions in the adult/aged brain in health and disease.

**Title:** Redox dysregulation in the effects of prenatal stress on GABAergic progenitor migration in embryonic brain

**Authors: *J. BITTLE**, H. GION, K. MAPUSKAR, M. MCCORMICK, M. DAILEY, D. SPITZ, H. STEVENS
Univ. of Iowa, Iowa City, IA

**Abstract:** Stress experienced by the mother during pregnancy is associated with an increased risk of psychiatric disorders in her offspring, but the cellular mechanisms by which prenatal stress (PS) affects the developing brain have yet to be identified. Our lab has shown that PS disrupts inhibitory neuron migration and subsequent maturation. The disruption of inhibitory neural circuitry during fetal development can have crucial, long-lasting consequences for neuronal function into adolescence and adulthood. The balance between oxidative and reductive processes is critical during rapid periods of cell growth and differentiation, so small changes in the level of reactive oxygen species (ROS) due to PS could have significant effects on developing GABAergic systems. We used four approaches to investigate redox imbalance as a mechanism for PS effects on GABAergic migration, utilizing a mouse model of repetitive restraint stress starting on embryonic day 12 (E12). First, the administration to pregnant dams of N-acetylcysteine, a common antioxidant supplement, during prenatal stress rescued delay of GABAergic interneuron migration *($p < 0.01$)*. Second, antioxidants were altered by PS in the brain of E13 embryos—thioredoxin reductase (Txnrd) and glutathione peroxidase (GPx). PS led to a decrease in Txnrd ($p$=0.06) enzyme activity level, but an increase in *Txnrd* gene expression ($p$=0.06), and a decrease in GPx *($p$=0.19)* enzyme activity level and gene expression ($p < .05$), suggesting alterations in redox balance. We also found changes in *Sestrin1* and *Sestrin3* gene expression levels. Third, dihydroethidium, a fluorescent indicator of the most common oxygen free radical, superoxide, was increased by 50% ($p$=0.06) in E13 brains of PS embryos, suggesting greater levels of ROS. Fourth, live imaging experiments of embryonic brain slice tissue are ongoing to explore how redox imbalance affects GABAergic cell migration. Using time lapse imaging, we are assessing direction and rate of movement of individual GAD67GFP+ neural progenitors in superficial and deep migratory streams from the medial ganglionic eminence into the neocortex, incubated in either standard artificial cerebral spinal fluid (aCSF) or aCSF with a pro-oxidant, hydrogen peroxide. These experiments together will elucidate the role of oxidative and reductive processes in the effects of PS on GABAergic interneuron migration. Redox dysregulation may play a significant role in the elusive mechanisms by which persistent cellular changes are induced in the developing brain by maternal PS. Knowledge of these mechanisms could lead to novel interventions for those at risk for psychiatric disorders.

**Abstract:** The proliferation and migration of cerebellar neurons and glia are critical to the correct establishment of cerebellar folia and lamina during development, as well as proper functioning of these circuits in adulthood. Previous studies have carefully described the development of nearly all types of cerebellar neurons and glia; however, less is known about pia-associated cells. Using wild-type rats and mice, as well as genetically-engineered mice, we provide novel anatomical data on pia-associated microglia of the cerebellum, which can be identified by several markers including Iba1 and Cx3cr1. Microglia are resident immune cells of the brain and derived from a macrophage lineage. We describe the density and morphology of these cells in the early postnatal cerebellum, a period when granule cells are actively proliferating and migrating. We also document the relationship between pia-associated microglia and malformations of cerebellar development. Namely, neuronal heterotopia consisting of granule cells that failed to migrate were associated with breaches in the pia and the absence of pia-associated microglia. Heterotopias were also characterized by changes in the morphology of Bergman glial fibers as well as in the distribution of proliferating and differentiating granule cells. Our data point to important interactions between pia-associated microglia, pial epithelial cells, Bergman glia, and granule cells in the development of cerebellar foliation and lamination.

**Title:** Drebrin regulates cytoskeletal dynamics in migratory GnRH neurons through interacting with CXCR4

**Authors: *Y. SHAN**, S. WRAY
NINDS, NIH, Bethesda, MD

**Abstract:** Movement of migrating neurons is regulated through rapid cytoskeletal modification (assembly/disassembly of actin filaments and microtubules) in response to guidance cues. However, the mechanism(s) by which guidance cues communicate to the cytoskeleton of migrating neurons remains unclear. GnRH neurons originate in nasal regions and migrate along olfactory sensory axons into the forebrain, where they regulate reproductive function. Numerous guidance cues ensure GnRH neurons reach their destination. Previous data indicates that: (1) stromal cell-derived factor 1 (SDF-1) via chemokine receptor type 4 (CXCR4) accelerates GnRH neuronal migration and, (2) capturing of microtubule plus ends to cortical actin in migrating GnRH neurons occurs via $Ca^{2+}$ dependent mechanisms. It is well known that during migration, cytoskeletal dynamics are regulated by cytoskeleton binding proteins. One binding protein, developmentally regulated brain protein (drebrin) has been proposed to directly interact with CXCR4 to promote actin polymerization at immune synaptic sites in T-cells and has been shown to interact with microtubule plus end binding protein EB3. Thus, drebrin is a promising candidate that may connect SDF1/CXCR4 signaling to cytoskeletal dynamics in migrating GnRH neurons. In the current study, drebrin was found to be robustly expressed along the cortical actin of migrating GnRH neurons, and was colocalized with the early expressed microtubule plus ending binding protein EB1. This expression pattern is consistent with drebrin guiding microtubule bundles into the actin cortex in migrating neurons. Confocal microscopy revealed colocalization of drebrin and CXCR4 in GnRH neurons, suggesting that communication between receptor and cytoskeletal regulator is through direct binding. Functional migration assays were performed using mouse nasal explants and pharmacological inhibition of drebrin by BTP2 (a CRAC channel blocker). Depending on the paradigm used, pre-treatment with BTP2 abrogated the effects of either CXCR4 agonists or antagonists, while not affecting migration driven via GABAARs. These data support an interaction between drebrin and CXCR4 and provide a mechanism by which guidance cues communicate to the cytoskeleton of migrating neurons.

**Abstract:** It is becoming evident that the properties of neural stem cells (NSCs) are highly heterogeneous depending on their locations and/or the developmental origin. A subset of posterior NSCs have recently shown to be derived from tail tip neuromesodermal progenitors (NMPs) which exhibit bipotential to produce either neural cells or mesodermal cells. Junctional neurulation is a unique developmental program where primary and secondary neurulation meets to shape a discrete region of the spinal cord. This transition zone of junctional neurulation is highly susceptible to neural tube defects. In vivo lineage tracing with TcreER2:Rosa-EGFP transgenic mice revealed that NMPs-NSCs born at E10 are confined to the secondary neural tube at the lumbosacral level that overlaps dorsally with primary neural tube to form the junctional neural tube. NMPs-NSCs born at E8 primarily contribute to spinal cord somatic sensory neurons. Interestingly, here we discovered that NSCs in the secondary neurulation regions is significantly adhesive and exhibit collective migration properties comparing to the NSCs in the primary neurulation region. And activation of Wnt/β-catenin signalling significantly altered primary neural tube-NSCs toward secondary neural tube-NSC-like phenotypes. These data illustrate that different adhesive properties of NSCs along with longitudinal axis of neural tubes may be implicated in the formation of junctional neurulation.

**Title:** Regulation of cortical principal neuron migration by KCC2

**Authors: *M. PUSKARJOV**[1], M. MAVROVIC[1], P. UVAROV[1], L. VUTSKITS[2], K. KAILA[1]
[1]Univ. of Helsinki, Helsinki, Finland; [2]Univ. of Geneva Med. Sch., Geneva, Switzerland

**Abstract:** The laminar organization of the cerebral cortex comes about as result of sequential migration of neurons in an inside-out manner. Migration defects emerge as a common denominator in a number of developmental brain disorders, including seizures and autism, however the cellular and molecular mechanisms at play are poorly known. The qualitative maturation of $GABA_AR$-signaling has been proposed to act as a regulator of neuronal migration rate. The ontogenetic shift from depolarizing to hyperpolarizing GABA signaling is mediated by up-regulation of KCC2, which lowers neuronal $Cl^-$ concentration. Notably, KCC2 is a

multifunctional protein which, in addition to its role as a K-Cl cotransporter, interacts with the actin cytoskeleton in an ion transport-independent manner. Up-regulation of KCC2-mediated $Cl^-$ extrusion has been shown to regulate interneuron migration, but it is not clear whether and how KCC2 might affect principal neuron migration. Using $KCC2^{-/-}$ constitutive knockout mice we first demonstrate that global loss of this neuron-specific protein does not perturb gross cortical lamination. Then, using *in utero* electroporation of cre-recombinase in conditional $KCC2^{lox/lox}$ mice to achieve specific ablation of KCC2 in a subpopulation of migrating somatosensory principal neurons, we show that loss of KCC2 results in marked acceleration in the rate of migration of these cells. Our preliminary data suggest that this effect is rescued by co-electroporation of cre together with either wildtype KCC2 or a transport-inactive KCC2 variant that retains cytoskeletal interaction. Our data suggest a novel ion transport-independent role for KCC2 in controlling the migration rate of cortical principal neurons.

**Title:** Ephrin-B expression in inhibitory neurons controls cortical excitatory-inhibitory homeostasis and seizure activity

**Authors: A. TALEBIAN**, R. BRITTON, S. AMMANUEL, J. R. GIBSON, *M. HENKEMEYER
UT Southwestern, Dallas, TX

**Abstract: Introduction.** Excitatory-inhibitory (E/I) homeostasis is crucial for normal brain function and disruption of this balance is related to numerous psychiatric disorders associated with seizures. Several studies demonstrate the importance of EphB receptor tyrosine kinases and their transmembrane ephrin-B ligands in excitatory neurons and their synapses. However, the contribution of ephrin-B/EphB interactions in inhibitory neurons is largely unknown. Here we describe roles for ephrin-Bs in early migration of inhibitory neurons into the cortex and find how they help establishing normal populations of interneurons and E/I homeostasis in the brain. **Methods.** Using conditional triple mutants (TM) and an inhibitory neuron specific Cre driver (Dlx1/2-Cre), we selectively deleted the three ephrin-B genes and assessed seizure activity, cortical excitability, and interneuron migration and population into the cortex and hippocampus.

Our analysis was aided by a Rosa26-stop-tdTomato reporter of Cre activity and GAD65-GFP and GAD67-GFP reporters of the two main subtypes of inhibitory neurons. In addition to TM+Cre mutants, the involvement of ephrin-B reverse signaling was assessed using intracellular truncation and point mutant mice. **Results.** TM+Cre and EB2/EB3 reverse signaling mutants exhibited audiogenic seizures and increased cortical excitability as measured by electrophysiological recordings of up states. Morphological analysis demonstrated reduced migration of cortical/hippocampal interneurons in development (E13.5-E15.5) and reduced populations in adult brains. **Conclusion.** Our data indicate inhibitory neuron expressed ephrin-B proteins and their interactions with EphB receptors are critical for normal tangential migration of interneurons in the developing brain. They further show that loss of these molecules affects E/I homeostasis and leads to cortical hyperexcitability.

**Abstract:** Neural crest cells migrate extensively to form the autonomic nervous system including sympathetic, parasympathetic and enteric ganglia essential for regulating bodily homeostasis. Our previous work demonstrated that parasympathetic ganglia derive from Schwann cell

precursors (SCPs) and migrate along their preganglionic nerves to locate close to their target tissues (Espinosa-Medina et al., 2014). SCPs were previously known to give rise to melanocytes, endoneurial fibroblasts and dental mesenchymal cells as well as Schwann cells in vivo, and our study extends their fate to neurons. More recent evidences suggested that enteric ganglia, which innervate the gastrointestinal tract, might also derive from SCPs and my present work focuses on this subject. Most of the enteric nervous system is known to derive from the neural crest that lies at the level of somites 1 to 7, classically designated as the "vagal crest". These crest cells invade the digestive tract in a rostro-caudal wave of migration from the foregut to the hindgut in ways that have been extensively studied. In contrast, remarkably little is known about the initial phase of this colonization, that brings enteric precursors into the foregut, i.e. the esophagus and stomach. Here we show that the so-called "vagal crest" subsumes two populations of enteric precursors with contrasted origins, initial paths and modes of migration, and final destinations. Neural crest cells adjacent to somites 1 and 2 produce SCPs that colonize the esophagus and stomach, guided by the vagus nerve. Neural crest cells adjacent to somites 3 to 7 belong to the sympathetic crest: they enter a ventral pathway, seed the sympathetic chain, overshoot the aortas and colonize the entire digestive tract thence. Accordingly, enteric ganglia, like sympathetic ones, depend on signaling by Neuregulin-1 through the tyrosine kinase receptor ErbB3, while half of the esophageal ganglia, like parasympathetic ones, require the nerve-associated form of Neuregulin-1. The implication of the ErbB3 signaling system in the prenatal development of the enteric nervous system might bear relevance to Hirschprung disease, with which alleles of Neuregulin 1 were found associated.

**Title:** Effects of alcohol abuse on proliferating cells, neural stem cells and immature cells in the adult human hippocampus

**Authors: *T. WARDI LE MAITRE**[1], G. DHANABALAN[1], N. BOGDANOVIC[2], K. ALKASS[1], H. DRUID[3]
[1]Oncology-Pathology, [2]Dept. for Neurobio., Karolinska Institutet, Stockholm, Sweden; [3]Forensic Medicine, Karolinska Institutet, Stockholm, Sweden

**Abstract:** In animal studies, impaired adult hippocampal neurogenesis is associated with behavioral pathologies including addiction to alcohol. We hypothesize that alcohol abuse may have a detrimental effect on the neurogenic pool of the dentate gyrus in the human hippocampus. In this study we investigate whether alcohol abuse affects the number of proliferating cells, neural stem cells and immature neurons in samples from postmortem human hippocampus. The specimens were isolated from deceased donors with an on-going alcohol abuse, and from controls with no alcohol overconsumption. Mid-hippocampal sections were immunostained for Ki67, a marker for cell proliferation, Sox2, a neural stem cell marker and DCX, a marker for immature neurons. Immunoreactivity was counted in alcoholic subjects and compared to controls. Counting was performed in the three layers of dentate gyrus; the subgranular zone, the granular cell layer and the molecular layer. Our data showed reduced numbers of proliferating cells, neural stem cells and immature neurons in the dentate gyrus. This reduction was most prominent in the subgranular zone, and uniformly distributed across the distances from the granule cell layer. Further, alcohol abusers showed a more pronounced reduction of Sox2 positive cells than DCX positive cells, suggesting that alcohol primarily causes a depletion of the neural stem cell pool and that immature neurons are secondarily affected.
These results are in agreement with observations of impaired adult hippocampal neurogenesis in animal studies and lend further support for the association between hippocampal dysfunction and alcohol abuse.

**Title:** The role of Camdi during GnRH cell migration

**Authors: *H. CHO**
NIH/NINDS, Bethesda, MD

**Abstract:** In the developing nervous system, newly born neurons must correctly migrate from their place of origin to their final location to form proper neural circuits. Failure of neurons to properly self-assemble into functional circuits is thought to underlie a number of neurological disorders. To study molecular mechanisms controlling neuronal migration, the linkage between failure of gonadotropin-releasing hormone (GnRH) cell migration and a specific phenotype of Kallmann syndrome provides a model system with unique attributes to unravel steps controlling neuronal migration. Recently, we reported a novel mutation (p.R724X) in the *CCDC141* gene in Kallmann syndrome patients that also have a partial loss of function mutation in *FEZF1*. Since the *FEZF1* mutation showed 50% activity, we wondered whether the mutation in *CCDC141* was also involved in the phenotype. To study *CCDC141* in GnRH cell migration, Ccdc141 expression in mouse embryos was examined. We showed that 1) Ccdc141 was expressed in migrating GnRH neurons and that 2) knockdown of Ccdc141 using siRNA reduced GnRH neuronal migration but not olfactory axon outgrowth. To further investigate the role of Ccdc141 *in vivo*, we obtained *Ccdc141* KO mice and are analyzing the number of GnRH cells in the brain. Preliminary data indicate that *Ccdc141* KOs have only ~50% of GnRH cells as compared with WT mice. Further time points are being examined to determine the impact of loss of Ccdc141on GnRH cell migration and survival during development. Our new data from KO mice are consistent with Ccdc141 playing a role in GnRH cell migration. We are currently characterizing the effect of Ccdc141 on cytoskeletal dynamics and/or calcium flux in GnRH cells during the cell migration. This study will provide new insight regarding the role of Ccdc141 involved in neuronal cell migration and pathogenic mechanism of Kallmann syndrome.

**Abstract:** Cell migration is a dynamic, ATP dependent process, essential for brain development. The dynamic morphological remodeling of migrating cells leads to the formation of protein aggregates, organelle damage and plasma membrane leftovers. One of the intracellular catabolic pathways that maintain cellular homeostasis is autophagy. Here we evaluated the involvement of autophagy and its link to energy level in neuronal migration. We used rostral migratory stream of adult mice as a model and found that autophagy-related proteins are present in 60% of neuroblasts. Time-lapse imaging of autophagosomes labeled with GFP-RFP-LC3 shows an active autophagic flux with an increase in the density of autophagosomes during stationary phases. Pharmacological alteration of cell migration led to the changes in autophagy, by increasing the level of LC3 lipidated form (LC3-II) which is specifically associated with autophagosomes. This was accompanied by changes in the expression of focal adhesion (FA) molecules. On the other hand, genetic impairment of autophagy in neuroblasts either using inducible Atg5 KO mice or by CRISPR/Cas9 technology targeting ULK1 and ULK2 decreased the distance of cell migration because of an increase in the percentage of stationary periods. The same deficit is observed when AMPK, an energy sensor and autophagy activator, is blocked by CompoundC, hinting a role of energy levels in autophagy activation. Energy monitoring by live imaging in neuroblasts, using PercevalHR, a ratiometric sensor of ATP/ADP, shows a decrease of energy during migratory phases and an increase during stationary periods. This result, correlated with an increase in autophagosomes during stationary periods, reinforces the link between energy and autophagy. We next asked if the level of autophagy is also altered in some neurodevelopmental disorders resulting from affected neuronal migration. Individuals suffering from a form of neuronal periventricular heterotopias have mutations in genes encoding cadherin ligand (Dchs1) and receptor (Fat4). We first determined the expression of autophagy-related proteins in human organoids derived from neural progenitor cells (NPC) of healthy individuals and subjects with mutated Fat4 and Dchs1 genes. We observed a striking change in the LC3-II as well as in the expression of FA molecules. Graft of human NPC into mouse postnatal neurogenic regions also revealed alterations in cell migration of cells derived from subjects with Fat4 and Dchs1 mutations. Altogether, we show that autophagy may be activated because of energetic needs and is required for cell migration under normal and pathological conditions.

**Title:** New neuronal migration: Spatial distribution in the Nidopallium Caudale (NC) of the adult avian brain

**Authors: *M. A. ATAMNA**[1], A. HEFETZ[2], A. BARNEA[3]
[1]Tel-Aviv Univ., Tel Aviv-Yafo, Israel; [2]Zoology, Tel-Aviv Univ., Tel-Aviv, Israel; [3]The Open Univ. of Israel, Raanana, Israel

**Abstract:** This study engages with the process of neurogenesis in adult birds, in which new neurons are born in the ventricular zone, and then migrate over long distances to other brain regions. We investigated the patterns of such migration process of the new neurons in brains of male zebra finches *(Taeniopygia guttata*) using BrdU treatment and recording, quantitatively and spatially, their distribution neurons in the Nidopallium Caudale (NC) at several time points after their birth: 7, 21, 35, and 42 days.
In birds, the NC is a brain region in the telencephalon that consists of three sub-regions: **Nidopallium caudalomediale** (NCM) - is important for song perception and discrimination, storage of auditory memories, and is analogous to supragranular layers of the auditory cortex of mammals. **Nidopallium caudolaterale** (NCL) - is an associative region that is important for cognition, and has a role in working memory, decision-making behaviors (including those required for judgments of numerical ability, reversal learning, and reward prediction), and is considered functionally equivalent to the prefrontal cortex in mammals. **Nidopallium caudocentral** (NCC) - is involved in neuroendocrine and autonomic functions and is limbic in nature.
Overall, density of new neurons in the NC did not show age-dependence changes, but varied significantly between its sub-regions. A higher percentage of new neurons occurred in the NCM, compared with the two other sub regions (NCC and NCL), at all the time points, even though NCM is the smallest sub-region. In addition, NCC and NCL exhibited similar levels of neuronal recruitment. This non-random spatial distribution of new neurons in the NC suggests that its sub-regions differ in their amount of plasticity. The greater plasticity of NCM might further imply that song perception and discrimination in male zebra finches require higher rates of neuronal turnover, compared with the functions that are processed in the two other sub-regions. This differential neuronal plasticity within the NC supports the previously suggested division of this large brain region, which is based on connectivity patterns, dopaminergic innervations, and induction of ZENK.

**Abstract:** Paxillin, Hic-5 and leupaxin are homologous focal adhesion adaptor proteins that coordinate cytoskeletal rearrangements in response to integrin-signaling and changing extracellular environments. Leupaxin is not expressed in the brain cortex while Hic-5 null mice have no described cortical phenotype and paxillin null mice die prior to brain development. Thus, the function of this family of proteins during cortical development is unknown. Here, we find that Hic-5 deficient mice are postnatal viable with normal cortical layering. Mice with a neural-specific deletion of paxillin (*Nes-Cre:Pxn$^{F/F}$*) are also postnatal viable, but show evidence of a cortical neuron migration delay that is evident pre and perinatally, but is not detected at postnatal day 35 (P35). This phenotype is not modified by Hic-5 deficiency (double knockout). Specific deletion of paxillin in postmitotic neurons (*NEX-Cre:Pxn$^{F/F}$*) also causes the migration delay, suggesting a requirement for paxillin in actively migrating neurons. *In utero* electroporation of a Cre-expression construct into *Pxn$^{F/F}$* embryonic cortex identified a cell-autonomous requirement paxillin and revealed that paxillin-deficient migrating neurons have significantly shorter leading processes that exhibited multiple swellings in comparison to control. Multiphoton imaging of cortical explants reveals that paxillin-deficient neurons migrate 30% slower than control neurons. This morphological phenotype is similar to the reported phenotype produced by conditional deletion of focal adhesion kinase (FAK), a critical signaling partner of paxillin and suggests that paxillin functions with FAK in a cell-autonomous manner, to control the morphology and speed of migrating neurons during cortical development.

**Abstract:** How neurons undergo multipolar-to-bipolar transition (MBT) in the upper intermediate zone (IZ) to migrate radially towards the cortical plate remains unclear. Reelin-induced tyrosine phosphorylation of Disabled-1 is essential for radial migration. We have previously shown that alternative splicing produces multiple Dab1 isoforms with different tyrosine motifs and differential ability to recruit downstream effectors. Here we report that splicing of exons 7&8 and 9bc occurs in a mutually-exclusive fashion in the IZ of the neocortex, dynamically regulating the inclusion and activities of Dab1 tyrosine motifs. Our *in utero* electroporation studies show that expression of Dab1 isoforms missing exons 7&8 or retaining exons 9bc in WT neurons delayed cortical neuronal migration with attenuated Dab1 tyrosine phosphorylation, and disrupted leading process extension and orientation of multipolar neurons in the multipolar accumulation zone (MAZ). Introducing the canonical Dab1 form, but not those missing exons 7&8 or retaining exons 9bc, into Dab1-deficient neurons promoted MBT and rescued neuronal migration defects, suggesting that alternative splicing of Dab1 modulates the tyrosine motif switch and mediates MBT of cortical neurons. Our study reveals a critical mechanism for coordinated control of Reelin-mediated neuronal migration at both pre- and post-translational levels.

**Abstract:** Migrating cortical neurons move through long, highly stereotypical paths until they reach their targets by detecting cues in the environment, thought to be gradients in the concentration of various neurotrophic factors. However, observed paths are rarely smooth curves, indicating that guidance is not fully deterministic. Understanding the stochastic events that underlie these migration patterns could lead to new insights for the study of development and connectivity of the cortex, and may help how migration occurs (or fails to occur) in the presence of intermittent and/or noisy cues. To that end, we conducted long time-lapse analysis of cortical GABAergic interneurons and projection glutamatergic neurons as the neurons navigated, either freely in a cell-dissociated milieu or in cue-oriented spaces in cell-culture dishes. Migration patterns were then extracted algorithmically and analyzed. For both types of neuron, with or without cues, we calculate the fractal dimension of the tracks, to determine their stochastic component, which was modelled as a random walk. We further measure track characteristic persistence length and correlation function, and the deterministic response to constant-gradient cues. We use this data to test a stochastic model that regards neuronal migration as the additive combination of these three effects , and look for evidence of interaction effects. We seek to further characterize the response to cue by isolating the deterministic response to varying-gradient cues.

**Abstract:** Cigarette smoking during pregnancy is a major public health concern because it can have detrimental effects on both the mother and her child. For example, developmental nicotine exposure (DNE) is associated with increased risk for ADHD, conduct disorder, learning disabilities, anxiety, epilepsy, and depression. The GABA neurotransmitter system is known to be altered in many of these developmental disorders raising the possibility that DNE may target the GABA system in the developing brain. During embryonic development, the majority of the GABA neurons originate in the medial ganglionic eminence of the basal forebrain and migrate tangentially to regions of the dorsal forebrain. Here we examined the effects of DNE on the GABAergic system during the embryonic period using a GAD67-GFP knock-in mouse model. In this model, GABA neurons are GFP+, facilitating their identification. Female mice were exposed

to plain drinking water or water containing nicotine (100 or 200 µg/ml) beginning 3 weeks prior to conception and throughout pregnancy. We found that DNE produces a significant increase in the number of GABA neurons in the intermediate and marginal zones of the dorsal forebrain in 15-day old embryos in both the nicotine groups, suggesting that DNE alters the GABA neuron migration from the basal to the dorsal forebrain. Since perturbation of developmental pathways can lead to lasting changes in the mature brain, ongoing studies are examining the effects of DNE on the number and location of GABA neurons in the mature brain.

**Title:** Differentiation of human induced pluripotent stem cell (hiPSC)-derived neurons in mouse hippocampal slice cultures

**Authors: *T. HIRAGI**[1], M. ANDOH[1], T. ARAKI[2], T. SHIRAKAWA[3], T. ONO[2], R. KOYAMA[1], Y. IKEGAYA[1]
[1]Grad Sch. Pharma Sci, Univ. Tokyo, Tokyo, Japan; [2]Discovery Technol. Labs., Mitsubishi Tanabe Pharma Corp., Saitama, Japan; [3]Res. Unit/Innovative Med. Sci., Mitsubishi Tanabe Pharma Corp., Kanagawa, Japan

**Abstract:** Potential clinical applications of neurons derived from human induced pluripotent stem cells (hiPSC-neurons) for drug screening and transplantation therapies have received considerable attention. However, it remains unclear whether and how transplanted hiPSC-neurons are incorporated into pre-existing neural circuits. Here we developed a co-culture system of hiPSC-neurons and mouse hippocampal slices to examine the differentiation of hiPSC-neurons in pre-existing neural circuits. hiPSC-neurons that were transplanted in the neuronal cell layers of hippocampal slice cultures expressed the hippocampal neuron-specific markers HuB and Prox1 after 7 days of culture. In contrast, hiPSC-neurons that were transplanted outside the neuronal cell layers often expressed the astrocytic marker GFAP. Furthermore, hiPSC-neurons in the dentate granule cell layer grew to exhibit dentate granule cell-like morphologies, including besom-shaped dendrites. Similarly, hiPSC-neurons in the CA1 pyramidal cell layer grew to

exhibit CA1 pyramidal cell-like morphologies, including primary apical and multiple basal dendrites with synaptic spines. Additionally, hiPSC-neurons in the CA1 pyramidal cell layer projected axons toward the entorhinal cortex as observed *in vivo*. These data suggest that hiPSC-neurons were anatomically integrated into pre-existing neural circuits in a region-specific manner. Thus, the co-culture system will be useful for the study of efficient strategies to differentiate transplanted hiPSC-neurons in recipients.

**Abstract:** Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease caused by the loss of both upper and lower motor neurons (MNs) leading to paralysis of the voluntary muscles with death ensuing within 2-5 years of clinical onset due to respiratory failure. Most of the research on ALS encompasses the use of transgenic SOD1-familial model and the sporadic rat models (both *in-vivo* and *in-vitro*) derived using Cerebrospinal Fluid (CSF) from ALS patients. Although animal models aid in understanding the pathogenesis and disease progression to a considerable extent, they may not faithfully reproduce the human syndrome due to species differences. Hence, there is a critical need for the use of cells from human source to understand the disease pathogenesis and overcome the pit falls associated with poor correlation between the animal models and the human disease .In this study, we have attempted to establish a pre-clinical model, which involves determining the response of human Embryonic Stem Cells (hESCs) derived spinal MNs to CSF from sporadic ALS patients. hESCs (BJNHem20) were maintained on inactivated mouse embryonic fibroblasts and differntiated into motor neurons using retinoic acid and purmorphamine. They were characterized using RT-PCR, immunostaining and flow

cytometry. Differentiated cells were positive for a panel of MN specific markers HB9, Islet1, FOXP1 and Choline Acetyl Transferase. At the ultra-structural level, hESC derived MNs showed loosely spread Nissl substances, neurofilaments and the neuronal processes carrying mitochondria characteristic of neurons. Extracellular recordings were performed from MNs at different days of maturation using Multi Electrode Array. MNs generated spontaneous action potentials at Day23 and fired with <5 Hz and >5 Hz frequencies characteristic of principal and putative interneurons respectively. The principal neurons fired more number of spikes on Day33 of maturation compared to other days. MNs at Day33 were exposed to ALS-CSF and the following changes were observed: altered expression of neurotrophic factors and cytoskeletal proteins; organelle dysmorphology at the ultra-structural level; reduced activity of mitochondrial respiratory chain complexes; trend of decrease in BCL2/Bax ratio and up-regulated expression of Caspase 9. With the wealth of data already built around animal/ cell culture model of sporadic ALS in our laboratory, our humanized model was able to reproduce multiple factors involved in the pathogenesis of ALS validating the utility of this model for future studies.

**Title:** Stemdiff cerebral organoid kit: A new tool for the culture of 3-D brain organoids derived from human pluripotent stem cells

**Authors: *V. M. LEE**[1], L. H. CHEW[1], A. AÑONUEVO[1], S. LLOYD-BURTON[1], A. C. EAVES[1,2], T. E. THOMAS[1], S. A. LOUIS[1]
[1]Res. and Develop., STEMCELL Technologies Inc, Vancouver, BC, Canada; [2]Terry Fox Lab., BC Cancer Agency, Vancouver, BC, Canada

**Abstract:** 2-D neural cultures derived from human pluripotent stem cells (hPSCs), including human embryonic and induced pluripotent stem cells (hESCs or hiPSCs), are useful models with which to study the nervous system, but they are limited in their capacity to fully recapitulate the complex organization of brain tissues. Lancaster et al. (Nature 2013) established a hPSC-based organoid culture system that models the major features of early human brain development. Based on the published media formulations, we developed the STEMdiff™ Cerebral Organoid Kit to enable generation of organoids in a simple and highly reproducible manner. This kit contains 2 basal media and 5 supplements, which are combined to prepare four separate complete media

corresponding to the 4 stages of cerebral organoid formation. hPSCs maintained in mTeSR1™ were single-cell dissociated and cultured in Embryoid Body (EB) Formation Medium in U-Bottom plates (day 1 - 5, Stage 1). The resulting EBs were then transferred to Induction Medium (day 6 - 7, Stage 2); next, they were expanded by embedding in Corning® Matrigel® and cultured in Expansion Medium (day 7 - 10, Stage 3). The expanded organoids were then cultured in Maturation Medium, with agitation, for extended periods of time (day 10 - 40+, Stage 4). Morphological analysis of organoids was performed on days 5, 7, 10 and 40, which are the endpoints of Stages 1 - 4 respectively. Organoids at Day 40 were analyzed by RT-qPCR or cryosectioned and processed for immunofluorescence (>3 organoids per analysis; 2 hESCs, n = 2 and 2 iPSCs, n = 2). We achieved high efficiencies across multiple cell lines (2 hESCs, n = 2 and 2 iPSCs, n = 2) for EB generation (100% success, n = 128/128), expansion (>95% exhibited extensive folding of neuroepithelia, n = 104/107) and maturation (>60% of organoids were >1 mm in diameter with dense cores , n = 62/94). These outcomes are a significant improvement upon the published protocol and reagents, with which <30% of the generated organoids had the desired morphology. In vivo, the human cortex consists of progenitor and neuronal populations that organize into distinct layers. The mature organoids generated here exhibited a similar architecture with neural progenitors (SOX2+, PAX6+) localized in apical regions surrounding a central ventricle. Adjacent to the apical progenitors, neuronal progenitors (TBR2+, Ki-67+) were found abutting neurons (CTIP2+, MAP2+, TBR1+), resembling the intermediate zone and cortical plate regions. Taken together, our data demonstrate that the STEMdiff™ Cerebral Organoid Kit supports highly efficient generation and expansion of cerebral organoids, and improves upon currently available methods.

**Title:** Characterization of Caudal Cell Mass (CCM): A key to understanding secondary neurulation in chick embryo

**Authors: *V. KIM**[1], A. ZAIDI[1], S. KIM[1], K. WANG[3], J. LEE[2,3]
[1]Anat., [2]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Div. of Pediatric Neurosurg., Seoul Natl. Univ. Children's Hosp., Seoul, Korea, Republic of

**Abstract:** Background>
The Caudal Cell Mass (CCM) is an aggregated mass of progenitor cells situated near the tail bud. In the chick embryo, it has been previously confirmed that the CCM ultimately gives rise to the secondary neural tube and therefore is well involved in secondary neurulation. It is necessary to gain a better understanding of the identity of progenitor cells in the caudal cell mass active during secondary neurulation and their molecular background in both spatial and temporal manner. Characterization of this region will provide future implications for solving the limited knowledge on the mechanisms at fault during the failure of neural tube closure, which are ultimately responsible for Neural Tube Defects, the most common birth defect in newborns to current date. However, the cellular identity of the CCM is not well known.
Materials and Methods>
We have used a carefully selected set of mesenchymal and neural markers to identify the temporal characteristics of the CCM throughout embryonic development in chicks. As mesenchymal markers, Brachyury T, CD44, CD29 were closely examined. Neural markers were listed as Sox2, Nkx1.2, and N-cadherin. The RNA expression level and protein level were analyzed using qPCR and immunohistochemistry. Different stages during development of chick embryo (Hamburger and Hamilton stage from 12 to 35) were examined. By analyzing the trend of marker expression, we were able to illustrate the progenitors present at specific stages and how their expression levels change throughout development.
Results>
The immunohistochemistry results show most prominent staining at the earlier stages by the mesenchymal markers, especially However, the stage for the most high expression did not correlated as much.Results suggest that the CCM maintains mesenchymal character at an early stage, and this decreases through development. Neural character on the other hand seems to maintain presence throughout.
Conclusion>
Our findings suggest that the caudal cell mass starts out as an aggregated mass of neuromesenchymal progenitor (NMP) cells with strong expression of both neural and mesenchymal characters, and with development it maintains neural character but gradually loses the mesenchymal character.

**Abstract:** Induced pluripotent stem cell (iPSC) derived neurons are valuable for disease modeling and drug screening. Several protocols have been developed for forebrain cortical differentiation. Many neuronal differentiation protocols deliver soluble brain derived neurotrophic factor (BDNF) and/or glial cell-derived neurotrophic factor (GDNF) to support neuronal production and survival. These require refeeding every other day. This bolus delivery system imperfectly models the more stable in vivo environment: with excess levels of growth factor protein immediately after refeeding, followed by lowering levels due to growth factor instability down to suboptimal prior to the next feed. Furthermore, this process is labor intensive, and wastes valuable neurotrophic factor protein. PLGA microspheres (StemBead®) have previously been shown to control the release of fibroblast growth factor 2 (FGF2) for the maintenance of iPSCs. The goal of the current study was to determine if controlled release of growth factors with PLGA microspheres could deliver BDNF and GDNF in a more stable and effective manner.
Growth factor microspheres were optimized for size and levels of released protein. A size range of 10-20μm produced sustained growth factor levels in culture medium for 6+ days, measured both biochemically and functionally. To generate forebrain cortical neurons, iPSCs were first differentiated into neural precursor cells (NPCs) by forming embryoid bodies in neural induction media with dual SMAD inhibition on poly-L-Ornithine-Laminin substrate. Pax6, Nestin, and Sox2 -positive NPCs were differentiated using N2/B27, DMEM/F12, Neurobasal base media supplemented with either soluble factor every 2-day feeding or StemBeads® growth factor delivery with every 4-day feeding. In our 30-day protocol, stabilization of BDNF protein levels using controlled release PLGA microspheres improves the neurite outgrowth and branching of MAP2 positive iPSC derived neurons when compared to soluble growth factor delivery. Preliminary data suggest GDNF responses are similarly improved with controlled release. Parallel studies using iPSCs from neurodegenerative disease individuals are in progress. In summary, controlled release of BDNF and GDNF using PLGA StemBeads® reduces time, cost, and effort, while generating more complex human iPSC derived neurons for use in disease phenotyping and therapeutic testing.

**Title:** Default patterning of human pluripotent stem cells results in pan-cortical and CGE/LGE-like subpallial specification

**Authors: *C. FLORUTA**[1], M. FISCHER[2], R. DU[3], H. KANG[4], J. L. STEIN[5], J. P. WEICK[2]
[1]Neurosci., [2]Neurosciences, [3]UNM Comprehensive Cancer Ctr., [4]Dept. of Intrnl. Med., Univ. of New Mexico, Albuquerque, NM; [5]Dept. of Genet. & UNC Neurosci. Ctr., Univ. of North Carolina Sch. of Med., Chapel Hill, NC

**Abstract:** Previous studies have reported that human pluripotent stem cells (hPSCs) generate dorsal forebrain, cortical-like neurons under default differentiation in the absence of patterning morphogens. While a preponderance of neurons do express cortical layer markers and are glutamatergic, their regional specification remains unclear. Furthermore, a significant population of GABAergic neurons also develop under non-directed conditions. To gain insight into the diversity of neuronal populations generated by default patterning we first performed bioinformatic analyses using Transition Mapping (TMAP), CoNTExT, and WGCNA on developmental transcriptome data to allow us to examine the overall regional and temporal specification compared to *in vivo* human brain samples. Temporally, we found that day 50 hPSNs resembled mid-gestational fetal brains, and displayed a panoply of functional markers of synaptic transmission. In addition, gene expression profiles of default differentiated hPSNs represent a pan-cortical identity with expression of markers that are differentially expressed across rodent cortex. Spatially, our analyses revealed significant overlap with multiple layers of developing human pallium. However, we also identified a robust subpallial transcriptional profile, as evinced by the presence of markers for GABAergic progenitors and post-mitotic neurons including *DLX1/2/5/6, ASCL1, GAD1, SST, NPY, CALB2*, and multiple GABA receptor subunits. Interestingly, using qPCR, the preponderance of expressed subpallial markers showed significant overlap with genes expressed in CGE/LGE domains (e.g. *NR2F2, MEIS2, FOXP4, PBX1*), but not MGE domains (e.g. *NKX2-1, GBX1/2, LHX6*). CGE identity was further confirmed by increased COUPTFII and Calretinin (CALB2) staining in GABA-positive cells. Interestingly, WNT inhibition following neural induction caused hPSNs to adopt a significantly more dorsal regionalization, with a higher correlation between *in vivo* cortex and significant reductions in GABAergic neuronal gene expression. Taken together, our data point to a WNT-dependent patterning of LGE/CGE-like GABAergic neurons from default-patterned cells, and

provide a more comprehensive understanding of the signaling event leading to the diverse population of hPSNs generated by default patterning.

**Title:** Augmented stem cell potential in response to environmental enrichment is seen in juveniles but not adults

**Authors: *K. CHANDLER**[1], H. DOSSO[1], N. SALMASO[1,2]
[1]Neurosci., Carleton Univ., Ottawa, ON, Canada; [2]Child Study Center, Yale Univ., New Haven, NJ

**Abstract:** Early in telencephalic development, neural stem cells are born in the ventricular zone and migrate through the cortex before differentiating into neurons and glia. Adult neurogenesis, however, is limited to specific niches in the brain: the dentate gyrus of the hippocampus (DG) and the subventricular zone (SVZ). The proliferation and differentiation potential of these neural stem cells is plastic and shows changes across states and in response to environmental manipulations. It has previously been shown that short-term environmental enrichment (Enr) is sufficient to increase the proliferation and differentiation of the GFAP+ stem cell pool in juvenile mice. Because longer-term Enr protocols are typically used to induce behavioural and functional recovery in adult mice, it is expected that that short-term Enr will be sufficient to induce an increase in neural stem cell potential only in juveniles. Using male C57 wildtype mice, we examined the potential of SVZ and DG NSCs in vitro following short-term Enr using neurosphere assays in both juvenile (P35) and adult (P90) mice. The assays were examined for NS number, size, and differentiation potential. We also examined changes in cognitive and anxiety behaviour. As hypothesized, we found that the short-term Enr increased learning and memory in juvenile mice, but not in the adult mice. These changes paralleled increased proliferation and differentiation of the stem cell pool in juveniles that was less pronounced in

adults, suggesting developmental decreases in NSC potential in response to short-term environmental manipulations.

**Title:** Retinal organoids derived from human pluripotent stem cells exhibit a defined ganglion cell layer and allow for the modeling of glaucomatous autophagy deficits and neurodegeneration

**Authors: *K. LANGER**[1], A. SRIDHAR[2], H. TSENG[3], J. S. MEYER[1]
[1]Biol., IUPUI, Indianapolis, IN; [2]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [3]Ophthalmology, Duke Univ., Durham, NC

**Abstract:** Retinal organoids are three-dimensional structures derived from human pluripotent stem cells (hPSCs) mimicking both the temporal the spatial organization of the native retina. The ability to derive retinal cells in such a way allows for a model closely resembling the spatiotemporal development of the human retina. Furthermore, retinal cells derived in this manner would be more likely to exhibit a full complement of features associated with bona fide retinal neurons. Although numerous studies have demonstrated the development and functionality of photoreceptors in retinal organoids, the development of retinal ganglion cells (RGCs) within organoids has been mostly overlooked. RGCs provide the vital pathway between the eye and the brain, allowing for the ability to see. In neurodegenerative diseases of the eye, such as glaucoma, this vital connection is damaged, resulting in loss of vision and blindness. As the mechanisms by which this degeneration occurs remain unclear and few therapeutic options are available, the development of retinal organoids represents an exciting and novel approach for the study of RGC development and disease. Thus, efforts were focused on the generation of RGCs within inner layers of retinal organoids with this differentiation occurring through identifiable stages closely resembling retinogenesis. Furthermore, the ability for retinal organoids to serve as an effective model for glaucomatous degeneration of RGCs was investigated by using hPSCs derived from a glaucoma patient with the E50K mutation in the Optineruin gene. RGCs derived in this fashion exhibited autophagy deficits such as the accumulation of LC3 aggregrates, as well as increased activation of apoptotic markers within the RGC layers of the organoid.

Treatment of patient-derived RGCs with autophagy activators was further performed to determine the link between autophagy disruption and apoptotic cell death. Thus, the results of study represent the first efforts to utilize retinal organoids to effectively model the development of RGCs within organoid structures, as well as serve as a novel approach for the modeling of glaucomatous neurodegeneration.

**Abstract:** Wnt ligands comprise a family of glycoproteins that participate in cell-cell communication and regulate diverse processes during development including stem cell-renewal and differentiation. In the brain, the Wnt signaling is implicated in dendrite development, synapse formation and synaptic plasticity. Specifically, the Wnt5a ligand that is expressed in hippocampal neurons, is essential for dendritic spine morphogenesis and dendrite maintenance. Here, we evaluated the role of Wnt5a in cell-renewal and differentiation of adult neural progenitor cells (aNPCs) isolated from the hippocampus of 6-week-old mice. Proliferating aNPCs were maintained in serum free media supplemented with EGF and FGF-2. Proliferation was measured by BrdU incorporation. Differentiation was induced by growth factors withdrawal. Neuronal and astrocytic differentiation was evaluated using specific markers. We determined that treatment with Wnt5a, as well as Wnt3a used as control, increased proliferation of aNPCs. After growth factors withdrawal only Wnt5a induced neuronal differentiation without affecting differentiation into astrocytes. In agreement, Wnt5a-knockdown in aNPCs by lentivirus-mediated shRNA reduced neuronal differentiation not affecting astrocytic differentiation. Finally, we evaluated morphological development of aNPCs-derived neurons, which show a significant increase in dendritic complexity 2, 4 and 6 days after induction of differentiation. Wnt5a-knockdown reduced dendritic arborization of aNPC-derived neurons compared to neurons expressing control shRNA. Our data indicate that Wnt5a stimulates self-renewal of

proliferating aNPCs, and induces neuronal differentiation and morphological development of differentiating aNPCs, suggesting that Wnt5a may control the development of new neurons in the adult brain.

**Title:** Developmental characterization of human induced neurons

**Authors: *L. GIAM**, X. DU, I. T. HULL, T. C. SUDHOF
Stanford Univ., Stanford, CA

**Abstract:** Our lab recently reported that a single transcription factor (Neurogenin-2) can drive the differentiation of human embryonic stem cells into functional induced neurons (iNs) over several weeks. These iNs express synaptic markers at both transcript and protein levels and exhibit electrophysiological properties of excitatory neurons. This reduced system presents many opportunities, but in order to be useful for genetic screens and manipulations, we must understand the transcriptomic and proteomic profiles of these neurons in both immature and mature states. We developed strategies to culture pure iNs that were functionally equivalent to previous iNs grown on mouse glial cells in order to label proteins quantitatively using stable isotope labeling of amino acids (SILAC) and conduct RNAseq.

**Title:** Global gene expression changes associated with neuronalisation of the cortically-derived neural stem cell line CTX0E16: Potential implications for neurodevelopmental diseases

**Authors: *R. R. DUARTE**[1], T. R. POWELL[1], G. ANDERSON[1], D. F. NIXON[2], G. BREEN[1], S. LEE[1], R. M. MURRAY[1], N. J. BRAY[3], D. P. SRIVASTAVA[1]

**Abstract:** **INTRODUCTION** The human neural progenitor cell line CTX0E16 is a robust source of forebrain-like glutamatergic cortical neurons that display intrinsic functional properties (Anderson et al., 2015). This cell line was obtained from the embryonic cortex of a 12-week gestation XY fetus, and conditionally immortalised by ectopic expression of the c-Myc$^{ER\ TAM}$ transgene (Pollock et al, 2006). This construct allows the stem cells to be maintained in a proliferative stage under the presence of hydroxytamoxifen (4-OHT) and certain trophic factors in the medium, while removal of 4-OHT and maintenance of cells in a differentiation medium will stimulate neuronalisation. Understanding the global gene expression changes occurring during neuronalisation of this *in vitro* model, and their relationship with genetic association studies of schizophrenia and autism, might reveal clues to the biological processes impaired in these neurodevelopmental diseases. **METHODS** The CTX0E16 cell line was provided by ReNeuron (www.reneuron.com) through a Material Transfer Agreement. Total RNA was extracted from neural progenitor cells (NPCs) and from cells submitted to the neuronalisation protocol during 28 days (DD28) (n=3) (Anderson et al., 2015). DNA-free RNA samples were submitted to the IoPPN Genomics & Biomarker Core Facility for analysis in the Illumina HT12 v4 chip. Raw fluorescence probe intensity values were extracted using GenomeStudio, and subsequently background-corrected and log-transformed in R using the lumi package. Genes differentially expressed (t-test) at a false-discovery rate < 0.05 (FDR, q-value < 0.05) were submitted to Weighted correlation network analysis (WGCNA) and gene ontology (GO) analysis. MAGMA was used to investigate, in the list of differentially expressed genes, a potential enrichment for genes previously implicated in schizophrenia and autism by genome-wide association studies (GWAS). **HYPOTHESIS** Our assumption is that neurodevelopmental diseases such as schizophrenia and autism might share a genetic component with processes driving early cortical maturation, which can be modelled *in vitro*. **EXPECTED RESULTS** We

expect to identify and annotate sets of genes involved in cortical maturation that are additionally involved in the aetiology of schizophrenia and autism, which, furthermore, are believed to be disturbed in these diseases.

**Title:** Molecular and functional characterization of hiPSCs derived dopaminergic neurons

**Authors: *C. ÜBERBACHER**
EURAC Res., Bolzano, Italy

**Abstract:** Parkinson's disease (PD) is a chronic progressive neurodegenerative disorder characterized by loss of dopaminergic (DA) neurons in the *substantia nigra pars compacta* and by intracellular inclusions (Lewy bodies) in surviving neurons. The focal loss of neurons makes the disease particularly interesting for the stem cell field as it makes it an attractive target for patient derived cell substitution therapy. Therefore, in the recent years iPSCs have become a very important resource for the *in vitro* generation of a cell model of PD.
Current standard protocols for defining maturity of iPSC derived DA neurons are illustrating expression of Tyrosine Hydroxylase (TH) along with varying midbrain markers like Lmx1a/b, FOXA2 and OTX2, paired with firing of action potentials of TH positive neurons. However, despite showing primary function of neurons as in the transduction of a chemoelectrical signal, positive electrophysiological identification of these cells are limited to single action potentials, lacking the display of synaptic function.
We aim to address the electrophysiological development of iPSC derived DA neurons, using an established differentiation protocol (Kriks *et al*.). Under these conditions, we observed expression of molecular and functional characteristics of DA identity including expression of FOXA2, LMX1A, TH and PITX3. We also observe co-staining of TH with GIRK2 channel, a feature of A9 DA neurons, the subtype most susceptible to degeneration in PD. Additionally, we will supplement this protocol to accelerate this neuronal development, with particular attention to synapse function.
We tracked the markers expression over time to understand the timing of midbrain DA neuron cell faith definition. The maturation process of cells was monitored throughout the differentiation by staining for markers of mature DA neurons (NURR1, MAPT/Tau) and synapse formation

(PSD95, Synaptophysin) by Western Blot and immunocytochemical assays as well as qRT-PCR for monitoring transcriptional activation.
To assess neuronal properties, whole-cell patch clamp recordings are obtained from neurons, measuring spontaneous and evoked action potentials, $Na^+$-, $K^+$-and $Ca^{2+}$ mediated currents and miniature excitatory post-synaptic currents.
Finally, we assess expression of Dopamine Transporter (DAT), Aromatic L-amino acid decarboxylase (AADC) and TH by immunocytochemistry over time and monitor stimulated DA release by MS-HPLC analysis of the culture media.
The data presents a thorough characterization of an *in vitro* derived neuronal model that could allow a better understanding of maturation process of iPSC derived DA neurons.

**Title:** Lineage reprogramming of astroglia into different neurons

**Authors: *M. CHOUCHANE**[1], A. FARIAS[2], D. MOURA[1], M. HILSCHER[3], R. LEAO[2], M. COSTA[2]
[1]Neurolog. surgery, UCSF, San Francisco, CA; [2]UFRN, Natal, Brazil; [3]Vienna Univ. of Technol., Vienna, Austria

**Abstract:** Astroglial cells isolated from the rodent postnatal cerebral cortex are particularly susceptible to lineage reprogramming into neurons. However, it remains unknown whether other astroglial populations retain the same potential. Likewise, little is known about the fate of induced neurons (iNs) *in vivo*. In this study we addressed these questions using two different astroglial populations isolated from the postnatal brain reprogrammed either with *Neurogenin-2* or *Achaete scute homolog-1*. We show that cerebellum (CerebAstro) and cerebral cortex astroglia (CtxAstro) generates iNs with distinctive neurochemical and morphological properties. Both astroglial populations contribute iNs to the olfactory bulb following transplantation in the postnatal and adult mouse subventricular zone. However, only CtxAstro transfected with Neurog2 differentiate into pyramidal-like iNs after transplantation in the postnatal cerebral

cortex. Altogether, our data indicate that the origin of the astroglial population and TF used for reprogramming, as well as the region of integration, affect the fate of iNs.

**Title:** A role of the SHH-GLI pathway in neuronal reprogramming in the adult mouse spinal cord

**Authors: *L. WANG**, C.-L. ZHANG
Mol. biology, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

**Abstract:** Regeneration of new neurons may provide the much needed cells for neural repair after traumatic injury to the central nervous system. We recently showed that the stem cell factor SOX2 is sufficient to in vivo reprogram the reactive glial cells to mature neurons in both the adult mouse brain and spinal cord. SOX2-mediated in vivo reprogramming passes through ASCL1+ neuroprogenitors and DCX+ neuroblasts prior to neuronal maturation. This reprogramming process is further regulated by the p53-p21 pathway through controlling cell cycle progression. In current study, we examined additional signaling pathways for their role in determining regional identity and subtypes of reprogrammed spinal neurons. We found that the SHH-GLI pathway greatly influences the activity of induced neuroprogenitors and neuroblasts in a region-specific manner. Different components of this pathway exhibit differential regulation on the reprogramming process. Through genetic lineage mapping and rabies-mediated tracing, we are further examining the role of SHH-GLI signaling on subtypes and neural networks of the reprogrammed neurons in the adult spinal cord. The results of this study may contribute to the molecular insights into the in vivo reprogramming process and provide a foundation for future clinical translation of neural regeneration-based therapies.

**Abstract:** Modeling human brain development *in vitro* is critically important to improve our understanding of neuropsychiatric disorders. As part of the PsychENCODE project, we generated human induced pluripotent stem cells (hiPSCs)-derived neural organoids to study early genetic programs in forebrain development and define to what extent they can recapitulate human embryonic and fetal brain development. We established iPSC lines from skin fibroblasts of three human prenatal brain specimens and two clones per specimen were differentiated into telencephalic organoids over a time course (TD 0, TD 11, TD 30). We examined transcriptomes and gene regulatory regions in the temporal series of hiPSCs-derived organoids as compared to donor-identical brain tissue from ventricular/subventricular zone and cortical plate. To this end, we utilized RNA- and histone chromatin immunoprecipitation (ChIP)-sequencing. The organoids were characterized by immunocytochemistry and qPCR, and expression of radial glial markers and mature cortical neurons confirmed telencephalic fate. Hierarchical clustering of the organoids' transcriptomes demonstrated stage-specific clustering according to time course of *in vitro* development. Mapping organoids' transcriptomes against the BrainSpan dataset suggested highest correlations with neocortex and showed their progressive maturation *in vitro* across time, corresponding to post-conceptional weeks 8-16 of human fetal development. We then inferred transcriptional alterations, by differential gene expression, between each time point and the two brain regions analyzed. We found, as expected, a large number of differentially expressed genes (~5000) between TD 0 and brain, and a decreasing number at TD 11 and TD 31, suggesting a stronger, albeit incomplete similarity of the organoids at the later time points, consistent with the

previous classification. In parallel, we studied differences in epigenetic regulation by performing ChIP-seq, to identify promoters and enhancers of active genes at different developmental stages. Hierarchical clustering of H3K27ac and H3K4me3 peaks demonstrated clustering of organoids with fetal brain samples from our and external databases, whereas adult brain samples formed a separate cluster. Differential peak detection followed by gene ontology analysis revealed that, along differentiation, genes associated with increased H3K4me3/H3K27ac levels are involved in nervous system development while genes associated with decreased H3K4me3/H3k27ac levels are more relevant to cell cycle. These data suggest that organoids recapitulate transcriptome and epigenome features of fetal human brain.

**Title:** Generation and rapid maturation of cortical layer V glutamatergic neurons from human iPSCs

**Authors: B. DUNGAR**, K. XU, M. HENDRICKSON, *Z.-W. DU
BrainXell Inc., Madison, WI

**Abstract:** Numerous neurological and psychiatric disorders involve glutamatergic neurons specific to one or more of the six cortical layers. Death or malfunction of these specific neurons underlies disease pathophysiology and disrupts higher cognitive function. Study of these neurons may reveal the molecular mechanisms behind their vulnerability and enable development of more relevant disease models. Toward this goal, we developed protocols to efficiently produce layer V cortical glutamatergic neurons. Both normal and patient iPSCs were first induced to a neural fate and then patterned to glutamatergic neuronal progenitors (>90% SOX1+/PAX+). Using novel combinations of small molecules, the late-stage progenitors can be expanded up to 500-fold, which allows for production of large and consistent batches of neurons. Finally, the progenitors were plated in medium containing a specialized maturation supplement that rapidly yields morphological and functional maturation. After treating with this cocktail, neurons displayed extensive neurite outgrowth within 3 days, expressed pre- and post-synaptic mature markers within 7 days, and exhibited electrophysiological activity within 2 weeks. Seven days

post-plating, the cultures were >90% neurons (MAP2+) with the following breakdown by layer identity: ~90% layer V (CTIP2+/ FOXP2-/ SATB2-), ~8% layer VI (FOXP2+), and ~2% layer II-IV (SATB2+). Thus, our novel differentiation protocol generates a pure neuronal culture that is highly enriched for cortical glutamatergic neurons with a layer V identity. Coupled with the ability to generate very large batches (>1 billion neurons) and bring about rapid maturation, layer V cortical neurons present a highly relevant model system for drug discovery and development.

**Abstract:** Parkinson’s disease (PD) is a chronic progressive neurodegenerative disease in which dopaminergic neurons originating in the substantia nigra degenerate, resulting in loss of motor control. Treatment with L-DOPA can initially restore dopaminergic (DA) levels and motor function, but does not treat the disease. At the onset of symptoms and diagnosis about 70% of the midbrain DA neurons have degenerated, at which stage treatment with therapeutics to prevent cell loss is too late. Instead, neural transplantation with midbrain dopamine neurons can

specifically replace the DA cell population and provide functional motor benefits in patients with PD. The use of pluripotent stem cell derived neurons provides the opportunity to overcome current limitations posed by fetal donor tissue in PD. For this approach, robust and reproducible protocols for differentiation of pluripotent stem cells toward ventral midbrain dopaminergic fates are essential. We have previously published two differentiation protocols that generate midbrain dopaminergic neurons (Cooper O. et al., Mol Cell Neurosci. 2010 Nov;45(3):258-66 and Sundberg M., et al., Stem Cells. 2013 Aug;31(8):1548-62). Our recent efforts have led to an efficient xeno-free and feeder-free protocol that we have successfully 1) transplanted into 6-OHDA lesioned rats using both a fresh and frozen-thawed cell preparation, with successful graft survival and behavioral recovery, 2) used for autologous transplants in parkinsonian primates and 3) used in vitro in cell vulnerability and drug-discovery studies. Here we have compared factors commonly used in protocols for differentiation of iPSCs into midbrain dopaminergic neurons and show that the ideal concentrations, timing of addition, as well as protein isoforms (FGF8a vs. FGF8b) differ depending on the underlying protocol and procedure. As the reality of using midbrain dopaminergic neurons derived from pluripotent stem cells for transplantation is getting closer to the clinic, an understanding and clarification of the differences in the protocols proposed for such use is essential.

**Title:** Nrf2 as a biomarker of oxidative stress induced by rotenone in a human iPSC neuronal model

**Authors: *F. PISTOLLATO**, D. ZAGOURA, D. CANOVAS-JORDA, A. PRICE
Directorate F – Health, Consumers and Reference Materials, Directorate Gen. Joint Res. Ctr., Ispra, Italy

**Abstract:** Human induced pluripotent stem cells (hiPSCs) can be expanded and efficiently differentiated into different types of neuronal and glial cells, serving as test systems for toxicity testing and, in particular, for the assessment of different pathways involved in neurotoxicity. Here we show that hiPSC-derived neuronal cells can be used to measure the activation of the Nrf2 signaling pathway, a key regulator of the antioxidant-response-element-(ARE)-driven cellular defence mechanism against oxidative stress. Our data indicate that both an acute and repeated dose treatment with rotenone, an inhibitor of mitochondrial complex I and an inducer of

Parkinson-like features can elicit activation of Nrf2, leading to an induction of astrocyte activation, reduction of neurite length and dopaminergic neuronal cell death. These data suggest that this hiPSC model can be applicable to the new toxicity testing paradigm, in which chemicals are assessed based on their ability to perturb biological pathways.

**Title:** Role of FKBP5 disinhibition in neuronal development: Cerebral organoids as a model for stress-related disorders

**Authors: *S. MARTINELLI**, C. CRUCEANU, R. DI GIAIMO, C. KYROUSI, S. CAPPELLO, E. B. BINDER
Max Planck Inst. of Psychiatry, Munich, Germany

**Abstract:** Introduction
FKBP5 is best known as a co-chaperone of the glucocorticoid receptor (GR), involved in the regulation of the hypothalamic-pituitary-adrenal (HPA)-axis. GR activation induces FKBP5 expression, which, on one side, leads to the inhibition of the GR itself and, on the other, regulates a plethora of cellular pathways including neural-specific ones. Several studies have demonstrated that increased levels of FKBP5 in the context of gene x early adversity interactions (GxE) correlate with a number of stress-related disorders. Furthermore, postmortem studies have found increased FKBP5 levels in several brain regions in a number of psychiatric disorders. These human findings have been corroborated by studies in animal models, but due to the difficulty in accessing human neural tissue, studies in human have mainly been limited to non-neuronal samples.
Aim
The aim of this project is to investigate, in a human neuronal system, the effect of FKBP5 disinhibition on neuronal differentiation and development to better understand the molecular and cellular mechanisms that link GxE to the onset of psychiatric disorders.
Methods
We use human induced pluripotent stem cells (hiPSC) reprogrammed from fibroblasts. hiPSC are differentiated into neural progenitor cells (NPC) and mature neurons and to generate cerebral organoids in accordance to the Lancaster and Knoblich protocol (2014). FKBP5 expression is assessed at the RNA level using qPCR, RNA seq and a quantitative fluorescent based in situ

hybridization system. At the protein level, we use immunohistochemistry (IHC) and western blot. Neuronal maturation is assessed using specific pluripotency and differentiation markers. To mimic external stressors, we treat the cells and organoids at different maturation stages with dexamethasone (dex), a GR agonist.
Results
Consistently with the literature, we observed low levels of FKBP5 expression across neuronal differentiation. With dex treatment, RNA levels of FKBP5 increased in both NPC and mature neurons. Interestingly, with IHC, we observed a marked increase specifically in the germinal zone of dex-treated organoids.
We are currently proceeding with the overexpression of FKBP5 in organoids, by co-electroporating FKBP5 and GFP expressing plasmids into ventricles and analyzing the differences in migration and maturation of neural progenitors and radial glial cells.
Conclusion
FKBP5 is expressed in iPSC derived neuron and brain organoids and regulated by glucocorticoids. These systems may thus present interesting models to investigate the impact of enhanced FKBP5 expression on neuronal development and differentiation.

Biol. and Genet., Johns Hopkins Sch. of Med., Baltimore, MD; [7]Wilmer Eye Inst., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Retinal ganglion cells (RGCs) serve as a vital connection between the eye and the brain and as such, degenerative diseases and injuries which cause the loss of RGCs often lead to blindness. Human pluripotent stem cells (hPSCs) are attractive candidates for cell replacement therapies, due to the ability to direct their differentiation into any desired cell type, including RGCs. However, in order for successful replacement of RGCs to occur, axons must extend across significant distances to reach their targets. Additionally, once this axonal pathfinding is accomplished, these axons must also be able to form functional synaptic connections. Significant obstacles remain before the implementation of hPSC-derived RGCs for cell replacement. The development of a reliable in vitro model of RGC development and axonal outgrowth would allow for the direct examination of those factors influencing axonal outgrowth and connectivity, with the goal of eventually translating these findings into customized strategies for cell replacement in vivo. As such, efforts thus far have focused on the development of effective and reliable assays with which to test the ability of hPSC-derived RGCs to extend axons in response to a variety of extrinsic cues. Initially, RGCs were characterized by immunocytochemistry for the expression of several RGC-associated markers. Growth cones were observed at the leading edge of extending neurites, with these growth cones enriched for F-actin and expressing receptors essential for axonal pathfinding. Live imaging revealed growth cones that were highly dynamic and motile over time. Subsequently, the ability to enhance RGC neurite outgrowth was analyzed in response to multiple factors, including varying substrates, culture media and growth factors. Enriched populations of RGCs were isolated and plated to allow for neurite outgrowth, with significant outgrowth observed within the first 24 hours. Optimized assays allowed for neurite growth over 1mm in this time. The results of this study demonstrate the robust ability of hPSC-derived RGCs to extend axons over long distances. hPSC-derived retinal organoids recapitulate the stratification of the human retina and produce RGCs with expected phenotypes. Opportunities exist by which to control the directionality of axonal outgrowth as well. Finally, RGC axons and growth cones are significantly influenced by substrate composition and growth factor signaling. Overall, these results will facilitate the replacement of RGCs following their loss due to disease and degeneration, as extensive axonal outgrowth will be critical for the development of personalized transplant therapies for optic neuropathies.

**Abstract:** Human induced pluripotent stem (iPS) cell-derived neurons and astrocytes are attractive cellular tools for nervous system disease modeling and drug screening. Optimal utilization of these tools requires differentiation protocols that efficiently generate functional cell phenotypes in vitro. As nervous system function is dependent on networked neuronal activity involving both neuronal and astrocytic synaptic functions, we examined astrocyte effects on the functional maturation of neurons from human iPS cell-derived neural stem cells (NSCs). We first demonstrate human iPS cell-derived NSCs can be rapidly differentiated in culture to either neurons or astrocytes with characteristic cellular, molecular and physiological features. Although differentiated neurons were capable of firing multiple action potentials (APs), few cells developed spontaneous electrical activity in culture. We show spontaneous electrical activity was significantly increased by neuronal differentiation of human NSCs on feeder layers of neonatal mouse cortical astrocytes. In contrast, co-culture on feeder layers of isogenic human iPS cell-derived astrocytes had no positive effect on spontaneous neuronal activity. Forced cell cycle exit and enhanced GABA and calcium signaling further increased the frequency of spontaneous electrical activity and multiple AP firing in co-cultured human neurons. Spontaneous electrical activity was dependent on glutamate receptor-channel function and occurred without changes in $I_{Na}$, $I_K$, $V_m$ and AP properties of iPS cell-derived neurons. These data demonstrate co-culture with neonatal mouse cortical astrocytes but not human isogenic iPS cell-derived astrocytes stimulates glutamatergic synaptic transmission between iPS cell-derived neurons in culture. We present RNA-sequencing data for an immature, fetal-like status of our human iPS cell-derived astrocytes as one possible explanation for their failure to enhance synaptic activity.

**Title:** Vascular regeneration by reprogramming of ng2-derived angiogenic cells in the inner ear

**Authors: *X. SHI, Dr.**, X. WANG
Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

**Abstract:** Can damaged or degenerated vessels be regenerated in the ear? The question is important as disruption of cochlear blood flow is seen in a wide variety of hearing disorders including loud sound-induced hearing loss (*endothelial injury*), ageing-related hearing loss (lost vascular density), and genetic hearing loss (i.e.,Norrie disease: *strial avascularization*). Progression in CBF pathology can parallel progression in hair cell and hearing loss. However, new vessel growth in the ear has not been studied, nor has the role of angiogenesis in hearing. In this study, using a vascular damage model created by depleting pericytes (PC) in the cochlea which is in conjunction with an established ex vivo tissue explant mode, we demonstrate for the first time that damaged vascular function (blood labyrinth barrier) can be restored by activating the vascular endothelial growth factor signal. Moreover, using transgenic neural/glial antigen 2 (NG2) fluorescent reporter mice, we have shown the progenitors of "*de novo*" strial vessels are pre-existing ECs and converted perivascular NG2-derived cells. Most important, the pattern of the newly formed vessels resembles the natural 'mesh pattern' of *in situ* strial vessels, with both lumen and expression of tight junctions. Taken together, our data shows that damaged strial microvessels can be regenerated by reprogramming of NG2-derived angiogenic cells. The restoration of functional vasculature may be crucial for restoration of vascular dysfunction related hearing loss.

**Title:** An elite model of reprogramming - Neural Crest cells are the preferred origin for cell Reprogramming

**Authors: *A. FAHMY**[1], J. XU[2], I. BROKHMAN[3], B. L. COLES-TAKABE[1], D. J. VAN DER KOOY[4]
[1]Mol. Genet., [3]prof. van der Kooy lab, [2]Univ. of Toronto, Toronto, ON, Canada; [4]Dept Med. Genet, Univ. Toronto, Toronto, ON, Canada

**Abstract:** The discoveries made by Yamanaka et al and other groups in reprogramming somatic cells either to pluripotent stem cells (called induced pluripotent stem cells, or iPSCs) or directly to other differentiated cells has opened a new field in stem cell research. However, these reprogramming techniques are plagued by problems relating to the efficiency of the process and the poor understanding of their cellular mechanisms. Several studies were able to improve the efficiency of reprogramming by manipulating chromatin remodeling factors. Despite this there is still no clear and non-ambiguous study which shows if all differentiated cells have the potential of being reprogrammed or whether there exists an elite subpopulation of cells that are selectively being reprogrammed. We hypothesise that a primary source of iPSCs and directly reprogrammed cells are neural crest stem cells (NCSCs) found in culture. It is well established that multipotent NCSCs migrate to many parts of the developing embryo where they can produce a vast array of cell types; some of these NCSCs remain as undifferentiated stem cells throughout adulthood. We traced the lineage of neural crest cells in mice embryos using a Wnt1-Cre and ROSA-TdTomato reporter system. We found that YFP positive cells (NC derived) were present in the primary cell culture and they increased in proportion with passage number. This shows that there exists neural crest derived cells in cultures identical to those used in reprogramming studies. We reprogrammed skin samples of mouse embryonic fibroblasts (MEFs) and found that 100% of the iPSCs produced were YFP positive (from NC origin). In cell populations that have been sorted for NC derived and non-NC derived cells, we observed that the NC pure population reprogrammed at an efficiency 10-fold higher, while very few non-NC cells were able to reprogrammed to iPSCs (albeit at a lower efficiency when compared to unsorted populations). Despite the fact that some of the iPSC colonies were produced from non-NC cells, this may not suggest that some non-NC cells also are reprogrammed, as the efficiency of the cre labeling may not be 100%. The same results have been observed when reprogramming skin cells to neurons

using three neuronal transcriptional factors (Brn2, Ascl1, Myt1l). These studies can help better understand the cellular mechanism of reprogramming and will help devise more efficient techniques of reprogramming that could contribute to new therapies for treating neurodegenerative diseases.

**Abstract:** Human cell types differentiated from induced pluripotent stem cells (iPSC) offer an attractive source of cellular material for both toxicity screening and drug discovery because of the biologically relevant systems they can represent *in vitro*. In combination with cutting-edge instrumentation, iPSC-derived cells be used to explore functionality of human cells and to identify phenotypes for disease modeling. The FDSS uCell from Hamamatsu is a kinetic plate reader that is equipped with a high speed camera, an integrated dispenser head, and electrical field stimulation capability that enables intracellular ion measurement in live neuronal cell type. In this poster, we highlight the development of cell-based assays on the FDSS uCell to measure calcium handling in human iPSC-derived neurons. Specifically, we utilized GABAergic, glutamatergic, and dopaminergic neurons in both mono-culture and co-culture with iPSC-derived astrocytes. Addition of agonists that activate excitatory receptors, such as AMPA-R, Glutamate receptor, and NMDA-R, result in robust responses in calcium flux. Furthermore, we have also developed a method to measure spontaneous calcium oscillations, most importantly in iPSC-derived glutamatergic neurons, where these cells have been used to test the effects of various small-molecules as potentially seizurogenic. Finally, we have also leveraged the power of iPSC technology to illustrate phenotypic data from disease-specific or patient-derived samples, including a mutant KCNT1 channel that represents a rare but severe epilepsy syndrome. Taken together, these examples should help to create new avenues for safety assessment and toxicology studies, as well as serve as a template for future opportunities in modeling disease with human iPS cells.

**Title:** Differentiation and enrichment of subtypes of cortical interneurons using human induced pluripotent stem cell derived serum free embryoid bodies

**Authors: *R. M. DERANIEH**, M. W. NESTOR
Program in Neurosci. - Human Stem Cell Neurophysiol., Hussman Inst. For Autism, Baltimore, MD

**Abstract:** Background: Dysfunction of interneurons is implicated in several neurodevelopmental disorders including epilepsy, schizophrenia, bipolar disorder and autism. Interneurons play an important role in modulating circuit function. The effect of interneurons on circuits is dependent on the subtype specificity of these cells. The calcium-binding protein expressing neurons, including calbindin (CB), calretinin (CR), and parvalbumin (PV)-positive neurons make up major classes of interneurons in the brain. The underlying mechanism whereby they elicit their effect in cortical circuity that has been built using human induced pluripotent stem cells (hiPSCs) is not well understood. This is largely due to the lack of an efficient process for generating subtypes of interneurons. Although much progress has been made in the past few years, current protocols generate mixed neuronal cultures, often involving forced expression, and only a small percentage of interneurons are generated.
Objective: Here, we demonstrate a novel approach to differentiate and enrich for specific subtypes of human interneurons.
Methods: Using hiPSCs, serum free embryoid bodies (SFEBs) were generated and induced using standard dual-SMAD inhibition combined with placement of the SFEBs on Millipore Organotypic inserts (Nestor et al., 2013). After placement, SFEBs were differentiated for 3-4 weeks. Interneurons were isolated using magnetic activated cell sorting, after which the neurons were allowed to recover for 2 weeks on poly-L-ornithine and laminin.
Results: Quantification analysis demonstrated substantial enrichment for CB, CR, and PV

positive neurons and a 2-fold increase in their numbers in comparison to populations generated in conventional 2D cultures.
Conclusions: This approach will facilitate the study of subtype-specific human interneurons to answer questions pertaining to the mechanism(s) that underlie the pathophysiology of several neurodevelopmental disorders. It also offers the potential to identify novel drug targets for the development of therapeutics for the treatment of these disorders.

**Abstract:** Autism spectrum disorder (ASD) is a highly heterogeneous neuro-developmental disorder classically characterized by communication deficits, repetitive behaviors, and difficulties with social interactions. Recently it has been proposed that this broad array of impairments may be reflect a more fundamental, underlying, disruption in timing and time perception. However, studies of temporal processing in ASD individuals have produced mixed results. Animal models have served as a valuable tool for elucidating behavioral and neurobiological mechanisms of ASD. Valproic Acid (VPA) is an environmental toxin that has been linked to ASD. The VPA rodent model has become one of the most widely used animal analogues of ASD. Here, we examined whether *in utero* exposure to VPA can generate specific behavioral deficits related to temporal processing. Pregnant rats were exposed to VPA (500mg/kg, i.p.) on gestation day 12.5. Pups from each group were weaned and temporal processing was tested using temporal bisection, peak interval, and impulsive choice tasks. In addition, the rats were assessed on a battery of standard behavioral tests that measured motor function, perseverative and exploratory behavior, anxiety, memory, and social interactions. Across the three temporal processing tasks, the VPA group was more heterogeneous, with a subgroup of animals showing decreased response inhibition on the timing tasks and lack of sensitivity to delay in the impulsive choice task, compared to controls. On the other behavioral tasks, VPA animals demonstrated normal performance on the motor and memory tasks, but were significantly different from control animals on some measure of perseveration, anxiety, and

social interaction. These findings have important implications for characterizing the behavioral abnormalities of the VPA model and understanding the temporal processing dynamics observed in humans with ASD.

**Title:** Epigenetics, DNA methylation, and potential biomarkers for fetal alcohol spectrum disorders

**Authors: S. AMIRI**, C. OLSON, W. XU, G. HICKS, J. R. DAVIE, *M. RASTEGAR
Dept. of Biochem. and Med. Genet., Univ. of Manitoba, Winnipeg, MB, Canada

**Abstract:** Epigenetics control gene expression and cellular identity through orchestrated molecular events that are not directly reflected by the genomic DNA sequences. Recent discoveries have highlighted the importance of epigenetic modifications in brain development, neuroscience, and mental health. Such mechanisms include histone post-translational modifications (PTMs), DNA methylation, the action of regulatory RNA molecules, and chromatin remodelling, among others. While histone PTMs constitute the most diverse type of epigenetic modifications, DNA methylation is perhaps the best-studied epigenetic modification that links environmental factors to neuroscience and mental health.
Fetal Alcohol Spectrum Disorders (FASD) refer to a broad spectrum of neurodevelopmental disorders of the brain that are caused by prenatal alcohol exposure. FASD is a life-long disorder that is associated with mental disability, facial abnormalities, impaired cognitive and behavioural symptoms. Through a collaborative team effort, we aim for a combination of genome-wide and candidate gene approach to study the role of DNA methylation in deregulated gene expression program of brain-derived neural stem cells along with *in vivo* studies in mice, in order to identify potential biomarkers for FASD. Such biomarkers are critically important for the diagnosis of FASD cases, where the patient does not show any facial characteristics of FASD.
FASD is one the most common neurodevelopmental disorders in the Western World with a frequency of 1-2% and over 6 billion dollars spending per year (only in Canada) for FASD-associated health-related cost and productivity-loss in the affected individuals. Currently, FASD

has no cure or effective therapy strategy. Identification of potential FASD biomarkers is critically important for early detection of the disease for intervention strategies during the time period that the brain is still under development.

**Title:** Maternal antibodies in Autism spectrum disorder: Toward protection studies

**Authors: *L. BRIMBERG**[1], S. MADER[2], D. COMOLETTI[3], P. HUERTA[2], B. VOLPE[2], B. DIAMOND[2]
[1]Ctr. for Autoimmune and Musculoskeletal Dis., The Feinstein Inst. for Med. Res., Manhasset, NY; [2]Dept. of Autoimmunity, Feinstein Inst. for Med. Res., Manhasset, NY; [3]Robert Wood Johnson Med. Sch., New Brunswick, NJ

**Abstract:** The concept that the in utero environment, and specifically maternal antibodies, can contribute to the development of Autism spectrum disorders (ASD) has been entertained for over a decade, but only recently have specific antibodies been identified. Studies, including our own, have shown that significantly more mothers of children with ASD have brain-reactive antibodies than controls. The hypothesis is that these anti-brain antibodies exploit a natural mechanism of immune protection of the fetus, cross the placenta, and, at a time when the fetal brain is not protected by a competent blood brain barrier, they perturb fetal brain development. To study the antigenic specificities of maternal brain-reactive antibodies and their contribution to ASD pathogenicity, we generated brain-reactive monoclonal antibodies from B cells of women with a child with ASD. We focused on a monoclonal antibody found to bind the extracellular domain of contactin-associated protein-like 2 (Caspr2). Interestingly, anti-Caspr2 antibodies are frequent in

women with brain-reactive serology and a child with ASD. To address its pathogenicity, we intravenously administered either non-brain reactive control antibody B1 or C6 (anti-Caspr2) to pregnant mice on gestational day E13.5. We demonstrated that male but not female mice exposed in utero to the C6 monoclonal antibody display abnormal cortical development at E15.5 with a thinner cortical plate and a reduced number of proliferating cells. Decreased dendritic complexity of excitatory neurons and reduced numbers of inhibitory neurons in the hippocampus, are present in adult offspring. Moreover, they exhibit impairments in sociability, flexible learning, and repetitive behavior. We believe that this effect might cause by anti-Caspr2 antibody mediated internalization of AMPA receptors in fetal neurons. Our initial model is based on a single exposure to the antibody. To capture better the human condition we have generated a new model where anti-Caspr2 antibodies are present during gestation. Female mice were immunized with the extracellular portion of Caspr2. When they exhibited titers to Caspr2, they were housed with a male to generate timed pregnancies. Male fetuses of dams harboring anti-Caspr2 antibodies showed thinning of the cortical plate and reduced proliferating cells at E15.5 similar to our previous results in male fetuses exposed in utero to C6. This histopathology was not seen in fetuses of control mice. We are currently characterizing the behavioral phenotype of offspring born to dams immunized with Caspr2, and developing therapeutic strategies to block the harmful effect of the antibodies.

**Title:** Maternal factors promote autism-like behaviors in offspring

**Authors: *J. HUH**
Univ. of Massachusetts Med. Sch., Worcester, MA

**Abstract:** Maternal immune activation (MIA) contributes to the development of autism-like phenotypes in both primate and rodent offspring. In humans, epidemiological studies suggest that exposure of fetuses to maternal inflammation increases the likelihood of developing Autism Spectrum Disorder (ASD). We recently reported that Th17 cells, $CD4^+$ T helper effector cells expressing inflammatory cytokines such as interleukin 17a (IL-17a), are required in pregnant mice to induce behavioral as well as brain pathologies in the offspring. However, it is unclear if

other maternal factors are required to promote MIA-associated phenotypes. Moreover, underlying mechanisms by which MIA leads to immune cell activation with a systematic increase of IL-17a are not well understood. Our recent data to address these questions will be discussed.

**Title:** Maternal P2X7 receptors drive offspring autism-like behaviour in mice

**Authors: *B. SPERLAGH**, G. HORVÁTH, L. OTROKOCSI, Á. KITTEL
Inst. of Exptl. Med., Budapest, Hungary

**Abstract:** Maternal immune activation is a principal environmental risk factor contributing to neurodevelopmental psychiatric disorders, including autism spectrum disorder (ASD). Maternal infection is associated with the later emergence of ASD compromising foetal brain development at critical periods of pregnancy, and the elevation of maternal pro-inflammatory cytokines has been causally linked to perinatal brain reprogramming. However, the molecular signalling pathway that converts maternal immune activation to pathologically relevant neurodevelopmental abnormalities in the offspring has been unclear until now. The NLRP3 inflammasome signalling pathway, triggered by the co-activation of P2X7 purinergic receptors is an intracellular multiprotein complex responsible for the conversion of innate immune response to inflammation in response to exogenous and endogenous danger signals. Here we report that activation of maternal P2X7 receptors is necessary and sufficient to transduce maternal immune activation (MIA) to autistic phenotype in the offspring. We show that whilst maternal immune activation by poly(I:C) injections to pregnant wild-type mouse dams elicits autism-like phenotype in their offspring, including social deficit, impairment of sensorimotor coordination, repetitive behaviours, atrophy of cerebellar Purkinje cells and destruction of synapses, no such alterations are observed in mice genetically deficient in P2X7 receptors. The effect of P2X7 gene deficiency could be reproduced by maternal treatment with specific P2X7 receptor antagonist JNJ7965567 (20 mg/kg i.p.). Genetic deletion and pharmacological inhibition of maternal P2X7

receptors also effectively counteracted the induction of IL-6 in the maternal plasma and foetal brain, whilst postnatal P2X7 receptor inhibition alleviates behavioural and morphological alterations in the offspring. Our results offer a therapeutic possibility for early prevention and treatment of ASD, the increasingly prevalent psychiatric disorder in children.

**Abstract:** Prenatal air pollution (diesel exhaust particles; DEP) combined with maternal stress (MS) during the last trimester of gestation act synergistically on offspring to promote long lasting changes in neuroimmune function and deficits in communication and social behavior. Both changes in immune function and behavior are consistently more severe in males, in agreement with literature suggesting males are more vulnerable to immune activation early in life, resulting in increased vulnerability to neurodevelopmental diseases such as autism. Microglia are the primary immune cells in the CNS, they are important in immune host defense and are involved in the developmental pruning of synapses. Previous research has demonstrated that transgenic manipulation of microglia number or function alters synaptic development resulting in brain dysfunction. However, it is unclear whether environmentally relevant immune activation produces a similar phenotype. In this study, we aimed to determine whether prenatal DEP and MS (DEP/MS) alters microglia infiltration and cortical development in the anterior cingulate cortex and motor cortex, brain regions implicated in autism and social behavior. Mouse dams were intermittently exposed via oropharyngeal aspiration to DEP (50 μg × 6 doses) or vehicle (VEH) throughout gestation. This exposure was combined with standard housing for dams or nest material restriction (a model of maternal stress) during the last third of gestation. Prenatal DEP/MS altered social communication behavior in male offspring. At P15, prenatal DEP/MS resulted in changes in synapse number, microglial infiltration and neuronal distribution in cortical regions implicated in autism. Taken together, these results suggest that environmental

risk factors can alter microglia development/function, resulting in changes in brain development commonly seen in autism. This model thus affords a unique opportunity to explore environmentally relevant cellular and molecular mechanisms that contribute to neurodevelopmental disorders.

**Abstract:** Maternal health is crucial to neurodevelopment. Recent studies suggest that there is a correlation between gestational diabetes mellitus (GDM) and occurrence of Autism Spectrum Disorders (ASD). In GDM, human placental lactogen (HPL) and human placental growth hormone (HPGH) production promote hyperglycemia which remains persistent as a result of insufficient insulin production or insulin resistance. Although a pregravid body mass index (BMI) of 25 does increase the risk for GDM, it is not a prerequisite. To model the impacts of hyperglycemia without obesity on offspring neurodevelopment, we behaviorally phenotyped offspring of non-obese hyperglycemic dams. Dams were provided with glucose in their drinking water to induce gestational hyperglycemia. The male offspring of hyperglycemic dams (125-200 ug/dL) exhibited anxiety in open field test and elevated plus maze. These mice also harbored impairments in spatial learning in the Water-T-Maze test. Female offspring of hyperglycemic damn had greater obsessive compulsive tendencies in marble burying test, were less social in a social exploration test and showed a depressive tendency. Our data suggests that maternal hyperglycemia results in sex-specific behavioral changes in offspring that are relevant to ASDs and other developmental disabilities.

**Abstract:** Autism Spectrum Disorder (ASD) consists of a range of neurodevelopmental conditions that disproportionately affect males in a 4 to 1 ratio and negatively impact everyday functioning beginning early in childhood. It is characterized by impairments in social interactions and communication, repetitive behaviors, and restricted interests or activities. Both incidence and prevalence of ASD have been markedly increasing over the past few decades, reaching 1 in every 68 children in 2010.
Factors in the *in-utero* environment alter neural development and therefore have been proposed to influence ASD susceptibility. One such risk factor is maternal brain reactive antibodies which penetrate the fetal brain after crossing the placenta and the immature blood brain barrier. We have developed a mouse model of maternal anti-brain antibody induced ASD using C6, an anti-brain antibody isolated from mothers of children with ASD. C6 targets Contactin Associated Protein-Like 2 (CASPR2), a protein expressed in neurons that has been implicated in ASD. C57Bl/6 fetuses (E15.5) exposed to C6 *in-utero* have a thinned cortical plate and a diminished population of progenitor cells in the ventricular zone. Furthermore, *in-utero* C6 exposure leads to ASD-like behaviors in adult mice. Interestingly, these neuroanatomical and behavioral phenotypes only affected males. Identifying the factors that contribute to these sex dependent effects of C6 could help us to understand the male bias in ASD.
In this study, we investigated the role of sex-chromosome and gonadal hormone differences in determining the susceptibility to C6. Specifically, we examined if susceptibility to the effects of C6 is increased by Y chromosome or male gonadal hormones, and decreased by the X chromosome or female gonadal hormones. We used the “Four Core Genotypes” mouse model, which allows for gonadal sex to be independent from sex chromosome complement, to isolate the genetic from the hormonal determinants of the sex-specific phenotypes. We analyzed DAPI stained sections from E15.5 fetuses exposed *in-utero* to C6 or to B1 isotype control for cortical

plate thickness. For this purpose, we developed a computer program that measures cortical plate and cortex areas, and calculates their ratio. The program was designed to increase objectivity and reproducibility of measurements. We found that higher levels of male hormones (represented by $XY^{-}$TgSry and XXTgSry gonadal males) and presence of the Y chromosome (represented by $XY^{-}$ gonadal female) significantly increased the susceptibility to develop a thinned cortical plate. Therefore, both gonadal hormones and sex chromosomes play a role in determining the susceptibility to C6.

**Title:** Altered dopaminergic markers in the basal ganglia in autism

**Authors: *K. SUBRAMANIAN**[1], J.-J. SOGHOMONIAN[2], C. BRANDENBURG[1], K. ZHANG[3], I. SULKAJ[3], B. RANDOLPH[3], G. J. BLATT[1]
[1]Neurosci., Hussman Inst. for Autism, Baltimore, MD; [2]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [3]Boston Univ., Boston, MA

**Abstract:** The main output for midbrain dopamine neurons is to the basal ganglia (BG). The BG are connected to the cerebral cortex and the cerebellum. Specific circuits within the BG are involved in motor and non-motor functions. Bilateral BG lesions lead to social communication challenges and/or repetitive behaviors. Specific lesions observed in such patients have remarkable similarity to behaviors observed in individuals with autism. A recent study on the prevalence of Parkinsonism found a significantly higher rate (20-27%) among individuals with autism compared to the general population (0.1%-0.9%), suggesting shared neurobiological origins and pathways. Since altered dopaminergic neurotransmission leads to classic Parkinson's symptoms, changes to the dopamine system within the BG in postmortem autism brain tissues was examined. Receptor autoradiography was used to measure dopamine type 1 (Drd1) and dopamine type 2 (Drd2) receptors in the caudate (CAU), putamen (PUT), nucleus accumbens (NAC) and subthalamic nucleus (STN). In situ hybridization histochemistry was utilized to measure mRNA levels of Drd2 receptors in the CAU and PUT. There was a significant increase in the density of Drd2 receptors in the NAC ($p=0.03$) and a trend towards significance in the STN ($p=0.0985$). In the striatum there was no significant change in the CAU ($p=0.2262$) or PUT ($p=0.1069$) individually. However, when taken together, CAU and PUT resulted in significantly

higher Drd2 receptor density values (p=0.0431). Also, significantly higher expression of Drd2 receptor mRNA was found in the CAU (p=0.00462) and the PUT (p=0.0483) of autism brains compared to age and sex-matched controls. In addition, no significant change between autism and controls for Drd1 receptor density was observed in any of the examined areas. In summary, the data suggests that specific regions of the BG in autism have significant increases in Drd2 receptor density and mRNA expression but not in Drd1. Since Drd2 is preferentially expressed in the indirect pathway of the BG and is considered to be important to inhibit unwanted actions, altered activation of Drd2 could act to dysregulate unintended actions contributing to stereotypy in autism. Taken together these data indicate a region-specific circuit specific change in the dopamine pathway in autism that could contribute to an excitatory/inhibitory (E/I) imbalance and increased risk for Parkinsonism. Future studies will aim to examine whether there are other neuromodulators whose expression is altered that may also impact the BG circuitry.

**Title:** Mitochondrial dysfunction and oxidative stress in rat brain prenatally exposed to valproic acid

**Authors: *K. MATSUO**, Y. YABUKI, K. FUKUNAGA
Dept. of Pharmacol., Tohoku Univ. Grad Sch. of Pharm Sci., Sendai/Miyagi, Japan

**Abstract:** Autism spectrum disorders (ASD) are a neurodevelopmental diseases characterized by social communication deficits and learning disability. Mitochondrial dysfunction and oxidative stress are strongly related to brain pathology in ASD. It is well known that prenatal exposure to valproic acid (VPA) increases a risk of pediatric ASD. We addressed a question whether autism-like behaviors in prenatally VPA-exposed rats (VPA rats) are associated with mitochondrial dysfunction and oxidative stress in brain. Prenatal VPA exposure (600 mg/kg, p.o.) at E12.5 was conducted and male rats were subjected to memory and social interaction tasks at 5-6 weeks of age. Prenatal VPA exposure elicited impairments in spatial reference memory, object recognition and social interaction. Enzymatic activities of mitochondrial electron transport chain complexes I

and II were decreased, while complex IV activity was elevated in hippocampus of VPA rats. These abnormal enzymatic activities were accompanied by reduced ATP production. The autism-like behaviors in VPA rats were improved by treatment with oxytocin (12 μg/kg, i.n.), which is a therapeutic neuropeptide improving social deficits in ASD patients. Interestingly, treatment with 5-aminolevulinic acid (ALA; 30 mg/kg, p.o.), which is a precursor of heme, restored impaired enzymatic activities of mitochondrial electron transport chain and reduced ATP production. ALA also suppressed elevated oxidative damage in hippocampus of VPA rats. Taken together, ALA ameliorates mitochondrial dysfunction and oxidative damage, thereby improving autism-like behaviors in VPA rats.

**Title:** A novel role of S100B in neuronal trace metal homeostasis associated with dysregulation of autism-associated signaling pathways

**Authors: *S. HAGMEYER**[1,2], J. S. CRISTÓVÃO[3], T. M. BOECKERS[4], C. M. GOMES[3], A. M. GRABRUCKER[1,4]
[1]Univ. Limerick, Dept. of Biol. Scie, Limerick, Ireland; [2]Mol. Analysis of Synaptopathies, Neurol. Dept., Neurocenter of Ulm Univ., Ulm, Germany; [3]Biosystems and Integrative Sci. Inst., Univ. de Lisboa, Lisbon, Portugal; [4]Instiute for Anat. and Cell Biol., Ulm Univ., Ulm, Germany

**Abstract:** Several studies reporting elevated levels of the cytokine S100B in autism spectrum disorders (ASD) patients show an association between symptom severity and S100B levels. In addition, the gene encoding for S100B has been recently identified as an autism risk gene. However, the precise role of S100B in the development of ASD is still unknown. Structural analyses of S100B have shown that the protein harbors calcium and zinc binding sites. Thus, we hypothesize a role in regulating neuronal trace metals. Intriguingly, alterations in neuronal trace metals homeostasis have been repeatedly associated with ASD and this might provide a possible mechanism how S100B is implicated in the development of ASD. Therefore, we investigated whether S100B might affect neuronal trace metal levels using primary hippocampal neurons. Additionally, we evaluated whether the zinc-dependent postsynaptic SHANK proteins known involved in synapse formation, composition, and function and associated with ASD, are affected by S100B induced alterations in neuronal trace metals. We show that high S100B levels lead to significant changes in intracellular zinc levels of primary hippocampal neurons. These changes were abolished by the supplementation of zinc. Further, using a mutant of S100B with reduced

zinc binding capacity, we proof that the observed reduction of intracellular zinc levels indeed results from S100B´s zinc binding. Zinc levels, in contrast to calcium levels, were highly affected. By altering intracellular zinc levels, the exposure of neurons to S100B affects the ASD-associated SHANK protein concentration at synapses. Thus, taken together, our results represent a possible connection of different environmental factors (inflammation, trace metal dysregulation) that have been all reported to be involved in the development of ASD and point towards a combined action at glutamatergic synapses resulting in synaptic dysfunction

**Title:** Embryonic exposure to fluoxetine selectively reduces communication and increases anxiety in male mice while increasing repetitive behaviors in both sexes

**Authors: *M. P. LEUSSIS**, E. A. PETERSON, A. POWERS
Psychology Dept., Emmanuel Col., Boston, MA

**Abstract:** Genetic and environmental factors contribute to autism spectrum disorder (ASD), yet little is known about which environmental factors increase the risk for ASD. Selective serotonin reuptake inhibitor (SSRI) use during pregnancy has increased in recent years. Epidemiological studies have linked SSRI use during pregnancy to a small but significant increase in risk of ASD. The specific long-term neurobiological consequences of prenatal SSRI exposure require further evaluation. This study examined the effects of prenatal exposure to fluoxetine in mice on behaviors relevant to ASD from neonatal development through adulthood. C57BL/6J dams were administered fluoxetine at 0.6 (low) or 6.0 (high) mg/kg/day or saline from embryonic days 8 to 18. Juvenile mice were tested in a developmental test battery that measured ultrasonic vocalizations and neuromotor reflex development. In adulthood, offspring were tested in a battery designed to examine changes in ASD-related social/communicative behaviors, repetitive behaviors, and anxiety behaviors. In juvenile mice, prenatal exposure to fluoxetine sex-dependently reduced the frequency of ultrasonic vocalizations in male mice. Fluoxetine did not detrimentally affect neuromotor development. Both adult males and females prenatally exposed to high, but not low, doses of fluoxetine exhibited an increase in repetitive behaviors in the marble burying task. However, males exposed to fluoxetine exhibited an increase in anxiety in the elevated plus maze, whereas females did not show any change in anxiety. Fluoxetine exposure did not affect behavior in the social preference test, self-grooming or passive

avoidance. Results suggest that males are more sensitive than females to disruptions in serotonin balance during prenatal development, producing long-term changes in behaviors including communication deficits, increased repetitive behaviors, and heightened anxiety. These findings highlight the need for more systematic studies to evaluate the impact of fluoxetine exposure during other periods of prenatal or early neonatal development.

**Title:** Volatile organic chemical exposure affects general development and CNS cell type marker gene expression in zebrafish embryos

**Authors: *B. S. CARTER**, D. L. THOMAS, Y. Z. PRYOR, J. G. RUFFATTO
Neurosci., Oberlin Col., Oberlin, OH

**Abstract:** The role of environmental factors in neurodevelopment and Autism Spectrum Disorders (ASD) is not well characterized. Recent epidemiological findings suggest that exposure of pregnant mothers to volatile organic chemicals (VOCs) has a direct correlation with increased ASD prevalence in their children. However, there have been no studies to date to test how such chemicals impact brain development and if they regulate ASD-associated physiology. We investigated the impact of multiple VOCs (e.g. methylene chloride, trichloroethylene) on neurodevelopment in zebrafish embryos. Titration experiments defined phenotypic and lethal dosage for each chemical; gross morphological phenotypes were observed by brightfield microscopy, and gene expression of different CNS cell type markers were measured by qPCR. Initial results indicate VOCs can induce dose-dependent changes in overall development of zebrafish embryos and result in decreased CNS cell type marker expression for multiple neurotransmitter systems, including excitatory and inhibitory neurons. The character of these effects varies between specific VOCs. Our findings suggest that volatile organic chemicals can regulate neurodevelopment and likely do so through multiple mechanisms. Future experiments characterizing these mechanisms can inform appropriate usage of these chemicals and may add to knowledge of the molecular biology underlying ASD.

**Abstract:** Irisin, the newly discovered myokine, is responsible for the formation of brite (brown in white) or beige adipocytes. Interestingly, Irisin was detected in the Purkinje cells of cerebellum, cerebrospinal fluid (CSF) and paraventricular neurons in hypothalamic region. Irisin has been proposed to play a role in neural cell differentiation, to be involved in dendritic spine formation, and to have a correlation with gene expression of brain-derived neurotrophic factor (BDNF) and homocysteine blood levels. Autism spectrum disorder (ASD) is a multifaceted neurodevelopmental disorder where genetic and environmental factors play a role in its development and pathogenesis. The arrest of neural development, with reduced dendritic spine density, and reduction and incursion in Purkinje cells are some of the neuropathological hallmarks of ASD. In addition, BDNF has been implicated in the pathogenesis of ASD and, recently, homocysteine has also been implicated as the main environmental factor in the pathogenesis of ASD. Given the aforementioned factors that have been demonstrated to be in relation to ASD and Irisin, and being not investigated before according to the authors' knowledge, we aimed to compare Irisin plasma levels in Jordanian children affected by ASD to their age and gender matching healthy controls. The quantitative measurements of Irisin in human plasma samples have been performed using commercial enzyme linked immunosorbent assay (ELISA) kit (EK-067-16, Phoenix Pharmaceuticals Inc., CA, USA), phonetics and EEG assessments have been obtained through medical reports. The preliminary findings of this study were: 1) Irisin level in ASD patients were significantly less compared to their control group. 2) Irisin level was decreased in ASD patients with abnormal EEG or those who are non-phonetic compared to other ASD patients; however it did not reach significance 3) There was no correlation of Irisin plasma level with age of ASD patients or controls.

**Title:** A preliminary investigation on prenatal stress and associated risk factors for development of autism spectrum disorder

**Authors: *S. GOVINDARAJ**[1], P. KANAGASABAI[2], R. RAJAN[1]
[1]Physiol., Univ. of Madras, Chennai, India; [2]Holistic Solutions for Autism, Swabhimaan, Chennai, India

**Abstract: Background:** Stress is an inevitable part of human life, people begin to experience stress at early stages of life, even before birth. Prenatal stress has been linked to several diseases and disorders including many adverse neurobehavioral outcomes, which may share pathophysiology of autism. The severity depends on intensity, duration and time period of stress exposure. Autism Spectrum Disorder (ASD) is the heterogeneous neurodevelopmental disorder with unknown etiology and characterized by impairment in social interaction, communication deficits, restrictive and repetitive behavior. Generally, the incidence of ASD is more in male than female. At present globally it has been estimated the ratio of the ASD against normal children is 1 in 100-150, in the USA 1 in 88 children, in the UK 1 in 64 and in the South Korea 1 in 38.
**Objective:** The present study is to investigate the possible association of prenatal stress as a risk factor for the development of ASD in the offspring.
**Study design:** The questionnaire-based retrospective survey study was conducted and it consists of fifty mothers of children who has been already diagnosed with ASD aged between two to seven years and fifty mothers of children with no diagnosis of any kind of neurodevelopmental diseases aged between two to seven years. The ASD subjects were recruited from “Swabhimaan Holistic Solution for Autism”, is a special school for children with ASD. The data collection was done by distributing the questionnaires to the mothers of children with ASD. For control group, the data collection was done from “New Wisdom School” (Chennai, India).
**Result:** The study reveals that higher incidence of different sources of prenatal stress such as occupational stress, illness of family members, the estrangement of spouse and conflicts with family members were found in mothers’ of ASD children. The ASD group also showed a higher incidence of prematurity, birth complications, health problems, maternal illnesses, and advanced maternal age compared with the normal population. Additionally, people who were

experienced moderate and severe level of stressful experiences during first and second trimester showed severe autistic features.

**Abstract:** Autism spectrum disorders (ASD) are neurodevelopmental disorders characterized by their core symptoms - delayed acquisition of speech, deficits in social interactions and stereotypic behaviors. Genetic factors might be responsible or facilitate the occurrence of ASD but in addition to a combination of ASD-related genes, specific environmental factors may act as risk factors triggering the development of ASD. A growing amount of research indicates that abnormalities in the gastrointestinal (GI) system during development might be a factor in ASD. Many patients with ASD have symptoms associated with GI disorders. We hypothesize that metal ion imbalances during pregnancy are linked to disturbances in the gastrointestinal (GI) tract and may be an important factor for the development of the ASD associated pathology. Zinc status influences and is influenced by multiple factors and an interdependence of prenatal and early life stress, immune system abnormalities, impaired GI functions, and zinc deficiency is hypothesized, linking several environmental factors discussed in ASD in a common proposed mechanism. Here, we show that maternal zinc deficiency leads to GI abnormalities in the offspring, triggering the impairment in metal absorption in the GI tract, but also mediating inflammatory responses. We show that maternal zinc deficiency causes alterations in the Microbiome of the offspring and alters specific inflammatory markers. The alterations in species of microbiota are similar to reported differences in humans with ASD. The inflammatory markers altered are also similar to the ones reported in human patients with ASD. Thus, we provide a link between several environmental factors in autism. Furthermore, to prevent the detected alterations, we characterize novel nutraceuticals that might overcome imbalances of dietary zinc absorption.

**Title:** Elevated microglial populations in the cerebral cortex in autism spectrum disorders

**Authors: *M. S. MANIERKA**
Integrative Program in Neurosci., Univ. of Nevada Reno, Reno, NV

**Abstract:** Critical for both immune defense and synaptic development, microglia may play a key role in the etiology of autism spectrum disorders (ASD). These dynamic cells shift between several morphological states to fulfill a variety of functions, including synapse maintenance and pruning, and primary immune defense. Signs of increased inflammation in the brain and an excess number of immature synapses found in ASD may be the result of abnormal microglial function during development. Previous research has suggested an increase in microglial density in the prefrontal cortex of ASD patients. Given the broad spectrum of autism cognitive symptoms, it seems unlikely that any etiological factor could be restricted to a single cortical region. Instead, we predict that elevated microglial populations are a widespread feature of the ASD cortex.
To explore this possibility, we compared the cortical densities of two unique glial types: microglia and oligodendrocytes. Density counts were conducted in the supragranular layers (II and III) of posterior parietal cortex (Brodmann area 7) in six autistic and six neurotypical controls, and in the lateral/superior temporal cortex (Brodmann areas 21/22) in five autistic and three neurotypical controls. Tissue blocks were sectioned at 40µm across the cortical layers and stained with thionin to label Nissl bodies. To estimate cell population densities, counts were acquired from multiple tissue sections taken from each block using an optical dissector (Stereologer, SRC Inc.). In both parietal and temporal cortices, microglial densities were significantly increased in the ASD subjects. No difference in oligodendrocyte density was found between ASD and neurotypical groups. These findings support a persistent generalized increase in microglial density in the ASD cortex. The ‘distraction’ of an immune challenge during critical periods of synaptic development could prompt excess proliferation of microglia, as these cells attempt to fulfill both developmental and immunological functions in the ASD cortex. Given that this density increase is observed across tissue samples from adolescents and adults, the disruption to microglial populations is hypothesized to be a chronic cortical feature linked to ASD. Further work is needed to determine if microglial disturbances are correlated with other synaptic and cortical patterning changes associated with ASD.

**Abstract:** Autism is a neurodevelopmental disorder with persistent deficits in social communication and social interaction, and restricted and repetitive patterns of behavior, interest, or activities, affecting 1-2.5% of all children. But the pathophysiology of autism is still poorly understood. Recently, increased excitation/inhibition ratio has been proposed as one of the characteristic pathophysiological mechanisms of autism. Deterioration of gamma band oscillations (GBO) was observed in children with autism spectrum disorders or in the animal model of autism. We reported that parvalbumin (PV) neurons in the basal forebrain (BF) play a key role in regulating GBO in the cerebral cortex by activating inhibitory interneurons in the cerebral cortex. Therefore, we hypothesized that the repeated stimulation of BF PV neurons might rectify the excitation/inhibition imbalance by increasing inhibitory neuronal activities in the cortex. First, we developed autism mouse model using intrauterine valproic acid exposure on embryonic day 10.5 of PV::Cre mice in which the expression of Cre recombinase is specifically controlled by PV expression. Secondly, when PV::Cre autism model mice were born, we injected viral vector (AAV5-DIO-ChR2-EYFP) into the basal forebrain, and implanted fiber optic cannula and electrodes for electrophysiological recordings after 2 weeks. After recovery, intermittent photostimulation at 40 Hz was given for 2 hours a day at the beginning of dark period, and repeated for one week. Before and after the one-week optogenetic stimulation, a series of behavioral assessments were to be carried out, including, but not limited to, three chamber test, nest building behavior, open field test, and novel object recognition test. Optogenetic GBO generation was also compared between before and after 1-week photostimulation period. Molecular markers for excitatory (PSD-95, vGluT1, alpha-CaMKII and synaptophysin) and inhibitory (GAD67, Reelin, and connexin 36) were measured in both treatment and non-treatment groups. The experiments are in progress and the results are pending. We are investigating whether E/I balance is restored in molecular markers and

electrophysiology, and consequently the behavioral abnormalities of autism mouse model is reduced by repeated photostimulation of BF PV neurons. We cautiously expect that effective activation of the inhibitory neural network in the cortex may have therapeutic implication in autism model mice.

**Abstract:** Accumulating evidence suggests that maternal immune challenge during gestational and perinatal periods can have lasting effects on neurodevelopment. Previous work has demonstrated that the offspring of pregnant mice treated with immunoreactive agents can exhibit a behavioral phenotype with key features of autism spectrum disorder (ASD). This work is complemented by previous observations that some individuals with ASD exhibit atypical expression of proinflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α). Previous immune challenges have primarily employed agents (e.g., PolyI:C, lipopolysaccharide) that target subtypes 3 and 4 of the Toll-like receptor (TLR) family, a class of receptor proteins that regulates the innate immune response. The current study sought to manipulate TLR7, thereby expanding the repertoire of innate immune targets studied. In addition to its novelty as a target in maternal immune activation models of autism, TLR7 is highly expressed in the placenta, its expression is developmentally regulated in the brain during the perinatal period, and its activity has been implicated in the pathogenesis of systemic autoimmune disease and preeclampsia, both putative ASD risk factors. Activation of TLR-7 by its selective agonist, imiquimod (IMQ), represents a potentially novel approach with which to model immune-mediated ASD phenotypes in mice. Pregnant dams were administered 3 subcutaneous injections of the TLR-7 agonist or saline vehicle on embryonic day 12, 14, and 16, and the

offspring were subjected to a battery of ASD-relevant behavioral assays at various developmental time-points. Offspring of dams treated with IMQ exhibit a profound behavioral phenotype characterized by atypical patterns of ultrasonic vocalization, increased repetitive behaviors, reduced anxiety-like behavior, fragmented social behavior, and hyperactivity under some (but not all) testing conditions. Although there is some overlap between this phenotype and those observed in other maternal immune activation models used in the study of ASDs, it differs in several behavioral domains and therefore may enable new insights on immune involvement in other psychiatric disorders characterized by these signs.

**Title:** Impaired Purkinje neuron dendritic development and motor dysfunction in a VPA-induced mouse autism model

**Authors: R. WANG**, J. TAN, Y. ZHENG, *L. ZHANG
GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou, China

**Abstract:** Autistic spectrum disorder (ASD) is now believed to be correlated with cerebellar developmental deficits by various transgenic mouse models. However, due to heterogeneity of ASD related genetic factors, single gene mutation may not cover the whole picture of ASD pathology in cerebellum. We thus employed maternal exposure of valproic acid (VPA) to generate a mouse ASD model, on which the post-natal development of cerebellar Purkinje cells (PCs) was investigated along with motor function. We found significantly reduced PCs number in most lobules of cerebellar cortex in adult VPA offspring mice. These mice also showed elevated apoptosis in neuron progenitor cells in cerebellar cortex. Golgi staining showed reduced dendritic branching complexity of PCs in VPA-treated mice. In consistent with those developmental disorders, those mice showed impaired motor coordination or motor learning functions on Rota-rod and a new LadderScan behavioral paradigm, in addition to impaired social preference and novelty. Further molecular studies showed that these abnormalities were

correlated with alternation in brain derived neurotropic factor (BDNF) -receptor tyrosine kinase B (TrkB) pathway. In summary, our study showed dendritic under-development in cerebellar Purkinje neurons and impaired motor function, both of which were accompanied with social deficits. These results further supported the involvement of cerebellar disorder in ASD pathology.

**Abstract:** Increasing evidence suggests a role for inflammatory processes in autism spectrum disorders (ASDs). Some individuals with ASDs show elevated inflammatory markers and neuroimmune responses, as well as epidemiological association with familial autoimmune disorders. These findings raise the possibility that there is a subtype of ASD that is immunological in origin. Previous research in mice has shown that immune system activation during critical developmental periods can result in a phenotype that reproduces some of the core features of ASD. We have recently developed a “multiple hit” immune model, whereby mice are exposed to repeated perinatal immune insults. In this model, pregnant mice are injected with the viral mimic poly(I:C) (20 mg/kg) on gestational day 12.5 in accordance to an established model of maternal immune activation. A subset of these offspring receives a second injection of LPS (lipopolysaccharide) (10 mg/kg) to induce a robust innate immune response on postnatal day 9. We have previously found that this model leads to a state of persistent immune activation in offspring, which persists into adulthood, as well as a pronounced ASD-like behavioral phenotype with mice displaying deficits in social and communication-like behavior, increased repetitive behavior. Here, we examine the effect of this multiple hit immune activation model on two

physiological measures that are commonly dysregulated in individuals with ASD: sleep and electroencephalography (EEG) epileptiform activity. A wireless transmitter enabling continuous data collection was implanted at postnatal week 6 and measurements of EEG, electromyography (EMG), activity, and temperature were recorded for several weeks. Two time points were examined, one at 7 weeks of age and a second at 13 weeks to examine changes across development. There were marked changes in sleep patterns (increased slow-wave sleep) and changes in EEG spectral power that resembles those found in individuals with ASD. Considering that epilepsy is found in a higher percentage of individuals with ASD, we examined EEG recordings from perinatal immune-activated mice for the presence of epileptiform activity. Analysis revealed that a large proportion of the mice that received postnatal LPS displayed heightened levels of epileptiform activity (spike-wave discharge) during sleep. In sum, perinatal immune activation resulted in alterations in sleep and epileptiform activity resembling aspects of ASD, further supporting a potential immunological involvement in ASD and co-morbid seizure disorders.

**Abstract:** Autism spectrum disorder (ASD) is a neurodevelopmental disorder. It characterized by a socio-communicational impairment with restricted or repetitive interest and activity. In addition, sleep and GI disturbances as well as the decrease in bone density are also noticed in many patients with ASD. These defects, especially the one that related to the bone density, highlight the possible role of vitamin D in the development of ASD. In addition to its role in calcium homeostasis, studies suggested that vitamin D work as a neurosteroid hormone which plays a crucial role in brain development by its involvement in cell proliferation and

differentiation. Moreover, Vitamin D is suggested to play a role in brain detoxification. In addition, it also considered as a prohormone that exerts its functions through its active metabolites. Vitamin D is obtained from natural sources either from dietary vegetable as Vitamin $D_2$, also known as ergocalciferol, or as cholecalciferol D3 which obtained from animals or produced in the skin. Both $D_2$ and $D_3$ are biologically inert, and is subsequently converted in the liver to 25-hydroxyvitamin D (25[OH]D), which consist the major circulating form of vitamin D, and then in the kidney and other organs to 1,25-dihydroxyvitamin D, the active form of vitamin D. Recently, many studies highlighted the decreased level of (25[OH]D) in autistics. Moreover, Vitamin D supplement shows improvement in the behavior, IQ, sleep pattern and other symptoms associated with ASD. **Hence the aim of this study was to examine the association between 25[OH]D blood levels and autism in Jordan** To study that, serum total 25-hydroxycalciferol (25-OH-D) level was measured in 65 ASD patient and 70 age and gender matched healthy controls using LCMSMS. In addition Serum calcium levels were also measured using the automated standard laboratory method. Our data revealed 1) statistically significant lower levels of 25-OH-D in ASD group compared to controls, 2) and no significant difference was found in calcium levels. These data suggest a possible role of low vitamin D in the pathophysiology of ASD, yet its role is in a mechanism other than affecting calcium levels.

**Abstract:** Depression is a serious mood disorder that may require antidepressant use during pregnancy. Safety concerns have been raised about the effects of selective-serotonin reuptake

inhibiting (SSRI) antidepressants on fetal brain development and their potential to increase the risk of autism in developmentally exposed offspring. The most commonly prescribed SSRI for use during pregnancy is fluoxetine (Prozac). Fluoxetine blocks serotonin (5-HT) reuptake by the 5-HT transporter. 5-HT is vital for shaping neural circuitry during development, and aberrant fetal 5-HT levels can increase the risk of autism, which is diagnosed based on the dual manifestation of social behavior deficits and repetitive behaviors. Fetal 5-HT availability may be highly dependent upon maternal availability of its precursor, tryptophan (TRP), hence, elucidation of the relationship between maternal and fetal TRP and 5-HT demand and availability is crucial to understanding their role in autism susceptibility. Using a mouse model of maternal SSRI exposure with dietary TRP manipulations during pregnancy and lactation, we measured the social interaction and novelty preference, as well as repetitive behavior of adolescent offspring. In recent studies we demonstrated that a daily sub-therapeutic dose (1 mg/kg) of fluoxetine, or a maternal dietary TRP depletion, is able to impair offspring sociability with sexually dimorphic relevance to hallmark autistic behaviors. Exposed males demonstrated worsened social behavior outcomes, while exposed females tended to be more impacted in repetitive behavior measures. Our early results suggest that males may be more sensitive to in utero exposure to 5-HT altering factors, and that males and females may compensate for their developmentally altering effects by different mechanisms. We hypothesize that a clinically relevant dose (10 mg/kg) of fluoxetine will lead to severe behavioral impairments compared to controls, and that TRP depletion will compound these outcomes, but may be rescued with the addition of a TRP enhanced maternal diet. We also anticipate finding higher levels of 5-HT turnover in fluoxetine exposed offspring brain tissue, and impairments in serotonergic neurodevelopment in offspring exposed to these 5-HT depleting manipulations. We aim to demonstrate if a maternal therapeutic dose of SSRI is able to cause developmental serotonergic system impairments that could cause persistent sociability and repetitive behavior deficits that might help to explain the increased incidence of autism in offspring who were developmentally exposed to SSRI's.

**Title:** Implication of MUNC18-1-gene abnormalities in neurodevelopmental disorders

**Authors: *K.-I. NAGATA**, N. HAMADA, H. TABATA
Inst. For Developmental Research, Aichi Human Service Ctr., Kasugai, Japan

**Abstract:** While Munc18-1 is essential for presynaptic vesicle fusion in developed neurons, this molecule is likely to be involved in brain development since gene abnormalities in *MUNC18-1* (*STXBP1*) cause early infantile epileptic encephalopathy with suppression-burst (Ohtahara syndrome), neonatal epileptic encephalopathy and other neurodevelopmental disorders. We analyzed physiological and pathophysiological relevance of Munc18-1 during the cortical development. Munc18-1-knockdown impaired cortical neuron positioning during mouse corticogenesis. Time-lapse imaging revealed that the mispositioning was attributable to defects in radial migration in the intermediate zone and cortical plate. Munc18-1-binding protein, Syntaxin1A, was also critical for radial migration downstream of Munc18-1. As for the underlying mechanism, Munc18-1-knockdown in cortical neurons hampered post-Golgi vesicle trafficking and subsequent vesicle fusion at the plasma membrane *in vivo* and *in vitro*, respectively. Notably, Syntaxin1A-silencing did not affect the post-Golgi vesicle trafficking. These data indicate that Munc18-1 may regulate radial migration by modulating not only vesicle fusion at the plasma membrane to distribute various proteins to the cell surface but also preceding vesicle transport from Golgi to the plasma membrane. Although knockdown experiments suggests that Syntaxin1A does not participate in the post-Golgi vesicle trafficking, it was supposed to regulate subsequent vesicle fusion under the control of Munc18-1. Taken together, functional abnormalities of MUNC18-1 may induce aberrant cortical neuron migration leading to functional defects of cerebral cortex, and consequently contribute to the pathophysiologies of infantile epilepsies and other neurodevelopmental disorders with MUNC18-1 abnormalities.

**Title:** Folate receptor 1 is necessary for neural plate cell apical constriction during neural tube formation

**Authors: O. A. BALASHOVA**[1], O. VISINA[2], *L. N. BORODINSKY[3]
[1]Physiol. & Membrane Biol. - Shriners Hosp. for Children, [2]Shriners Hosp. for Children - Physiol. & Membrane Biol., [3]Univ. of California Davis, Sacramento, CA

**Abstract:** Folate supplementation prevents up to 70% of neural tube defects (NTDs), which result from a failure of neural tube closure during embryogenesis. The elucidation of the mechanisms underlying folate action has been challenging. Our study introduces *Xenopus laevis* as a model to determine the cellular and molecular mechanisms involved in folate action during neural tube formation.
We find that knockdown of folate receptor 1 (FOLR1) impairs neural tube formation and leads to NTDs. FOLR1 knockdown in neural plate cells only is sufficient to induce NTDs. FOLR1-deficient neural plate cells fail to constrict, resulting in widening of the neural plate midline and defective neural tube closure. Our results demonstrate that FOLR1 interacts with the adherens junction component C-cadherin and its molecular partner β-catenin. We find that neural plate cells undergoing apical constriction contain C-cadherin-immunopositive puncta associated with early endosomes, which suggests that C-cadherin endocytosis is involved in reduction of the apical surface in constricting cells. FOLR1 knockdown in the medial neural plate is accompanied by a decrease in the number of C-cadherin-containing endosomes in superficial cells. In addition, FOLR1 interacts with the insulin-like growth factor 1 receptor (IGF1R) and incubation of neurulating embryos with folinic acid leads to an increase in calcium transients in the neural plate and Akt activation. Moreover, FOLR1 knockdown results in a decrease in spontaneous calcium transients in the neural plate.
Altogether, these results support a model in which folate binding to FOLR1 triggers a specific signaling pathway that regulates cell adhesion and cytoskeletal dynamics essential for the formation of the neural tube.

**Title:** IGFBP3 deficiency leads to behavior impairment with monoaminergic dysfunction

**Authors: *M. ITOH**[1], H. DAI[2]
[1]Natl. Ctr. of Neurol. and Psychiatry, Kodaira/Tokyo, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

**Abstract:** Insulin-like growth factor binding protein-3 (IGFBP3) regulates IGF bioactivity, induces apoptosis and inhibits cell growth independent of IGFs, but the functional role of IGFBP3 in the brain is not clear. In the present study, we revealed the effect of IGFBP3 on the brain by characterizing the phenotype of *igfbp3*-null mice. Compared to wild-type mice, *igfbp3*-null mice showed significantly decreased IGF-1 content in the brain but showed no change in weights of brain and body. In *igfbp3*-null mice the number of dendritic spines was significantly reduced, and the dendritic diameter was thin. In addition, in *igfbp3*-null mice, a decrease in phosphorylated Akt and ERK1/2 significantly reduced PSD-95 expression, and GAD65/67 expression was significantly decreased. These results indicate that IGFBP3 deficiency impairs neuronal structure and signaling. In behavioral studies, *igfbp3*-null mice were hyperactive, and a Y-maze alternation test revealed impaired spatial working memory, but no anxiety-like behavior. Monoaminergic analysis using HPLC indicated that *igfbp3*-null mice showed lower levels of dopamine and serotonin compared to wild-type mice, suggesting an abnormal monoaminergic neurotransmission. In conclusion, our studies demonstrated that the deletion of IGFBP3 results in behavioral impairments that are associated with abnormal synaptic function and monoaminergic neurotransmission, which helps to characterize the critical role of IGFBP3 in the brain.

**Abstract:** DNA methylation is an essential epigenetic modification with a key role in brain development and synaptic plasticity. In mammalian genomes, DNA methylation typically occurs at cytosines in a CG-dinucleotide context (mCG), whereas substantial non-CG methylation (denoted mCH) is a unique feature of the epigenomes of neurons and, to a lesser extent, glial cells. Our earlier re-sults showed that mCH accumulates in brain during post-natal development, in parallel with syn-aptogenesis and neuronal maturation. The de novo DNA methyltransferase Dnmt3a is highly expressed in brain at this time, suggesting mCH accumulation in neurons may require precise regulation of Dnmt3a activity.
To test this hypothesis, we used isolation of nuclei tagged in specific cell types (INTACT). We produced a mouse carrying the INTACT construct and expressing Cre driven by the NeuroD6 promoter to establish a conditional Dnmt3a knockout (KO) mouse. In this mouse, Dnmt3a deletion from cortical and hippocampal pyramidal neurons occurs during the mid-embryonic phase, around embryonic day 13-15. Using the INTACT nuclear envelope tag, we isolated py-ramidal nuclei from frontal cortex and hippocampus from animals at postnatal day 39 to profile DNA methylation and transcription using MethylC-seq and RNA-seq, respectively. Compared to control animals, mCH was eliminated in pyramidal neurons from Dnmt3a KO animals in both brain regions, supporting the role of Dnmt3a in postnatal mCH accumulation. Global mCG levels in the Dnmt3a-KO animals were 10% lower in KO, and we identified hun-dreds of thousands differentially methylated regions (DMRs) with lower mCG in KO compared with controls. RNA-seq data from matched tissue samples displayed altered transcriptional ex-pression at hundreds of genes in the KO samples, with more pronounced changes in frontal cor-tex than hippocampus. In contrast with the largely unidirectional shifts in methylation levels, gene expression changes in the KO were balanced with similar numbers of up- and down-regulated genes. These results indicate that Dnmt3a is required for the non-CG methylation ac-cumulation in mouse brain. Dnmt3a alters both CG and non-CG methylation post-natally and is essential for the dynamic balance of the gene regulatory network during neuronal development.

**Abstract:** Early life experience influences stress reactivity and mental health through effects on cognitive-emotional functions that are, in part, linked to gene expression pattern in the dorsal and ventral hippocampus. The hippocampal dentate gyrus (DG) is a major site for experience-dependent plasticity that associates with sustained effects on transcriptional activity, potentially mediated via epigenetic modifications including DNA methylation. We used whole genome bisulfite sequencing and Tet-assisted bisulfite sequencing (TAB-Seq) to profile DNA methylation and hydroxymethylation, respectively, in the DG of mice raised in standard housing (SH) and enriched environment (EE). These data were integrated with transcriptome (RNA-Seq) information from the same tissue. Because of the substantial molecular, functional and connectivity differences between the dorsal and ventral poles of the DG (dDG and vDG, respectively), we separately dissected these regions to examine their responses to EE.
Dorsal and ventral poles of the DG showed remarkable diversity in gene expression, with significant differential expression of 53% of all genes that are expressed in either region. Among the DE genes, a similar number of genes were upregulated in the dorsal and the ventral regions. We identified 152 genes differentially expressed in EE compared to SH in the dDG and 72 in vDG, including activity regulated immediate early genes *Fos*, *Egr2* and *Npas4*. Next, we identified over 10,000 differentially methylated regions (DMRs) between dDG and vDG in SH samples. Animals raised in EE showed nearly 60% more DMRs, suggesting that experience may support the molecular differentiation of the dorsal and ventral DG. Our results show that despite

consisting primarily of dentate granule cells, the dDG and vDG show substantial molecular diversity that may be supported by underlying differences in DNA methylation.

**Abstract:** DNA methylation is an epigenetic mechanism fundamental for establishing and maintaining cellular phenotypes throughout the lifespan of an individual. While occurring mainly in a cytosine-guanine (CG)-dinucleotide context, brain tissue also contains a substantial amount of non-CG methylation (mCH), whose accumulation coincides with transcriptional changes during synaptogenesis and neuronal maturation. The de novo DNA methyltransferase Dnmt3a is highly expressed in the brain during that period, and our preliminary in vivo and in vitro data suggest that this enzyme is responsible for the accumulation of mCH during the second postnatal week. Now, we have created a conditional Dnmt3a knockout mouse in which Dnmt3a deletion from pyramidal neurons occurs during late embryonic stage (around embryonic day E15, Neurod6-Cre). Gene ontology analysis of RNA-seq data from pyramidal neurons in the prefrontal cortex of our mouse revealed that the class of genes controlling neural excitability and synaptic functions was significantly downregulated, suggesting a likely role in information transmission. In preliminary behavioral experiments, we found our mouse to be viable, fertile and devoid of motor deficits, which contrasts with reports showing that animals with an earlier

Dnmt3a embryonic deletion (~E9, Nestin-Cre) underperformed on tests of neuromuscular function and motor coordination. Results from further behavioral testing, electrophysiological experiments and morphological analysis, which are currently underway, will help clarify the role of Dnmt3a in brain function.

**Abstract:** Developmental exposure to prenatal stress (PS) as well as the neurotoxicant lead (Pb) can affect brain development and adversely influence behavior and cognition potentially through influences on the epigenome. Epigenetic gene regulation is crucial for normal brain development and misregulation in any form can result in neurodevelopmental disorders. Post-translational histone modifications (PTHMs) are an integral and dynamic component of the epigenetic machinery involved in gene regulation and the influence of PS and Pb exposures on PTHMs, from early developmental stages to adulthood, has not been studied. Here we examined the effects of Pb±PS on global levels of activating marks H3K9ac and H3K4me3 and repressive marks H3K9me2 and H3K27me3 in mouse hippocampus (HIPP) and frontal cortex (FC) at different developmental stages: E18, PND0, PND6 and PND60. Dams were exposed to 0 or 100ppm Pb before breeding followed by no PS (NS) or PS resulting in four treatment groups: 0-NS (control), 0-PS, 100-NS and 100-PS. Global levels of PTHMs varied from E18 through adulthood in control mice and were influenced by sex and brain-region. The normal developmental trajectory of PTHM levels was further modified by Pb±PS in a sex-, brain region- and age-dependent manner. Females appeared to show a preferential response to Pb alone in FC

and differentially to PS alone and combined Pb+PS in HIPP. In males, PS-induced increases were seen in FC, whereas PS produced reductions in HIPP; Pb-related increases occurred in both regions. Pb±PS-based changes continued to be observed in adulthood (PND60), demonstrating the lasting effect of these early life environmental events on these histone marks. These results add to our understanding of the epigenetic consequences of developmental Pb and PS exposures and support the need for additional studies to understand the functional significance of changes in PTHM levels on expression of individual genes and functional pathways.

**Title:** Investigating the role of the schizophrenia risk gene ZNF804A in early brain development

**Authors: *Y. ZHOU**, F. DONG, Y. MAO
Biol., Penn State Univ., State College, PA

**Abstract:** ZNF804a was the first gene to reach genome-wide significance for psychosis when SNP rs1344706 was shown to be significantly associated combining SZ and bipolar disorder diagnoses. Several follow up genome-wide associated studies (GWAS) have replicated the association of rs1344706 with SZ and other psychosis in different populations. Although the association with SZ has been reported since 2008, the molecular function of ZNF804a remains unclear. We found that ZNF804a expression is high in the embryonic brain but decreased in the adulthood and ZNF804a localizes in both nucleus and dendrites. We performed in utero electroporation using B6 wild type mice on embryonic day 15 (E15) and transfected the neuronal progenitor cells with ZNF804a overexpression (OE) and knockdown (KD) constructs, both were tagged with GFP. On E18, the electroporated embryos were collected and the brains were processed with cryo-sectioning and fluorescent immunocytochemistry (ICC) staining. Quantitated results of GFP positive neuron showed overexpressing ZNF804a in utero significantly increased the migration of new born neuron, while knockdown endogenous ZNF804a significantly decreased the neuronal migration. To determine how ZNF804a regulates neuronal migration, we conducted the yeast two hybrid screen and identified novel proteins that interact with ZNF804a. Taken together, our study paved the road of understanding the molecular mechanism of ZNF804a and demonstrated its significant role for major mental illness in neuronal development.

**Abstract:** The rapid spread of Zika virus (ZIKV) and its association with abnormal brain development constitute a global health emergency. Congenital ZIKV infection produces a range of mild to severe pathologies, including microcephaly. These pathologies are specific to fetal brain tissue, where neural stem cells are targeted. To understand the pathophysiology of ZIKV infection, we use an *in vivo* mouse model of fetal brain development that recapitulates the human cytoarchitecture of early to mid-gestation. ZIKV PRVABC59, isolated from the blood of a patient in Puerto Rico in December 2015, is used to characterize ZIKV infection of neural progenitors and resulting changes in mouse brain development. Multiple dose concentrations, routes of administration, and inoculation periods are investigated at several points during gestation to characterize the development of congenital Zika syndrome. The targeted neural precursor types are identified at various stages of brain development using in utero electroporation. Changes in neuronal proliferation and migration are then quantified to inform the etiology of microcephaly. ZIKV injections with concurrent use of in utero electroporation allow for labeling of neural progenitor subtypes and identification of lineages susceptible to infection and transmission of ZIKV. Immunohistochemistry enables co-labeling of ZIKV positive cells and electroporated cells to determine cell-type specific infection by the virus in the developing brain. Infection of embryos allows for the study of developing mice and also cross-transmission between infected fetuses and the maternal circulation. This model provides a platform for robust *in vivo* screens of potential pharmacotherapeutics designed to limit ZIKV transmission and promote healthy development in infected fetuses that are also safe during pregnancy. Together, ZIKV infections in mothers and in developing mice at varying doses, inoculations, and stage in development combined with cell type specific in utero electroporation techniques will further elucidate the etiology of congenital Zika syndrome and microcephaly in an *in vivo* model of mammalian development.

**Abstract:** It has been reported that the commonly used general anesthetics such as sevoflurane induce neurotoxicity in developing brains. However, there has been limited research evaluating whether and how anesthetic agents affect bio-lipids, the most abundant components of the brain other than water. Thus, assessing lipid profiles, especially from blood samples, may assist in the early detection of the neurotoxic effects that can be associated with general anesthesia.
Postnatal day (PND) 5 or 6 monkeys were randomly assigned to control (room-air; n=4) and sevoflurane-exposed (n=4) groups. Sevoflurane was delivered using an agent-specific vaporizer for 9 hours at a clinically-relevant concentration of 2.5%. Blood samples were collected at 0, 2, 4, 8 and 9 h during exposure in both the control and sevoflurane-exposed groups. Lipid extractions and analyses were performed using a mass spectrometer. 4-h after completion of anesthetic exposures, frontal cortical tissue was collected for histochemical and Western blot analyses.
Serum lipidomic analysis demonstrated that the levels of critical lipid components including acylcarnitines, phosphatidylcholines (PC) and phosphatidylethanolamines (PE) were significantly decreased during prolonged exposure to sevoflurane. In contrast, the amounts of triglyceride (TAG) and 4-hydroxynonenal were increased to abnormally high levels in sevoflurane-exposed monkeys. Consistently, histochemical staining and Western blot analyses of Bax protein revealed increased neuronal apoptotic damage after sevoflurane exposure.
These data suggest that prolonged exposure of neonatal monkeys to a clinically-relavent concentration of sevoflurane resulted in significant changes in lipid metabolism and subsequently, neuronal apoptotic damage. Monitoring specific lipid changes may provide

insights into the molecular mechanism(s) underlying general anesthetic-induced neurotoxicity and serve as sensitive biomarkers for the early detection of anesthetic-induced neuronal damage. Supported by NCTR /FDA

**Abstract:** During these decades, neurodevelopmental diseases such as autism spectrum disorder (ASD) have been increased dramatically. Part of the reason can be parental aging caused by the rise of marriage age. Human epidemiological studies have repeatedly indicated that advanced paternal age, rather than maternal one, increases risk for ASD. Thus we have established a mouse model to challenge the underlying molecular mechanism for transgenerational epigenetic inheritance from sperm to offspring. We confirmed that advanced paternal age impaired vocal communication in their F1 pups and affected sensorimotor gating and spatial learning in adult. These phenotypes in F1 were rescued in F2 offspring when they were derived from young F1 father, suggesting epigenetic changes in sperm rather than increase of genetic mutation. Comprehensive DNA methylome analyses further revealed drastic changes in aged sperm, i.e., 96 hypomethylated and 16 hypermethylated genome loci, including NRSF/REST repressor motif in common. NRSF/REST was also identified from “transcription factor enrichment analyses”. We also found several schizophrenia/autism related genes in hypomethylated loci but not in hypermethylated ones. We are now struggling to obtain gene expression data for drawing a possible scenario how specific hypomethylated genome loci may result in disreguration of various genes related with neural development.

**Abstract:** Identified nearly a century ago, Canavan Disease (CD) is a fatal progressive childhood Leukodystrophy. It has not been curable due to the lack of understanding the early mechanisms of disease onset and its progression. First detected in Jewish decedents, now identified throughout the world within diverse ethnic background. CD is a result of mutation in Aspartoacylase (Aspa/ACY2) gene expressed in oligodendrocytes (OLs) in the brain. Presently 65 confirmed Aspa gene mutations has been identified with varied severity ranging from mild cognitive loss as in Autism, to severe spongy white matter and early death. The Aspa enzyme metabolizes N-acetylaspartate (NAA) to provide acetyl-CoA, thought to be the major source for lipid synthesis used for myelin formation, and ATP production in mitochondria. In the absence of Aspa enzyme, NAA level increases progressively in plasma and urine, which is detectable in affected infants. In CD infants, however, acetate therapy was not effective when tried after the onset of disease symptoms. Working with animal models of CD, our lab and others have contributed to the understanding of disease severity. We had also reported death of OLs, astrocytes and neurons in the brain. In our recent studies, we focused on early developmental gene expression by Gene Array and Metabolomics studies at P10, P20, from the onset to the peak stage of myelination in a mouse model of CD. The results presented expression profiles of multiple significant target genes resulting in alteration of structural and metabolic pathways. Our gene and protein analysis further validated impairment of these up- and down-regulated genes and altered pathways in ASPA mutants, suggesting possibility of other direct or indirect role of ASPA in CNS health and disease. In a therapeutic approach, we performed Aspa gene editing via homologous recombination using donor DNA and zinc finger nuclease (Zfn) technology in

newborn Aspa KO mouse neural cells. ASPA locus was targeted for gene editing to integrate the correct copy of the Aspa gene followed by termination codon to stop expression of the mutated gene. In addition, we have generated another cell line by integrating full Aspa gene at the safe harbor site using Rosa26-Zfn away from the Aspa gene mutation site within the same cell. Working with WT, KO and two above described edited cells, we have now validated molecular changes by gene expression analysis. The results also verified the fact that our Gene Trap method used to generate mutant mice strain does not contribute towards identified altered genes, hence are relevant to CD pathology.

**Abstract:** Overwhelming evidence suggests that Schizophrenia (SCZ) is a neurodevelopmental disorder with a strong genetic underpinning. Genome-wide association studies identified numerous SCZ risk genes, including rare variants of members of the *SEMAPHORIN (SEMA)* family of axon guidance molecules and their receptors the *PLEXINs (PLXNs)*. Human variants of *PLXNA2* lead to reduced *PLXNA2* gene expression in the forebrain and increased SCZ susceptibility. The underlying biology and neural circuitry perturbed by *SEMA/PLXNA2* mutations that can cause SCZ symptoms in patients remain unknown. We show that in mice global *Plxna2* deficiency (*Plxna2*$^{-/-}$) disrupts migration and proliferation of early-born dentate granule cells (GCs) as they travel from the primary neuroepithelium to the dentate gyrus (DG) primordium. Genetic labeling of Nestin$^{+}$ cells in the postnatal *Plxna2*$^{-/-}$ DG revealed a significant

decrease in the stem cell population and reduction in DG overall size. PlxnA2 is expressed by migrating GCs and PlxnA2 forward signaling through its rasGAP domain is required for proper GC migration *in vivo*. Loss of *Sema5A* leads to a similar GC migration defect. *In vitro*, Sema5A/PlxnA2 signaling causes rapid collapse of COS7 cells. Cell collapse depends on a functional PlxnA2-rasGAP domain and the small GTPase Rap1b. Morphological defects in the adult *Plxna2*$^{-/-}$ hippocampus include dispersion of the granule cell layer and aberrant GC-CA3 connectivity, reminiscent of temporal lobe epilepsy. However, *Plxna2*$^{-/-}$ mice are not epileptic, as assessed by EEG recordings with epidural electrodes. Behavioral studies with *Plxna2*$^{-/-}$ mice revealed selective defects in contextual fear conditioning but not in cued fear conditioning. *Plxna2*$^{-/-}$ mice show reduced sociability in the 3-chamber-approach test and a striking reduction of PPI (Pre-Pulse Inhibition) of the acoustic startle response. Selective disruption of the PlxnA2-rasGAP activity recapitulates the PPI phenotype observed in *Plnxa2*$^{-/-}$ mice. Collectively, our studies identify a novel mechanism for GC migration and reveal SCZ-like behaviors caused by disruption of PlxnA2-rasGAP forward signaling. Insights into the neural circuits affected by *PLXNA2* mutations and characterization of the biochemical pathways regulated by PlxnA2-rasGAP signaling may be exploited therapeutically in psychiatric disorders.

**Title:** Alteration of cortical-striatal circuits in a new genetic mouse model of infantile spasms and seizures

**Authors: *A. PIRONE**, C. DULLA, M. JACOB
Dept. of Neurosci., Tufts Med. Sch., Boston, MA

**Abstract:** Infantile spasms (IS) constitute a catastrophic childhood epilepsy syndrome characterized by neonatal spasms, lifelong seizures and cognitive deficits. Current frontline medications have mixed efficacy and cause severe side effects. Developing new effective treatments is essential, but requires knowledge of the underlying molecular and functional

changes, and the particular brain regions whose malfunction cause spasms and seizures. To gain insights into the pathophysiology of the disease, we have developed a new genetically modified mouse model of IS with conditional deletion in neurons of adenomatous polyposis coli protein (APC cKO), the major negative regulator of β-catenin/Wnt. The APC, β-catenin, Wnt pathway links to several IS-risk human genes. Further, missense variants in APC, predicted to be damaging, have been identified in individuals with epileptic encephalopathies. These correlations support the importance of elucidating how malfunction of this pathway alters the brain. APC cKO mice exhibit most of the features seen in individuals with IS *(Pirone et al., 2017)*. Neonatal APC cKOs, compared with wild-type littermates, exhibit high amplitude flexion-extension spasms and abnormal EEG recordings. Adult APC cKOs display spontaneous behavioral and electrographic seizures, as well as cognitive impairments. APC cKOs show brain structural changes consisting of corpus callosum agenesis, synaptic spine density on glutamatergic projection neurons, and aberrant organization of processes in the striatum. At the age of peak spasm intensity, postnatal day 9, APC cKOs display increases in excitatory synaptic activity, increased cortical glutamatergic inputs on dorsal striatum medium spiny neurons (MSNs). P9 MSNs also exhibit increases in mEPSC frequency, but no change in amplitude. Cortical-striatal connections function to regulate motor behaviors, and influence the formation of widespread network connections across many brain regions. Interestingly, the neonatal time window of the formation and maturation of cortical-striatal connections correlates with the age of IS-like motor spasms in APC cKOs. Our studies are elucidating whether malfunction of cortical-striatal circuits underlies spasms and progression to chronic seizures. We are also identifying novel molecular targets with potential for new, specifically targeted therapeutic interventions.

**Abstract:** Many genetic mutations that deteriorate neuronal functions could result developmental delay accompanying intellectual disability. In the hereditary genetic disorders, genetic mutations could be inherited in one of several patterns like autosomal dominant or autosomal recessive or X-linked inheritance. Next generation sequencing have disclosed many variants in one gene that elicit genetic disorders inherited in the different patterns. For example, each mutation in the same gene could result developmental disorders showing autosomal recessive inheritance or autosomal dominant inheritance. It has been suggested that dominant negative effects exerted by mutations elicit autosomal dominant inheritance. Here it might be questioned whether mutations inherited in autosomal recessive disorders could not exert dominant negative effects. We set new strategy to evaluate the degrees of dominant negative effects exerted by each mutation identified from one gene that results developmental delay. In conclusion, dominant negative effect exerted by mutations of autosomal dominant inheritance was stronger than autosomal recessive inheritance. These results suggest that each mutation might exert various degrees of dominant negative effects according to their properties of the mutated amino acids.

**Abstract:** Synapses are the relay points for information transfer in the nervous system. These remarkably complex connections are required for nervous system function, but surprisingly few genes have been directly linked to synapse integrity. Here, we leverage the resources available through the International Mouse Phenotyping Consortium (IMPC) to Identify Novel Synaptic Integrity Genes by High Throughput screening (INSIGHT). We computationally identify 446 genes of the available 4288 lines that play a role in regulating neural phenotypes. We then characterize 90 unique gene knockouts for novel architectural and synaptic defects using the organizational and functional advantages of murine retina. We evaluated key components of circuit integrity including neuronal and glial anatomy, synaptic lamination and distribution, as well as layer topography and organization. We uncover neural and synaptic regulatory roles for previously uncharacterized genes and document additional biological functions for genes with previously reported neural phenotypes. In addition, several of the synaptic regulatory genes we document play roles in human neural diseases, suggesting that this dataset may facilitate identification of novel disease causing alleles.

**Title:** mTOR-dependent ULK1phosphorylation is rapamycin resistant in neural-derived cells

**Authors:** *A. M. SOKOLOV, ***A. M. SOKOLOV**, D. M. FELICIANO
Biol. Sci., Clemson Univ., Clemson, SC

**Abstract:** The mammalian target of rapamycin (mTOR) is a protein kinase that partitions into two complexes, mTORC1 and mTORC2. mTORC1 stimulates anabolic but inhibits catabolic processes whereas mTORC2 regulates the cytoskeleton and cell survival. Appropriate mTOR activity during brain development is essential for proper formation and optimization of neuronal morphology. One mechanism that may contribute to these events is mTOR inhibitory phosphorylation of the pro-autophagic kinase Ulk1 at serine 757. We found that embryonic day 14.5 to postnatal day 21 forebrain lysates were immunoreactive for pULK1-757 which was detected in maturing neurons. We pharmacologically and genetically perturbed mTOR activity in neuro2a cells to determine the role of mTOR on Ulk1 phosphorylation. These experiments revealed that pUlk1-757 is rapamycin-insensitive but Torin1-sensitive. Genetic manipulations of mTORC1 activity produced proportional changes in pUlk1-757. We propose that the variable success of rapamycin analogues in correcting neurological manifestations in patients with elevated mTOR activity may be related to rapamycin resistance of mTORC1 phosphorylation of Ulk1.

**Abstract:** Nonsense-mediated decay (NMD) is an evolutionarily conserved surveillance mechanism that targets mRNAs undergoing premature translation termination as well as normal physiological transcripts for rapid degradation. NMD requires the function of three conserved Up-frameshift (Upf) factors (Upf1, Upf2, Upf3). In humans, mutations in *UPF2* and other NMD components are associated with intellectual disability and autism spectrum disorder (ASD). However, the biological mechanism by which deficient NMD leads to neurodevelopmental disorders remains unknown. Here we report that mice lacking Upf2 in the forebrain (Upf2 fb-KO mice) show learning and memory deficits and abnormal long-term potentiation (LTP) in the hippocampus. Moreover, Upf2 fb-KO mice showed behavioral endophenotypes associated with ASD and neuroanatomical abnormalities including a smaller corpus callosum which has previously been reported in patients with mutations in NMD genes. Given that the Upf proteins are evolutionarily conserved, we also investigated whether Upf2 is required for memory formation in *Drosophila.* Interestingly, long-term memory was impaired in flies with reduced Upf2 levels in the CNS, suggesting an evolutionarily conserved role for NMD in learning and memory. We are currently trying to identify the mRNAs whose expression is altered when NMD is dysfunctional in the brain of Upf2 fb-KO mice and the mechanisms by which impaired NMD causes behavioral and neurophysiological abnormalities.

**Abstract:** Genome-wide sequencing technologies have greatly contributed to our understanding of the genetic basis of autism spectrum disorders (ASD). Interestingly, a substantial number of ASD-related genes also express natural antisense transcripts (NATs). In some cases, these have been shown to play a regulatory role in gene expression and contribute to disease pathogenesis. However, a comprehensive study examining the relationship between ASD-related gene transcripts and their NAT partners is lacking. We used a strand-specific deep RNA sequencing approach (120 million reads/sample) to profile over 100 ASD-related genes and their NATs in a

brain region-specific manner at three discrete time points during mouse brain development. We isolated two ASD-relevant brain regions, medial prefrontal cortex (mPFC) and striatum (Str), from P7, P14, and P56 animals. Our analysis revealed that more than half of the examined ASD-related genes have NAT transcripts including novel ones; suggesting that more ASD-related genes than previously thought could be subject to NAT-mediated regulation. We found that expression levels of NATs were mostly negatively correlated with their related gene partners (~20%, r<-0.90), for example the serine protease, Prss12. However, there was also a small fraction of positively correlated genes identified (~5%, r>0.90), including the ubiquitin protein ligase, Ube3a. A small fraction of the examined NATs also showed region specific enrichment, suggesting potential brain region defining roles. Our findings contribute to the understanding of NAT regulation of ASD-related genes in mice to guide preclinical investigation toward an ultimate goal of developing novel therapeutic approaches in patients by manipulating NAT-mediated gene regulation in ASD.

**Abstract:** Early development is marked by spontaneous neuronal activity that occurs without the input of sensory experience. This is best demonstrated in the visual system, but has been shown to be a generalized phenomenon. By manipulating this activity in genetically defined neural populations within the prefrontal cortex, we can interfere with the normal formation of specific neural circuits. Many psychiatric disorders are thought to be neurodevelopmental, stemming

from malformation of neural circuits. These circuits are primarily found within the prefrontal cortex, where our manipulation will take place. Early disruptions to neural activity may result in behavioral changes that correlate with psychiatric phenotypes typical of disorders such as autism, anxiety, or depression. Using optogenetics, we can manipulate neuronal activity using light. Due to the young age of the animals used in this study, a non-invasive light source must be used. Our laboratory has created mice that conditionally express a luciferase protein, sbGLuc, tethered to a channelrhodopsin, VChR1. This luminescent opsin, or luminopsin (LMO3), produces light, and thus a neuronal response, in the presence of the substrate coelenterazine (CTZ), which can be delivered intraperitoneally (ip). Lox-Stop-Lox LMO3 mice were crossed with Cre driver lines (Emx-1, Dat), thus limiting expression of LMO3 to neuronal populations of interest. By delivering CTZ ip during post-natal days 4-14, alterations in the firing activity of specific neuronal populations can be induced in developing mouse pups. During adulthood, mice are then tested for depressive, anxiety, antisocial, and general locomotive behaviors. The results of this research will provide insight into the effect of altered developmental activity and its relationship to psychiatric disease.

**Abstract:** Recent evidence has pointed out that imprinted genes, which exert fundamental roles in embryonic development, are also important in the regulation of sleep and cognitive processes in adulthood. Moreover, sleep abnormalities and cognitive impairment are hallmarks of several neurodevelopmental disorders, suggesting that neurodevelopment is pivotal for the formation of sleep and cognition. However, the link between developmental mechanisms and sleep remains largely unknown. Recently, our group has demonstrated that loss of imprinting in the GNAS locus dramatically affects sleep physiology and cognitive functions in mice. GNAS main product, Gαs, codifies for the G protein α-subunit, one of the main players for intracellular cAMP generation in the central nervous system. In order to further understand the role of Gαs in neural development and sleep formation, we downregulated the expression of Gαs (by *in utero*

electroporation, IUE) in progenitors of the pyramidal neurons committed to upper layers of the prefrontal cortex in mice. We found that Gαs is involved in pyramidal neuron migration and morphological maturation. Specifically, Gαs defective neurons are characterized by more and longer branches; and notably, 20% of them are misplaced in the layer I of the prefrontal cortex. A total RNA sequencing of these IUE neurons supported our previous data indicating that Gαs is implicated in several processes controlling neurodevelopment and neural migration. New potential roles for this gene, not yet described in literature, are being confirmed. Moreover, we report that downregulation of Gαs staring from embryonal stages has also a modulatory effect on sleep in adult mice with an increase in NREM sleep and an anticipatory tendency to fall sleep after 6 hours of sleep deprivation. This proves that the imprinted gene Gαs, is responsible of the homeostatic control of sleep in prefrontal cortex circuits. Overall, this work provides new insights into the link between genomic imprinting, neurodevelopment and sleep.

**Title:** Inducible knockout of Lis1 in adult mice causes death following a progressive decline in autonomic functions

**Authors: *T. J. HINES**, S. SAHU, J. L. TWISS, D. S. SMITH
Biol. Sci., Univ. of South Carolina, Columbia, SC

**Abstract:** *Lis1* haploinsufficiency causes developmental brain abnormalities in humans and mice. Total loss of Lis1 is lethal early in embryogenesis. The cellular defects of Lis1 deficiency during development are often linked to its interactions with cytoplasmic dynein, a molecular motor that regulates spindle dynamics, cell migration, and intracellular transport. Lis1 expression remains high in adult rodent brains and we have found that Lis1 modulates dynein-dependent axon transport in cultured adult rat sensory neurons. We now report that Lis1 has a vital role in adult animals, as tamoxifen-inducible, Cre-ER mediated recombination led to rapid decline and death of all animals that carried the Cre-ER allele and the floxed Lis1 allele. Although Cre-ER expression was under the control of an actin promoter, tamoxifen-induced Cre activation was not uniform, occurring with different time delays in different cell types in multiple tissues including brain, heart, liver, kidney, lung, and muscle. In the brain, the most pronounced regions of Cre

activity were found in the midbrain, hindbrain and cerebellum. Cre activity was also prominent in peripheral neurons, and in cardiac and skeletal muscle. Mice were apparently healthy and fertile when activation of Cre was limited to cardiac muscle, so the drastic phenotype observed is likely due to a critical role of Lis1 in adult nervous tissues. Axon transport defects and an increase in the number of axonal varicosities are observed in cultured sensory neurons from KO mice. Additionally, there is an increase in the number of chromatolytic neurons in the brainstem of KO mice. These findings support a role for Lis1 in regulating axon transport in adult animals. The exact mechanisms underlying the neuronal pathology observed are being investigated further.

**Abstract:** Autism spectrum disorder (ASD) is a neurodevelopmental disorder with a strong yet complex genetic architecture. Recently, postzygotic mosaic mutations (PMMs), which arise after embryo fertilization and result in a mosaic mixture of mutated and non-mutated cells, have been implicated in overgrowth and neurodevelopmental disorders. Compared to germline variation, the mosaic nature of these mutations makes them inherently difficult to detect and validate. In previous ASD exome studies, we surprisingly found 5% of *de novo* mutations validated as

mosaic. Here, we sought to address the role exonic PMMs may play in ASD risk. We first re-evaluated previously published exonic *de novo* single nucleotide variant (SNV) mutations from a large cohort of ASD simplex families, the Simons Simplex Collection (SSC). We found 11% of these mutations showed characteristics consistent with putative PMMs. We then developed a robust and more sensitive custom PMM calling approach and high-throughput validation method to systematically evaluate PMMs within the SSC exome data. This approach leverages complementary callers, logistic regression modeling, and additional empirically determined heuristics. Applying this approach, we identified 470 PMMs in SSC children, 398 of which were not previously published as *de novo* mutations. PMMs comprised 22% of all SNV *de novo* mutations present in SSC children. Surprisingly, we found that probands had a significant burden of synonymous PMMs. Using multiple independent splicing prediction algorithms, we found probands are enriched for synonymous PMMs predicted to impact splicing. We did not observe a similar increased burden of missense PMMs. However, when we looked specifically at probands who do not already have a nonsynonymous germline mutation, we do see a stronger burden signal, particularly for PMMs impacting genes intolerant to mutation. These PMMs overlap high confidence ASD and neurodevelopmental disorder risk genes, suggesting common ASD risk targets for germline and mosaic mutations. We also identified PMMs in novel candidate risk genes associated with chromatin remodeling and neurodevelopment. We also evaluated PMMs in parents and find that 7-11% of parental mosaics are transmitted to children This equated to 6.8% of mutations appearing newly germline in the children occurring postzygotically in parents and underscores important implications for recurrence risk. Overall, we estimate that SNV PMMs contribute risk to 4-8% of simplex ASD cases. These findings argue for a role for SNV PMMs in ASD risk, similar in magnitude to other classes of *de novo* mutations, which warrants continued study in ASD and related disorders.

**Title:** Descending control dysfunctions related to pain hypersensitivity in a pharmacological mouse model of attention deficit hyperactivity disorder (ADHD)

**Authors: O. BOUCHATTA**[1], S. BA M'HAMED[2], R. B. BENAZZOUZ[1], N. KEREKES[3], P. FOSSAT[1], M. BENNIS[2], *M. LANDRY[1]
[1]Univ. Bordeaux, Bordeaux, France; [2]Univ. Cadi Ayyad, Marrakech, Morocco; [3]Univ. West, Trollhättan, Sweden

**Abstract: Aims:** Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder characterized by impaired attention and hyperactivity-impulsivity. Recent evidence pointed to pain hypersensitivity in adults with ADHD. The most widely used neurodevelopmental model of ADHD is obtained by neonatal brain lesion with 6-hydroxydopamine (6-OHDA) in rodents. Our objectives are **1)** to assess the symptoms of the 6-OHDA-mediated dopamine depletion model in mouse. **2)** To analyse comorbid pain behavior in this model. **3)** To highlight circuits and mechanisms underlying pain alterations in ADHD mouse model.
**Methods: 1)** We generated a mouse model at P5 by neonatal disruption of central dopaminergic pathways with 6-OHDA. To assess ADHD-like symptoms, spontaneous activity was evaluated after weaning (P24). At P40 (adulthood), anxiety, working memory, social interactions, inattention and impulsivity were assessed. **2)** We analyzed nociceptive responses to thermal and mechanical stimuli by using hot plate, acetone-evoked cooling and von-Frey filaments. **3)** Spinal neuron activity was further examined *in vivo* by unit recording after mechanical stimulus. Finally, we explored if the anterior cingulate cortex (ACC) is involved in the dysfunction of descending controls in ADHD-like mice. Hence, we recorded ACC activity, and the effects of ACC activation on mechanical stimuli-evoked responses in spinal cord wide-dynamic-range (WDR) neurons.
**Results: 1)** At P24, ADHD-like mice exhibited hyperactivity. At P40, ADHD-like mice showed anxiety, antisocial behavior, increased aggressiveness, and mildly impaired short-term memory. We also demonstrated attention deficit and increased impulsivity in ADHD-like mice. **2)** Mice with neonatal dopamine depletion exhibited a marked increase in both thermal and mechanical sensitivity. Dopamine depletion also increased pain sensitivity in persistent pain conditions. **3)** Electrophysiological recordings showed increased neuronal activity in response to both innocuous and noxious stimuli in the ADHD-like group. Moreover, our data indicated that ACC neurons are hyper-activated in ADHD-like mice. Finally, we found that the electrical stimulation of controlateral ACC increased the responses of WDR neurons to innocuous and noxious stimuli. Our results demonstrated the validity of the neonatal 6-OHDA model to mimic ADHD syndrome. Taken together, our data demonstrated that ADHD conditions induced pain hypersensitivity that is likely mediated by alterations of descending controls and hyperactivation of WDR spinal cord neurons. We also suggest that the deregulation of ACC may be at the origin of descending control dysfunction.

**Title:** Further evidence supporting a role of the dyslexia susceptibility gene KIAA0319 in neuronal migration revealed by a novel technique that investigates cellular forces

**Authors: *R. DIAZ**[1], N. M. KRONENBERG[2], P. LIEHM[2], A. MARTINELLI[1], M. C. GATHER[2], S. PARACCHINI[1]
[1]Sch. of Med., [2]Sch. of Physics, Univ. of St Andrews, St Andrews, United Kingdom

**Abstract:** Dyslexia is a disorder with a strong heritable component. Several dyslexia candidate genes affect brain development through their role in cilia. Cilia are small organelles that protrude from the surface of the cell and have a function in crucial developmental events such as cell differentiation and migration. *KIAA0319* is a dyslexia susceptibility gene of unknown function highly expressed in brain during embryonic development and also expressed in ciliated tissues. Experiments in rats suggest that KIAA0319 plays an important role in neuronal migration, a process essential for the formation of brain cortex. KIAA0319 is a transmembrane protein that contains five extracellular PKD domains. This structure is consistent with its proposed role in cell migration, as PKD domains are thought to be involved in the interaction of the cell with specific external molecules.
To assess the effect of KIAA0319 in cilia formation and function, and to investigate its effects in migration and cell adhesion, we have created KIAA0319 knockouts in RPE1 human cell line using CRISPR-Cas9. RPE1 are ciliated cells derived from human retina pigmented epithelium commonly used to study ciliogenesis and cilia function. We have used these knockout cell lines to characterize the mechanical forces cells exert during migration using Elastic Resonator

Interference Stress Microscopy (ERISM). ERISM is a recently developed functional imaging modality for the mapping of cellular forces, which allows for continuous monitoring of mechanical cell-substrate interactions over long periods of time and with high displacement resolution (Kronenberg et al., 2017, accepted). Contrary to other techniques to measure cell forces, ERISM requires no zero-force reference which enables long-term studies and allows further investigation of cells, e.g. by immunostaining.
Our results show that the knockout of KIAA0319 has an effect in cell motility, migration and attachment, three processes that depend on cytoskeleton dynamics. KIAA0319 knockouts apply stronger forces to the substrate and have slower movements compared to the wild type. In addition, we have found that the force patterns exerted during migration vary significantly between wild type and knockout cells, and that the cells show different behavior when their cytoskeleton function is disturbed by inhibition of actin polymerization. These results point to a possible role for KIAA0319 in triggering cytoskeleton responses and, given its transmembrane location, suggest a role of KIAA0319 as signal transducer of extracellular cues.
The result of this study is the first evidence of the role of KIAA0319 in neuronal migration on a cellular level.

**Abstract:** The Naples High-Excitability (NHE) rat is a well-known animal model system for ADHD that show hyperactivity and impaired non-selective and selective attention associated with increased activity in the mesocortical dopamine (DA) branch. A Subtractive library study

on Prefrontal Cortex (PFC) has shown that the NMDAR1 glutamate receptor gene was hyper-expressed in NHE compared to Random Bred control rats (NRB). The aim of this study was on three levels: i) to investigate the proteic level of NMDAR1 glutamate receptor subunit in the PFC, by western-blot analysis; ii) to clarify the functional relevance of the higher NMDAR1 expression, by behavioral analysis after acute treatments with different concentrations of the non-competitive antagonist MK801; iii) to study the plasticity of the NMDAR1 system after subchronic MK801 treatments by behavioural analysis in NHE and NRB rats. To this aim young-adult male rats of NHE and NRB lines were used. In exp. 1 western-blot analysis was carried out on left and right hemisphere separately. In exp. 2 acute MK801 (0.0, 0.0001, 0.001, and 0.01 mg/kg) was given intraperitoneally (i.p.). Finally, in exp. 3, subchronic MK801 (0.01 mg/kg) was given i.p. daily over 14 days. Then, NHE and NRB rats were exposed to a spatial novelty (Làt-maze) where horizontal (HA) and vertical (VA) activity were monitored. The results confirmed the higher level of NMDAR1 subunit expression in the left PFC of NHE rats, as previously observed with the Subtractive library assay. In particular, the higher level of NMDAR1 in NHE accounted for 30% of NRB rats. Acute treatments with MK801 increased HA in both NHE and NRB rats at the dose of 0.01mg/kg only. In contrast, MK801 exerted an inverted-U action upon VA frequency and the highest dose decreased its duration in NRB rats only. After subchronic treatment with MK801, the level of the NMDAR1 subunit increased in the PFC of NRB rats by 78%. Moreover, the latter finding was not associated with a higher activity level. In conclusion, the higher level of the NMDAR1 subunit in the PFC of NHE rats reveals a disintegrated interface due, supposedly, to lack of glutamate inputs from anterior thalamus and up-regulation of postsynaptic sites. Data demonstrate that this disintegrated prefrontal interface does not produce a hyperactivity but rather is expressed through an altered nonselective attention. In turn it may reflect an unbalanced glutamate control of prefrontal output leading eventually to distorted prefronto-striatal neurotransmission.

**Title:** Extrasynaptic $GABA_A$ receptors in age-related differences to ethanol responsively during social interaction

**Authors: J. M. CARTER**, C. A. DANNENHOFFER, *D. F. WERNER, L. P. SPEAR
Binghamton Univ., Binghamton, NY

**Abstract:** Adolescents differ from adults in terms of responsiveness to a number of ethanol effects that may serve to promote higher intake during adolescence, but the neural underpinnings of these age differences have yet to be detailed. Given that prior studies suggest that extrasynaptic $GABA_A$ receptor tonic inhibition is attenuated in adolescents, but more sensitive to ethanol compared to adults (Fleming et al., 2007), the current study further characterized age-related differences in the $GABA_A$ receptor delta subunit commonly associated with extrasynaptic receptors as well as their regulation following ethanol exposure in late developing regions. Social interactions as well as locomotor activity/sedation were used to dose-dependently assess potential age differences in the effects of pharmacological stimulation of $GABA_A$ receptors containing this subunit. For biochemical analyses, tissue was isolated from adolescent (P35) and adult subjects (P75) and processed for synaptosomal analysis. For behavioral studies, subjects were injected (i.p.) with 0.0, 1.0, 2.0 or 4.0 mg/kg of the selective $GABA_A$ receptor agonist THIP that demonstrates a preference for delta subunit-containing $GABA_A$ receptors. Animals were then placed alone in a novel social interaction chamber for 30 minutes during which time locomotor activity was assessed prior to introduction of an unfamiliar age- and sex-matched partner for a 10 minute social interaction test. Sessions were recorded for later assessment of social behaviors and social preference/avoidance. Intoxication ratings were also conducted using the Chandler/Crews rating scale. Results indicate that $GABA_A$ receptor delta subunit basal expression was noticeably reduced in the hippocampus and prefrontal cortex of adolescents compared to adults. Preliminary data further suggest that delta subunits are down-regulated 1 hour following a moderate dose of ethanol in adolescents, but not in adults. Behaviorally, the delta-containing receptor selective agonist THIP increased initial locomotor activity during habituation, followed by dose-dependent sedation, corresponding increases in social inhibition, and significant intoxication ratings – effects that were evident in adolescents but not in adults. Taken together, these results suggest that activity at delta-containing extrasynaptic $GABA_A$ receptors parallels the locomotor stimulant and sedative/intoxicating behavioral responses of ethanol, and that their down-regulation may be contributing factor in age-dependent differences in ethanol-induced social inhibition, likely a result of sedation.

**Title:** In adolescence, elevation of GABA activity in the dentate granule cell induced by neonatal maternal separation is related with reduction of dentate gyrus-CA3 synaptic plasticity, anxiety- and aggressive-like behavior

**Authors: *S. SHIN**, S. MIN
Eulji Univ., daejun, Korea, Republic of

**Abstract:** Neonatal maternal separation (MS) is one of the animal models for emotional disorder such as anxiety and depression. Thus far, MS study has been done by many researchers on many different kinds of species from rats to apes and produced a lot of behavioral results. However, the effects of MS on the synaptic plasticity of the hippocampus remain imperfect understanding. This study investigated the effects on the behavioral changes and mechanisms of the synapse plasticity in the hippocampus in MS mice. Following a periodic neonatal MS (4-hour a day, during 19 days), adolescent mice were employed for behavioral experiments for depression, learning, memory, anxious and aggressive behavior using the forced swimming test (FST), Y-maze, Morris water maze (MWM), elevated plus maze (EPM), three consecutive days of the open field test, the social interaction test, the tube-dominance test and the resident-intruder test. The results showed that there was no difference in FST, Y-maze, and MWM performance. However, MS mice showed more anxiety-like behavior in the EPM test and aggressive-like behavior in the tube-dominance and resident-intruder tests. In addition, the magnitude of long-term potentiation (LTP) and release probability in the dentate gyrus (DG)-CA3 synapses were significantly reduced in the MS group but not in the CA3-CA1 synapse. Thereafter, the excitatory postsynaptic currents (EPSCs) and inhibitory postsynaptic currents (IPSC) were measured in the hippocampal dentate granule cells by using patch clamp recording. MS mice showed elevated gamma-aminobutyric acid$_A$ ($GABA_A$) receptor-mediated IPSCs in the ventral hippocampal dentate granule cell. These results indicate that early life stress based on MS may induce anxiety- and aggressive-like behavior during adolescence, and these behavioral alterations are associated with reduced synaptic plasticity and release probability at the DG-CA3 synapses. In addition, these changes can be associated with the elevation of the $GABA_A$ receptor-mediated IPSCs in the ventral hippocampal dentate gyrus, although the precise mechanism between the alterations of behavior and the synaptic plasticity remains to be elucidated.

**Title:** Adolescent stress induces long-lasting increases in social anxiety: A role for basolateral amygdala kappa opioid receptors

**Authors: *M. R. DIAZ**[1], J. HERMAN[3], T. DEAK[4], E. I. VARLINSKAYA[2]
[1]Psychology, [2]Dept Psychol, Binghamton Univ., Binghamton, NY; [3]Binghamton Univ. - SUNY, Binghamton, NY; [4]Behavioral Neurosci. Program, Dept. of Psychology, Binghamton University-SUNY, Binghamton, NY

**Abstract:** Adolescence is a developmental period marked by robust neural alterations and heightened vulnerability to stress, a factor that is highly associated with increased risk for emotional processing deficits, such as anxiety. Stress-induced upregulation of the dynorphin/kappa opioid receptor (DYN/KOR) system is thought to underlie the negative affect associated with stress. The basolateral amygdala (BLA) is a key structure involved in anxiety, and neuromodulatory systems, such as the DYN/KOR system, can 1) regulate BLA neural activity in an age-dependent manner in stress-naïve animals and 2) underlie stress-induced anxiety in adults. However, the role of the DYN/KOR system in modulating stress-induced anxiety in adolescents or the long-lasting effects of adolescent stress are unknown. To test this, we have assessed the impact of an acute, 2-day forced swim stress (FSS - 10 min each day) on adolescent (~postnatal day (P) 35) and adult Sprague-Dawley rats (~P70) using behavioral, molecular and electrophysiological techniques. Adolescent males, but not adult males or females of either age, demonstrate social anxiety-like behavioral alterations indexed via significantly reduced social interaction/preference when tested 24 hr following FSS. While there are no FSS-induced changes in expression of genes related to the DYN/KOR system in the BLA, these behavioral alterations are associated with a robust switch in BLA KOR function consistent with an anxiogenic phenotype. Furthermore, adolescent-stressed males display persistent reduced social behavior in adulthood, which is significantly exacerbated by a 2$^{nd}$ stressor in adulthood. This is the first study to demonstrate a KOR-dependent mechanism that underlies adolescent- and sex-specific social anxiety induced by stress. Importantly, these findings provide evidence

for potential KOR-dependent mechanisms that may contribute to pathophysiological interactions with subsequent stress challenges.

**Title:** Nandrolone during adolescence increase sensitization to cocaine in juvenile, but not in adult male rats

**Authors: J. A. FREIRE, Mr.**, C. J. RIVERO, Mr., *A. C. SEGARRA
Physiol Dept, Univ. of Puerto Rico, San Juan, PR

**Abstract:** The use of anabolic androgenic steroids (AAS) by adolescents is rising. Adolescents seek AAS because of their anabolic properties, unaware of the effects these might have on the developing reproductive and nervous system. Previous studies show that AAS cross-sensitize with other drugs of abuse such as cocaine. We investigated the effect of AAS exposure during adolescence on cocaine sensitization during adolescence (day 40) and adulthood (day 60) in male rats. For 10 consecutive days, starting on day 28, adolescent male rats received daily injections of nandrolone decanoate (20mg/kg/sc) or of vehicle. When they reached 40 or 64 days of age, they were tested for locomotor sensitization to cocaine. From days 1-5 and at days 13 and 23 rats received an injection of cocaine (15 mg/kg/ip). Their locomotor response to cocaine was measured at days 1, 5, 13 and 23. Nandrolone exacerbates the acute response to cocaine in juveniles as well as in adult rats.
Rats tested as juveniles sensitized to cocaine only when re-exposed to cocaine after a 7 day withdrawal period. However, those treated with nandrolone showed sensitization after 5 days of repeated cocaine administration. In comparison, rats tested as adults sensitized to cocaine after 5 days of repeated cocaine administration, whereas those treated with nandrolone did not show a progressive increase in locomotor activity after repeated cocaine administration. These data indicate that exposure to AAS during adolescence exert long lasting effects on the locomotor activating effects of cocaine.

**Title:** Akt signaling is involved in neonatal stress-induced autistic-like behaviors

**Authors: *X. ZHANG**, Z. ZHOU
Inst. of Life Sci., Southeast Univ., Jiangsu, China

**Abstract:** The serine/threonine kinase Akt, also known as protein kinase B, plays an essential role in diverse signaling transduction pathways, such as cell survival, proliferation, apoptosis, cell migration, glucose metabolism and cell-cycle progression. A critical period of brain development refers to a specific time window during early postnatal life, when the brain is extremely flexible to acquire certain information or environment stimuli. It is known that brain circuits can be shaped by experience during critical period, which modulates adult emotion, cognition and behaviors. Although accumulating studies have indicated that aberrant Akt signaling underlies pathogenesis of complex human disorders including diabetes, cancer and neurological diseases, little is known about the function of Akt signaling in brain development during the critical period. We employed maternal separation, a commonly used early life stress model, to investigate the functions of Akt signaling cascade in neonatal brain development. With a combination of behavioral, electrophysiological and biochemical assays, our results suggest an important role of Akt signaling in synaptic modulation during the critical period, and that neonatal stress may cause autistic-like behaviors in adult mice through the Akt signaling pathway.

**Abstract:** Caffeine and nicotine are on top of the list of psychoactive substances consumed in the world. Epidemiological data demonstrate that co-consumption is frequent and experimental studies provide evidence of interactions between these drugs. Caffeine is consumed throughout life, while smoking usually starts during adolescence.
Accordingly, the objective of this study was to evaluate, during adolescence of Swiss mice, the effects of chronic exposure to caffeine on the susceptibility to nicotine. Caffeine exposure extended from the first day of mating until the last day of the behavioral tests. The animals were split into 3 experimental groups: CAF0.3 - free access to caffeine 0.3g/L as the only source of liquid (n=13 litters); CAF0.1 - free access to caffeine 0.1g/L as the only source of liquid (n=8 litters); control group (CG) - free access to drinking water (n=10 litters). On PN30 (PN = post natal day), animals from each litter were submitted to the conditioned place preference (CPP) or open field (OF) test. In the CPP, the time spent in the chamber paired with nicotine (0.5mg/Kg, i.p.) before and after conditioning was analyzed. In the OF, nicotine (0.5mg/Kg, i.p.) or saline was administered immediately before the test. We evaluated total ambulation (locomotor activity) and the time spent in the center of the arena (as a measure of anxiety-like behavior). Mice developed preference for the nicotine-paired compartment in the CPP and caffeine failed to interfere with the effect of nicotine ($F_{1.39} = 11.4$; $p \leq 0.01$). In the OF, acute nicotine increased locomotion, and chronic caffeine exposure failed to affect this nicotine-evoked response ($F_{1.112} = 8.5$; $p \leq 0.01$). Interestingly, caffeine was anxiogenic at the higher dose ($F_{2.51} = 3.9$; $p \leq 0.05$; CAF0.3 ≤ CG; $p=0.05$; CAF0.3 ≤ CAF0.1; $p=0.05$), and this effect was reversed by nicotine. Altogether, these data suggest that chronic caffeine exposure does not alter reward properties of nicotine during early adolescence. Nevertheless, functional interactions between these drugs were identified in the anxiety-like behavior, requiring further studies to better understand the mechanisms that underlie these interactions.

**Title:** Puberty-dependent and puberty-independent regulation of exploration, novelty seeking, and social motivation across adolescent development

**Authors: R. F. KYNE**[1], Q. E. CARROLL[2], L. M. BROWN[2], K. C. SCHATZ[2], A. C. HO[2], L. LIN[2], *M. J. PAUL[2]
[1]Neurosci., [2]Psychology, Univ. at Buffalo, SUNY, Buffalo, NY

**Abstract:** Alongside the activation of pubertal hormones, adolescents exhibit marked increases in risk-taking, novelty seeking, and social interaction. Whether these adolescent changes are driven by, or merely coincide with, elevated pubertal hormones has been difficult to discern. Seasonal breeders that delay pubertal development during the non-breeding season could provide unique opportunities to investigate the role of pubertal hormones in adolescent development in structurally and genetically intact animals. Siberian hamsters (*Phodopus sungorus*) born in long, summer-like day lengths (LDs) undergo rapid pubertal development, whereas those born in short, winter-like day lengths (SDs) delay puberty by 5 months to synchronize their breeding with the following spring. If pubertal hormones drive the behavioural changes seen across adolescence, these changes should be delayed in SD-reared hamsters. Here, we asked 1) whether LD-reared hamsters increase exploration, novelty seeking, and social motivation during adolescence, and if so, 2) whether their developmental profile is delayed in SD-reared hamsters. Male and female LD- and SD-reared hamsters were tested in the light/dark box, novel object, and social approach tests as juveniles (postnatal day [P]20), early-adolescents (P30), late adolescents (P45-50), young adults (P70-90), or adults (P195-235) to assess developmental changes in the above-mentioned behaviours. For both male and female LD-reared hamsters, exploration (time spent in the light portion of the arena), novelty seeking (time spent investigating a novel object), and social motivation (time spent investigating a novel animal) increased during adolescence and subsequently declined in young adults (exploration and novelty seeking) or adults (social motivation). SD-rearing did not alter the timing of developmental increases in these behaviours. The developmental decline in exploration and novelty seeking, however, was delayed to coincide with puberty, and this was particularly striking in females. Pubertal influences on the decline in social motivation could not be assessed because of the late decline in LD-reared hamsters. These data suggest that the developmental rise in exploratory drive, novelty seeking, and social motivation during adolescence is regulated by puberty-independent mechanisms, whereas the decline in exploration and novelty seeking is brought about by puberty-dependent mechanisms. Ongoing experiments are using the Siberian hamster model to investigate the neural and endocrine substrates that mediate puberty-dependent and puberty-independent influences on adolescent-typical behaviours.

**Title:** Ketamine treatment during late adolescent impairs with structure-specificity the inhibitory synaptic transmission and working memory during adulthood

**Authors: *M. PÉREZ LIZAMA, SR**[1], C. MORALES[1], O. SANTANDER[1], I. GOMEZ[2], P. R. MOYA[2], M. FUENZALIDA[2]
[2]Dept. de Fisiologia, [1]Univ. De Valparaiso, Valparaiso, Chile

**Abstract:** Repeated insults during adolescence leads to dysregulation GABAergic system, a disruption that confers several behavioral and pathophysiological features in rats that resemble human schizophrenia (SZ). The N-Methyl-D-Aspartate receptor (NMDAR) hypofunction model suggest that SZ is associated with loss of NMDAR on corticolimbic parvalbumin positive (PV+)-expressing GABAergic interneurons, leading to disinhibition of pyramidal cells and cortical desynchronization. However, the presumed changes on GABAergic system in both medial prefrontal cortex (mPFC) and hippocampus (HPC) have not been tested yet. Here, we examined whether administration of NMDAR antagonist ketamine (Ket) during late adolescent period results in long-lasting deficits in behavior, neurochemical levels, and GABAergic synaptic transmission in the adult mPFC and HPC. Prolonged exposure of Ket induces long-lasting changes on behavior during adulthood, such as anxiety-like behavior, social withdrawal, and impairment of WM-PFC dependent. Moreover, Ket-treatment reduced PV+ and GAD67 levels on mPFC, without alterations on HPC. However, Ket-treatment did not cause changes in amphetamine-induced hyperlocomotion, which is related to GABAergic normal system on HPC. At neuronal levels, Ket-treatment reduces the frequency of both spontaneous inhibitory postsynaptic current (sIPSC) and miniature (mIPSC) respectively. Ket-treatment modifies the short-term synaptic plasticity: reducing paired pulse depression (PPD) and decrease the synaptic depression during a 10 Hz stimulus train. Together, our results provide a strong experimental support for hypothesis that cortical functions are more susceptibility to derangement by NMDAR hypofunction than HPC during late adolescence, showed apparent structure specificity. Thus,

mPFC could be a primary site of schizophrenia pathogenesis during late adolescent period by neurochemical and GABAergic changes.

**Title:** Developmental regulation of prefrontal plasticity by endocannabinoid-CB1R signaling *In vivo*

**Authors: *H. M. MOLLA**, D. R. THOMASES, K. Y. TSENG
Dept. of Cell. and Mol. Pharmacol., The Chicago Med. Sch. At RFUMS, North Chicago, IL

**Abstract:** Prefrontal cortex (PFC) maturation during adolescence is characterized by structural and functional changes, which involve the remodeling of GABAergic and glutamatergic transmission, as well as changes in endocannabinoid mediated signaling. Despite the modifications that occur within each of these systems, the manner in which the endocannabinoid system interacts with glutamate and GABA transmission in the PFC during the adolescent transition remains unknown. To address this, we conducted local field potential recordings *in vivo* and examined how manipulations of the endocannabinoid-CB1R system affects PFC responses to basolateral amygdala (BLA) and ventral hippocampal (vHipp) stimulation. Pharmacological activation and inactivation of CB1Rs revealed that the recruitment of endocannabinoid-CB1R signaling does not become functionally online until adulthood. Once present, CB1R signaling exerts inhibitory control over both LTP and LTD from afferents originating from the BLA and vHipp. Importantly, this modulation primarily involves the endocannabinoids 2-AG, and anandamide, although the effects of the former are more dominant. Furthermore, our results indicate that CB1R signaling exerts a more powerful inhibitory control of the BLA to PFC transmission. Together, these results show that the endocannabinoid-CB1R signaling in the PFC is developmentally regulated and emerges to control the gain of afferent drive.

**Title:** Prenatal ethanol exposure reduces sensitivity to the aversive effects of ethanol in adolescence and increases later preference for a 5% ethanol solution in males but not females

**Authors: *J. K. GORE-LANGTON**, L. P. SPEAR
Binghamton Univ., Binghamton, NY

**Abstract:** Insensitivity to the aversive effects of ethanol (EtOH) has been suggested to increase the risk of developing problem drinking behaviors (Schramm-Sapyta et al., 2010). Such aversive effects have been reported to be attenuated in infant rats following EtOH exposure late in gestation (Pautassi et al, 2012). To further examine effects of gestational EtOH exposure on later EtOH aversion and intake, we first investigated the impact of intragastric administration of a moderate dose (2 g/kg) of 20% EtOH from gestational days 17-20 on the aversive effects of EtOH indexed via conditioned taste aversion (CTA) in early adolescence (postnatal days [P] 28-34). Beginning on P 28 (+/- 1 day), male and female Sprague-Dawley rats were given 30 min access to a supersaccharin solution (0.125% saccharin and 3% sucrose in water) paired with an intraperitoneal injection of EtOH (0, 1, 1.25, 1.5 or 1.75 g/kg). This cycle was repeated every other day for 3 more sessions, providing the opportunity to track emergence of CTA over days. Water pre-exposed males showed significant CTA at 1 g/kg and higher, whereas significant CTA did not emerge in EtOH- exposed males until a dose of 1.5 g/kg and above. Females, in contrast showed significant CTA beginning at 1.25 g/kg regardless of prenatal exposure condition. We then investigated whether the same prenatal exposure would increase EtOH consumption in adulthood. At the beginning of the dark cycle, pair-housed rats (P56-60) were separated by a wire-mesh divider and each was presented with 3 bottles containing 0, 5 and 10% EtOH for 18 hours (19:15-13:15). Dividers were then removed and water access only was provided. Such 3-bottle access was provided every other day for 3 weekly sessions, with 2 days off between weeks (e.g., a M, W, F schedule). In the first access week, drinking was initiated by using 1% sucrose as the vehicle for all 3 solutions, with a 0.5% sucrose solution used in the second week, and water provided as the vehicle in the final week. Two days following the final 18-hour drinking session, rats were given 30-minute access to all bottles and trunk bloods collected to determine blood EtOH content. Males that were prenatally exposed to EtOH showed a significantly greater preference and intake (g/kg) of the 5% EtOH solution on weeks 2 and 3 than water exposed males, whereas no prenatal exposure effect was observed with the 10% EtOH solution. In

contrast, no intake differences were observed in females. Thus, late gestational exposure to EtOH induces a male-specific attenuation in EtOH's aversive effects, which could contribute to the increases observed in later EtOH consumption.

**Title:** The role of microglia in comorbidity between adolescent asthma and anxiety

**Authors: *J. I. CAULFIELD**[1], S. A. CAVIGELLI[2]
[1]The Pennsylvania State Univ., University Park, PA; [2]Biobehavioral Hlth., Pennsylvania State Univ., University Park, PA

**Abstract:** Adolescence is a developmental period sensitive to perturbations that can affect adult neuronal and behavioral processes associated with internalizing disorders, like anxiety and depression. Asthma is a common adolescent chronic health challenge, affecting 9% of U.S. adolescents, and often comorbid with anxiety and depression. However, little is known about the neurobehavioral impacts of chronic adolescent asthma. Microglia, the resident immune cells of the brain, become activated in response to peripheral insult, and their over-activation has been implicated in neuropsychiatric disorder development. The mechanism underlying the comorbidity of asthma and internalizing disorders, and the involvement of microglia in this relationship, has not been established. Our lab has developed a BALB/c mouse model for chronic adolescent asthma, individually manipulating two components of allergic asthma: airway inflammation (via repeated exposure to house dust mite extract, HDM) and labored breathing (via repeated exposure to methacholine, MCH). Previously published results from the lab have demonstrated that mice exposed to adolescent labored breathing had significantly higher adult anxiety-related neurobiological and behavioral symptoms than unexposed mice. The present study tested acute effects of airway inflammation and labored breathing on microglia activation,

immune marker expression in brain and peripheral tissue, and corticosterone production. We documented these processes in juveniles (postnatal day [P] 21) and near-adults (P56) at 0, 1, 2, 4, 8, or 24 hours after final asthma treatment (HDM or MCH). Classic pro-inflammatory (*IL-6, TNF-α, IL-1β*) were measured in lung, spleen, and hippocampus, and additional markers for microglia (*Cd11b, Iba-1*) were examined in hippocampus. Finally, corticosteroids were measured from serum and feces. Preliminary evidence indicates that weekly MCH exposure led to elevated *Cd11b* expression (indicative of increased microglial activity) compared to controls. Study results suggest that microglia may be involved in one specific pathway that leads to increased internalizing symptoms with asthma.

**Title:** The role of redox dysregulation in behavior and perineuronal net formation after prenatal stress

**Authors: *P. ABBOTT**[1], H. E. STEVENS[2]
[1]Psychiatry, [2]Univ. of Iowa, Iowa City, IA

**Abstract:** Objective: Our lab seeks to understand mechanisms by which early developmental events increase the risk of psychiatric illness. The purpose of this ongoing study is to determine further whether the effects of prenatal stress behavior, GABAergic neurons, and associated perineuronal nets may involve redox dysregulation.
Background: We have found previously that prenatal stress alters cortical GABAergic interneuron maturation in the postnatal period, as evidenced by shifts in the developmental trajectories of cortical populations. How prenatal stress may affect the maturation of inhibitory neurons in other ways is not clear. The formation of extracellular perineuronal nets (PNNs) around GABAergic neurons has been implicated in regulating developmental plasticity and GABAergic cortical maturation. PNNs and their “protection” of GABAergic neurons are influenced by redox dysregulation, a possible mechanism by which prenatal stress influences the brain. To examine these issues, we measured juvenile and adult behavior and PNN structures in a mouse model of prenatal stress (PS). We targeted one aspect of redox dysregulation, by administering a known antioxidant, N-acetylcysteine (NAC).
Methods: In a cohort of pregnant female CD1 mice, bred to GAD67GFP+/- males, half underwent PS: 45 minutes within a restraining tube three times a day starting at embryonic day 12 (E12), seven days prior to parturition. Mothers and pups were given either normal drinking

water or NAC (2 mg/mL) in drinking water from postpartum to weaning. Offspring were tested on the open field as juveniles and on the 3-chambered social task, elevated plus maze, and open field as adults. Using stereological approaches with immunostaining, we examined GABAergic neurons for the presence and absence of PNN envelopment in medial frontal cortex (mFC). Results: PS resulted in an increase in anxiety and motor inhibition in juveniles and adults, as well as reduced sociability in adults. Our data suggest a partial amelioration of these behavioral changes with postnatal NAC administration. We have found that PS reduces PNN envelopment around GABAergic neurons in juvenile mFC. Stereological counts in the mFC of juvenile NAC exposed animals are ongoing.
Conclusion: The effects of PS on anxiety-like and social behavior may involve redox dysregulation during the postnatal period. PNN formation was reduced in mFC after PS and may also be influenced by postnatal antioxidant administration. Ongoing studies are focused on direct measurement of redox dysregulation in the postnatal brain of our PS model. These studies have translational implications for developing better interventions for psychiatric disorders.

**Title:** Estrogen modulates ethanol-induced memory deficit in post-pubertal female rats

**Authors: *R. SIRCAR**[1,2], J. TRAVIS[2]
[1]New York City Col. of Technol., New York, NY; [2]The City Col. of New York, New York, NY

**Abstract:** Ethanol impairs memory, particularly hippocampus-related memory functions, in adolescent rats. Most studies in literature have reported ethanol-induced memory deficit in pre-pubertal rats. Here we report the effect of ethanol in post-pubertal male and female adolescent rats. Adolescent rats were administered a single injection of ethanol (2 g/kg) intraperitoneally or equivalent volumes. Female rats were ovariectomized and given hormonal supplementation (estrogen and/or progesterone). Controls included sham-operated and vehicle-treated animals. Rats were trained in the fear conditioning paradigm, and 24h later they were tested for: (i) contextual fear conditioning in the same training chamber, and (ii) cued fear memory in a modified test chamber. Freezing during contextual and cued fear conditioning tasks were recorded, and freezing scores were computed for each animal. Acute ethanol-treatment in intact post-pubertal female rats showed significant disruptions in hippocampus-related contextual

memory but not amygdala-associated cued fear memory. Post-pubertal male rats did not show any ethanol-induced memory deficit. In ovariectomized post-pubertal female rats, exogenously administered estrogen, along with or without progesterone, altered the sensitivity of ethanol-induced memory impairment in. Our data suggests that female gonadal hormones modulate ethanol-induced memory impairment in post-pubertal female animals.

**Title:** Environmental enrichment promotes generation of new oligodendrocytes and attenuates hypoxia-induced perinatal white matter injury

**Authors: *T. FORBES**[1], B. JABLONSKA[2], V. GALLO[3]
[1]Children's Natl. Hlth. Syst., Washington, DC; [2]Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington, DC; [3]Ctr. for Neurosci Resesarch, CRI, Children's Natl. Med. Ct, Washington, DC

**Abstract:** Hypoxic damage to the developing brain sustained as a consequence of preterm birth is associated with permanent neurodevelopmental disabilities. This oxygenation failure predisposes preterm infants to white matter (WM) injury and is associated with many anatomical changes, the most distinctive of which is damage to the periventricular WM. This diffuse WM injury results in the loss of glial cells and causes a significant disruption in myelination, which leads to cognitive and behavioral impairments throughout childhood. Here, we focus on utilization of an enriched environment to attenuate the effects of perinatal hypoxia (HX) on WM development.
Environmental enrichment (EE) is a noninvasive combination of social and physical enhancement of surroundings that provides mammals with more complex social interactions, exposure to novel stimuli, and an opportunity for voluntary physical activity. Previous studies demonstrated that the environment affects both neural plasticity and functional recovery after brain injury. Furthermore, social, family, and environmental factors contribute to improved cognitive outcome of premature children. Therefore, the environment plays a crucial role in promoting functional recovery in the CNS, and may play a role in the repair of developing WM after HX injury.
Data obtained using an established rodent model demonstrate that EE ameliorates the effects of

perinatal HX and enhances oligodendrocyte regeneration after injury. Further, EE improved performance on a WM-specific behavioral task. *This project will test the hypothesis that the resultant oligodendrogenesis and behavioral improvement seen following HX and subsequent EE will lead to enhanced myelination.* Control experiments will be performed to determine the relative individual contributions of locomotor activity and increased socialization, as well as an investigation of alternate time-sensitive paradigms of EE to determine whether critical periods of exposure and recovery exist. Further, using genetic manipulation, we will determine if WM-dependent behavioral improvements seen with EE require de novo myelination.
While considerable progress has been made in identifying and modulating the mechanisms involved in premature brain injury, additional research is needed. The proposed study will not only shed light on the cellular and molecular mechanisms of WM injury, but will also aid in the development of new therapeutic approaches for enhancing recovery after early postnatal hypoxic injury during critical periods of neurodevelopment.

**Title:** Prevent the onset of cognitive deficits induced by cannabis abuse during adolescence: Benefits of 5-$HT_6$/mTOR pathway early blockade

**Authors: *C. BECAMEL**, C. BERTHOUX, E. DOUCET, J. BOCKAERT, P. MARIN
Inst. of Functional Genomic, Montpellier, France

**Abstract:** Cannabis is the most commonly abused illicit drug and its consumption by young people has increased for the last decades. Cannabis abuse during adolescence confers an increased risk for developing psychiatric disorders such as schizophrenia, suggesting common pathological mechanisms. Recently, we demonstrated that activation of mTOR by prefrontal 5-$HT_6$ receptors is responsible for cognitive impairments in developmental models of schizophrenia. In line with these findings and the role of mTOR in the amnesic-like effects induced by acute administration of Δ9-tetrahydrocannabinol (THC), we hypothesized that non-physiological mTOR activation might likewise underlie cognitive impairments in cannabis abusers during adolescence.
Here, we characterized the role of the 5-HT6-mTOR pathway in the perturbations of cortical synaptic transmission and associated cognitive deficits elicited in a model of chronic-THC

consumption during adolescence. We also explored whether blocking 5-HT6 receptor-elicited mTOR activation during adolescence could be used as disease modifier to prevent the onset of cognitive deficits caused by perturbations of neural development at a critical period of adolescence in abusers of cannabis.Our results show an increased mTOR activity in the prefrontal cortex, in mice injected chronically with THC during adolescence. Moreover, administration of a 5-HT6 antagonist during adolescence abolishes this non-physiological mTOR activation at the adult stage. The balance of excitatory and inhibitory synaptic transmission and the intrinsic neuronal properties are also altered in THC-injected mice compared to controls. Again, administration of a 5-HT6 antagonist during adolescence prevents these alterations. Correspondingly, the deficit in novel object recognition and sociability observed in THC-injected mice was also prevented by administration of a $5\text{-HT}_6$ antagonist during adolescence. Collectively, these results indicate that blocking the $5\text{-HT}_6$/mTOR pathway, at a critical period of adolescence, prevents the deficits induced by cannabis intake during adolescence. It offers a new perspective for preventing the emergence of cognitive deficits, not only in young cannabis abusers but also in individuals with high risk of developing schizophrenia.

**Title:** Conditioned inhibition as a mechanism for enhancing fear regulation during adolescence

**Authors: *H. C. MEYER**, F. S. LEE
Psychiatry, Weill Cornell Med., New York, NY

**Abstract:** Although fear responses facilitate self-preservation by increasing vigilance and helping an animal avoid potential danger, the inability to regulate fear responses can be maladaptive when it prevents the animal from engaging in other goal-directed activities. Altered fear regulation has been shown to be a key feature of a number of mood disorders including anxiety and post-traumatic stress disorder. Anxiety disorders are highly prevalent in developing populations, with diagnoses peaking during adolescence. Unfortunately, conventional behavioral treatments that are based on the principles of fear extinction learning, such as cognitive behavioral therapy, are ineffective for a notable percentage of the adolescent population. Thus, a better understanding of the development of fear acquisition and regulation is necessary to inform

the advent of behavioral interventions better suited for this period. Previously, our lab has established a “sensitive period” for fear learning during peri-adolescence, during which rapid fluctuations in plasticity result in heightened cued fear that is resistant to extinction. To extend this work, we have recently carried out a series of studies investigating the ontogeny of fear regulation in adolescent mice. Specifically, we exposed mice to a cue predicting the explicit absence of an aversive outcome that develops ‘safe’ properties capable of modulating fear responding through a process referred to as conditioned inhibition. Our data show that adolescent mice (postnatal day/PND 29) exhibit enhanced fear regulation (i.e., a reduction in freezing behavior) relative to adult mice when exposed to a ‘safe’ cue, despite similar responding to a distinct ‘fear’ cue that had previously been paired with a footshock. Moreover, when mice were exposed to a compound presentation of both cues, levels of freezing relative to those observed during the ‘fear’ cue alone were reduced to a greater extent in adolescents than adults. These data suggest that exposure to cues that facilitate fear regulation during adolescence may have benefits beyond those seen in adults, an effect that may be mediated by the heightened plasticity in fear circuitry during this sensitive period. Our lab has also previously shown a window of contextual fear suppression specifically during adolescence. The present data replicate this finding and indicate a potential interaction between contextual fear and the efficacy of learning about cues in service of fear regulation.

**Title:** Impact of juvenile cannabinoid receptor targeting on adult restrictive-repetitive behaviors and cytokine expression

**Authors: C. AMAYA**[1], M. LEONARD[1], L. FERREIRA[2], N. A. WITT[2], H. XIA[3], S. T. SCHULTZ[2], *G. G. GOULD[2]
[1]Voelcker Biomed. Res. Acad., [2]Physiol., UT Hlth., San Antonio, TX; [3]CAMD, 59th Med. Wing Sci. and Technol., San Antonio, TX

**Abstract:** Restrictive-repetitive behaviors are a core autism symptom that can be modeled in mice for behavioral pharmacology studies. Marble burying is an index of repetitive behavior that is sensitive to sedatives. In prior studies, administration of WIN55,212-2 (0.1 mg/kg), a cannabinoid receptor ($CB_1$ and $CB_2$) agonist, attenuated burying. Yet marble burying captures only “lower order” repetition, paralleling stereotopies like repetitive movements or manipulation of objects. To examine higher order restrictive “perseverative” behaviors such as insistence on sameness (narrow interests), cognitive flexibility or “reversal learning” tests provide more insight. The water T-maze for mice is modified approach to measure potential efficacy of therapeutics to this end. The test is for a position habit reinforced by successfully locating a platform to escape from water. Following acquisition, the platform position is changed to assess reversal learning. Since the $CB_1$ agonist WIN 55,212-2 acutely suppressed burying, we hypothesized targeting $CB_1$ and/or $CB_2$ receptors in adolescence might persistently alter burying and reversal learning. We compared effects of juvenile sub-chronic exposures to cannabinoid agonists, inverse agonists, and fatty acid amid hydrolase (FAAH) inhibitors in water T-maze and marble burying in adulthood. We found the cannabinoid agonist WIN 55,212-2 delayed habit acquisition. Mice administered FAAH inhibitors such as URB597 or AM404 (a product of acetaminophen metabolism) exhibited delays in reversal, with no reduction in burying. Treatment with the CB1 inverse-agonist AM251 accelerated reversal. In a pilot study, serum collected after behavior was used for cytokine measures using a Biorad Bio-plex mouse cytokine 23-plex panel. Eotxain levels, which inhibit neurogenesis, were high in C57BL6 treated as juveniles with >100 mg/kg acetaminophen. These mice also had elevated TNFalpha and G-CSF, which act as granulocyte stimulation factors. By contrast eotaxin levels were low and along with G-CSF unaffected by acetaminophen, while TNFalpha expression was reduced in acetaminophen treated BTBR mice relative to controls. Studies to determine if these effects can be diminished by adipose derived mesenchymal stem cell treatments are ongoing.

**Title:** Maternal nicotine exposure elicits multigenerational nicotine preference and sex-specific behavioral anomalies in adolescent mice

**Authors: *J. M. BUCK**[1], H. C. O'NEILL[2], J. A. STITZEL[3]
[1]Integrative Physiol. and Neuroscience; Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO; [3]Inst. Behav Genet., [2]Univ. of Colorado Boulder Inst. for Behavioral Genet., Boulder, CO

**Abstract:** Approximately 10% of pregnant women smoke during the third trimester, and maternal smoking during pregnancy is associated with pre-mature birth, low birth weight, and neuropsychological abnormalities such as ADHD. The present research addresses a void in the literature concerning the multigenerational effects of maternal nicotine (NIC) exposure on locomotor activity and anxiety-like behaviors before, during, and after voluntary NIC consumption in adolescent mice. To model persistent maternal NIC intake preceding and during pregnancy, female C57BL/6J mice (F0) were exposed to NIC (200 µg/mL) in drinking water beginning thirty days prior to mating with a NIC-naïve male and continuing throughout pregnancy and pre-weaning of offspring. F1 generation offspring were subsequently mated to obtain an F2 generation of the NIC-exposed maternal line. The four-bottle choice test (FBCT) was conducted during adolescence in an activity-monitoring home cage (HC) apparatus to assess NIC preference at 0, 25, 50, and 100 µg/mL and to measure baseline (BL) and NIC-induced activity differences between F1 and F2 mice and relative to NIC-naïve (VEH) mice. Acute locomotor activity in a novel environment and anxiety-like behaviors were also assessed via the Open Field test (OFT) at BL and both prior to and following a 24-hour withdrawal (WD) period. Results from the FBCT imply a predisposition to NIC consumption in F1 and F2 generation offspring, coupled with NIC concentration-dependent generational differences in NIC preference. Both F1 and F2 mice consume significantly more NIC than VEH. F1 mice do not display differential NIC preference for any concentration tested. Conversely, F2 mice exhibit significantly greater preference for the 25 µg/mL NIC concentration relative to F1 and VEH, but were comparable to F1 at 50 µg/mL and to VEH at 100 µg/mL. Activity-monitoring data collected during the FBCT indicate sex-specific differences in HC activity and circadian rhythmicity at BL and during NIC consumption and WD. F2 mice display sensitization to the locomotor-activating effects of voluntary NIC intake in the OFT that is absent in F1, suggesting NIC-induced generational differences in acute locomotor response to a novel environment. Analysis of anxiety-like behaviors is ongoing. Taken together, our data suggest that maternal NIC exposure confers increased NIC preference in F1 and F2 generations, coupled with BL and NIC-induced differences in locomotor activity in familiar and novel environments. These findings warrant further research to delineate putative epigenetic mechanisms underlying the multigenerational effects of maternal NIC exposure on NIC intake and activity.

**Title:** Chronic Methylphenidate exposure in adolescent rats promotes reversible decreases in [3H] MK-801 binding

**Authors: *K. JALLOH**[1], J. HAMILTON[1], M. HADJIARGYROU[2], D. KOMATSU[3], P. THANOS[1]
[1]Res. Inst. On Addictions, Buffalo, NY; [2]New York Inst. of Technol., Old Westbury, NY; [3]Stony Brook Univ., Stony Brook, NY

**Abstract: Abstract**
Attention deficit hyperactivity disorder (ADHD) is a common neurodevelopmental disorder affecting approximately 11% of children in the US (Center for Disease Control and Prevention [CDC], 2011). Methylphenidate (MP; Ritalin) is a widely used medication to treat children with ADHD. However, the long-term effects of MP treatment during adolescence is poorly characterized in the literature. The aim of this study is to determine the effects of chronic exposure to MP on the NMDA glutamate receptor. To do this, we employed a previous established drinking paradigm that has been shown to deliver MP doses similar to those seen in patients treated for ADHD (Thanos et al., 2015). Briefly, Sprague-Dawley rats were divided into three treatment groups with voluntary access to either water, low dose (LD) MP, or high dose (HD) MP. 4 mg/kg MP (LD) and 30 mg/kg (HD) were used during the first hour of access (09:00-10:00) and 10mg/kg (LD) or 60mg/kg (HD) were used for remaining seven hours (10:00-17:00). Immediately following a 3-month period of treatment, half of these rats were sacrificed and the remaining half went through an additional 4-week abstinence period before they were sacrificed. In vitro autoradiography was carried out with [3H] MK801 to examine NMDA receptor expression in the brain. Immediately following treatment, the HD MP group showed decreases in [3H] MK-801 binding compared to the water group in the Rhinal (39.5%), Piriform (30.4%), Auditory (34.6%), Visual (13.1%), Amygdala (34.1%) and Hippocampus (34.9%). In addition, differences between the LD and HD groups were found in various cortical and subcortical regions. These effects were short-lived, as no differences between treatment groups were seen following 4 weeks of abstinence. The results of the current study demonstrate the powerful, but reversible effects of long-term MP use on the glutamate system in the brain.

**Title:** Alpha7 nicotinic acetylcholine receptor silent agonists, but not agonists, reduce LPS-induced TNF-alpha release from primary microglia cells

**Authors:** ***J. D. MIKKELSEN**, M. SØRENSEN, L. PINBORG
Univ. Copenhagen - Rigshospitalet, Copenhagen, Denmark

**Abstract:** The penta-homomeric alpha7 nicotinic acetylcholine receptor (nAChR) is a ligand-gated ion-channel, and activation of the receptor leads to inward flow of calcium and natrium. It is considered that the receptor also signal via other intracellular signaling pathways, and that this is mediated via another receptor mechanism. It has been shown that a subset of alpha7 nAChR modulators such as NS6740 and GTS-21 activate the receptor through a calcium-independent metabotropic mechanism. These are partial agonists, and are both characterized to be acting at very low efficacy and therefore termed silent agonists. Previous studies carried out in THP-1 or Jurkat cell lines, conveys anti-inflammatory properties by reducing the inflammatory cytokine releases after stimulation with these alpha7 nAChR silent agonists. In this study, we characterized the pharmacology of the alpha7 nAChR in cultured primary rat and human microglial cells. The human cells were isolated from neurosurgical temporal cortex samples. We could confirm the anti-inflammatory effects of the silent agonists NS6740 and GTS-21 in human and rat cells. Both compounds reduced a lipopolysaccharide (LPS)-induced TNF-alpha release in cultured primary human microglial cells significantly at concentrations of 30 uM, and full effect was achieved at 100 uM of both compounds. By contrast, full and more efficacious partial agonists such as acetylcholine, nicotine and SSR180791 had no effect. Furthermore, the effects could not be blocked by co-administration of MLA. Notably, NS6740 found to be active in our studies also induce non-conducting conformational states of the receptor, and effects in pain models, but the precise mechanisms of receptor modulation and downstream signaling by NS6740 remain unknown.

**Title:** Exploring the role of lynx2, a cholinergic modulator, in anxiety mechanisms: A mouse to human correlative study

**Authors: *K. R. ANDERSON**, H. WANG, J. M. MIWA
Biol. Sci., Lehigh Univ., Bethlehem, PA

**Abstract:** It is estimated that 18% of the US adult population are suffering with an anxiety disorder and that only one third of these individuals are receiving any kind of treatment. Even though anxiety disorders are the most common mental illness, they are misunderstood and sufferers often go without treatment, leading to costly medical bills to treat associated illnesses/symptoms and a lower quality of life. Most current anxiety treatments are sedative based or anti-depressants, which only mask the symptoms instead of treating the cause. Although the brain regions associated with anxiety and some underlying mechanisms have been identified, these findings do not address the entire need. To address the cause, it will be necessary to understand the biological underpinnings of anxiety dysregulation.
There is evidence that anxious patients may try to self-medicate through the intake of nicotine, which targets the nicotinic acetylcholine receptors (nAChRs) of the cholinergic system. Specific nAChR subtypes have been implicated in regulating the network excitability of the amygdala, the brain region widely implicated as the mediator of the emotional output of fear and anxiety phenotypes across species. Cholinergic modulation, therefore, is a mechanism for the investigation of anxiolytic strategies. To untangle the role of the cholinergic system we are studying the role of a cholinergic modulator, lynx2. The lynx2 protein binds to and suppresses to

nAChRs in the amygdala and subsequent removal of the lynx2 gene increases baseline anxiety-like behaviors across several paradigms (light-dark assay, elevated plus maze, social interaction test).
We hypothesize that lynx2 modulation of anxiety circuits underlies anxiety regulation. To address this, we are pairing behavioral pharmacology assays and electrophysiology to study anxiety behaviors such as fear extinction. Functional comparative studies are in progress to understand how the knowledge of lynx2 functioning in the mouse anxiety-like behaviors can be applied to humans. We hypothesize further investigation into lynx2 and cholinergic pathway modulation can aid in understanding the biological basis of anxiety.

**Title:** α-Conotoxin antagonism extended to subunit interfaces outside of conventional nicotinic acetylcholine receptor agonist binding sites

**Authors: *B. EATON**[1], S. CHRISTENSEN[2], J. MCINTOSH[2,4,3], P. WHITEAKER[1]
[1]Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [2]Dept. of Biol., Univ. of Utah, Salt Lake Cty, UT; [3]Dept. of Psychiatry, Univ. of Utah, Salt Lake City, UT; [4]George E. Whalen Veterans Affairs Med. Ctr., Salt Lake City, UT

**Abstract:** α-Conotoxins (α-Ctxs) have demonstrated exceptional selectivity between subtypes of nicotinic acetylcholine receptors (nAChR), making them invaluable research reagents. α-Ctxs identified to date have exhibited competitive antagonist activity, binding to orthosteric agonist sites located at nAChR subunit interfaces. However, many features of agonist binding interfaces are conserved at the other subunit interfaces within the nAChR assembly. We therefore sought to determine if novel α-Ctxs could antagonize nAChR function by binding outside of conventionally-recognized agonist binding interfaces. First, a library of 460 α-Ctxs was screened *in vitro* using $^{86}Rb^{+}$ efflux to measure function of nAChR populations that were heterologously

expressed in SH-EP1 cells. The abilities of candidate α-Ctxs to block carbamylcholine-evoked function of α3β4- and α3β4α5-nAChR (the latter expressed from a fully-concatenated pentameric construct) were compared. α-Ctxs were also screened at SH-EP1 cells expressing α4β2-nAChR, as an initial control to identify off-target activity. A total of 10 α-Ctxs were identified which appeared to preferentially block function of α3β4α5- over α3β4-nAChR. Since α5 subunits do not contribute to traditionally recognized orthosteric agonist sites, this indicated α-Ctx antagonism through non-conventional sites. These initial hits were next subjected to orthogonal testing using two-electrode voltage-clamp electrophysiology. Activity was compared across nAChR with defined $(\alpha3\beta4)_2\beta4$, $(\alpha3\beta4)_2\alpha3$, or $(\alpha3\beta4)_2\alpha5$ subunit stoichiometries, expressed from concatenated nAChR constructs in *Xenopus laevis* oocytes. Of the 10 initial hits, 7 were validated as having isoform-specific selectivity (in some cases greater than ten-fold). All validated hits exhibited nanomolar $K_d$ values (in some cases low-nM). We intend to develop these leads to improve isoform selectivity and determine selectivity across a wider range of non α3β4*-nAChR subtypes. α3β4*- and α5*-nAChR have been extensively implicated in nicotine addiction, somatic signs of withdrawal, and regulation of reward. However, the roles that various isoforms of α3β4*- and α5*-nAChR play remain uncharacterized. Optimized derivatives of the leads described here have the potential to address this important outstanding question. More generally, our findings provide proof of concept for the use of α-Ctxs to identify selectively, and antagonize potently, nAChR subtypes through sites in addition to conventionally-recognized agonist binding interfaces, greatly extending the range of potential *in vitro* and *in vivo* α-Ctx applications.

**Title:** Nicotinic acetylcholine receptors (nAChR) control the release of norepinephrine in the mouse spinal cord

**Authors: *P. SCHOLZE**, F. GRÖSSL, S. HUCK
Med. Univ. Vienna, Vienna, Austria

**Abstract:** Nicotinic acetylcholine receptors (nAChR) are of obvious clinical interest: In the peripheral nervous system, the receptors are vital for neurotransmission at the neuromuscular

junction and in vegetative ganglia. In the central nervous system nAChRs have been connected with addiction, learning and memory, neurodegeneration and development. In addition nAChRs are known to play an important role in pain processing of noxious stimuli and in neuropathic pain. The precise mechanism of nicotine induced analgesia is unknown, but could possibly be mediated by stimulating norepinephrine (NE) release in the spinal cord.
In the current study we present data on nicotine-induced release of NE in spinal cord slices. Slices were loaded with 3H-NE, placed in superfusion chambers and neurotransmitter release was stimulated using nicotinic agonists and electrical pulses. In wild-type (WT) mice, nicotine induced a TTX and concentration dependent release of 3H-NE with a half maximal outflow at 7 µM. This release was unaffected by the addition of the α7-nAChR-antagonist methyllycaconitin (MLA), but completely blocked by mecamylamine a non-selective nAChR antagonist. In spinal cord slices of β2-knockout mice nicotine induced release was slightly reduced, while slices of β4-knockout mice showed less than 50% of nicotine induced 3H-NE release compared to WT. Release was unaffected in α5- and α7-knockout mice. Electric stimulation trigged neurotransmitter release in WT spinal cord slices to a similar extent as nicotine.
Nicotine induced 3H-NE release from rat spinal cord slices was significantly smaller compared to mice, indicating a clear species difference. NE-outflow after electric stimulation, however, was only slightly smaller in rat than in mouse spinal cord slices.
Finally we studied the subunit composition of nAChRs in the spinal cord. These receptors are made up by 9α and 3β subunits that can assemble into a multitude of different homo- or hetero-pentameric receptors. It is of central importance to know the exact subunit composition, since it determines the pharmacological and biophysical properties of individual receptor subtypes. Solubilized nAChR were labeled with 3H-epibatidine and precipitated using our self-generated highly subunit-specific antibodies. 85% of all receptors were found to contain the subunits α4β2*; 10% α3β4* and the rest α2β2 or α3β2. In β2 knockout animals all receptors contain an α3β4-backbone, with 70% being pure α3β4- receptors and 30% α3α4β4. In β4 knock out animals nearly all receptors were α4β2*- nAChRs.
Our results confirm that both α4β2- and α3β4-containing nAChRs are critical for [3H]-NE release in the mouse spinal cord.

**Title:** Mecamylamine stimulates dorsal raphe serotonergic neurons by increasing glutamate release

**Authors: O. HERNANDEZ**[1], *S. P. MIHAILESCU[2]
[1]Physiol., [2]Fac. of Medicine, UNAM, Mexico City, Mexico

**Abstract:** Mecamylamine (MCM) is a non-specific and non-competitive blocker of nicotinic acetylcholine receptors (nAChRs), originally used as an antihypertensive drug. Previous studies suggested that MCM increases the activity of the brain serotonergic system by stimulating dorsal raphe nucleus (DRN) serotonergic neurons (Mihailescu et al., 1997), by inducing serotonin (5-HT) release (Kenny et al., 2000; Reuben and Clark, 2000) and blocking 5-HT re-uptake (Ma et al., 2006). Animal studies indicated that MCM produces antidepressant effects in rats (Rabenstein et al., 2006). Unfortunately, these laboratory results could not be confirmed by clinical trials in which seorotonin re-uptake inhibitors were associated with mecamylamine (Dunbar 2009) to obtain stronger antidepressant effects. The present study was destined to determine the mechanisms through which MCM increases the firing frequency of 5-HT DRN neurons. Experiments were performed in brain slices obtained from young (19-21 postnatal days) Wistar rats. The electrical activity of 5-HT DRN neurons was recorded using the whole cell patch clamp technique, in both voltage - and current clamp configurations. MCM, bath administered (3 uM), induced an increase of 5-HT DRN neurons firing rate by approx. 30 %, as assessed through intensity-frequency curves. In other experiments, MCM (3 uM) induced a transient (6-8 min) increase in the frequency of 5-HT DRN neuron glutamatergic spontaneous excitatory postsynaptic currents (sEPSCs) by approx. 100 %. This effect was prevented by slice pre-treatment with the glutamate receptor antagonist 6-Ciano-7-nitroquinoxalina-2,3-diona (CNQX, 10 uM). Pre-treatment of slices with the alfa4beta2 nAChRs specific antagonist dihydro-beta-erythroidine (DHbetaE) (0.1 uM) reduced the increase in frequency of glutamatergic sEPSCs induced by MCM to approx. 70%.These results suggest that MCM induces glutamate release in the DRN by stimulating alpha4beta2 nAChRs of glutamatergic terminals. At its turn glutamate induces the increase in firing rate of 5-HT DRN neurons. A similar mechanism explains the increase in firing rate of 5-HT DRN neurons induced by nicotine (Garduño et al., 2012).

**Title:** Nicotinic modulation modelling of hierarchal inhibitory circuit control over resting state ultra-slow dynamics in the prefrontal cortex: Application to schizophrenia-related pathology

**Authors: *M. E. ROOY**[1], F. KOUKOULI[2], U. MASKOS[3], B. S. GUTKIN[4]
[1]Ecole Normale Supérieure, Paris, France; [2]Inst. Pasteur, Paris, France; [3]Inst. Pasteur, Paris Cedex 15, France; [4]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

**Abstract:** The prefrontal cortex (PFC), key for higher order cognitive processes, exhibits spontaneous activity that is altered in schizophrenia [1]. Cortical acetylcholine (ACh) release modulates PFC activity via nicotinic acetylcholine receptors (nAChRs) [2] specifically expressed within a hierarchical circuit of inhibitory neurons within layer II/III [3]. Parvalbumin (PV) interneurons, expressing α7 nAChRs subunits [2], target pyramidal cells axosomaticaly, exerting divisive effects on their activity. Somatostatin (SOM) interneurons, expressing both α7 and β2 nAChRs subunits [2], target the dendrites of pyramidal cells, exerting substractive inhibition [4]. The α5 nAChRs subunits are expressed only by vasoactive intestinal polypeptide (VIP) interneurons [5], that preferentially inhibit the SOM cells [6]. In vivo two-photon imaging showed that neural activity of PFC in mice is characterized by synchronous ultra-slow fluctuations, with alternating periods of high and low activity [7]. Genetic deletion of specific nAChRs subunits disrupted these ultra-slow fluctuations, leading to changes in synchrony and duration of activity states. Furthermore, mice expressing a human polymorphism in the α5 nAChRs subunits (α5SNP) associated with high risk for nicotine addiction and schizophrenia [8, 9], show reduced spontaneous activity in the PFC that is reversed by nicotine [3]. Using a circuit modeling approach, we studied the roles of distinct GABAergic interneurons in the generation of synchronous ultra-slow fluctuations. In order to study the effects of substractive vs. divisive inhibition on bistable dynamics in the pyramidal neuron, by the SOM and PV interneuron populations respectively, we used population firing rate modelling incorporating both mechanisms [10], and simulated the effects of nAChRs knock outs. With our model, we could fully account for the changes seen in resting state dynamics under the genetic modifications. We further predict that SOM interneurons play dominant role in the changes of activity-state structure seen in mutant mice, and in the restauration of activity to basal levels recorded in α5SNP mice under nicotine application.

**Title:** Walking in the chemical space combined with functional study to identify new molecules active at the α7 neuronal nicotinic acetylcholine receptors

**Authors: *S. BERTRAND**[1], T. SCHAER[1], C. DELALANDE[2], K. MEIER[2], D. BERTRAND[1], J.-L. REYMOND[2]
[1]Hiqscreen, Vesenaz - GE, Switzerland; [2]Chem. and Biochem., Univ. of Bern, Bern, Switzerland

**Abstract:** The computer guided exploration of the yet unknown chemical space such as the Chemical Universe Database GDB-17 containing all possible small organic molecules up to 17 atoms and its fragment subset FDB-17,[1] is one of the richest tools available today to identify new active molecules for a given target.[2] Extending our previous drug discovery efforts at the α7 nicotinic acetylcholine receptors (nAChRs),[3] we have identified promising regions of the chemical space and refined our virtual screening strategies, in particular focusing on optimizing pharmacological characteristics such as crossing the blood brain barrier and specifically aiming at the modulation of the receptors.
Properties of the promising candidate molecules were then assessed using functional investigations at the human α7 nAChRs expressed in *Xenopus* oocytes by taking advantage of the automated HiClamp system. Evaluation was conducted by first determining that these molecules are deprived of agonistic activity and then by measuring their effects on the responses evoked by low concentrations of acetylcholine using a protocol of irregular receptor stimulation (also referenced as priming). Priming of the α7 receptors is known to correlate with procognitive activity, which suggests that molecules identified with this experimental paradigm should be promising candidates to restore age or disease related cognitive deficits.
The observation that cotinine, the inactive metabolite of nicotine, causes a significant priming at the human α7 nAChRs but is deprived of any agonistic activity provided a further initial condition to adjust the computer screening. We performed a virtual screen of FDB-17 for new analogs of cotinine using fingerprint based similarity, and selected eleven compounds for further characterization based on 3D-shape and pharmacophore based comparisons and commercial availability. Functional testing of these eleven molecules revealed that none of them evoked currents when applied alone at α7 receptors but that five of them caused a significant potentiation (> 1.5 fold) of the response evoked by 40 μM acetylcholine.

Illustrating the power of combination of computer guided exploration of the chemical space and functional studies, these results also demonstrate the possibility to discover novel active molecules at the human α7 nAChRs with pharmacological profiles differing from the currently known compounds.

**Abstract:** Tobacco abuse contributes to several disease states that are estimated to account for >8 million human deaths per year by 2030. The primary reinforcing properties of nicotine are mediated by its actions at neuronal nicotinic acetylcholine receptors (nAChR). The subcellular localization of ion channels is intrinsically tied to their function, and we note that the relationship between nAChR localization and function is a largely uninvestigated aspect of nAChR biology. This is due, in part, to a lack of tools for interrogating the location of functional nAChRs in native systems. To remediate this limitation and expand our understanding of nAChR neurobiology, we developed a photoactivatable nicotine (PA-Nic) molecule. PA-Nic employs an unconventional quaternary ammonium linkage that is chemically stable and elicits a desirable red-shift in absorption maximum. Utilizing patch clamp electrophysiology in acute *ex vivo* mouse brain slices, we show that photochemical uncaging of PA-Nic generates free nicotine in a spatially and temporally controllable manner. We confirm that flash-evoked currents are mediated by nAChRs through mecamylamine inhibition and additional biophysical experiments. By leveraging light-dependent temporal control of nicotine release, we generate photochemical dose-response curves mediated by native nAChRs in the medial habenula (MHb) to interpeduncular nucleus (IPN) circuit, a critical pathway that modulates nicotine addiction and withdrawal. Flash-evoked photochemical dose-response curves suggest the main effect of chronic nicotine is to increase the total number of functional surface receptors, without influencing the potency of nicotine at those receptors. Using 2-photon laser scanning microscopy and laser flash photolysis, we demonstrate that spatially selective PA-Nic uncaging elicits nAChR currents at distinct subcellular locales. MHb neurons expressed nAChRs in most subcellular locations, but interestingly, these neurons may exhibit preferential surface expression near the soma and proximal dendritic segment relative to distal dendrites. Uncaging responses were enhanced on somata and dendritic processes of neurons from mice exposed to chronic nicotine, suggesting that chronic nicotine may sensitize MHb neurons to nicotine or cholinergic input via multiple cellular mechanisms. Finally, we find that PA-Nic is useful in 2-photon photolysis, suggesting this probe could be used to precisely localize nAChRs at discrete cellular locations. In summary, PA-Nic is a versatile and useful new probe for examining nAChR functional activity, likely enabling new discoveries pertaining to cholinergic transmission.

**Title:** Novel α3β2 neuronal nicotinic acetylcholine receptor stable transfection cell line with inducible promoter to change subunit expression ratios

**Authors: *S. N. SUDWEEKS**[1], A. SEGO[2]
[1]Physiol. and Dev. Biol., [2]Neurosci., Brigham Young Univ., Provo, UT

**Abstract:** Nicotinic acetylcholine receptors (nAChR) are found widely throughout the brain both pre- and post-synaptically and participate in a number of physiological functions. Recent research from our lab has shown that α3 and β2 are the most commonly co-expressed nAChR subunit mRNAs in CA1 hippocampal interneurons from the stratum radiatum and stratum oriens, leading us to believe that the α3β2 nAChR is one of the most prevalent nAChR type in these specific interneurons. Recordings from whole cell electrophysiology in Xenopus leavis of the α3β2 nAChR show that there are two distinct α3β2 nAChR subtypes - likely ($(\alpha3)_3(\beta2)_2$ and $(\alpha3)_2(B2)_3$). Given the unique distribution of the α3β2 nAChR, it is worthwhile to explore its role in memory and cognition and as a potential target for pharmaceutical based cognitive therapies. The proposed study is to make an α3β2 stably transfected cell line with a tetracycline (TET) inducible promoter in HEK-293 cells. The TET inducible promotor will allow for quantitative control of the expression ratios between the two subunits such that two likely α3β2 stoichiometries ($(\alpha3)_3(\beta2)_2$ and $(\alpha3)_2(B2)_3$) can be separated and voluntarily induced. This new stably transfected cell line will allow for study and characterization of the α3β2 nAChR in a mammalian environment via whole cell electrophysiology recordings, which will 1) confirm recent α3β2 recordings from Xenopus laevis 2) provide kinetic differentiation amongst the two likely α3β2 stoichiometries and 3) provide a cell line for screening α3β2 targeted cognitive therapies.

**Title:** GTS-21 has cell-specific anti-inflammatory effects that are independent of α7 nicotinic receptors

**Authors: B. K. GARG**, *R. H. LORING
Pharmaceut. Sci., Northeastern Univ., Boston, MA

**Abstract:** GTS-21 is a partial agonist for α7 nicotinic acetylcholine receptors (nAChRs) that is widely used to study the cholinergic anti-inflammatory pathway (e.g. Hilderman et al. *Clin*

*Kidney J.* ***8:***599, 2015 or Norman et al. *J. Neurosci.* ***31:***3446, 2011). However, Nullens et al. (*Shock*. ***45*:**450, 2016) report that GTS-21 is effective in a sepsis model in both wild type (WT) and α7 knockout (α7-KO) mice. To evaluate possible α7-independent anti-inflammatory GTS-21 effects at a molecular level, we investigated two cell lines and macrophages from both WT and α7-KO mice. The first cell line, GH4C1 cells, readily expresses α7 nAChRs when transfected, and respond to the inflammatory cytokine tumor necrosis factor (TNF) when co-transfected with an NFκB-driven alkaline phosphatase (AP) reporter gene (NFκB: Nuclear factor kappa light chain enhancer of B cells, part of a major pro-inflammatory signaling pathway). However, GTS-21 blocks neither TNF-induced phosphorylation of IκB nor AP secretion (both indicators of NFκB activation in these cells). These results suggest that GTS-21 stimulation is insufficient to block TNF-induced inflammatory markers in GH4C1 cells expressing α7 nAChRs. In our hands, the macrophage-like RAW264.7 cell line expresses neither α7 mRNA nor surface α7 nAChRs detected by alpha-bungarotoxin (BGT) binding (See however, Yue et al. *Int. Immunopharmacol*. ***29:*** 504, 2015). 50 μM GTS-21 significantly blocked lipopolysaccharide (LPS)-driven IκB phosphorylation and TNF secretion in RAW264.7 cells, but this latter effect was not prevented by the α7 nAChR antagonists BGT (12.5 μM) or methyllycaconitine (MLA, 10 μM). Finally, mouse WT macrophages express both α7 mRNA and surface BGT binding, while macrophages from α7-KO mice do not. 50 μM GTS-21 significantly blocks both LPS-induced phospho-IκB, and secretion of TNF as well as secretion of the cytokine interleukin-6 in macrophages from both WT and α7-KO mice. A minor fraction of these GTS-21 effects were blocked by BGT and MLA in WT macrophages, but these antagonists had no effect on GTS-21 in α7-KO macrophages. These results suggest that GTS-21 may have different effects on TNF- and LPS-induced inflammatory signaling, and the majority of GTS-21 anti-inflammatory effects are independent of α7 nAChRs in these model systems. Thus, care should be taken interpreting studies using GTS-21 to study α7 nAChR anti-inflammatory effects.

**Abstract:** Neuronal nicotinic acetylcholine receptors (nAChRs) regulate the function of multiple neurotransmitter pathways throughout the central nervous system. This includes nAChRs found on the proopiomelanocortin neurons in the hypothalamus. Activation of these nAChRs by nicotine causes a decrease in the consumption of food in rodents. While nicotine is a non-selective agonist for nAChRs there are other compounds known as Positive Allosteric Modulators (PAMs) that demonstrate selectivity for different nAChR subtypes. In this study we tested the effect of subtype selective allosteric modulators for nAChRs on the body weight of CD-1 mice. Levamisole, an allosteric modulator for the α3β4 subtype of nAChRs, prevented weight gain in mice that were fed a high fat diet. PNU-120596 and desformylflustrabromine were observed to be selective PAMs for the α7 and α4β2 nAChR, respectively. Both of these compounds failed to prevent weight gain in the CD-1 mice. These results suggest that the modulation of hypothalamic α3β4 nAChRs is an important factor in regulating food intake, and the PAMs for these receptors need further investigation as potential therapeutic agents for controlling weight gain.

**Authors: *J. KING**[1], E. K. BAK, 22030[1], N. KABBANI[2]
[1]George Mason Univ., Fairfax, VA; [2]Mol. Neurosci, Krasnow Inst., Fairfax, VA

**Abstract:** α7 nicotinic acetylcholine receptors (α7 nAChRs) are abundant in the mammalian nervous system and play an important role in regulating the structure and function of synapses in development and adulthood. The α7 nAChR has a high permeability to extracellular calcium and can promote the release of intracellular calcium from local ER stores through both ionotropic and metabotropic signaling. Studies show that ligand activation of the α7 nAChR can direct

cytoskeletal assembly in both pre- and postsynaptic compartments. Here we show that stimulation of the α7 nAChR fosters rapid microfilament disassembly via calcium driven calpain cleavage of spectrin at the growth cone. α7 nAChR mediated calpain activation attenuates microtubule elongation at the growth cone leading to changes in neurite outgrowth and branching. These studies reveal a novel role for α7 nAChR mediated calcium signaling via calpain activity in cytoskeletal growth and in the developing nervous system with implications for the treatment of various neurodegenerative diseases.

**Abstract:** Neuronal nicotinic acetylcholine receptors (nAChRs), especially the α4β2 and α7 subtypes, are expressed in pain transmission pathways and involved in the pathophysiology of neuropathic and inflammatory pains. As such, nAChR-based therapeutics represents a potential strategy to alleviate pain while avoiding the high abuse liability associated with opioid analgesics. To this end, the antinociceptive effects of nonselective nAChR agonists as well as agonists/allosteric modulators selective for α4β2 or α7 nAChR have been demonstrated in a wide range of preclinical and clinical models of pain. In this study, we examine the antinociceptive effects of desformylflustrabromine (dFBr), a naturally occurring positive allosteric modulator of α4β2 nAChR, in *in vivo* rat model of acute pain. Hot-plate and tail-flick nociceptive responses and electronic von Frey anesthesiometer were used to measure the ability of dFBr to increase latency to thermal and mechanical sensitivity, respectively. Intraperitoneal injection of dFBr dose-dependently increased time for hind paw-licking behavior in hot-plate test (~300% at 20 mg/kg) and increased mechanical threshold for paw withdrawal in the von Frey test. dFBr antinociceptive effect was characterized with a fast onset time and short duration. Following intraperitoneal injection, dFBr maximum antinociceptive effect was achieved within ~30 minutes and animals returned to baseline value in 3-4 hours. Experiments are in progress to evaluate the effect of co-administration of dFBr with nicotinic agonists (e.g. nicotine, choline) or antagonists (e.g. dihydro-β-erythroidine) on thermal and mechanical pain latencies. Additionally, blood,

CSF, and brains were collected to determine systemic and brain dFBr levels following intraperitoneal injection.

**Title:** Region-specific changes in nAChR subunit expression following chronic co-application of nicotine with either (-)-menthol or (±)-menthol in the murine brain

**Authors: *M. J. MULCAHY**[1], S. M. HUARD[1], J. H. WANG[1], H. A. LESTER[2]
[2]Biol. and Biol. Engin., [1]Caltech, Pasadena, CA

**Abstract:** Nicotinic acetylcholine receptors (nAChRs) are pentameric cation channels that are expressed in the mammalian central nervous system, the peripheral nervous system, and the neuromuscular junction. Eleven neuronal nAChR subunits have been identified in mammals (α2-7, α9-10, β2-4). Chronic administration of nicotine has been shown to increase the total amount of α4 and β2 subunits in specific brain regions. Menthol is a common cigarette flavoring added to tobacco products as either (-)-menthol or (±)-menthol. We investigated the effect of chronic nicotine, and nicotine co-administered with either (-)-menthol or (±)-menthol in several previously uninvestigated murine brain regions for changes in total β2 nAChR subunit protein expression using western blot analysis. Absence of β2 immunoreactivity was confirmed in both β2 knockout and α4 knockout mice. Male C57bl/6 mice were separated into four treatment groups, vehicle (ethanol), nicotine (2mg/kg/hr) in vehicle, nicotine + (±)-menthol (2mg/kg/hr), and nicotine + (-)-menthol (2 mg/kg/hr) administered via osmotic minipumps for 12 days. In most of the brain regions evaluated, β2 nAChR subunit expression was increased following chronic nicotine. In several regions, co-administration of menthol enhanced β2 nAChR subunit expression over nicotine alone. A comprehensive understanding of upregulation or downregulation of nAChR expression in different brain regions will facilitate our understanding of the effects of nicotine and nicotine + menthol exposure in the mammalian CNS.

**Title:** Neurosteroid modulation of α4β2* nicotinic acetylcholine receptors in the prefrontal cortex

**Authors: *B. Y. CHUNG**, C. D. C. BAILEY
Dept. of Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

**Abstract:** Acetylcholine (ACh) modulation of neurotransmission within the medial prefrontal cortex (mPFC) is important for higher-order cognitive functions including attention and working memory. This role for ACh is met in part through the activation of α4β2* nicotinic acetylcholine receptors (nAChRs) that are present on pyramidal neurons within layer VI of the mPFC. The neurosteroid 3α-hydroxy-5α-pregnan-20-one (3α,5α-THP, allopregnanolone) is produced *de novo* in the brain in response to acute stress. While it is well-known that 3α-5α-THP provides anxiolytic action by potentiating the function of gamma-aminobutyric acid type A ($GABA_A$) receptors, studies in reduced preparations suggest that it also negatively modulates the function of α4β2* nAChRs. Since ACh neurotransmission within the mPFC supports cognitive functions that may be compromised during stress, we sought to determine whether 3α-5α-THP negatively modulates the function of α4β2* nAChRs within living mPFC layer VI pyramidal neurons. Whole-cell electrophysiology experiments were performed in brain slices prepared from male and female CD1-strain mice at postnatal days 14 to 21. Five-minute exposure to 3α-5α-THP did not affect inward current responses to 1 mM ACh at α4β2* nAChRs on mPFC layer VI neurons. However, a longer 20-minute exposure to 3α-5α-THP significantly inhibited ACh responses in both sexes, with a greater inhibition observed in female mice. This inhibition of ACh action at α4β2* nAChRs persisted in the presence of blockers for GABAergic and glutamatergic signaling. Interestingly, this inhibition was not observed in either sex following 20-minute exposure to the synthetic 3α-5α-THP analogue 3α-hydroxy-3β-methyl-5α-pragnan-20-one (ganaxolone), suggesting that 3α-5α-THP may act indirectly at α4β2* nAChRs in brain slice following back-conversion to the neuroactive intermediate 5α-pregnan-3,20-dione (5α-DHP). Ongoing experiments aim to determine and characterize specific entities within the 3α-5α-THP synthesis pathway that directly inhibit the function of α4β2* nAChRs in our experimental preparation. Results from this study demonstrate that stress-induced neuroactive steroids within the 3α-5α-THP synthesis pathway negatively modulate α4β2* nAChRs on mPFC layer VI

neurons, which may disrupt the critical role for these neurons to support normal cognitive function during periods of stress.

**Title:** A hierarchy of interneuronal nicotinic receptors in mouse prefrontal cortex and ultra-slow fluctuations

**Authors: F. KOUKOULI**[1], M. E. ROOY[4], J.-P. CHANGEUX[2], *U. MASKOS[3]
[1]Inst. Pasteur, Paris cedex 15, France; [2]Inst. Pasteur, Paris, France; [3]Inst. Pasteur, Paris Cedex 15, France; [4]Ecole Normale Supérieure, Paris, France

**Abstract:** The prefrontal cortex (PFC) underlies higher cognitive processes that are modulated by cholinergic inputs largely via nicotinic acetylcholine receptors (nAChRs). This brain region exhibits spontaneous activity, which is altered in neuropsychiatric disorders, such as schizophrenia. Human genetic studies have highlighted the polymorphic nature of specific nAChR genes that increase risk for smoking and schizophrenia. Using *in vivo* two-photon imaging, CRISPR/Cas9 technology and pharmacological interventions in the PFC of awake mice, we show that different nAChR subunits control spontaneous PFC activity through a hierarchical inhibitory circuit. Specifically, in mice expressing the human α5 SNP associated with nicotine addiction and schizophrenia and α5 knockout (KO) mice, lower activity of vasoactive intestinal polypeptide (VIP) interneurons resulted in an increased somatostatin (SOM) interneuron inhibitory drive over layer II/III pyramidal neurons. Chronic nicotine administration reverses the hypofrontality observed in α5 SNP mice through possible desensitization of β2 subunits in SOM interneurons. Importantly, we show that β2 nAChR subunits play a key role in the generation of ultra-slow fluctuations (USFs) in the PFC and are specifically required for synchronized activity patterns. These USFs are similar to activity described in the human brain, linked to conscious processing. We can show that chronic application of nAChR antagonists disrupts the generation of USFs and mimics the β2 KO phenotype. Interestingly, expression of the A beta peptide, a hallmark of Alzheimer's disease, exerts a similar effect. This work paves

the way towards new therapeutic strategies targeting nicotinic receptors in mental disorders, and shows that the mouse can serve as an experimental model for brain activity previously thought to be human-specific.

**Title:** Synthesis of α-conotoxin analogs using non-natural amino acids to selectively target α3β2 nicotinic acetylcholine receptors

**Authors: *A. J. HONE**[1], J. GAJEWIAK[2], J. MCINTOSH[2]
[1]Biol., Univ. of Utah, Salt Lake City, UT; [2]Univ. Utah, Salt Lake Cty, UT

**Abstract:** The α3β2 nicotinic acetylcholine receptor (nAChR) subtype is expressed by neurons in both the central and peripheral nervous systems of rodents. In the CNS, α3β2-containing receptors are present in medial habenula-interpeduncular tract nuclei, optic tract, and dopaminergic cell bodies in the ventral tegmental area. Peripherally, α3β2 nAChRs are abundant in autonomic ganglia neurons including those found in superior cervical, nodose and intracardiac ganglia. This receptor subtype is also potentially expressed by dorsal root ganglia neurons. However, unequivocal pharmacological identification has been difficult due to the lack of subtype-selective ligands that can distinguish α3β2 from other closely related subtypes particularly α3β4, α6β2β3, and α6β4. We used α-contoxin PeIA as a platform to develop analogs with increased selectivity for α3β2 over α6β2β3 nAChRs. Electrophysiology experiments in *Xenopus laevis* oocytes have shown that native PeIA shows no ability to distinguish between rat α3β2 ($IC_{50}$ = 19 nM) and α6β2β3 ($IC_{50}$ = 17 nM) nAChRs. However, previous structure-function studies have identified positions in PeIA that are critical for selectivity for α3β2 or α6β2β3 nAChRs. Substitution of these critical residues with non-natural amino acids increased the potency and selectivity for α3β2 over α6β2β3 nAChRs expressed in oocytes. Multiple substitutions generated a PeIA analog that showed a ~50-fold increase in potency over the native peptide for inhibition of α3β2 and was ~70-fold more potent on α3β2 than the α6β2β3 subtype. Furthermore, the analog was ~100-fold and ~1,000-fold more selective for α3β2 over α6β4 and

α3β4 subtypes, respectively. This analog may be useful for pharmacologically identifying α3β2 nAChRs in neurons that express multiple closely related subtypes.

**Title:** Characterizing acetylcholine signaling in glioblastoma

**Authors: *E. G. THOMPSON**[1,2], H. SONTHEIMER[3]
[1]Virginia Tech-Carilion Res. Inst., Roanoke, VA; [2]Univ. of Alabama-Birmingham, Birmingham, AL; [3]Sch. of Med. and Res. Inst., Virginia Tech. Sch. of Neurosci., Roanoke, VA

**Abstract:** Primary brain tumors, gliomas, have thus far evaded effective treatment making them a tremendous challenge clinically. This is due in part to the aggressive, invasive nature of glioma cells to infiltrate the surrounding brain tissue away from the main tumor mass, making complete surgical resection impossible. Consequently, efforts to better characterize the unique features of glioma cells could impact the manner in which these tumors are treated, leading to improved prognosis for patients. Interestingly, gliomas are frequently found in supratentorial brain regions that are richly innervated by cholinergic fibers originating in the basal forebrain. However, whether gliomas sense acetylcholine via acetylcholine receptors (AChR) and whether this affects their biology has not been well studied. In this study, we profiled the expression of AChRs in a cohort of glioma samples, including: cell lines, patient-derived xenografts, and resected glioma tissue from 11 patients. Using RT-qPCR we found that all samples expressed both muscarinic and nicotinic AChRs. Stimulation with AChR agonists lead to a robust intracellular calcium increase, suggesting these receptors are functional and could be modulating mechanisms critical in tumor biology, such as migration, invasion, and proliferation. Because intracellular vesicle fusion is known to be a calcium-dependent process, we first investigated whether the calcium increase we observed upon AChR activation could be influencing the release of proteolytic enzymes. The matrix metalloproteinase (MMP) family is a large group of proteases that is collectively capable of degrading all components of the extracellular matrix. Although MMPs are essential enzymes in various physiological processes such as angiogenesis, morphogenesis,

and tissue repair, they are also associated with many pathological conditions including glioma. We found that all glioma samples expressed MMPs and upon stimulation with AChR agonists MMP release was significantly increased compared to controls. We next determined what level of protein regulation was responsible for this increase in MMP release: transcription, translation, and/or vesicle fusion. Finally, we performed invasion assays to determine if the significant increase in MMP release also enhanced the ability of glioma cells to invade through complex matrices. Our studies suggest that acetylcholine signaling is important in glioma biology and may be targeted to affect cell invasion, provided specific agonists can be developed.

**Abstract:** Tobacco use is the leading cause of preventable death in the US as there are established links between smoking and cardiovascular and pulmonary diseases as well as cancers. However numerous studies have also indicated a relationship between smoking and mental health problems such as anxiety and stress disorders. In addition, with the recent developments in genetics, now we know that the effects of substance of abuse are not confined within the same generation but they may be transgenerationally transmitted through epigenetics mechanisms. In light of these developments, we recently investigated the effects of paternal

nicotine exposure on fear learning and memory in subsequent generations where male adult C57BL/6J mice received either chronic nicotine (Nic-Sired group; 28 days, 12.6 mg/kg/d) or chronic saline (Sal-Sired group) exposure. Our results showed that paternal nicotine exposure resulted in augmented fear learning and recovery in the F1 and F2 generations. In addition, paternal nicotine also altered hippocampal cholinergic function. Specifically, we found that the Nic-Sired F1 and F2 generation mice had an altered response to the enhancing effects of acute nicotine on hippocampus-dependent fear learning. Moreover, using electrochemical recordings, we found that paternal nicotine reduced nicotine-evoked acetylcholine release in both ventral and dorsal hippocampus and potassium-evoked acetylcholine release only in the ventral hippocampus in F1 generation mice. In line with these findings, the results of our whole transcriptome RNA-Seq experiment demonstrated that alterations in fear learning and hippocampal cholinergic function were accompanied by changes in ventral hippocampal gene expression in several pathways including the “Choline Synapse” and “MAPK” pathways. Furthermore, we found that in the Nic-Sired group, expression of two genes (*Chrna3* and *Chrnb4*) within the gene cluster that encode α3/α5/β4 nicotinic acetylcholine receptors (nAChRs) was reduced in the ventral hippocampus. However, although the dorsal hippocampus showed expression changes in the genes within the MAPK pathway, we did not find expression changes in the “Choline Synapse” pathway for dorsal hippocampus. Together, our results suggest that paternal nicotine exposure leads to alterations in the hippocampal cholinergic function and expression changes in the associated gene pathways.

**Title:** AMPA-receptor specific biogenesis complexes control synaptic transmission and intellectual disability

**Authors: J. SCHWENK**[1], A. BRECHET[1], S. BOUDKKAZI[1], G. ZOLLES[1], W. BILDL[1], A. KULIK[1], U. SCHULTE[1], L. COLLEAUX[2], R. ABOU JAMRA[3], *B. FAKLER[1]

[1]Inst. of Physiol., Freiburg, Germany; [2]INSERM UMR 1163, Inst. IMAGINE, Paris, France; [3]Inst. of Human Genet., Leipzig, Germany

**Abstract:** AMPA-type glutamate receptors (AMPARs) mediate the majority of fast excitatory synaptic transmission in the CNS. They are macromolecular complexes composed of GluA1-4 proteins, the pore-forming subunits arranged as tetramers, accompanied by a defined set of interacting proteins. The latter determine properties and cellular functions by modulating gating and membrane trafficking of AMPARs that are key processes for adjusting synaptic efficacy. Here, by using quantitative mass spectrometry we identify AMPAR complexes that transiently form in the endoplasmic reticulum (ER) and lack the core-subunits typical for synaptic AMPARs. Subcellular interactome studies unravel the composition of these ER AMPARs, which contain as central components FRRS1l and CPT1c. These two proteins bind specifically and cooperatively to the pore-forming GluA1-4 proteins. Using in-vitro and in-vivo knock-down experiments, we demonstrate a specific role for these ER complexes in priming the assembly of AMPA receptors and their trafficking to the synapse. The lack of FRRS1l protein by virus-driven deletion impairs (1) the associations of GluA proteins with their inner core subunits TARPs, Cornichons and GSG1l and (2) causes a reduction in the number of AMPARs at synaptic and extra-synaptic sites. In addition, whole exome sequence analysis show that bi-allelic mutations in the human *FRRS1L* gene cause severe intellectual disability with cognitive impairment, speech delay and epileptic activity. Together, our results provide insight into the early biogenesis of AMPARs and demonstrate its pronounced impact on synaptic transmission and brain function.

**Title:** Functional characterization of the potent AMPA positive allosteric modulator S 47445

**Authors: *S. BRETIN**[1], L. DANOBER[2], T. SCHAER[3], S. BERTRAND[3], D. C. BERTRAND[3]
[1]Inst. de Recherches Internationales Servier, Suresnes Cedex, France; [2]Inst. de Recherches Servier, Croissy, France; [3]Hiqscreen, Vesenaz - GE, Switzerland

**Abstract:** The findings that positive allosteric modulators of the AMPA receptors display procognitive and antidepressant-like effects that would be valuable for the treatment of neurological or psychiatric diseases such as Alzheimer or major depression [1], prompted the

search of new molecules showing enough efficacy and selectivity at these glutamate receptors receptor subtypes. The compound S 47445 showed efficacy in different in vivo animal models assessing cognition or antidepressant/anxiolytic-like effects [2; 3]. Calling for further characterization of the mode of action of S 47445, functional experiments on recombinant human AMPA receptors expressed in *Xenopus* oocytes or mammalian cells were conducted. These experiments revealed without ambiguity that S 47445 acts as a potent positive allosteric modulator at the human AMPA receptors displaying only a modest preference on the multiple receptor subtypes (GluA1/2/4 flip and flop variants). Already efficacious at concentrations as 100 nM, potentiation caused by S 47445 was maintained in presence of repetitive glutamate pulses and showed no reduction over the time frame (30min). Potentiation was observed independently of the expression system (HEK 293 or oocytes) and was associated with an increase of the sensitivity to glutamate, maximal amplitude of the response and reduced receptor desensitization, which are the hallmark of a positive allosteric modulator. Exposure to the negative allosteric modulator GYKI 52466 (from 10 to 100µM) inhibited the potentiation caused by S 47445 (at 1µM) in a concentration dependent manner. Competition experiments revealed, however, that these two molecules are acting at distinct binding site and confirmed the previous results obtained with AMPA/Kainate chimera [4] suggesting that S 47445 binds in the extracellular domain of the AMPA receptors. This drug is currently evaluated in clinical phase 2 studies in Alzheimer's disease patients and in patients with Major depressive disorder.[1] Lynch G (2006) Glutamate-based therapeutic approaches: ampakines. **Title:** AMPA and kainate receptors differentially modulate navigation in *C. elegans*

**Authors: *P. J. MALDONADO-CATALA**[1], P. BROCKIE[2], J. MELLEM[2], D. MADSEN[2], A. V. MARICQ[2]
[2]Biol., [1]Univ. of Utah, Salt Lake City, UT

**Abstract:** The nematode C. elegans is capable of detecting environmental cues and modifying its behavior accordingly. For example, worms can navigate towards attractive odors and favorable temperatures. The neuronal circuits underlying these behaviors have been identified via cell-ablation studies; however, how the neurons in these circuits modulate navigation towards an attractant is not well understood. The RIA interneurons integrate information from sensory neurons in these circuits and send information to a variety of interneurons and motor neurons. Interestingly, the GLR-3 and GLR-6 kainate subtype of ionotropic glutamate receptors (iGluRs) are exclusively expressed in RIA, which also express the GLR-1 AMPA-type iGluR. Electrophysiological analysis revealed that GLR-3 and GLR-6 form a heteromeric iGluR that is gated by both glutamate and kainate. In addition, the glutamate-gated current mediated by GLR-3 and GLR-6 is distinctly different from the AMPAR-mediated current. Furthermore, *glr-1* and *glr- 3/6* knockout animals show deficits in chemotaxis to the odorants, similar to those observed in worms lacking the RIA interneurons. Here, we show a novel role for AMPA and kainata receptors in the modulation of backwards locomotion during chemotaxis. In addition, our studies reveal a differential role for these receptors in neuronal activation and behavior.

**Title:** FRRS1L associates with dynein vesicles and is critical for glutamatergic synaptic transmission

**Authors: *W. HAN**, H. WANG, J. LI, X. GU, W. LU
NIH/NINDS, Bethesda, MD

**Abstract:** In the mammalian brain, AMPA receptor (AMPAR)-mediated excitatory synaptic transmission is critically regulated by the receptor auxiliary subunits. Recent proteomic studies have identified that Ferric Chelate Reductase 1 Like protein (FRRS1L), whose mutations in human lead to epilepsy, choreoathetosis, and cognitive deficits, is present in native AMPAR complexes in the brain. However, the role of FRRS1L in the regulation of glutamatergic synaptic transmission remains unknown. Here we report that FRRS1L is an integral membrane protein that interacts with GluA1 and GluA2 subunits of AMPARs. In mouse hippocampal neurons, over-expressed FRRS1L partially co-localizes with endogenous GluA1 and primarily localizes at

non-synaptic membranes. Importantly, immunoisolation of neuronal vesicles from mouse hippocampi reveals that FRRS1L is localized at dynein, but not kinesin, vesicles, suggesting that FRRS1L-containing vesicles are primarily transported by the motor protein, especially dynein, in neurons. Functionally, over-expression of FRRS1L does not alter glutamatergic synaptic transmission in CA1 pyramidal neurons in organotypic hippocampal slice cultures. In contrast, CRISPR-based single-cell knockout of FRRS1L strongly reduces neuronal surface and total expression levels of GluA1, and significantly impairs AMPAR-mediated synaptic transmission in mouse hippocampal neurons both in vitro and in vivo. Taken together, these data reveal a unique subcellular distribution of FRRS1L in neurons and demonstrate an important role of FRRS1L in the regulation of excitatory synaptic strength.

**Title:** An insensitive kainate receptor mediates reliable signaling in the retina

**Authors: *S. H. DEVRIES**
Northwestern Univ., Chicago, IL

**Abstract: Objective:** Synapses are optimized for efficient communication, but what are the principles of optimization when a single presynaptic terminal has multiple postsynaptic partners with different receptor and contact properties? Here, we describe a synaptic contact between a mammalian cone and the cb1a, one of 5 types of Off bipolar cells. cb1a cells use kainate receptors and make a single contact on a 5 µm diameter cone terminal that is 200-500 nm from the nearest transmitter release sites. We tested whether this synaptic contact is relatively insensitive to released glutamate based on its distance from release sites and found, surprisingly, that sensitivity is further diminished by the expression of an unusual low affinity receptor. **Methods:** We compared the number of vesicles released by a cone to the number detected by a postsynaptic bipolar cell by recording from synaptically connected pairs in voltage clamp in retinal slices. Cone transmitter release was evoked by applying a train of depolarizing pulses from -70 mV and measured by monitoring the anion conductance of the presynaptic glutamate transporter. To obtain glutamate concentration-response curves, the recording pipette was used to slowly withdraw a bipolar cell's soma from the slice leaving behind a tracer filled axon and connected dendrite. Somatic responses to a range of glutamate concentrations (0.22 – 18.0 mM)

were probed by rapid perfusion. Cell types were identified by epifluorescence. AMPA receptors (~20% of the receptors on cb3a/b cells) were blocked with GYKI53655. **Results:** We compared the responses of two Off bipolar cell types, cb1a and cb3a/b, both of which make basal contacts with cones and express UBP310-sensitive kainate receptors. Paired recordings revealed a non-linearity at both the cone to cb3a/b and cb1a cell synapses that followed a power law with exponents of 2.2 ± 0.1 and 3.2 ± 0.4 (n=8 each), respectively. In response to rapid glutamate application, cb3a/b cell receptors had an $EC_{50}$ of 0.37 ± 0.15 mM (n=6), whereas cb1a receptors had an $EC_{50}$ of 1.4 ± 0.4 mM (n=6) or about 4 times higher. **Conclusion:** The combination of distance from release sites and low affinity receptor means that the simultaneous release of at least 3 vesicles from nearby ribbons is required to produce a detectable cb1a cell response. This thresholding will eliminate the noise associated with cone transmitter release at steady voltages which typically involves stochastic sepscs. Only cone membrane depolarizations that result from light absorption will produce coordinate vesicle fusion and responses in cb1a cells. The cone to cb1a cell synapse sacrifices sensitivity for certainty by using a low affinity kainate receptor.

**Abstract:** AMPA receptors (AMPARs) are glutamate-gated cation channels that mediate the majority of fast excitatory neurotransmission in the central nervous system. AMPARs are tetrameric assemblies of GluA1 to GluA4 subunits. Cryo-EM and X-ray crystal structures of homomeric and heteromeric AMPARs has recently been provided; showing a highly modular receptor architecture with an extracellular domain containing four glutamate binding sites coupled to a transmembrane domain containing the central ion channel. AMPARs also contain an intracellular domain (ICD) formed of C-terminals from each subunit. The ICD is important for interactions with intracellular proteins and contains multiple regulatory phosphorylation sites, but the structure and mechanistic role of the ICD is poorly understood; in part because the ICD is not resolved in present structures. We have used a Förster Resonance Energy Transfer (FRET)

approach to study intramolecular distances and dynamics of the ICD in homomeric and heteromeric AMPARs by insertion of fluorescent proteins (FPs) at various intracellular positions in the GluA1 and GluA2 subunits. Using fluorescence life-time imaging (FLIM) to determine FRET efficiencies between FPs in the ICD or a membrane dye, we determine relative distances within the ICD and to the membrane. Furthermore, we investigate the effect of phosphorylation mimicking mutations in the GluA1 subunit on FRET and identify mutation-induced changes that suggest the phosphorylation state of GluA1 C-terminal can change the structure of the ICD.

**Abstract:** GRID1 gene encodes GluD1, which forms with GluD2 the delta family of ionotropic glutamate receptors. GluDs have remained orphan of a pore-opening ligand since their cloning, raising doubts on their function as ion channels, until the recent demonstration that GluD2

channels opening is triggered by mGlu1 activation through the canonical Gq/phospholipase C/protein kinase C pathway, and plays a key role in slow glutamatergic transmission in the cerebellum. Human mutations of the GRID1 gene are associated with schizophrenia but the explicit role of GluD1 in brain circuits is unknown. GluD1 is localized at the postsynaptic density of excitatory synapses and its expression increases during postnatal development. Based on the known function of its paralog GluD2 in cerebellum, we searched for a role of GluD1 in slow glutamatergic transmission mediated by metabotropic receptor mGlu1 in midbrain dopamine neurons, whose dysfunction is a hallmark of schizophrenia. We found that an mGlu1 agonist elicits a slow depolarizing current in HEK cells co-expressing mGlu1 and GluD1, but not in cells expressing mGlu1 or GluD1 alone. This current is prevented by additional co-expression of a dominant-negative GluD1 dead pore mutant. We then characterized mGlu1-dependent currents in dopamine neurons from midbrain slices. Both the agonist-evoked and the slow postsynaptic currents are abolished by expression of the dominant-negative GluD1 mutant, pointing to the involvement of native GluD1 channels in these currents. Likewise, both mGlu1-dependent currents are suppressed in GRID1 knockout mice, which reportedly display endophenotypes relevant for schizophrenia. Our results deorphanize GluD1, unravel its key role in slow glutamatergic transmission and provide insights into how GRID1 gene alterations can lead to dopaminergic dysfunctions in schizophrenia.

**Title:** Bidirectional modulation of heteromeric acid-sensing ion channel 1a/3 channels by zinc

**Authors: *X. CHU**[1], Q. JIANG[2]
[1]Basic Med. Sci., Univ. of Missouri Kansas City, Kansas City, MO; [2]Univ. of Missouri-kansas City, Kansas City, MO

**Abstract:** Acid-sensing ion channels 1a and 3 subunits are expressed in sensory neurons and retina. Here, we found that heteromeric ASIC1a/3 channels expressed in CHO cells, are regulated by physiological concentration of zinc with dual effects. Co-application of zinc dose-dependently potentiates both the peak amplitude and sustained component of heteromeric ASIC1a/3 channel currents, pretreatment with zinc between 3 to 100 μM exerts the same potentiation as co-application. However, pretreatment with zinc induced the significant inhibition

of heteromeric ASIC1a/3 channels when concentration of zinc is over 100 μM. The potentiation of heteromeric ASIC1a/3 channels by zinc is pH-dependent, as zinc shifts the pH-dependences of ASIC1a/3 current from a $pH_{50}$ of 6.5 to 6.9; while the inhibition of ASIC1a/3 currents by zinc is pH-independent. The inhibition of ASIC1a/3 currents by pre-applied zinc was independent of pH activation, steady-state desensitization, voltage, or extracellular $Ca^{2+}$. Further, systemic mutation of histidine residues in extracellular domain of ASIC3, but not ASIC1a subunit abolished the zinc effects on heteromeric ASIC1a/3 channels. These findings suggest that histidines (located in the ASIC3) in the extracellular domain of heteromeric ASIC1a/3 subunit is critical for zinc-mediated effect.

**Title:** CMPDA is a novel potent positive allosteric AMPA receptor modulator affecting synaptic transmission and plasticity with distinct effects in SorCS3-deficient hippocampus

**Authors: *M. M. HOLM**[1], B. MORENO-LÓPEZ[2], V. GARCÍA-MORALES[1,2]
[1]Dept. of Biomedicine, Aarhus Univ., Aarhus C, Denmark; [2]Univ. of Cádiz, Cádiz, Spain

**Abstract:** Fine-tuning of excitatory transmission in the brain can be achieved by allosteric modulation. Positive allosteric modulators (PAMs) of AMPA receptors have been shown to improve memory, facilitate synaptic transmission, promote synaptic plasticity and increase BDNF levels. Conversely, there is a risk of tipping the delicate excitatory-inhibitory balance in the brain. We have recently documented that SorCS3 (sortilin-related receptor CNS expressed 3)-deficient synapses display impaired synaptic transmission and plasticity [Breiderhoff et al., 2013, PLoS ONE, Christiansen et al., 2017, Hippocampus]. Consequently, we hypothesized that PAMs may improve SorCS3-deficient synapses.
Here we employed a novel subunit-bridging PAM entitled phenyl-1,4-bis-alkylsulfonamide (CMPDA) [Timm et al., 2011, Molecular Pharmacology]. To analyze the modulator in native synapses, and to test our hypothesis, we prepared acute brain slices (400 μm) from the SorCS3-deficient mouse model [Breiderhoff et al., 2013, PLoS ONE]. We focused on young adult animals (P55 - P65) of both sexes. Field excitatory postsynaptic potentials (fEPSPs) were recorded in CA1 upon Shaffer collateral stimulation and CMPDA was added to standard artificial cerebrospinal fluid (ACSF) and applied by bath perfusion.

0.1 µM CMPDA potentiated fEPSP slopes about 1.9-fold in wild-type and 1.7-fold in knockout. Increasing the concentration to 1 µM potentiated the fEPSP slopes about 3-fold in wild-type and 4.5-fold in knockout compared to baseline. Interestingly, 0.1 µM CMPDA rescued an intermediate frequency protocol (1 x 100 pulses at 50 Hz) more profoundly in knockout, and even promoted a strong long-term potentiation (LTP) protocol (2 x 100 pulses at 100 Hz). Paired stimulations revealed that 1 µM reduced the paired-pulse facilitation at all intervals, while 0.1 µM increased the facilitation selectively at 50 ms, and only in knockout. Intriguingly, 3 µM produced pronounced pathological epileptiform activity, revealing repeated pyramidal cell firing, even upon single stimulations. This was observed as repetitive population spikes measured by recordings in the pyramidal cell body layer.
In summary, CMPDA positively affects synaptic impairments in SorCS3 knockout. The allosteric modulator enhances synaptic transmission and plasticity, but triggers epileptiform activity, even at relatively low concentrations.

**Abstract:** Altering AMPA receptor (AMPAR) content at synapses is a key mechanism underlying the regulation of synaptic strength during learning and memory. Previous work demonstrated that *SynDIG1* (Synapse Differentiation Induced Gene 1) encodes a transmembrane AMPAR associated protein that regulates excitatory synapse strength and number (Kalashnikova et al., 2010; Chenaux et al., 2016). The related protein SynDIG4 [SD4, also known as Prrt1 (Proline rich transmembrane protein 1)] has been identified as a component of AMPAR complexes. Here we investigate the role of SD4 in excitatory synapse development and function. SD4 modifies AMPAR gating properties in a subunit dependent manner. SD4 slows the deactivation kinetics of both GluA1 homomers and GluA1/2 heteromers and it has a synergistic effect in the presence of TARPγ8. SD4 also reduces the desensitization of GluA1 homomers with or without TARPγ8, but it has no significant effect on the desensitization of heteromeric GluA1/2. SD4 does not alter recovery from desensitization of either GluA1 homomers or GluA1/2 heteromers. Two week old SD4 knockout (KO) mice exhibit reduced miniature excitatory postsynaptic current (mEPSC) amplitude in CA1, which is corroborated by immunocytochemistry, suggesting that loss of SD4 results in weaker synapses. Remarkably, adult SD4 KO mice show complete loss of long-term potentiation (LTP) induced by a single 100 Hz tetanus without a striking reduction in synaptic transmission. Furthermore, SD4 KO mice exhibit deficits in two independent cognitive assays, Morris water maze acquisition and novel object recognition, indicating that loss of SD4 directly impacts higher order circuit function. Previously, we showed that SD4 co-localizes with the AMPAR subunit GluA1 at non-synaptic sites in neurons and brain sections (Kirk et al, 2016), implying that SD4 influences primarily extrasynaptic AMPARs. We propose that SD4 maintains a pool of extrasynaptic AMPARs critical for synaptic potentiation that manifests as altered circuit function in the mature brain. The finding that loss of SD4 abolishes LTP without an impact on synaptic transmission is particularly significant in light of current evidence indicating that an extra/non-synaptic reserve pool of receptors is critical for LTP (Granger et al., 2013), consistent with our hypothesis that SD4 establishes a reserve pool of GluA1-containing AMPARs critical for potentiation.

**Title:** Spatial assembly of heteromeric AMPA receptors

**Authors: *Y. SHI**
MOE Key Lab. of Model Animal for Dis. Study, Nanjing Biomed. Researc, Nanjing Univ., Jiang Su, China

**Abstract:** AMPA-type glutamate receptors (AMPARs) mediate fast excitatory neurotransmission and predominantly assemble as heterotetramers in brain. Recently the crystal structures of homotetrameric GluA2 demonstrate AMPARs are assembled with two pairs of conformationally distinct subunits, in a dimer of dimers formation. However, the structure of heteromeric AMPARs remain unclear. Guided by the GluA2 structure, we performed cysteine mutant crosslinking experiments in full-length GluA1/A2 aiming to draw the heteromeric AMPAR architecture. We found the amino-terminal domains (ATDs) determine the first level heterodimer formation. When the dimers further assemble into tetramers, GluA1 and GluA2 subunits have preferred positions, possessing a 1-2-1-2 spatial assembly. By swapping the critical sequences, we surprisingly found that the spatial assembly pattern is controlled by the excisable signal peptides. Replacements with an unrelated GluK2 signal peptide demonstrate that GluA1 signal peptide plays a critical role in determining the spatial priority. Our study thus uncovers the spatial assembly of an important type of glutamate receptors in brain and reveals a novel function of signal peptides.

**Title:** ABHD6 negatively regulates the surface delivery and synaptic function of AMPA receptors

**Authors: *M. WEI**
Peking Univ., Beijing City, China

**Abstract:** In the brain, AMPA-type glutamate receptors are major postsynaptic receptors at excitatory synapses that mediate fast neurotransmission and synaptic plasticity. ABHD6, a monoacylglycerol lipase, was previously found to be a component of AMPA receptor macromolecular complexes, but its physiological significance in the function of AMPA receptors (AMPARs) has remained unclear. Our study showed that overexpression of ABHD6 in neurons drastically reduced excitatory neurotransmission mediated by AMPA but not by NMDARs at excitatory synapses. Inactivation of ABHD6 expression significantly increased excitatory neurotransmission at excitatory synapses. Interestingly, overexpression of ABHD6 reduced glutamate-induced currents and the surface expression of GluAs in HEK293T cells expressing GluA1-4 and stargazin, suggesting a direct functional interaction between these two proteins. The C-terminal tail of GluAs was required for the binding between of ABHD6 and GluA1. Mutagenesis analysis revealed a short C-terminal sequence in the GluAs that was essential for the inhibitory effect of ABHD6. The hydrolase activity of ABHD6 was not required for the effects of ABHD6 on AMPAR function in either neurons or transfected HEK293T cells. Using CRISPR/Cas9, we generated ABHD6 KO mice. We found that, the surface and total GluA1 expression levels increased significantly in KO mice compared to these of the wt mice. Thus, these findings reveal a novel and unexpected mechanism governing AMPAR trafficking at synapses through ABHD6.

**Title:** Emergence of circuit and behavioral deficits following conditional AMPAR deletion in CGE-derived interneurons

**Authors: *G. AKGUL**[1], C. J. MCBAIN[2]
[1]Natl. Inst. of Hlth., Bethesda, MD; [2]Lab. Cell/Molec Neurosci, NIH, Bethesda, MD

**Abstract:** GABAergic interneurons (INs) critically regulate information flow in the brain and their dysfunction is implicated in many disease states such as epilepsy, schizophrenia and autism. In the hippocampus, they drive early network activity (giant depolarizing potentials, GDP) that is critical for circuit maturation and synchronize pyramidal cell ensembles in adult hippocampus. INs are derived from two progenitor pools located in the ganglionic eminences (CGE and MGE) and migrate to hippocampus during early development. Although MGE-INs have been highly studied, due to the lack of specific genetic tools, characterization of CGE-INs has lagged. Afferent driven recruitment of CGE-INs within local circuits is principally mediated by AMPARs. Here, we examined the role of these receptors in both the maturation and function of CGE-INs in mouse hippocampus during development. To this end, we generated a conditional knockout (KO) mouse that lacks AMPARs selectively in CGE-INs by crossing the 5HT3AR-Cre and floxed-GluA1-GluA2-GluA3 lines. Electrophysiological evaluation in hippocampal slice preparations demonstrated that excitatory synaptic drive onto CGE INs was reduced by 95% in KO mice from neonatal ages through adulthood confirming our genetic knockout strategy. We then probed for potential perturbations in the network activity at both neonatal (P5) and juvenile (P17-21) stages. In KO neonates the GDP frequency was significantly decreased in CA1 hippocampus compared with WTs demonstrating a critical role for AMPAR function in CGE-INs for the coordination of these early network rhythms. In juvenile KO mice, feedforward/feedback inhibition onto CA1 pyramidal cells was significantly impaired when compared to WT. Next we investigated the possible emergence of behavioral abnormalities that may potentially result from these described circuit deficits. In our initial screen, we found that while home cage locomotor activity of adult KO mice was normal, a clear novelty-induced hyperlocomotion and anxiety-like behavior in open-field maze tests was apparent when compared to WTs. In follow up studies, hippocampal dependent behaviors including working memory performance will be assayed using the Morris water maze and T-maze. Taken together our study aims to elucidate the role(s) of AMPARs in the development and maturation of specific cohorts of inhibitory INs and thus may possibly provide new targets for therapeutic treatments for developmental neurological circuit disorders.

**Abstract:** Vesicular neurotransmitter release at the presynaptic terminal is triggered by activation of voltage-dependent calcium channels (VDCCs). Previous reports have indicated that the precision of vesicular release is determined by the coupling distance between VDCCs and docked vesicles. Another factor which controls the synaptic vesicular release is the molecular machinery consists of membrane-bound proteins, expressed in synaptic vesicles or active zones, which directly/indirectly interact with calcium channels. Although alteration of VDCCs distribution or their association with these presynaptic molecules could contribute to presynaptic plasticity, little is known how they change in an activity-dependent manner. We previously reported that Cav2.1 subunits of P/Q-type calcium channels are concentrated in the presynaptic active zones of parallel fiber-Purkinje cell (PF-PC) synapses, and that they make a few clusters within the active zone. In the present report, we used SDS-digested freeze-fracture replica labeling to examine the distribution patterns of Cav2.1, RIM1/2, Munc13-1, Neurexin and CASK in PF active zone, at steady state condition and optogenetically or physiologically stimulated conditions. At steady state, about 20 immunogold particles for Cav2.1 were found per active zone, making 1-2 clusters with 5-6 particles per cluster. Quantitative analysis using a fitted simulation showed significant co-clustering of Cav2.1 with RIM1/2 and Neurexin but not with CASK. After *in vivo* optogenetic stimulation with a condition that induces long-term depression (LTD) of PF-PC synapses *in vitro*, we found that the number of Cav2.1 significantly decreased just after the stimulation then twice increased 30 min after the stimulation. The distribution pattern of Cav2.1 was modified in a time-dependent manner, whereas the active zone size was not changed. Significant increase in the number of Cav2.1 was also observed after horizontal optokinetic response (HOKR) training in mice and the acrobatic motor skill training in rats. Notably, the increase of Cav2.1 was observed in acute slices both after inducing LTD by optogenetic stimulation and inducing long-term potentiation by Forskolin treatment at PF-PC synapses. The number of Neurexin but not others also increased 30 min after the optogenetic stimulation. The co-clustering and relative distance of RIM1/2, Munc13-1 and Neurexin to Cav2.1 showed differential patterns of activity-dependent change. These results shed light on potential mechanisms underlying the presynaptic plasticity induced by dynamics of VDCCs and their association to presynaptic molecules.

**Abstract:** Activity-dependent gene transcription is critical for long-term synaptic plasticity and memory formation. Neuronal excitation activates voltage-gated L-type ($Ca_V1.x$) $Ca^{2+}$ channels (LTCCs) in the plasma membrane to initiate a signaling pathway that results in nuclear CREB phosphorylation and immediate early gene expression. Activation of this long-range pathway requires recruitment of $Ca^{2+}$/calmodulin-dependent protein kinase II (CaMKII) to a nanodomain in the immediate vicinity of the LTCC via an unknown mechanism. Here, we performed a non-biased screen and showed that activated CaMKII strongly interacts with a novel binding motif in the N-terminal domain (NTD) of the $Ca_V1.3$ LTCC α1 subunit that is not conserved in $Ca_V2$ or $Ca_V3$ calcium channels. Mutations in the $Ca_V1.3$ α1 subunit NTD or in the CaMKII catalytic domain that largely prevent the *in vitro* interaction also disrupt CaMKII association with intact

LTCC complexes. Furthermore, these same mutations interfere with excitation-transcription coupling in cultured hippocampal neurons. Lastly, we found that LTCC NTD also interacts with other intracellular components of the calcium channel complex, making it a potential candidate that links voltage-induced channel conformational change to nuclear signaling. Taken together, our findings define a novel molecular interaction with the neuronal LTCC that is critical for the initiation of a long-range signal to the nucleus that is critical for learning and memory.

**Abstract:** Tissue-specific alternative processing of precursor mRNAs is a major source of protein diversity in the nervous system. Alternative splicing, a feature of >95% of mammalian genes, is critical for development and function of the nervous system, and it is implicated in a growing number of disorders. We have shown that the selection of one exon over another, during $Ca_V2.2$ pre-mRNA splicing, explains the unique properties of $Ca_V2.2$ channels in nociceptors including their strong sensitivity to inhibition by mu-opioid receptors. We also showed previously that, following nerve injury, the fraction of e37a-containing $Ca_V2.2$ mRNAs in dorsal root ganglia of rat is reduced compared to naïve ganglia, with a concomitant reduction in morphine sensitivity. Here we determine the molecular mechanism that explains cell-specific exon choice at the 37 locus of *CACNA1B*; the $Ca_V2.2$ encoding gene. Contrary to most published examples of splicing, we failed to find a role for a RNA binding protein in e37a splicing, but rather we showed that the multi-zinc finger DNA binding protein CCCTC-binding factor (CTCF) binds in a 60bp region in *CACNA1B* e37a. CTCF is an ubiquitous regulator of DNA in all cells, but it has also been implicated in alternative pre mRNA splicing. Here we present several lines of evidence that CTCF binding within e37a in *CACNA1B* promotes e37a inclusion in $Ca_V2.2$ mRNAs and that its binding is regulated by cell-specific methylation within, or close to e37a of

*CACNA1B*. We found that reduced methylation by a 48 hr treatment with 10 µM of 5-Azacitidine (20.89 ± 2.76 % of control measured by 5-mC DNA ELISA) in the DRG-derived F11 cell line resulted in a 2.02 ± 0.09 fold-increase in e37a expression relative to control. We discovered that DNMT3a, but not DNMT1 or DNMT3b, is the methyltransferase that regulates e37a inclusion. For example, siRNA knock down of DNMT1 did not affect e37a-$Ca_V2.2$ mRNA levels (1.169 ± 0.03 fold of siRNA control). DNMT3a is increased in DRG in peripheral nerve injury models consistent with our findings that e37a levels are reduced in injured but not uninjured DRG, a finding that we repeated using qRT-CPR to quantify e37a levels in mice.

**Abstract:** Inhibition of voltage-gated calcium (Cav) channels is a potential therapy for many cardiovascular and neurological diseases. Neuronal Cav1/Cav2 channels are typically composed of α, β and α2δ subunits. The β-subunits of voltage-gated $Ca^{2+}$ channels are cytoplasmic proteins that increase the surface expression of the pore-forming α subunit of $Ca^{2+}$ channels and regulate the biophysical properties of the channel. They do so via a high-affinity protein-protein interaction pocket with the α-subunit of Cavs. Thus, targeting the Cav α-β interaction should result in a new class of calcium channel antagonists with therapeutic potential in nervous system disorders involving dysregulation of calcium. To date, there are no small molecules that physically and selectively disrupt the α-β protein-protein interaction. Here, structure-based virtual screening of a commercial library of 500,000 small molecules docked to the β-subunit led to the identification of 49 compounds. Compound **SGM-45** binds to Cavβ2a, inhibits calcium influx via N-type voltage-gated calcium (Cav2.2) channels reconstituted with different beta subunits (except beta 4) and in rat dorsal root ganglion (DRG) neurons, and is a selective inhibitor of Cav2.2. We also found decreased surface Cav2.2 in DRGs following incubation with **SGM-45**, implicating block of surface expression as a mechanism of action of **SGM-45**. Constellation pharmacology revealed actions of **SGM-45** on a heterogeneous population of

DRGs including those responsive to acetylcholine, mustard oil, ATP, histamine, and capsaicin. Of relevance for pain, we found that **SGM-45** decreases calcium influx during periods of high activity by promoting accumulation of channels in an inactivated state. As certain pain conditions have been associated with hyperexcitability of sensory neurons, it is possible that **SGM-45** could allow for increased accumulation of inactivated Cav2.2 in these neurons. Finally, **SGM-45** reversed mechanical allodynia and thermal hyperalgesia in rats subjected to a plantar incision of the paw, an accepted model of human post-surgical pain. Our study will generate new tools to investigate Cav α-β interactions and underscores the importance of targeting this interaction for development of pain therapeutics.

**Abstract:** Autism Spectrum Disorder (ASD) is characterized by a disorder of synaptic function and plasticity required for normal signal processing, as found in Fragile X syndrome (FXS). In FXS, the expression of Fragile X Mental Retardation Protein (FMRP) is lost, removing its role in regulating mRNA translation of multiple protein targets, including kinases such as CaMKII. Here, we examine the effects of FXS on low voltage-activated T-type (Cav3.1) calcium channels in Purkinje cells and their role in evoking long-term potentiation (LTP) of parallel fiber input. Recordings were made *in vitro* from *wt* mice expressing ChR2 in relation to the L7 promoter in Purkinje cells, and EPSPs selectively evoked postsynaptically by injecting a parallel fiber simulated EPSC at the soma. Delivering a theta burst pattern of light pulses resulted in a rapid LTP of the postsynaptic EPSP that was blocked by the Cav3 channel blockers mibefradil or TTA-P2. Calcium influx restricted to Cav3 channels further promoted phosphorylation of alphaCaMKII in the cytoplasm and CREB in the nucleus, as detected with phospho-specific antibodies. A direct role for CaMKII in Cav3-mediated LTP was shown by a significant

reduction in EPSP potentiation by the CaMKII blocker AIP. We further found that FMRP and Cav3.1 immunolabels colocalize in Purkinje cell somata, and that FMRP coimmunoprecipitates (coIPs) with Cav3.1 channels. Moreover, the coIP between Cav3.1 and FMRP was calcium-dependent in being detected at 0 µM [Ca] (BAPTA), 100 nM [Ca] (neuronal resting [Ca]), and 1 µM [Ca], but lost at 50 µM [Ca]. Infusing an N-terminal active fragment of FMRP in tsA-201 cells expressing Cav3.1 channels invoked a significant hyperpolarizing shift in the voltage-inactivation curve (Vh) that reduced Cav3.1 by ~60% near resting potentials. These data are important in revealing an activity-dependent association between Cav3.1 and FMRP that could enhance Cav3 calcium influx and CaMKII activation during repetitive inputs. We will test the hypothesis that a loss of FMRP in FXS will increase Cav3 calcium influx and CaMKII activation, increasing the probability of LTP that could disrupt signal processing in Purkinje cells.

**Abstract:** The L-type calcium channel 1.2 (Cav1.2) is the most prevalent LTCC in heart and brain tissue. Cav1.2 forms a complex that includes the beta-2 adrenergic receptor (b2AR), Gs, and AKAP-anchored PKA, allowing for upregulation of channel activity via a Gs-adenylyl cyclase-cAMP-PKA pathway. PKA phosphorylation of residue S1928 on the C-terminus of Cav1.2 is prominently regulated, but its physiological role has not been reported especially in

light of functional studies that argued against a regulatory role in the heart. We have defined here an agonist-triggered downregulation of b2AR that is specific to Cav1.2 in neurons. For local beta-adrenergic regulation of Cav1.2, b2AR binds to residues 1923-1948 of Cav1.2. Phosphorylation of S1928 induced by a b2AR agonist displaced b2AR from Cav1.2, resulting in a refractory period from further beta-adrenergic stimulation. S1928A knock-in mice do not show this refractory period. Although AMPARs also cluster at post-synaptic sites, they do not express these differences in b2AR association and regulation after b2AR stimulation. Hence, this desensitization mechanism by b2AR/cAMP/PKA/S1928 signaling is highly specific to Cav1.2 in the brain. Finally, we found that LTP induced by prolonged theta tetanus (PTT-LTP) depends on Cav1.2 and the b2AR/Cav1.2 association, emphasizing the physiological significance of this agonist-triggered dissociation of b2AR.

**Abstract:** Neurotransmission is one of the most important processes of neuronal communication that depends largely on calcium movement across ion permeable channels. Cyclin-dependent kinase 5 (cdk5) has been implicated in the regulation of neurotransmission in several studies which suggest that cdk5 exerts a direct regulation on various ion channels. In hippocampal synaptosomes for example, phosphorylation of P/Q type calcium channels prevents its interaction with SNAP25 and synaptotagmin 1, thereby inhibiting glutamate release from these terminals.
In this work, we studied the regulation by cdk5 of presynaptic L-type calcium channels, which regulate significantly the GABA release at striato-nigral terminals (Recillas et al., 2014). Through electrophysiology experiments in slices of substantia nigra pars reticulata (SNr) we

found that, by inhibiting cdk5 with olomoucine (50 μM) there is an increase of high potassium-evoked inhibitory post-synaptic currents (eIPSC) and that this increase can be prevented by adding the specific L-type calcium channel blocker, nifedipine (10 μM). This speaks of an inhibitory mechanism exerted by cdk5 on L-type calcium channels and, according to our previous results, it is due to phosphorylation by cdk5 of a serine residue located at the carboxyl terminus of L-type calcium channels.
Our results suggest a novel mechanism of regulation of neurotransmission at SNr by a phosphorylation event whose knowledge may be useful for the understanding about how GABAergic neurotransmission works and, in the future, for the development of therapeutic alternatives against neurodegenerative diseases such as Parkinson's.

**Abstract:** N-type voltage-gated calcium (CaV2.2) channels are critical determinants of increased neuronal excitability and neurotransmission accompanying persistent neuropathic pain. Despite CaV2.2 antagonism being recommended as first-line treatment for neuropathic pain, calcium-current blocking gabapentinoids inadequately alleviate chronic pain symptoms and are often mired by numerous side-effects. Collapsin response mediator protein 2 (CRMP2) targets CaV2.2 to the sensory neuron membrane, and allosterically modulates Cav2.2 functionally. A fifteen amino acid peptide (CBD3), derived from CRMP2, disrupts the functional protein-protein interaction between CRMP2 and CaV2.2 to inhibit calcium influx, transmitter release and acute, inflammatory and neuropathic pain. In this study, we set out to map the minimal domain of CBD3 necessary for its antinociceptive potential. Truncated as well as homology-guided mutant versions of CBD3 were generated and assessed using depolarization-evoked calcium influx in rat dorsal root ganglion (DRG) neurons, binding between CRMP2 and CaV2.2, whole-cell voltage

clamp electrophysiology, and behavioural effects in two models of experimental pain: post-surgical pain and HIV-induced sensory neuropathy induced by the viral glycoprotein 120 (gp120). The first six amino acids within CBD3 accounted for all in vitro activity and antinociception. Spinal administration of a prototypical peptide (TAT-CBD3-L5M) reversed pain behaviours. Homology-guided mutational analyses of these six amino acids identified at least two residues, alanine (at position one) and arginine (at position four), as critical for antinociception in two pain models. These results identify an antinociceptive scaffold core in CBD3 that can be used for development of small-molecule mimetics of CBD3.

**Abstract:** Uncoupling the protein-protein interaction between collapsin response mediator protein 2 (CRMP2) and N-type voltage-gated calcium channel (CaV2.2) with an allosteric CRMP2-derived peptide (CBD3) is antinociceptive in rodent models of inflammatory and neuropathic pain. We investigated the efficacy, duration of action, abuse potential, and neurobehavioral toxicity of an improved mutant CRMP2 peptide. A homopolyarginine (R9)-conjugated CBD3-A6K (R9-CBD3-A6K) peptide inhibited the CaV2.2-CRMP2 interaction in a concentration-dependent fashion and diminished surface expression of CaV2.2 and depolarization-evoked Ca influx in rat dorsal root ganglia neurons. In vitro studies demonstrated suppression of excitability of small-to-medium diameter dorsal root ganglion and inhibition of subtypes of voltage-gated Ca channels. Sprague-Dawley rats with tibial nerve injury had profound and long-lasting tactile allodynia and ongoing pain. Immediate administration of R9-CBD3-A6K produced enhanced dopamine release from the nucleus accumbens shell selectively

in injured animals, consistent with relief of ongoing pain. R9-CBD3-A6K, when administered repeatedly into the central nervous system ventricles of naive rats, did not result in a positive conditioned place preference demonstrating a lack of abusive liability. Continuous subcutaneous infusion of R9-CBD3-A6K over a 24- to 72-hour period reversed tactile allodynia and ongoing pain, demonstrating a lack of tolerance over this time course. Importantly, continuous infusion of R9-CBD3-A6K did not affect motor activity, anxiety, depression, or memory and learning. Collectively, these results validate the potential therapeutic significance of targeting the CaV-CRMP2 axis for treatment of neuropathic pain.

**Title:** Dissecting the role of the CRMP2-Neurofibromin complex on pain behaviors

**Authors: *S. BELLAMPALLI**[1], X.-F. YANG[2], A. MOUTAL[2], Y. WANG[4], A. DORAME[3], L. A. CHEW[2], E. T. DUSTRUDE[4], B. S. SCHMUTZLER[4], M. KHANNA[2], C. M. HINGTGEN[4], T. VANDERAH[2], R. KHANNA[1]
[1]pharmacology, Univ. of Arizona, Tucson, AZ; [3]UNiversity of Arizona, [2]UNiversity of Arizona, Tucson, AZ; [4]Indiana Univ., Indianapolis, IN

**Abstract:** Neurofibromatosis type 1 (NF1) is a relatively common genetic disease primarily linked to nervous system tumors that are associated with significant chronic pain. Enhanced pain sensitivity in NF1 patients may involve the sensitization of small-diameter nociceptive sensory neurons that are known to mediate nociceptive neurotransmission. Membrane relocalization of the presynaptic N-type voltage-gated $Ca^{2+}$ channel (CaV2.2), facilitates calcitonin gene-related peptide (CGRP) release, a neurotransmitter involved in pain. CRMP2, a protein interacting with Neurofibromin, is an important mediator of CaV2.2 trafficking. Here, we examine *how* the CRMP2-neurofibromin complex controls the activity of CaV2.2. A peptide-tiling array identified a peptide within CRMP2 that bound the C-terminus of Neurofibromin: CRMP2 Neurofibromin regulating peptide 1 (t-CNRP1; where tat is the charged transduction domain from HIV-1). We tested if uncoupling the neurofibromin-CRMP2 signaling cascade could (1) affect $Ca^{2+}$ channel activity and trafficking in sensory neurons; (2) regulate evoked release of CGRP in sensory neurons from wildtype and $Nf1^{+/-}$ mice; (3) induce functional phenotypic changes in sensory

neurons; and (4) affect nociceptive function in a rodent model of neuropathic pain. t-CNRP1 inhibited $K^+$-evoked $Ca^{2+}$ influx in sensory neurons, decreased CaV2.2 membrane localization, which was related to inhibition of the CaV2.2/CRMP2/neurofibromin protein complex as evidenced by GST-pull down and proximity ligation assay (PLA). t-CNRP1 decreased the evoked release of CGRP from $Nf1^{+/-}$ mice sensory neurons. Functional fingerprinting of sensory neuron population using constellation pharmacology, showed phenotypic changes in sensory neurons treated with t-CNRP1. Finally, intrathecal administration of t-CNRP1 reversed nociceptive behavior in rodent models of inflammatory pain and post-surgical pain. These results identify t-CNRP1 as a novel tool that uncouples the CRMP2/neurofibromin and CRMP2/CaV2.2 interactions, curbs CaV2.2 activity, CGRP release and reverses nociceptive behavior. Thus highlighting the potential therapeutic significance of targeting the Neurofibromin-CRMP2-CaV2.2 axis for treatment of pain.

**Title:** Modulation of N-type $Ca^{2+}$ currents by agmatine in rat celiac ganglion neurons

**Authors: *Y. KIM**, S. CHUNG
Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

**Abstract:** Agmatine suppresses peripheral sympathetic tone by modulating Cav2.2 channels in peripheral sympathetic neurons. However, the detailed cellular signaling mechanism underlying the agmatine-induced Cav2.2 inhibition remains unclear. Therefore, in the present study, we investigated the electrophysiological mechanism for the agmatine-induced inhibition of Cav2.2 current ($I_{Cav2.2}$) in rat celiac ganglion (CG) neurons. Consistent with previous reports, agmatine inhibited $I_{Cav2.2}$ in a VI manner. The agmatine-induced inhibition of the $I_{Cav2.2}$ current was also almost completely hindered by the blockade of the imidazoline $I_2$ receptor ($IR_2$), and an $IR_2$ agonist mimicked the inhibitory effect of agmatine on $I_{Cav2.2}$, implying involvement of $IR_2$. The agmatine-induced $I_{Cav2.2}$ inhibition was significantly hampered by the blockade of G protein or phospholipase C (PLC), but not by the pretreatment with pertussis toxin. In addition, diC8-phosphatidylinositol 4,5-bisphosphate ($PIP_2$) dialysis nearly completely hampered agmatine-induced inhibition, which became irreversible when $PIP_2$ resynthesis was blocked. These results suggest that in rat peripheral sympathetic neurons, agmatine-induced $IR_2$ activation suppresses

Cav2.2 channel voltage-independently, and that the PLC-dependent $PIP_2$ hydrolysis is responsible for the agmatine-induced suppression of the Cav2.2 channel. (This study was supported by a faculty research grant fromthe Pioneer Research Center Program through the National Research Foundation of Korea funded by the Ministry of Science,ICT and Future Planning (2012-0009525)).

**Title:** Regulation of $Ca_V3.2$ channels by Cyclin dependent kinase 5 (Cdk5)

**Authors: *A. CALDERÓN-RIVERA**[1,2], A. SANDOVAL[3], R. GONZÁLEZ-RAMÍREZ[4], R. FELIX[1]
[1]CINVESTAV, México City, Mexico; [2]FES-Iztacala UNAM, Tlalnepantla De Baz, Mexico; [3]FES Iztacala UNAM, Tlalnepantla DE Baz, Mexico; [4]Dept. of Mol. Biol. and Histocompatibility, "Dr. Manuel Gea González" Gen. Hospital, Ministry of Hlth., Mexico, Mexico

**Abstract:** The $Ca_V3.2$ channel is one of the three isoforms that belongs to the Low-Voltage Activated (LVA) or T-type calcium channel subfamily. LVA channels are responsible for $Ca^{2+}$ entry at subthreshold depolarizations, regulating neuronal excitability. Hence, $Ca_V3.2$ channels are important mediators of neurotransmitter release and it is acknowledged that changes in their functional expression pattern may play a role in pathological conditions such as neuropathic pain. Recently a phosphoproteomic analysis revealed the phosphorylation map for $Ca_V3.2$ channels, however, only a few kinases have been directly involved in this posttranslational modification. Here, we report that recombinant $Ca_V3.2$ channels heterologously expressed in HEK-293 cells are regulatory targets of Cdk5. Our results indicate that coexpression of the $Ca_V3.2$ channels with the protein kinase and its activator p35 significantly upregulates $Ca^{2+}$ macroscopic currents. Site directed mutagenesis of the putative phosphorylation sites to unphosphorylatable residues showed that the relevant Cdk5 sites for $Ca_V3.2$ channel regulation centres on two amino acid residues, S561 and S1987, located in the intracellular loop connecting the II and III repeats and the C-terminal of the $Ca_V3.2\alpha1$ pore-forming subunit of the channel, respectively. These findings unveil a novel mechanism for how phosphorylation may regulate $Ca_V3.2$ channels.

**Title:** Adrenergic signaling promotes T-type $Ca^{2+}$ channel mediated oscillatory discharges in nucleus ambiguus neurons

**Authors: *I. AIBA**, J. L. NOEBELS
Baylor Col. of Med., Houston, TX

**Abstract:** Nucleus ambiguus (NA) premotor neurons contribute to the majority of parasympathetic cardiac vagal nerve fibers to reduce cardiac excitability at the SA node, where aberrant regulation can cause vasovagal syncope and cardiac arrest. Prior electrophysiological studies identified various plasticity and regulatory mechanisms of NA neurons; however most studies were conducted on neonatal preparations and might have overlooked important regulatory mechanisms present in mature brainstem. We examined the excitability of NA neurons using *in vitro* acute slice preparations obtained from young adult mice (P20-P40). Cholinergic premotor NA neurons were identified based on their expression of tdTomato fluorescence in the Chat-Cre:floxed-tdTomato mouse line. In current-clamp recordings, a brief hyperpolarizing current evoked rebound action potentials (APs) immediately following break-in, while minutes of intracellular dialysis eliminated this discharge pattern in association with a marked reduction of input resistance. Supplying spermine (0.3-0.5mM) to the intracellular solution prevented this rundown effect, suggesting that endogenous intracellular polyamines may inhibit leak currents and maintain the rebound excitation pattern. Low voltage-activated, T-type calcium current is also required for generation of the rebound discharge in NA neurons. Voltage-clamp recordings detected a significant T-current in NA neurons, and T-type current inhibitors (i.e. Z944, TTA-P2) abolished the rebound action potentials. Central adrenergic signaling is known to be involved in synaptic regulation of cardiac vagal nerve activity. We examined whether modulation of intrinsic excitability is also involved in adrenergic modulation of NA neurons. Bath application of adrenergic agonists, epinephrine (10uM) and norepinephrine (20uM), significantly increased the intrinsic excitability of NA neurons; input resistance of NA neurons was significantly increased and single evoked rebound discharges (normally composed

of 1-2 APs) converted to regenerative oscillations with >10APs and lasting up to a few seconds. T-current inhibitors again completely eliminated the adrenergic induced oscillatory activity, suggesting that T-current mediates adrenergic potentiation of intrinsic NA neuron excitability. Together this study revealed a low threshold calcium current dependent oscillatory mechanism in NA neurons and suggests that, in addition to synaptic mechanisms, modulation of intrinsic excitability may be an important site for adrenergic regulation of cardiac vagal efferent nerve activity.

**Abstract:** N-type calcium channels ($Ca_V2.2$) are widely expressed in the brain and the peripheral nervous system, where they play important roles in the regulation of transmitter release. Although $Ca_V2.2$channel expression levels are precisely regulated, presently little is known regarding the molecules that mediate its synthesis and degradation. Previously, by using a combination of biochemical and functional analyses, we showed that the complex formed by the light chain 1 (LC1) of the microtubule-associated protein 1 B (MAP1B) and the ubiquitin-proteasome system (UPS) E2 enzyme UBE2L3, may interact with the $Ca_V2.2$ channels promoting ubiquitin-mediated degradation. The present report aims to gain insights into the possible degradation mechanisms of the neuronal $Ca_V2.2$ channel protein by the UPS. First, we identified the enzymes UBE3A and Parkin, members of the UPS E3 ubiquitin ligase family, as novel $Ca_V2.2$ channel binding partners. Immunoprecipitation assays confirmed the interaction between UBE3A and Parkin with $Ca_V2.2$ channels heterologously expressed in HEK-293 cells and in neural tissues. Parkin, but not UBE3A, overexpression led to a reduced protein level, and a decrease in the $Ca_V2.2$ channel current density. Patch clamp recordings performed in the presence of MG132 prevented the actions of Parkin suggesting enhanced channel proteasomal degradation. Together, these results indicate that Parkin mediates the proteasomal degradation of

$Ca_V2.2$. Our findings provide a novel insight into the underlying protein quality control mechanisms of $Ca_V$ channels.

**Abstract:** Voltage gated calcium channels ($Ca_V$) couple plasma membrane voltage changes to calcium influx, triggering calcium-dependent processes. This sequence of fact is crucial for shaping neuronal activity. Several $Ca_V$ subtypes exist and they have different time and place specific functions in neurons. Thus, great effort has been devoted to determine what elements can control $Ca_V$ activity in neurons. In this context, many G-protein coupled receptors (GPCR) activated cascades have been detected as powerful $Ca_V$ activity modulators. On the other hand, data about the control of trafficking and density of $Ca_V$ subtypes at specific location on the neuronal plasma membrane are spare. Here we describe that a GPCR that is constitutively active (GHSR1a) in absence of its agonist (ghrelin) inhibits the forward trafficking of several $Ca_V$ subtypes. We found that the mechanism implies retention of the channel complexes at the endoplasmic reticulum and the requirement of auxiliary subunit $Ca_V\beta$. Since the solely expression of GHSR1a is enough to control $Ca_V$ trafficking and this receptor is highly expressed in brain areas controlling food intake, reward and learning and memory, our finding could have a great impact in animal behavior. Thus, further experiments focusing on the function of each $Ca_V$ subtype function are required to deeply understand the scope of GHSR1a effect on neurons.

**Abstract:** CaV2.2 constitutes the pore subunit of N-type calcium channels, which are important for neurotransmitter release in the central and peripheral nervous system. Immunohistochemical detection of native CaV2.2 has not been possible until now due to the low expression of these channels, and lack of suitable antibodies. We have now developed a constitutive knock-in (KI) transgenic mouse, expressing CaV2.2 with an epitope tag (2xHA) inserted in the extracellular loop between S3 and S4 of Domain II (CaV2.2_HA KI). The tag did not affect the function of the channel when expressed in vitro (Cassidy et al., 2014). In the peripheral sensory nervous system, our data show CaV2.2_HA to be expressed on the cell surface of dorsal root ganglion neurons (DRGs). In the spinal cord, CaV2.2_HA is predominantly in the superficial laminae LI and LII of the dorsal horn, mainly in the primary afferent terminals, since HA staining is reduced following rhizotomy. These mice will be instrumental in the future to understand the presynaptic role of N-type calcium channels in physiological and pathological states and will also be of use to examine the trafficking and recycling of the channels in several neural cell types. **Abstract:** A hallmark of non-REM sleep is the anterior to posterior propagation of slow waves (0.5-4.5 Hz) [1] and has been implicated in learning and memory consolidation. However, the cellular and molecular basis underlying slow wave oscillations remains poorly understood. Generally, slow wave sleep signals have been studied using EEG in humans, or with invasive electrophysiology in animal models. However, EEG suffers from low spatial resolution, and electrophysiology in mice is usually invasive with sparse spatial sampling. More recently, calcium indicators have been used to detect slow wave sleep using microscopy, but usually in limited fields of view. Here, we use mesoscopic calcium imaging [2] to map slow wave sleep signals throughout the cortex. Specifically, we used genetically encoded mice with a fluorescent calcium indicator (GCaMP6 driven by a Thy1 promotor in cortical neurons) to monitor the cortical calcium dynamics during anesthesia, natural sleep, and wakefulness states. Cortex was imaged transcranially through an implanted chronic optical window with the skull-intact using optical intrinsic signal (OIS) imaging. This protocol enabled consistent, repeated measurements using a CCD camera with blue light fluorescence at 17Hz while simultaneously recording EEG/EMG for state of consciousness staging and measurement of cortical global field potentials. During sleep and anesthesia there was a peak in the GCaMP power spectra over the 0.7-3 Hz range that correlated to the EEG power spectra associated with non-REM slow waves concentrated in the motor, somatosensory, and visual cortices. By combining the spatial and temporal resolution of OIS, there was an anterior to posterior propagation of the slow wave oscillations during sleep and anesthesia that disappeared during wakefulness. Functional connectivity (FC) analysis showed a transition from a binary front to back pattern in anesthesia and sleep to a more complex/local connectivity pattern seen in wakefulness. This novel imaging technique allows for high spatial and temporal resolution to study whole brain neuronal phenomenon, to study the transition between sleep and wakefulness, and has potential for applications in health and disease. **Abstract:** Migraine is more than a headache. It is a complex brain disorder, characterized by a global dysfunction in multisensory information processing. Many migraineurs show heigthened cortical responses and impaired adaptation to repeated sensory stimulation in the period between headache attacks. The underlying cellular and network mechanisms are unknown. Given the evidence that thalamocortical (TC) networks are dysfunctional in migraine and that depression at TC synapses strongly contributes to fast adaptation of cortical responses, we studied TC synaptic transmission in a knockin mouse model of familial hemiplegic migraine type 1 (FHM1), which carry a gain-of-function mutation in the neuronal CaV2.1 calcium channel. We recorded the monosynaptic excitatory postsynaptic current (EPSC) and the disynaptic inhibitory postsynaptic current (IPSC) elicited in layer 4 (L4) regular spiking (RS) neurons of somatosensory cortex by extracellular stimulation in the ventrobasal thalamus in acute TC slices. Since the disynaptic IPSC is due to the feedforward inhibition produced by TC activation of L4 fast-spiking (FS) interneurons (INs), we also recorded the EPSC elicited by thalamic stimulation in these INs.
TC excitatory transmission on both L4 principal cells and FS INs as well as TC feedforward inhibition on RS neurons were all enhanced in FHM1 compared to WT mice. In WT mice, during repetitive thalamic stimulation at 10 Hz, short-term depression (STD) of feedforward inhibition on RS neurons and STD of the excitatory inputs on FS INs were both larger than STD of the excitatory inputs on RS neurons, resulting in a shift of the balance towards excitation during the train. In FHM1 mice, STD of the excitatory inputs on RS neurons was larger than in WT mice, as expected if the gain-of-function at TC-RS synapses is due to an increased probability of release. In contrast, STD of feedforward inhibition on RS neurons and STD of the excitatory input on FS INs were similar in WT and FHM1 mice. As a result, the shift of the balance towards excitation during repetitive thalamic stimulation was relatively smaller in FHM1 compared to WT mice.
In summary, our study shows enhanced thalamocortical synaptic transmission in a mouse model

of FHM1, and reveals a differential effect of the FHM1 mutation on short-term depression at TC synapses on L4 principal neurons and FS INs which leads to a cortical excitation-inhibition (E/I) imbalance during repetitive thalamic stimulation. These findings support the hypothesis that a reduced ability to dynamically maintain an appropriate E/I balance in different brain networks may underlie the global dysfunction in information processing typical of migraine.

**Title:** Development of T-type calcium channel bursting in thalamic association pathway precedes sensory pathways

**Authors: *Q. MIAO**[1], J. L. NOEBELS[1,2,3]
[1]Bayrlor Col. of Med., Dept. of Neurol., Houston, TX; [2]Dept. of Neurosci., Houston, TX; [3]Dept. of Mol. and Human Genet., Houston, TX

**Abstract:** Transient-type low-voltage activated calcium channels (T-channels) regulate the intrinsic excitability of thalamic cells and facilitate the genesis of rebound burst firing which enable thalamocortical oscillations and contribute to the modulation of brain states of awareness. The thalamus takes part in sensory, motor and cognitive functions by transmitting information to the cortex via numerous distinct nuclei. These nuclei are divided into two different categories: first order and higher order relays. First order nuclei receive driver input from the periphery or a subcortical source, while high-order nuclei mainly receive descending inputs from the cortex. Precise regulation of T channels is important for healthy thalamocortical processes since abnormal function of T-channels has been implicated in pathological conditions, including epilepsy, neuropathic pain, and sleep disorders. We examined whether different thalamic nuclei develop T-channel expression simultaneously during early development, or whether bursting in these pathways show distinctive stages of maturation? We performed whole-cell recordings in the developing mouse thalamus (postnatal day 3 to 35). We found that across subregions of the lateral thalamus, there is a high-to-low gradient from dorsal to ventral nuclei in the expression of T-channels. Specifically, all laterodorsal thalamic neurons projecting to associative retrosplenial cortex show a distinctively high expression of T-currents which enable them to fire low-threshold and rebound spikes in as early as one week old C57BL/6 mice. These spikes could be blocked by a T-channel specific blocker, Z944. At this age, a small fraction of neurons in other

higher-order nuclei including lateral posterior nucleus (LP), posterior complex (PO) and the dorsal part of medial geniculate complex (dMG) of the thalamus, can fire low-threshold and rebound spikes. In sharp contrast, similar low-threshold and rebound spikes in first-order primary sensory thalamic relay neurons, including visual (lateral geniculate nucleus, LGN), somatosensory (ventral posteromedial nucleus, VPM), and auditory (ventral part of medial geniculate complex, vMG) neurons appeared nearly one week later. This result indicates that higher-order thalamic relay neurons utilize firing supported by T-channels earlier than those in the primary sensory pathway. Although the functional development of associative cortex is poorly understood, our results reveal an early reliance on T-channels in the higher-order thalamic nuclei mediated thalamocortical pathway that might be critical for early development of limbic, spatial and cognitive processing.

**Title:** Medial to lateral density gradient of T-type calcium currents in substantia nigra dopamine neurons

**Authors: *S. JAGANNATH**[1], K. M. COSTA[1,2], J. ROEPER[1]
[1]Inst. of Neurophysiol., Goethe Univ. Frankfurt, Frankfurt am Main, Germany; [2]Intl. Max Planck Res. Sch. for Neural Circuits, Max Planck Inst. for Brain Res., Frankfurt am Main, Germany

**Abstract:** The substantia nigra (SN) dopamine (DA) neurons possess an intrinsic pacemaker mechanism that engages a variety of voltage-gated calcium channels (VGCCs). However, the functional contributions of distinct VGCCs are not well understood. Also, it is unclear whether VGCCs have uniform roles across the medial to lateral extent of the substantia nigra. Therefore, we investigated the densities and functional roles of VGCCs for pacemaker frequency and precision control across the entire SN using acute midbrain slices of adult (3-4month old) male C57BL/6N mice. For immunohistochemical and morphological identification all neurons were filled with neurobiotin and processed for TH-immunohistochemistry. Whole-cell patch-clamp experiments demonstrated that the density of low-voltage activated (LVA) calcium currents increased about 2-fold with a medial to lateral gradient across the SN (linear regression, slope = 20 pA/pF per 100µm, $r^2 = 0.12$, $p < 0.0001$; n = 132). In contrast, high-voltage activated (HVA) calcium current densities did not systematically vary with their medial to lateral positions ($r^2 <$

0.001, p = 0.732; n = 132). In addition, peak LVA calcium current amplitudes were reached at significantly more negative membrane potentials in lateral SN compared to medial DA SN neurons, while no differences in voltage dependence were observed for HVA peak currents. These results indicated a topographically organized diversity of LVA calcium channels for DA SN neurons along the medio-lateral axis. To study the functional implications of the LVA calcium channel gradient, we carried out cell-attached patch-clamp recordings to record changes of spontaneous pacemaker activity in response to the LVA ($Ca_v3$) calcium channel blocker nickel. In accordance with the differences in LVA calcium channels densities, bath application of 100 µM nickel decreased pacemaker precision (quantified as coefficient of variation, CV) to a greater extent in lateral compared to medial DA SN neurons (CV, lateral control: 12.2 ± 0.87 %, + 100 µM nickel: 17.2 ± 1.7 %, n = 17; p = 0.004; medial control: 12.1 ± 2.65 %, + 100 µM nickel: 15.1 ± 2.43 %, n = 13; p = 0.01). Taken together, these findings demonstrate that medial to lateral gradients of ion channel expression in DA SN neurons in the substantia nigra are associated with functional differences in pacemaker control.

**Title:** “Leaky” ryanodine receptors: Potential role in age-related cognitive decline and the pathogenesis of Alzheimer’s disease

**Authors: *D. DATTA**, A. F. T. ARNSTEN, C. D. PASPALAS
Yale Univ., New Haven, CT

**Abstract:** The newly evolved prefrontal cortex (PFC) mediates highest-order cognition, and is markedly afflicted in age-related cognitive disorders such as Alzheimer’s disease (AD). Within the PFC, modules of pyramidal cells in layer III microcircuits engage in recurrent excitation to sustain persistent neural firing required to maintain working memory, a prototypic cognitive function mediated by the PFC. With advancing age, rhesus monkeys show atrophy of dendritic spines in layer III, evidence of disinhibited cAMP-PKA-calcium signaling and a rise in phosphorylated tau. Ryanodine receptors (RyRs) mediate internal calcium release from the sarcoplasmic and smooth endoplasmic reticulum (SER), in myocytes and neurons, respectively. In aged cardiac muscle, elevated cAMP-PKA-calcium signaling due to age-related loss of the cAMP-specific phosphodiesterase, PDE4D, phosphorylates RyR2 (pRyR2), and increases

calcium conductance inducing calcium “leak”. We hypothesize that a similar sequence occurs in aging PFC due to its unique molecular regulation by cAMP, leading to cognitive deficits. Using high-resolution immunoelectron microscopy, we studied the localization and spatial interactions of pRyR2 and PDE4D in young vs. aged monkey and rodent PFC. Preliminary work shows pRyR2-reactive SER membranes in dendritic spines. A parallel study tested whether acute treatment with S107, a novel compound that stabilizes the interaction between pRyR2 and downstream signaling protein calstabin2 to prevent calcium leak in cardiac muscle, improved cognitive function in aging monkeys and rats. Our behavioral analysis using the delayed alternation task in aged rats suggests significant enhancement of spatial working memory following low doses of S107. S107 has already been shown to rescue cardiac deficits and protect from stress-induced hippocampal memory function, encouraging the success of this approach. This research may provide a novel therapeutic strategy for early protection of the higher brain circuits most vulnerable to degeneration. Together, these studies elucidate how molecular changes with age initiate the degenerative process in the PFC and reinforce the idea that dysregulated calcium signaling is a key event in susceptible cortical microcircuits, supporting early theories of AD etiology.

**Title:** T-type calcium channels contribute to neuronal excitability within the ventral tegmental area

**Authors: *M. E. TRACY**, S. TODOROVIC
Anesthesiol., Univ. of Colorado-Denver, Aurora, CO

**Abstract:** *Rationale* There is an emerging body of evidence that implicates a role of voltage gated calcium channels in contributing to the excitability of neurons within the mesolimbic reward system. While most research attention has centered on high voltage L-type calcium channel activity, the presence and role of the low voltage-gated T-type calcium channel has not been well explored. Therefore T-type calcium channel activity may represent an unexplored system that contributes to neuronal excitability within the ventral tegmental area (VTA). *Objectives* We tested the hypothesis that the CaV 3.1 T-type calcium channel plays an integral role in neuronal excitability in both dopaminergic and non-dopaminergic neurons of the ventral

tegmental area utilizing wild-type (WT) rats and mice, TH-eGFP knock-in rats and CaV 3.1 knock-out mice in acute horizontal brain slices of adolescent subjects.
*Results* In voltage clamp, we assessed first T-type channel activity with steady-state inactivation curves in both WT rats and mice and found similar mid-point of inactivation (V50) of -94.35 and -90.51 mV, respectively. Application of the selective pan-T-type channel antagonist TTA-P2 at 5 uM ablated these currents in both rats and mice. Furthermore, in CaV 3.1 knockout mice no currents were observed that matched the electrophysiological properties of T-type channels. In ensuing current-clamp experiments, we observed the presence of hyperpolarization-induced rebound action potentials in a subset of dopaminergic and non-dopaminergic neurons within the rat VTA. Following the application of 5 µM TTAP2, rebound action potentials were significantly inhibited ($p<0.01$).
*Conclusions* These results demonstrate for the first time that in a subset of neurons within the VTA, T-type CaV3.1 channels play a functional role in inducing repeated action potentials following brief periods of hyperpolarization. Given the complex role between inhibitory interneurons and dopaminergic neurons in the VTA in mediating temporally discrete motivated behaviors, these results suggest a substantial role for T-type channels.

**Title:** Cav3.1 channels are important for isoflurane inhibition of neuronal excitability in the central medial thalamic nucleus

**Authors: *T. TIMIC STAMENIC**, S. TODOROVIC
Anesthesiol., Univ. of Colorado Denver, Anschutz Med. Ca, Aurora, CO

**Abstract:** Thalamocortical circuits are important for the regulation of arousal and central medial nucleus (CeM) as a part of intralaminar thalamus acts as a key hub through which general anesthesia is initiated. It is well known that low-voltage-activated T-type calcium channels (T-channels) are abundantly expressed in the thalamus where they regulate neuronal excitability but their role in CeM during anesthesia was not examined. Here, we investigated properties of T-type calcium channels and effect of isoflurane in CeM using patch-clamp technique in acute coronal brain slices of adolescent wild type C57BL/6J (WT), 3.1 knock-out (KO) and 3.2 KO mice. Voltage-clamp recordings showed that there is a large depolarizing shift in steady-state activation curves of about 20 mV in 3.1 KO mice when compared with WT and 3.2 KO mice ($p<0.001$). Smaller but significant shift of about 4 mV was achieved in steady-state inactivation kinetics between 3.1 KO and 3.2 KO mice. Current density was also decreased by about 90% in 3.1 KO mice in comparison to WT and 3.2 KO mice ($p<0.001$). Additionally, 3.2 KO mice had a smaller decrease in current density of about 10% in comparison to WT mice ($p<0.05$). Isoflurane at clinically-relevant concentrations decreased T-current density by about 40% ($p<0.001$) and induced hyperpolarizing shift of 8 mV in WT mice in steady-state inactivation curves. Moreover, isoflurane reduced time constant of macroscopic current inactivation kinetics (tau). Current-clamp recordings revealed that there are no significant differences in tonic action potential frequency between WT, 3.1 KO and 3.2 KO mice. The statistically significant reduction in low-threshold spike (LTS) amplitude was in 3.2 KO in comparison to WT mice ($p<0.01$), while in 3.1 KO mice rebound burst with LTS was completely abolished. Finally, we used current-clamp recordings to investigate the effects of isoflurane on firing patterns and passive membrane properties of CeM neurons in WT and 3.1 KO mice. We found that isoflurane reduced tonic action potential frequency by 35% over the wide range (50—200 pA) of current injections ($p<0.001$), decreased LTS amplitude by 55% ($p<0.001$), while slightly increased input resistance by 15% ($p<0.001$) in WT mice. On contrary, isoflurane decreased tonic action potential frequency in Cav3.1 KO mice only during maximal current injections of 200 pA ($p<0.01$). We

conclude that 3.1 T-channels are dominant isoform in the CeM and that there is a profound sensitivity of these T-channels to isoflurane. These findings reveal a crucial role of T-channels in CeM in arousal suppression during isoflurane anesthesia.

**Abstract:** Homeostasis is form of neuronal plasticity that serves to maintain neuronal and network stability and works to oppose destabilizing Hebbian plasticity. Dysfunctional homeostatic plasticity has been suggested as a possible pathogenic mechanism underlying Autism Spectrum Disorders (ASD). To investigate this hypothesis, we studied multiple mechanisms of homeostatic adaptation in a mouse model (TS2-neo) of Timothy Syndrome (TiS). TiS is a syndromic form ASD that arises from a mutation in the pore-forming subunit of the $Ca_V1.2$ calcium channel (CaCh). TS2-neo animals display ASD behaviors and increased interictal activity, providing a validated animal model to study alterations in neuronal functioning both *in vitro* and *in vivo*. Our studies reveal intriguing differences in the homeostasis of synaptic weights and intrinsic excitability in TiS cortical pyramidal neurons. We have conducted a series of *in vitro* experiments to assess changes in the homeostatic plasticity of unitary neurotransmission and spike firing, using dissociated cultures from cortices of heterozygous TS2 and wild type (WT) siblings. We measured miniature postsynaptic currents (mEPSCs) of pyramidal neurons of TS2 and WT cultures between 13-16 days *in vitro* (DIV) and found that after 24h of action potential (AP) blockade by chronic tetrodotoxin (TTX) treatment, mEPSC amplitudes increased in both TS2 and WT pyramidal neurons. TS2-neo pyramidal neurons exhibited an exaggerated upregulation in amplitude and frequency. This was accompanied by higher intensity of GluA1-containing AMPA receptors at synapses in TS2 pyramidal neurons when compared to WT after TTX. In parallel, we observed a similarly exaggerated homeostatic adaptation of intrinsic excitability in TS2 neurons. Without chronic

TTX treatment, both WT and TS2 pyramidal neurons fired at similar frequencies in response to increasing current injections. These response frequencies increased after TTX treatment in both WT and TS2, with TS2 neurons firing spikes at higher frequencies and with longer half-widths than WT. Using electrophysiology and calcium imaging, we have identified differences in the spontaneous firing patterns of TS2 neurons and networks (compared to WT) only after engaging in homeostasis. Lastly, we have observed similar electrophysiological alterations in layer 2/3 pyramidal neurons in primary visual cortex recorded *ex vivo* from visually deprived WT and TS2 animals. These results suggest that $Ca_V1.2$ has a key role reporting levels of activity to numerous mechanisms of homeostatic autoregulation and encourage further exploration into the contribution of these dysfunctional mechanisms to ASD.

**Title:** Attenuated L-type $Ca^{2+}$ currents, inactivation gating and action potential firing in adrenal chromaffin cells of a Timothy syndrome mouse model (TS2-neo) with autistic traits

**Authors: *E. CARBONE**[1], C. CALORIO[1], L. GUARINA[1], D. GAVELLO[1], A. MARCANTONI[1], P. DEFILIPPI[1], F. BALZAC[1], E. TURCO[1], G. C. L. BETT[2], R. L. RASMUSSON[2]

**Abstract:** Timothy syndrome (TS) is a rare genetic disease caused by a single point mutation (G406R) in the pore forming α1-subunit of L-type Cav1.2 calcium channels (CACNA1C) that generates long-QT and autism spectrum disorder. TS exists in two forms: a milder (TS1) and a more severe (TS2) that arise from the same missense mutation (G406R) in the alternatively spliced exons (8A and 8) that code for the IS6 transmembrane segment of Cav1.2 channels (Splawski et al, 2004; 2005). TS2 is associated to the G406R mutation of exon 8 that is highly expressed in human brain and heart (Splawski et al, 2005) and causes marked decrease of Cav1.2 channel inactivation with consequent increased $Ca^{2+}$-entry into the cell.
Recently, Bader et al (2011) generated a TS2-like mouse with the G406R mutation in exon 8. Heterozygous and homozygous TS2 mice have low rate of survival. However, heterozygous

mice that are allowed to keep an inverted neo-cassette in exon 8A (TS2-neo) survive well to adulthood and are shown to recapitulate triad of autistic traits. Taking advantage of this mouse model and that Cav1.2 exon 8 is highly expressed in human adrenal glands (Splawsky et al, 2005), we studied the functional changes that the TS2 mutation induces to the $Ca^{2+}$ currents and action potential (AP) firing of adrenal chromaffin cells. Mouse chromaffin cells (MCCs) possess high densities of Cav1.2 and Cav1.3 channels (50% of total) and is thus a good cell model to test how the blunted expression of mutated Cav1.2 channels alter $Ca^{2+}$ currents and cell excitability. Here we show that $Ca^{2+}$ currents (N, P/Q, R and L-type) of MCCs of TS2-neo mice are strongly reduced with respect to WT. Peak $Ca^{2+}$ current is 84 vs 142 pA at +20 mV in 10 mM $Ca^{2+}$. The same 40% reduction is evident on the L-type currents obtained by subtracting DHP-insensitive currents (recorded in 5 μM nifedipine) from control, suggesting unspecific Cav channels down-regulation in mutated MCCs. TS2-neo L-type currents activate at about the same potential of WT currents ($V_{1/2}$ -19 vs -18 mV) but are significantly less inactivating as demonstrated by the 40% reduced rate of fast inactivation and the 45% attenuated "U-shaped" curve of $Ca^{2+}$-dependent inactivation. TS2-neo MCCs exhibit more negative resting potentials than WT (-54 vs -48 mV), which cause a reduced percentage of spontaneously firing MCCs (10 vs 70%). Evoked APs in mutated MCCs have unchanged rheobase (2-3 pA) but are typically undershoot. In conclusion, the TS-2 mutation causes a drastic decrease of functional Cav and Nav channels that support AP firing in MCCs. This may derive from the increased $Ca^{2+}$ leak into the cell at rest induced by the less inactivating Cav1.2 channels that are already available at $V_{rest}$.

**Title:** Local $Ca_V1$ L-type calcium channel activity synergistically signals to the nucleus

**Authors: *N. MANDELBERG**[1], B. LI[2], R. W. TSIEN[2]
[1]New York Univ. Sch. of Med., New York, NY; [2]Neurosci. Inst., New York Univ., New York, NY

**Abstract:** Excitation-transcription (E-T) coupling, the process by which electrical changes across a cell's membrane regulate transcription, is critical in neurons for many physiological processes. Intracellular calcium is an essential messenger in this process, making sources of neuronal calcium and their connections to the nucleus of great interest. L-type calcium ($Ca_V1$) channels dominate the control of gene expression from the dendrite, as calcium influx mobilizes a signaling cascade relying on the action of a group of calcium/calmodulin (CaM)-dependent kinsases (CaMKs) to activate the nuclear transcription factor calcium- and cAMP-response element binding protein (CREB). The constituents of this pathway are implicated not only in neuropsychiatric disease, but also in several processes essential for normal neuronal function. We have recently shown that $Ca_V1$ channels can signal through voltage-dependence conformational changes (VDC), which are able to synergize with the activity of other calcium-permeable channels. To determine how these interactions could contribute to neuronal E-T coupling, we pharmacologically isolated $Ca_V1$ VDC and ionic flux from *N*-methyl-D-aspartate (NMDA) receptors. Here we provide evidence that NMDA receptor stimulation requires $Ca_V1$ VDC to activate neuronal CREB. Furthermore, we use different calcium chelators and co-immunoprecipitation to show that this functional relationship between $Ca_V1$ and NMDA receptors is based on close spatial and structural relationships. Finally, we show that these channels contribute to CREB activation by quantal events in the absence of whole-cell spikes, suggesting that localized stimuli are capable of mobilizing these pathways to reach the nucleus. Together, these results suggest that $Ca_V1$ channels can exert control over neuronal transcription based on local signals that interact not only with downstream signaling partners, but other channels at the dendritic spine as well.

**Title:** Alterations of the $Ca_v1.4$ C-terminal automodulatory domain unmasks an atypical form of calmodulin regulation on $Ca^{2+}$-dependent inactivation and activation

**Authors: *B. WILLIAMS**[1,2], A. LEE[2]
[1]Interdisciplinary Grad. Program in Neurosci., [2]Mol. Physiol. & Biophysics, Otolaryngology Head-Neck Surgery, and Neurol., Univ. of Iowa, Iowa City, IA

**Abstract:** To support its role in mediating tonic exocytosis at the photoreceptor synapse, $Ca_v1.4$ L-type $Ca^{2+}$ channels undergo weak $Ca^{2+}$-dependent inactivation (CDI). The mechanism involves a C-terminal automodulatory domain (CTM) that competes with calmodulin (CaM) binding to the channel. A mutation that causes congenital stationary night blindness (CSNB2), K1591X, causes premature truncation of the channel just downstream of the CaM binding region and removal of the entire CTM. The mutant channels ($Ca_v1.4$K1591X) exhibit strong CDI and activation at more negative voltages than full-length channels similar to a splice variant ($Ca_v1.4\Delta$ex47) that lacks just a portion of the CTM. To determine if selective deletion of exon 47 causes distinct regulation of CDI and activation as compared to the K1591X mutation, we compared the properties of $Ca_v1.4$K1591X and $Ca_v1.4\Delta$ex47 in electrophysiological recordings of transfected HEK293T cells. We found key differences in how CaM regulates CDI of these channels. First, $Ca_v1.4$K1591X undergoes significantly faster CDI than $Ca_v1.4\Delta$ex47. Second, CDI of $Ca_v1.4\Delta$ex47 can be suppressed by dominant negative expression of CaM mutants that cannot bind $Ca^{2+}$ in either the C-terminal ($CaM_{34}$) or N-terminal ($CaM_{12}$) lobe, whereas only $CaM_{34}$ blunts CDI of $Ca_v1.4$K1591X. Third, $CaM_{12}$ reverses the negative shift in activation of $Ca_v1.4\Delta$ex47 but not of $Ca_v1.4$K1591X. We conclude that the deletion of exon 47 alters how CaM functionally interacts with the channel in a way that is not reproduced by the K1591X mutation, which may contribute to the pathological effects of K1591X for $Ca^{2+}$ signaling at the photoreceptor synapse.

**Title:** Rewiring of bipolar cells in a mouse model of congenital stationary night blindness type 2

**Authors: *I. KILICARSLAN**[1], H. SEITTER[1], E. STRETTOI[2], A. KOSCHAK[1]
[1]Pharmacol. and Toxicology Dept., Univ. of Innsbruck, Innsbruck, Austria; [2]Neurosci. Inst., Italian Natl. Res. Council (CNR), Pisa, Italy

**Abstract:** Human mutations in the CACNA1F gene - encoding Cav1.4 L-type calcium channels - are associated with congenital stationary night blindness type 2 (CSNB2). In the retina Cav1.4 channels are predominantly expressed at photoreceptor (PR) terminals and most likely also in bipolar cells (BC) where they allow sustained calcium influx and ensure neurotransmitter release. Due to their important role for PR synapse formation and maturation we compared two Cav1.4 mouse models (Cav1.4-KO, loss-of-function; Cav1.4-IT, gain-of-function) with respect to differential effects on retinal morphology. Both mouse models showed structural remodeling of rod BCs obvious from their elongated dendrites, the disrupted organization of the outer plexiform layer and immature PR synaptic ribbons. However, structural aberrations seemed more pronounced in Cav1.4-KO retinas. Immunohistochemical stainings using anti-PSD95 showed that in Cav1.4-IT PR terminals were mislocated in the ONL and contained mostly elongated ribbons as seen in co-stainings with the ribbon marker CtBP-E12 (*N = 4 for WT, Cav1.4-IT and Cav1.4-KO*). Co-staining with PKCα showed that in some displaced terminals contacts with rod BCs are still formed whereas in others invaginating contacts are absent. The latter suggested that those rod BCs however try to form new connections in the ONL. Cav1.4-KO mice ribbons showed only circular appearance and PSD95 protein was undetectable (*N = 3 for WT and Cav1.4-KO*). Preliminary analyses implicated that in retinas of older (28 weeks) Cav1.4-IT animals rod BC dendrites were completely lacking in the peripheral part of the retina, likely due to the absence of photoreceptors in the corresponding area. Using secretagogin as a marker for cone BCs in Cav1.4-IT animals we detected also sprouting cone BCs in 4 animals indicating that bipolar cells in the cone pathway are also affected. Our data support a crucial role of Cav1.4 channels for proper formation of photoreceptor to bipolar cell contacts. Moreover, we suggest that different Cav1.4 mutations can cause different types of morphological aberrations likely to affect also the functional outcome. Such differences may also explain subtle variations in the clinical manifestation of CSNB2.

**Title:** Light induced ganglion cell responses in Cav1.4 mutant mouse retinas

**Authors: *L. ZANETTI**, H. SEITTER, A. KOSCHAK
Pharmacol. and Toxicology, Leopold Franzens Univ. Für Innsbruck, Innsbruck, Austria

**Abstract:** Mutations in the CACNA1F gene encoding for the alpha1 subunit of Cav1.4 channels are known to cause Congenital Stationary Night Blindness Type 2 (CSNB2). Typical symptoms in CSNB2 are moderately low visual acuity, myopia, nystagmus and variable levels of night blindness or progressive photophobia. The Cav1.4 I745T (IT) mutation is associated with this disease and in heterologous expression system, has been shown to result in gain of Cav1.4 channel function. How such abnormal calcium influx can affect the retinal circuits is hardly known. Our previous work has demonstrated that the IT mutation caused disturbances in the signal transmission of mouse retinas using multielectrode array recordings upon visual stimulation in mesopic conditions. The aim of the current study is to further examine the ganglion cell (GC) activity of IT mouse retinas under both dim light (scotopic) and bright light (photopic) conditions, and by the means of multiple light stimuli aimed to detect specific GC response patterns. We confirmed a higher spontaneous firing rate in the absence of stimuli and a delayed response in both light conditions in IT whole-mount retinal preparations. In addition, compared to controls, IT retinas showed a diminished firing frequency within the stimulus (WT= 16 Hz, IT= 6.7 Hz, mean of 5 and 4 experiments respectively). The higher spontaneous firing rate and the decreased light-driven firing response likely account for the inability of GC to transduce efficiently visual signals. Of note many GC previously did not respond to full-field stimulation under mesopic light conditions. In this study, the analysis of the same cell in two different light conditions showed that ON and OFF responses of IT GC are largely lost during bright light: while 275 GCs responded to dim light, only 80 GC (N= 4) responded using bright light stimuli. Gaussian white noise stimulus analysis instead, showed a loss of GCs response also at scotopic level. These preliminary data indicate that, although scotopic and photopic pathways show similarly impaired responses, in the IT CSNB2 model the cone pathway might be more severely affected. Together our findings reflect what is seen in electroretinographic analyses of CSNB2 patients.

**Abstract:** $\alpha_2\delta$-4 is an auxiliary subunit of voltage-gated $Ca_v1.4$ L-type channels that are required for the development and mature exocytotic function of the photoreceptor ribbon synapse. Although human mutations in the CACNA2D4 gene encoding $\alpha_2\delta$-4 cause heterogeneous visual phenotypes and defects in synaptic transmission primarily by cone photoreceptors, abnormalities in rod but not cone synapses have been reported previously in $\alpha_2\delta$-4-deficient mice. Here, we describe a new knock-out ($\alpha_2\delta$-4 KO) mouse model in which both rod and cone synapses are disrupted but in different ways. In $\alpha_2\delta$-4 KO mice, ribbons and key synaptic proteins are lost to a greater extent from terminals of rods than cones, and ectopic ribbons and processes of horizontal cells and bipolar cells extend abnormally into the outer nuclear layer. $Ca_v1.4$ channels are progressively lost first in rods and later in cones of $\alpha_2\delta$-4 KO mice. Serial electron microscopy revealed an absence of invaginating horizontal and bipolar processes into $\alpha_2\delta$-4 KO cone pedicles, despite the presence of morphologically normal ribbons. Rod and cone synaptic transmission is nearly undetectable in electroretinograms of $\alpha_2\delta$-4 KO mice, despite the partial preservation of both rod- and cone-mediated vision in a behavioral assay. We conclude that $\alpha_2\delta$-4 plays an essential yet distinct role in maintaining the structural and functional integrity of rod and cone synapses, the disruption of which may contribute to visual impairment in humans with CACNA2D4 mutations.

**Title:** Mechanisms of modulating dendritic spine morphology by $Ca_V1.3$ L-type calcium channels

**Authors: *R. I. STANIKA**[1], J. STRIESSNIG[2], M. CAMPIGLIO[1], G. J. OBERMAIR[1]
[1]Dept. of Physiol. and Med. Physics, Med. Univ. Innsbruck, Innsbruck, Austria; [2]Dept. of Pharmacol. and Toxicology, Univ. of Innsbruck, Innsbruck, Austria

**Abstract:** L-type $Ca^{2+}$ channels (LTCC) regulate activity-dependent neuronal development, synaptic plasticity, and gene transcription and altered channel activity has been associated with aberrant brain function and neurological disease. Recently we demonstrated that the LTCC $Ca_V1.3$ modulates postsynaptic dendritic spine stability, thereby providing a potential mechanism linking channel function to pathological alterations. Expression of short $Ca_V1.3$ splice variants ($Ca_V1.3_{42A}$, $Ca_V1.3_{43S}$) or deletion of the C-terminal PDZ-binding sequence in the full-length $Ca_V1.3_L$ induced aberrant dendritic spine elongation, whereas expression of the full-length channel alone stabilized dendritic spines. The observed morphological changes correlated with increased somatic $Ca_V1.3$ currents and dendritic calcium signals suggesting a major role of the dendritic calcium load in the regulation of postsynaptic stability. Alternatively, signaling via the C-terminal PDZ-protein interactions may be involved in the structural synaptic remodeling. In order to provide novel insights into the underlying mechanisms, here we studied dendritic spine modulation by $Ca_V1.3$ channels in hippocampal cultures from $Ca_V1.3$ knockout mice and analyzed the consequences on postsynaptic AMPA receptor distribution and CaMKII autophosphorylation. Hippocampal neurons lacking $Ca_V1.3$ calcium channels showed normal dendritic development and dendritic spine formation. Reconstituting the neurons with full-length $Ca_V1.3_L$ resulted in a slightly increased spine density and a larger fraction of mature mushroom-like spine. Consistent with our previous findings the expression of a $Ca_V1.3$ channel with a deleted C-terminal PDZ-binding sequence ($Ca_V1.3_{\Delta ITTL}$) significantly increased spine size and induced the formation of more filopodia-like spines. These changes were accompanied by a redistribution of surface AMPA receptors from dendritic spines to shafts. Preliminary data indicated associated changes in the level of T286 autophosphorylated CaMKII thereby providing a link between $Ca_V1.3$ channel activity and F-actin-mediated dendritic spine remodeling. Taken together, our data suggest that calcium influx through $Ca_V1.3$ channels regulates dendritic

spine morphology via CaMKII/F-actin signaling and affects postsynaptic AMPA-receptor abundance.

**Title:** Tissue-specific and developmental expression of Cav1.3 splice isoforms in the I-II linker

**Authors:** ***B. LACARUBBA**[1], A. BUNDA[2], K. SAVAGE[3], T. FOXALL[3], A. S. ANDRADE[4]
[1]Biol. Sci., Univ. of New Hampshire, Durham, NH; [2]Univ. of New Hampshire, DURHAM, NH; [4]Dept. of Biol. Sci., [3]Univ. of New Hampshire, Durham, NH

**Abstract:** $Ca_V1.3$, an L-type voltage-gated calcium channel, is highly expressed in neurons and neuroendocrine cells. $Ca_V1.3$ is involved in several functions including neurotransmitter release, peptide release, pace-making activity and gene expression. The *CACNA1D* gene, the pore-forming subunit of $Ca_V1.3$, is linked to several neurological, gland and heart-related disorders including autism, primary aldosteronism and sinoatrial node dysfunction and deafness syndrome respectively. This suggests tissue-specific roles. Alternative splicing of the *CACNA1D* ($Ca_V1.3$) pre-mRNA is critical in generating molecular and functional diversity of $Ca_V1.3$. The cassette exon (e11) encodes for 20 amino acids within the I-II linker, and generates two isoforms e11 and Δ11. This region of the channel is important for membrane targeting, and coupling to signaling cascades, which opens the possibility that e11 affects cell-specific functions of $Ca_V1.3$. Genotype-tissue expression data from the GTEx portal suggests that $Ca_V1.3$ generates tissue-specific splice isoforms. Here we further characterized the tissue expression of e11 and Δ11 in a series of RNA samples derived from human tissues. In adult tissues, we found the highest levels of e11 expression relative to Δ11 in cortex (88 ± 1.2%), cerebellum (87 ± 0.4%) and hippocampus (82 ± 1.3 %), whereas less levels of expression are seen in spinal cord (44 ± 2.6%). Global knock out of the splicing factors Mbnl1, Mbnl2 and Rbfox1 show reduced expression of e11. These splicing factors are key for developmental regulation of alternative splicing, and suggest that e11 is also regulated during development. To test for this we quantified expression levels for e11 and Δ11 in RNA from fetal and adult human samples, and we found a striking switch from Δ11 to e11 (0% to 100%). We also performed a developmental curve in mouse whole brain tissue, and we found a similar pattern of expression relative to human tissues. Δ11

isoform dominates early in development, whereas the e11 isoform dominates later in development. This switch occurs during the critical period in mice (9-30 days). Our results show that e11 is tissue-specific and heavily regulated during development. Further studies will be performed to understand the functional relevance of this exon in native systems.

**Title:** Alternative splicing of $Ca_V2.2$ pre-mRNA influences cued fear conditioning in a sex-dependent manner

**Authors: *A. BUNDA**, B. LACARUBBA, A. ANDRADE
Univ. of New Hampshire, Durham, NH

**Abstract:** Presynaptic N-type ($Ca_V2.2$) voltage-gated calcium channels control transmitter release in various areas of the nervous system. Alternative splicing of the cassette exon 18a (e18a) on the cytoplasmic II-III linker of $Ca_V2.2$ generates two splice isoforms (+18a and Δ18a) with unique biophysical properties. 18a splice isoforms are more resistant to inactivation during repetitive stimulation, and produce larger calcium currents than Δ18a isoforms in both mammalian expression and native systems. Δ18a isoform is dominant over +18a (~87% vs ~13%) in medial prefrontal cortex (PFC), ventral hippocampus and amygdala. All these areas are involved in fear-related behavior. To assess the behavioral role of the cassette exon 18a in these brain areas, a mouse line was generated that globally expresses only the +18a isoform of $Ca_V2.2$ (18a-only), thus eliminating the ability of the system to exclude e18a. We performed several assays in both the 18a-only and wild-type (WT) mouse lines for both sexes, including contextual and cued fear conditioning to assess hippocampus and amygdala respectively, and cued fear extinction and retention to assess cortical areas. We found that 18a-only females show enhanced freezing to the cue during the initial five tones of fear extinction retention relative to WT (18a-only = 45.4 ± 8s, WT = 23.2 ± 6s, $p = 0.037$), indicating a potential e18a-dependent difference in cortical function. No differences were observed for females during fear acquisition, contextual fear conditioning or cued fear extinction. By contrast, males of both genotypes showed similar fear responses for all protocols. Our preliminary results suggest the repression of cassette exon 18a in $Ca_V2.2$ is important for retention of cued fear extinction in female mice. This may involve

PFC, but not amygdala or hippocampal areas. Given that e18a expression may influence the PFC, this area will be the target for future studies.

**Title:** Regulation of astrocyte calcium signaling and gliotransmission by store-operated CRAC channels

**Authors: *A. B. TOTH**, K. HORI, M. PRAKRIYA
Northwestern Univ., Chicago, IL

**Abstract:** Astrocytes comprise the major cell type in the central nervous system (CNS) and regulate numerous functions including CNS development, homeostasis, and repair. Recent evidence indicates that astrocytes also play a direct role in modulating synaptic transmission by secreting 'gliotransmitters' such as glutamate and ATP. To support their role in synaptic physiology, astrocytes are intimately associated with pre- and post-synaptic neuronal membranes in an anatomical unit known as the tripartite synapse, allowing astrocytes to sense neurotransmitters released by neurons and also communicate with neighboring neurons through the action of gliotransmitters. Previous studies have suggested that a major mechanism mediating gliotransmitter release is vesicular exocytosis evoked by elevations in intracellular [$Ca^{2+}$]. However, the molecular pathways and sources of $Ca^{2+}$ signaling involved in generating these $Ca^{2+}$ elevations remain poorly understood. Here, we investigate the mechanisms governing $Ca^{2+}$-dependent signaling and release of gliotransmitters in hippocampal astrocytes. Our results indicate that astrocytes exhibit store-operated $Ca^{2+}$ entry (SOCE) mediated by $Ca^{2+}$ release-activated $Ca^{2+}$ (CRAC) channels. SOCE is abolished in astrocytes from transgenic mice lacking the canonical CRAC channel proteins Orai1 or STIM1. Furthermore, store-operated $Ca^{2+}$ signals activated through metabotropic purinergic and glutamatergic receptors are abolished in CRAC channel knockout mice. These findings indicate that CRAC channels encoded by Orai1 and STIM1 are a major route of $Ca^{2+}$ entry in hippocampal astrocytes. Using bioluminescence assays, we found that activation of SOCE stimulates ATP secretion from astrocytes, which is dependent on $Ca^{2+}$ influx through CRAC channels. Using the styryl dye FM1-43 to track

exocytosis, we found that activating SOCE by store-depletion or purinergic agonists stimulates vesicular exocytosis in astrocytes. Exocytosis is blocked by inhibitors of SNARE cleavage (botulinum toxins) and by loading cells with BAPTA, consistent with a $Ca^{2+}$-dependent vesicular mechanism of release. Furthermore, genetic deletion of Orai1 expression significantly attenuates vesicular exocytosis in astrocytes. Together, our results show that CRAC channels regulate the $Ca^{2+}$ excitability of astrocytes and play a critical role in regulating gliotransmitter exocytosis. Because gliotransmitters are thought to actively modulate synaptic transmission, the regulation of gliotransmitter release by CRAC channels may have important implications for neuron-glia crosstalk and modulation of neuronal network activity.

**Title:** The role of store operated CRAC channels in mediating neural stem cell migration

**Authors: *A. K. SHUM**, T. DING, A. BELMADANI, R. MILLER, M. PRAKRIYA
Pharmacol., Northwestern Univ., Chicago, IL

**Abstract:** Adult neurogenesis persists as a remnant of neurodevelopment that is maintained in two neurogenic niches: the subventricular zone and the subgranular zone of the dentate gyrus. In the normal state of the brain, these two regions source the neural stem cells (NSCs) and their progenitors that migrate to their respective target sites guided by numerous extrinsic factors and gradients of chemoattractants. Similarly in the injured state of the brain, inflammatory mediators and chemokines guide NSCs towards sites of injury where they can form new neurons to replace those lost by damage. The chemokine, SDF1, and its receptor, CXCR4, are important regulatory factors that play an essential role in neurogenesis and progenitor migration. Chemokine signaling, concomitant with $Ca^{2+}$ transients, is necessary for mediating these downstream effector functions. As a multifunctional second messenger, $Ca^{2+}$ can play an instructive role in regulating cellular processes such as migration and differentiation of NSCs into mature neurons and glia. In NSCs, one pathway for $Ca^{2+}$ entry occurs through the opening of store operated $Ca^{2+}$ release-activated $Ca^{2+}$ (CRAC) channels encoded by the STIM1/Orai1 proteins. Understanding the functional relevance of interactions between an important class of extrinsic factors, the chemokines, and CRAC channels will determine to what extent chemokine-CRAC channel signaling is important for NSC migration. Previously, we have shown the role of CRAC channels

in NSCs in mediating proliferation. The goal of this study is to explore the role of CRAC channels for neural stem cell migration using *in vitro* and *in vivo* assays including genetic knockout and pharmacological suppression of CRAC channel expression/function. *In vitro* migration assays using boyden chambers reveal a deficit in the ability of NSCs to migrate in response to SDF1 chemokine gradients. We have also tracked migrating neural progenitors *in vivo*, by virally labeling neurogenic regions in mice with the calcium-sensitive genetically encoded indicator, GCAMP6. Slice $Ca^{2+}$ imaging and immunohistochemistry have revealed that whereas NSCs normally migrate to the olfactory bulb and integrate as differentiated interneurons, NSCs lacking Orai1 terminally differentiate early and fail to migrate completely to their target site. These results suggest store-operated calcium entry through Orai1 is necessary for SDF1 mediated chemotaxis of NSCs in vitro and for proper *in vivo* migration of NSCs to the olfactory bulb.

**Abstract:** KCC2 is a neuron-specific $K^+$-$Cl^-$ cotransporter essential for establishing the $Cl^-$ gradient required for hyperpolarizing inhibition. KCC2 is highly localized to excitatory synapses where it regulates spine morphogenesis and AMPA receptor confinement. Aberrant KCC2

function contributes to numerous human neurological disorders including epilepsy and neuropathic pain. Using unbiased functional proteomics, we identified the KCC2-interactome in the mouse brain to determine KCC2-protein interactions that regulate KCC2 function. Our analysis revealed that KCC2 interacts with a diverse set of proteins, and its most predominant interactors play important roles in postsynaptic receptor recycling. The most abundant KCC2 interactor is a neuronal endocytic regulatory protein termed PACSIN1 (SYNDAPIN1). We verified the PACSIN1-KCC2 interaction biochemically and demonstrated that shRNA knockdown of PACSIN1 in hippocampal neurons significantly increases KCC2 expression and hyperpolarizes the reversal potential for $Cl^-$. Overall, our global native-KCC2 interactome and subsequent characterization revealed PACSIN1 as a novel and potent negative regulator of KCC2.

**Abstract:** In mature neurons, the activity of the K-Cl transporter KCC2 plays an essential role in chloride homeostasis and thereby influences GABAergic transmission. Down-regulation of KCC2 has been reported in a variety of neurological and psychiatric conditions and is usually

thought to perturb neuronal activity through altered GABAergic transmission. However, KCC2 also interacts with various molecular partners including actin-related proteins and postsynaptic glutamate receptors. Thus, suppression of KCC2 expression triggers several opposing changes in synaptic function through chloride transport dependent and independent mechanisms. How these effects may combine to alter network activity and lead to the emergence of pathological activities remains difficult to predict.
Using viral-based chronic knock-down of KCC2 in rat hippocampal dentate gyrus, we observed very little effect on the strength of the GABAergic transmission in granule cells (GCs). Perforated patch recordings showed that the shift in EGABA induced by KCC2 suppression was almost fully compensated by a depolarization of the resting membrane potential. We explored the underlying mechanisms for this effect and identified a previously unknown interaction between KCC2 and the leak-potassium channel Trek-2. Thus, loss of KCC2 expression leads to a reduced expression of leak potassium currents and increased membrane excitability in hippocampal GCs. This resulted in an increased EPSP/spike coupling and enhanced recruitment of dentate GCs upon stimulation of entorhinal afferents. Increased GC excitability was associated with alterations of hippocampal rhythmogenesis, with enhanced theta-band activity power during specific behavioral states as detected in ECoG recordings.
Our results reveal a broad and critical role of KCC2 in the control of hippocampal circuit function through a variety of actions on synapses and intrinsic excitability. We propose that down-regulation of KCC2 expression in cortical neurons may result in alterations of rhythmic activities associated with cognitive functions and behavior. Our results suggest that diuretics that act solely to restore neuronal chloride concentration may not fully compensate for the loss of KCC2 under pathological conditions.

**Abstract:** GABA is the main inhibitory neurotransmitter in the adult brain, and provides fast inhibitory neurotransmission mostly through activation of GABAA receptors. As these receptors are mainly permeable to chloride ions, mechanisms controlling chloride homeostasis directly influence GABAergic transmission. In mature cortical neurons, intracellular chloride concentration is controlled by the activity of neuronal chloride/potassium co-transporter KCC2, the expression of which is down-regulated in several neurological and psychiatric conditions associated with cognitive impairment. In the pathology, KCC2 suppression may compromise network activity through alterations of GABA signaling and rhythmogenesis that underlie memory encoding and consolidation. In addition, recent studies revealed ion transport-independent functions of KCC2 at excitatory synapses. Thus, chronic KCC2 down-regulation in hippocampal neurons impairs both the efficacy and long-term potentiation of glutamatergic synapses through modifications of actin dynamics in dendritic spines. We therefore asked whether chronic down-regulation of KCC2 may impact cognitive performances in mice and explored the underlying mechanisms.
Using a viral-based, chronic extinction by RNA interference, we suppressed KCC2 expression in the dorsal hippocampus of adult mice and tested hippocampal LTP, learning and memory 2-4 weeks post-infection. Chronic KCC2 suppression impaired LTP both at perforant path synapses onto granule cells and Schaffer collateral synapses onto CA1 neurons. Next, we tested the behavioral impact of chronic KCC2 suppression in several hippocampus-dependent and independent memory tasks. In a fear conditioning paradigm, we found that contextual memory was specifically compromised upon KCC2 suppression in dorsal hippocampus while cued memory was intact. Next we asked whether these deficits primarily depend on alteration of GABAergic vs. glutamatergic signaling using overexpression of a dominant-negative peptide of KCC2. This approach allows us to specifically disrupt KCC2 interaction with protein partners without affecting its ion transport function. However this did not lead to detectable deficits in contextual memory, suggesting these did not primarily depend on KCC2 transport-independent functions.
We conclude that KCC2 down-regulation in the dorsal hippocampus compromises contextual memory, through mechanisms that remain to be fully explored. Strategies aiming to stabilize KCC2 membrane expression or restore chloride homeostasis may then prove beneficial in rescuing cognitive impairments in conditions associated with KCC2 down-regulation.

**Abstract:** Driven by the high intracellular $K^+$ concentrations maintained by $Na^+/K^+$ ATPase, K-Cl co-transporter KCC2 transports $K^+$ and $Cl^-$ out of cells. KCC2 is expressed almost exclusively in neurons where its proper function is required to maintain low intracellular $Cl^-$ concentrations that are crucial for the inhibitory neurotransmissions of γ-Aminobutyric acid (GABA) and glycine. Loss-of-function mutations of KCC2 cause a severe refractory epileptic encephalopathy in infants. The important role of KCC2 in controlling neuronal excitability is conserved in mice. KCC2 deficits cause frequent seizures in mice and resulted death. Here we examined the transporter activity of variously tagged KCC2 in mammalian cells and successfully solubilized and purified non-aggregated full-length KCC2. The purified KCC2 was characterized biochemically and with electron microscopy. The specific binding of KCC2 inhibitors to the purified KCC2 was demonstrated by surface plasmon resonance (SPR). Our study revealed important features of the molecular architecture of KCC2.

**Abstract:** The neuron specific K-Cl cotransporter KCC2 is the main $Cl^-$ extrusion mechanism in central neurons. Progressive up-regulation of KCC2 in neocortical and hippocampal principal neurons is known to take place during the first few postnatal weeks in altricial rodents such as the mouse and rat. In more precocious species such as the guinea pig, up-regulation of KCC2 and thus maturation of functionally inhibitory $GABA_AR$-mediated postsynaptic signaling in principal neurons is shifted towards life in utero. Functional up-regulation of KCC2 has been suggested to act as the key signal for ending the period of trophic GABA actions in brain development. Here we show using bidirectional pharmacological manipulation of KCC2 activity that this developmentally regulated $Cl^-$ transporter has an important role in controlling spontaneous network events already in the perinatal hippocampus of rats and mice.

**Abstract:** The mammalian target of rapamycin, mTOR (serine/threonine kinase) controls various functions in the cell such as cell growth and metabolism. Deregulation of mTOR has resulted into numerous human diseases for example cancer, obesity and diabetes. mTOR is composed of two different functional units, mTORC1 and mTORC2. mTORC1 is the main target of rapamycin and essentially regulates different biochemical reactions such as protein, lipid synthesis and autophagy which results into controlling cellular homoeostasis. Hence regulation of mTORC1 is crucial for cellular growth and development. mTORC1 functionality is controlled by energy levels, nutrients, and growth factors. Among this amino acids have emerged as a major regulator for mTORC1. The cellular metabolisms are regulated by various membrane transport proteins which mediate the transport of nutrient molecules across cell membranes. Solute carriers (SLCs) are one of the largest classes of membrane-bound transporter proteins. In neuronal cells various SLCs monitor numerous cellular processes, including the role of transporters for amino acids between cells and for neurotransmitter cycling. The SLC38 family includes eleven members and is also called sodium-coupled neutral amino acid transporters (SNATs). Members of the SLC38 family such as SLC38A2 and SLC38A9 act as mTOR sensors and regulate mTOR signaling cascade in response to different external stress. Different amino acids act as source of providing energy for intracellular protein turn over, nutrient transport through the plasma membrane, cell growth, migration as well as maintenance of cell integrity. The major goal of this study is to determine the in vitro function of SNAT10 in mTORC1 regulation and physiology using conditional knock out (KO) mice. We have discovered differences at the basal intracellular amino acid pool between SNAT10 KO primary neuronal cells. Under nutrient stress, SNAT10 KO cells showed increased concentrations of aspartic acid, glutamine and glutamine acid and a decreased basal level of total mTOR protein. We also investigated the role of SNAT10 under different cellular stress responses both oxidative stress and glutamate excitotoxicity. The knockout SNAT10 mice were subjected to different behavioral paradigms, including rotarod, beam walk, elevated plus maze and marble burying test where we investigated t the basal motor, cognitive and emotional behavior of the mice.

**Title:** Defining solute carrier distribution and function in the central nervous system

**Authors: *N. N. SCHWEIZER**, S. BAGCHI, R. FREDRIKSSON
Pharmaceut. Biosci., Uppsala Univ., Uppsala, Sweden

**Abstract:** Directed transport of nutrients, particularly amino acids, is a prerequisite for cell survival. This is to a large extent done by SLCs. Different SLC transporters are known to overlap in substrate specificities and in cellular location, and thus provide a redundancy in the systems they are involved in. For example, within the SLC38 family, several members likely constitute a yet unexplored regulatory network involved in the control of protein synthesis. Research on SLC transporters is often hampered by compensatory effects that mask the effect of a genetic or pharmacological intervention performed on one SLC. In a systematic approach to resolving global SLC distribution throughout the brain by high-throughput single-cell RNA sequencing we aim to map the co-expression of different SLC transporters with neuronal markers identifying neuronal types, such as excitatory vs. inhibitory or interneurons, in different anatomical structures throughout the mouse brain. The large data set generated through systematic single-cell RNA sequencing can potentially serve as basis for research on SLC functional compensation and ultimately to targeting SLCs in a more directed manner during pharmacological intervention in disease.

**Title:** Transcriptional regulation of the system $x_c^-$ light chain, xCT, in astrocytes

**Authors: *Y. HE**, C. P. ROSSER, J. SHI, J. A. HEWETT, S. J. HEWETT
Dept. of Biol., Syracuse Univ., Syracuse, NY

**Abstract:** The activity of system $x_c^-$ ($Sx_c^-$), a hetereomeric plasma membrane amino acid transporter, critically regulates intracellular glutathione synthesis/maintenance and extracellular glutamate levels in the central nervous system. In astrocytes, interleukin 1β (IL-1β), a prototypical inflammatory factor upregulated in various neurological diseases/disorders, facilitates $Sx_c^-$ expression via transcriptional (Jackman et al. 2010) and post-transcriptional (Shi et al. 2016) control of *Slc7a11*, the gene that encodes for the substrate specific light chain, xCT. While we reported that HuR mediates stabilization of astrocyte xCT mRNA following IL-1β treatment (Shi et al. 2016), the mechanism underlying transcriptional control has yet to be identified. IL-1β signals canonically through NF-κB and p38 MAPK pathways and non-canonically via a variety of other kinase systems. Thus, in this study we examined the potential signaling pathways by which IL-1β regulates xCT expression transcriptionally using pharmacological selective inhibitors. Primary mouse astrocytes were treated for 30-60 min with selective inhibitors of IκB kinase β (20 μM TPCA-1), p38 MAPK (10 μM SB 203580), PI3K (25 μM LY 294002), AKT (5 μM Akti-1/2), protein kinases A and C (20 μM H-7), or to a pan PKC inhibitor (1 μM Go 6983), followed by addition of IL-1β (3 ng/ml). Lysate samples were harvested 4 hr later and xCT mRNA expression levels measured via quantitative PCR. We found that the IL-1β-mediated increase in xCT expression was effectively attenuated by TPCA-1, SB 203580, LY 294002, H-7 but not Go 6983 or Akti-1/2, implicating involvement of NFκB, p38 MAPK, PI3K and PKA, but not PKC and AKT. Thus, our results reveal multiple layers of regulation of xCT expression in astrocytes by IL-1β signaling.

**Title:** Activation of AKT increases cell surface expression of System $x_c^-$

**Authors: *P. VERSLUIS**, A. GIBSON, M. SCHMIDT, D. SMITH, L. CHASE
Biochem., Hope Col., Holland, MI

**Abstract:** System $x_c^-$ is a heterodimeric plasma membrane transporter involved in the exchange of intracellular glutamate for extracellular cystine. As such, this transporter plays a critical role in the production of the antioxidant glutathione. Previous studies in our lab have demonstrated that there is an increase in cell surface expression within ten minutes of exposure to $H_2O_2$ in confluent U138MG human glioma cells. The study described herein sought to begin to characterize the mechanism by which $H_2O_2$ regulates the trafficking of xCT. We hypothesized that Akt signaling is necessary for $H_2O_2$-mediated trafficking of of xCT. A significant increase in Akt phosphorylation was observed in U138MG cells following ten-minute exposure to 3 mM $H_2O_2$ compared to vehicle-treated cells using western blot analysis. Treatment with the Akt inhibitor 10-DEBC (2.5µM) for 30 minutes prior to and during $H_2O_2$ exposure resulted in a decrease in $H_2O_2$-induced phosphorylation of Akt at Ser473. Similar inhibition of Akt phosphorylation at Thr308 was observed following treatment of cells with 1.0µM API-2. Next, we used simultaneous treatment of cultured glioma cells with both inhibitors in the presence of $H_2O_2$ and observed a reduction in the trafficking of endogenously expressed xCT to the plasma membrane. To determine if the regulation of xCT cell surface expression is not limited to human glioma cells, we also studied the role Akt plays in the trafficking of recombinant, transiently-expressed xCT in COS-7 cells. COS-7 cells transfected with myc-tagged xCT, 4F2HC and a constitutively active form of Akt showed higher levels of xCT localized to the membrane compared with cells transfected with a dominant negative form of Akt. Collectively, these data suggest that Akt is an important regulator of xCT cell surface expression. We are currently using a mutagenesis approach to determine if phosphorylation of xCT at putative Akt phosphorylation sites is necessary for increased cell surface localization of xCT.

**Title:** Regulation of System $x_c^-$: Effects of N-terminal and C-terminal mutations on xCT cell surface expression

**Authors: A. GIBSON**, P. VERSLUIS, M. SCHMIDT, *L. A. CHASE
Hope Col., Holland, MI

**Abstract:** System $x_c^-$ exchanges intracellular glutamate for extracellular cystine across the membrane of many cell types, including astrocytes. Its activity directly regulates the synthesis of the antioxidant glutathione and the extracellular concentration of glutamate in some areas of the brain. Dysregulation of the transporter can lead to excessive glutamate release and excitotoxic cell death or the depletion of glutathione stores and the development of oxidative stress. We recently demonstrated that oxidants acutely upregulate System $x_c^-$ activity by triggering the rapid redistribution of the transporter from intracellular compartments to the cell surface. Our current work suggests that the trafficking of the transporter may be regulated by ubiquitination and that oxidant exposure directly influences the ubiquitination of the transporter. Since increased ubiquitination tends to decrease the cell surface expression of many membrane transporters, we sought to test the hypothesis that System $x_c^-$ is ubiquitinated and that the ubiquitination status of the transporter regulates both its cell surface expression and activity. We have used a mutagenesis approach to disrupt putative ubiquitination sites and a putative ubiquitin ligase binding site within a myc-tagged System $x_c^-$ construct so that we can understand the role ubiquitination plays in regulating the cell surface expression of System $x_c^-$. There are seven highly conserved lysine residues within xCT that are located on the cytoplasmic side of the membrane. These residues are located at positions 4, 37, 41, 43, 422, 472, and 473. We have created mutant forms of this construct containing single or multiple lysine to arginine mutations so that we could assess the effect of these mutations on cell surface expression of System $x_c^-$. Using biotinylation assays and immunocytochemical analysis, we have demonstrated that mutation of the N-terminal lysine residues increases the cell surface expression of the transporter. We are currently assessing the ubiquitination status of these mutant transporters to determine if the changes in ubiquitination are associated with changes in the cell surface expression and activity of the transporter. In addition, we have identified a putative ubiquitin ligase binding site in the C-terminus of the transporter. Our preliminary studies suggest disruption of this binding site also leads to an increase in cell surface expression of the transporter. Collectively, these data suggest that System $x_c^-$ is regulated by changes in its

ubiquitination status such that factors which lead to diminished ubiquitination will allow for increased cell surface expression of the transporter.

**Title:** Extracellular matrix modulates system $x_c^-$ (SXC) mediated glutamate release from gliomas via CD44

**Authors: *J. MARTIN**[1,2], S. M. ROBERT[2], R. A. UMANS[2], H. SONTHEIMER[2]
[1]Virginia Tech., Roanoke, VA; [2]Virginia Tech. Carilion Res. Inst., Roanoke, VA

**Abstract:** Significant aberrations in biological function arise in glial-derived malignant tumors known as glioblastoma multiforme (GBM), many of which confer treatment resistance. An example found in GBM is the upregulation of a splice variant of the cell surface glycoprotein CD44, which correlates negatively with survival of patients and tumor-bearing mice. CD44 is a putative co-receptor of the cystine/glutamate antiporter system $x_c^-$ (SXC) that is upregulated in approximately half of GBM patients. SXC imports cystine for the synthesis of glutathione (GSH), an important intracellular antioxidant that confers protection from reactive oxygen species (ROS), as well as radiation and chemotherapy. In exchange for cystine, SXC releases glutamate into the peritumoral brain. When upregulated, SXC function results in assiduous glutamate release, creating an excitotoxic environment for surrounding neurons. We hypothesize that CD44 plays a role in regulating SXC function through stabilization of xCT, the catalytic subunit of the antiporter, in the cell membrane. This stabilization contributes to an increased number of functional SXC transporters, and as a result, increased cystine uptake, GSH synthesis, and enhanced resistance to oxidative stress. To test this hypothesis, we confirmed a putative interaction between CD44 and xCT. First, immunostaining of cells and tumor-bearing tissue slices revealed co-localization of CD44 and SXC on the cell membrane. Second, antibodies bound to CD44 immunoprecipitate xCT and vice versa, suggesting a physical interaction between CD44 and xCT. To determine whether CD44 regulates SXC function, we used a fluorometric glutamate assay to quantify glutamate release from SXC-expressing GBMs after treatment with siRNA against CD44. Knockdown of CD44 reduced glutamate release by half, compared to control cells. The addition of the CD44 ligand Hyaluronic acid (HA) to the medium for 24 hours caused a significant increase in glutamate release into the medium of CD44

expressing cells; conversely, incubation with the HA-degrading enzyme Hyaluronidase (HYAL) decreased glutamate release to sub-control levels. This regulation suggests a normal regulatory role for CD44 on SXC function. Consistent with this notion, extracellular HA expression correlates positively with xCT expression. These studies suggest that SXC is modulated by extracellular matrix activation via CD44, which provides an additional therapeutic target to reduce SXC function.

**Abstract:** The presubiculum contains head direction cells which are crucial for spatial navigation. Here, we explored the functional connectivity of the thalamic head directional input to superficial layer 3 neurons of the mouse presubiculum with double patch-clamp recordings, retrograde tracing and optogenetics. A viral vector containing channelrhodopsin-2 (ChR2) and a fluorescent reporter protein was injected in anterior thalamic nuclei (ATN). Presubicular slices were sectioned after 10 to 20 days. We found that ATN densely innervated superficial layers 1 and 3 of the presubiculum. Excitatory synaptic events were reliably recorded following photostimulation of ChR2 transfected ATN fibers in pyramidal neurons located in layer III of presubiculum. We show that presubicular pyramidal neurons projecting to medial entorhinal cortex were directly contacted, and synaptic responses persisted in the presence of TTX and 4AP. ATN fibers also directly excited fast spiking, parvalbumin expressing (PV) interneurons but not low threshold spiking, somatostatin expressing (SST) interneurons in layer 3 of

presubiculum. ATN-mediated excitation of pyramidal neurons was typically followed by a disynaptic inhibitory component probably due to feedforward inhibition. We show a high connectivity between presubicular pyramidal neurons and PV interneurons. Finally, we demonstrate optogenetic silencing of PV interneurons suppressed feedforward inhibition of principal neurons, confirming these interneurons are the major source of feedforward inhibition. Our data point to a distinct role of presubicular interneurons in head-direction tuning.

**Title:** Internal excitatory network in the subthalamic nucleus: An optogenetic functional mapping investigation

**Authors:** ***P. S. FREESTONE**[1], K. L. TODD[1], J. LIPSKI[2]
[2]Physiol., [1]Univ. of Auckland, Auckland, New Zealand

**Abstract:** The basal ganglia is a sub-cortical structure receiving a wide range of inputs almost from the entire brain. As such, it is involved in motor control, learning, memory and reward-driven behaviour. The subthalamic nucleus (STN), a major glutamatergic nucleus of the basal ganglia projecting to the substantia nigra pars reticulata (SNr) and pars compacta (SNc) nuclei, plays a crucial role in the *indirect* and *hyperdirect* pathways. Previous electrophysiological studies suggest that STN neurons also make internal synapses through axon collaterals with other glutamatergic neurons in the nucleus. Our aim is to apply the optogenetic technique of functional mapping to rapidly detect and investigate the connectivity between neurons within the STN, and to identify excitatory inputs through such collaterals. CD-1 mice expressed channelrhodopsin (H134R) under the CaMKIIα promotor after injection of the viral (AAV5) construct into the STN. Neuronal activity was monitored using whole-cell patch-clamp electrophysiological recordings from horizontal ventral midbrain slices (250 µm) containing the STN, SNr and SNc after 4-8 weeks expression. Functional mapping was conducted using a digital mirror device (*Polygon400*, MightEx) to sequentially illuminate squares (20-80 $\mu m^2$) of a grid (800 x 600 µm) in a pseudorandom fashion, while recording post-synaptic currents from single neurons. Using this approach, we have shown that focal photo-stimulation (6 $mW/mm^2$, 5 ms) at multiple discrete locations within the STN can evoke currents recorded from a single STN neuron. These

light-evoked currents are delayed (2-4 ms relative to the onset of photo-stimulation), and comprise of multiple peaks, confirming they are not due to direct activation of ChR2 in the recorded neuron. It remains to be investigated the exact nature of these internal glutamatergic connections within the STN, and what role they might have in determining the activity of their downstream projections.

**Title:** Mapping projection populations to striatal neurons

**Authors: *K. CHOI**[1,2], E. N. HOLLY[1,2], M. F. DAVATOLHAGH[3], K. BEIER[4], M. FUCCILLO[2]
[2]Dept. of Neurosci., [3]Dept. of Neuroscience, Neurosci. Grad. Group, [1]Univ. of Pennsylvania, Philadelphia, PA; [4]Stanford Univ., Stanford, CA

**Abstract:** The dorsomedial striatum (DMS) receives afferent inputs from cortex, thalamus and midbrain, and has been implicated in reward-sensitive motor behaviors. It is presently unclear whether projection neuron populations exhibit specific connectivity to the diverse cell types within the DMS - a key point in understanding the computations performed by these circuits during choice behaviors. We compared the anatomical and physiological connectivity of projection neurons that synapse on three major DMS cell types - D1 spiny projection neurons (SPN), and parvalbumin (PV) and somatostatin (SST) interneurons - using cell-type specific rabies virus tracing and optogenetic-mediated projection neuron recruitment. Starter cell populations were labeled with Cre-sensitive TVA expression via injection into either D1-Cre, PV-2a-Cre or SST-ires-Cre mice. After injection with pseudotyped rabies virus-EGFP, all starter cell populations demonstrated robust numbers of retrogradely labeled neurons originating in the orbitofrontal cortex, anterior cingulate/secondary motor cortex (ACC/M2), thalamus and globus pallidus externus. Despite subtle target cell-dependent differences for OFC and specific thalamic nuclei, we found similar numbers of retrogradely labeled neurons per starter cell for each postsynaptic target. While rabies virus methods have been regularly used to assess cell type-specific anatomical connectivity, it is unclear how these data correspond to physiological

measures of connectivity. To test this, we focused on the ACC - a major projection population to the DMS exhibiting no differences in anatomical connectivity. To quantitatively compare synaptic properties and postsynaptic recruitment as a function of input, we normalized the number of recruited afferent ACC fibers via the “optical component” of the striatal field while recording whole cell configuration in nearby genetically-labeled D1, PV and SST cells. Despite the similar anatomical connectivity by viral tracing, we found significant differences in excitatory synaptic strength, with PV interneurons exhibiting the strongest ACC synapses, followed by D1 SPNs, then SST interneurons. Differences in synaptic strength between ACC-PV and ACC-D1 SPN synapses resulted largely from synapse structure, while the weakness of ACC-SST synapses was a mixed effect of small release site number, low release probability and decreased postsynaptic responsiveness. Taken together, this suggests a model for striatal projection neuron connectivity in which postsynaptic cell type largely imposes diversity of physiological connectivity on a “skeleton" of non-specific anatomical connectivity.

**Title:** Morphological complexity of human substantia nigra synapses

**Authors: *S. J. MABRY**, J. K. ROCHE, R. C. ROBERTS
Psychiatry/Behavioral neurobiology, Univ. of Alabama Birmingham, Birmingham, AL

**Abstract:** The substantia nigra and ventral tegmental area (SN/VTA) are the largest dopaminergic nuclei in the brain and receive glutamatergic and GABAergic inputs that regulate dopaminergic neuronal activity. Abnormal dopamine transmission is affected in several diseases, most notably Parkinson’s disease and schizophrenia. While the cytoarchitecture, connectivity and neurotransmitter content of the SN/VTA has been examined extensively, especially in animal models, ultrastructural data in human SN/VTA is scarce. We examined 7 control cases: 4M&3F, 2AA&5C, 39.7±15.0 years, PMI=6.0±1.3 hours. Synapses in the vicinity of dopamine neurons were photographed in serial sections. In most parts of the brain, including human postmortem striatum and cortex, synapses can easily be characterized by the morphology of the postsynaptic density (PSD) into type 1 (thick PSD) and or type II (thin PSD), which correspond to excitatory and inhibitory neurotransmission, respectively. However, in the SN/VTA synaptic

morphology was much more complex, with many synapses containing a presynaptic density of varying shape and thickness. We identified six types of type 1 synapses, five types of type II synapses and synapses with intermediate PSDs. In synapses with presynaptic densities, these were thin or thick, and/or solid or elaborately irregular. PSDs were thin, thick or intermediate and solid or elaborately irregular. There were 1.119±0.173 mitochondria per axon terminal with similar numbers in classic type 1 or type II synapses. Recent studies have shown that neurons in the SN/VTA contain multiple transmitters, and use more than one transmitter in a given synapse which could lead to the variability in synaptic morphologies.

**Title:** Localization and functional study of synaptic vesicle protein synaptogyrin3 (SYNGR3) on dopaminergic neuronal system and its potential link to Nurr1

**Authors: *L. LI**[1], P. HO[1], H. LIU[1], Z. TSE[1], C. LAM[1], M. LEUNG[1], M. KUNG[1], D. B. RAMSDEN[2], S. HO[1]
[1]Dept. of Medicine, Li Ka Shing Fac. of Med., The Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Inst. of Metabolism and Systems Research, Univ. of Birminghm, Bermingham, United Kingdom

**Abstract: Background:** SYNGR3 is an integral synaptic vesicle protein in the synaptogyrin family. Among the three isoforms of synaptogyrin (SYNGR1-3), SYNGR3 is specifically expressed in brain. However, the physiological function of SYNGR3 in neurons is unknown. Previous studies have shown that SYNGR3 can physically interact with DAT protein [1]. Intracellular DA, if not properly sequestered, will undergo auto-oxidation leading to oxidative stress. Furthermore, we identified three non-canonical Nurr1 response elements (NBRE, AGGTCA) in 5’ flanking region of SYNGR3 gene. Nurr1 is an orphan nuclear receptors belonging to the transcription factor superfamily, which promotes differentiation and survival of dopaminergic (DA) neurons [2]. Therefore, we hypothesize that SYNGR3 has a role in dopaminergic neurons to facilitate dopamine re-take for vesicle packaging and dopamine

recycling, and Nurr1 may influence this process via regulating SYNGR3 expression.
**Method and Results:** Immunogold EM revealed that SYNGR3 was co-localized in close proximity with DAT in the striatal synaptic termini. Immunoprecipitation of DAT using anti-DAT antibody resulted in co-precipitation of SYNGR3 from mouse striatal lysates, and vice versa. Overexpression of SYNGR3 in SH-SY5Y cells caused significant increase in cellular DA uptake activity as compared with empty-vector controls. EMSA showed that Nurr1 proteins bound specifically to the three NBREs in the 5' flanking region of human SYNGR3 gene.
**Conclusion:** We demonstrated that overexpressing SYNGR3 in neuronal cells increased DA uptake efficiency, possibly via strengthening interaction between synaptic vesicles and DAT on the plasma membrane. Co-localization of SYNGR3 and DAT in striatal synapses may have functional significance to maintain DA homeostasis for normal motor movement and cognitive functions. Nurr1 may influence this process via regulating SYNGR3 expression.

**Abstract:** A clear promise of stem cell therapy is rewiring malfunctioning brains by replacing damaged neurons with new neurons derived from stem cells (SCNs). However, little is known about the functional endpoint of how neural stem cells establish synapses with each other and with pre-existing neurons. Current attempts to evaluate the efficacy of stem cell derived neuron (SCN) synapse formation rely on techniques that reveal only a small fraction of SCN synapses (<<1%) and little about the role of non-neuronal cells (e.g. astrocytes, microglia, etc.) in this process. We have developed a multi-scale imaging pipeline to identify and track SCN differentiation and integration into existing networks of neurons over complete brains. We will

couple synchrotron source micro X-ray tomography (μXCT) techniques unique to Argonne National Labs with our pipeline for automated serial electron microscopy (EM) ('connectomics'). We will use genetic labeling strategies to visualize and distinguish stem cells, their neuronal progeny, and their synapses from 'host' neurons and synapses in both EM and X-ray datasets. We will use this staining to allow seamless integration and traversal between sub-micron mapping of SCNs location over entire brains with μXCT and subsequent targeted reconstruction of their connectivity with nanometer scale EM. Ascertaining the 'rules' by which SCNs integrate into neuronal networks could reveal cellular and subcellular targets for increasing the therapeutic efficiency of SCNs as well as reveal fundamental processes by which neurons develop and make synapses in the brain.

**Title:** Mechanisms by which the prefrontal cortex distinguishes ventral hippocampal from mediodorsal thalamic inputs

**Authors: *E. TEBOUL**[1], S. CANETTA[1,2], S. S. BOLKAN[2], N. PADILLA COREANO[3], C. KELLENDONK[2,1]
[1]New York State Psychiatric Inst., New York, NY; [2]Columbia Univ., New York, NY; [3]MIT, Cambridge, MA

**Abstract:** The prefrontal cortex (PFC) serves as a hub for cognitive and affective behaviors including spatial working memory and anxiety. Two major sources of information to the PFC are provided by the ventral hippocampus (vHPC) and the mediodorsal thalamus (MD), both of which provide glutamatergic input to this structure. Despite this convergence of input, optogenetically silencing either the vHPC to PFC or MD to PFC inputs produces distinct behavioral responses. For example, silencing vHPC to PFC terminals decreases anxiety (Padilla-Coreano N et al, Neuron, 2016) and selectively impairs encoding of spatial working memory (Spellman T et al, Nature, 2015) while silencing MD to PFC terminals does not affect anxiety and instead selectively impairs maintenance of spatial working memory (Bolkan S et al, Nature Neuroscience, 2017). However, the mechanisms by which the prefrontal cortex is able to selectively distinguish between seemingly identical neurotransmitter inputs to generate behaviorally distinct responses is unknown.

To address this, we used optogenetics in combination with slice electrophysiology in the PFC to assess the functional connectivity and efficacy of synaptic transmission for both projections under different input frequencies. Using virally-delivered blue- or red-light activated ChR2 (Chronos and Chrimson, respectively), we investigated whether vHPC and MD cells project to the same PFC pyramidal cells and parvalbumin-expressing (PV) interneurons, and whether synaptic transmission from these two projections is differentially affected by input frequency. We found that all layer II/III PFC pyramidal cells sampled received input from the MD and from the vHPC. However, while all PV interneurons sampled received input from the MD, only a portion received input from the vHPC. We also found that MD versus vHPC inputs onto pyramidal cells could be distinguished based on their frequency-specific synaptic dynamics and that these differed from what was seen at synaptic inputs onto PV cells. Future experiments will examine functional connectivity and synaptic dynamics at MD and vHPC inputs onto other genetically defined interneuron populations as well as how these inputs to the PFC may be altered in an environmental risk factor model for schizophrenia with known PFC dysfunction.

**Title:** Mapping of excitatory and inhibitory activities of distinct neuronal populations in hippocampal slices using ArcLight

**Authors: *R. NAKAJIMA**, T. GEILLER, B. J. BAKER
Korea Inst. of Sci. and Technol., 39-1 Hawolgokdong, Seongbukgu, Seoul, Korea, Republic of

**Abstract:** To understand the brain circuitry, it is essential to clarify the functional connectivity among distinct neuronal populations. By using associated adeno virus in combination with cre-lox system, we expressed a genetically encoded voltage indicator, ArcLight, in specific neuronal populations of mouse hippocampus. The expression of ArcLight was limited either in $Ca^{2+}$/calmodulin-dependent protein kinase II alpha (CaMK2a) excitatory neurons or in parvalbumin (PV) interneurons in the CA1 hippocampus. We then observed the fluorescence

change of ArcLight by electrically stimulating Schaffer collateral in hippocampal CA1 region of slice preparations under fast-CCD camera. In excitatory neurons, ArcLight could detect glutamatergic depolarization as well as GABAergic hyperpolarization. On the other hand, we found that PV interneurons were strongly inhibited by voltage-gated potassium channels. In contrast to GCaMP6f which only detected excitatory responses, ArcLight could detect both excitatory and inhibitory responses from specific cell populations. ArcLight and similar probes are becoming a powerful paradigm for functional connectivity mapping of brain circuitry.

**Abstract:** Cholecystokinin expressing interneurons (CCK-INTs) are positioned to powerfully influence hippocampal information processing by providing strong feedforward and feedback inhibition to principal cells (PCs). However, despite a wealth of information describing intricate synaptic details of CCK-INTs (eg. depolarization induced suppression of inhibition (DSI)/asynchronous release (AR)), their network functions remain enigmatic. This relates to the fact that, beyond common developmental origins and CCK expression, CCK-INTs comprise a heterogeneous cohort with unique postsynaptic target preferences and molecular signatures. Interestingly, one subset of CCK-INTs, vesicular glutamate transporter 3- (VGluT3) expressing perisomatic targeting CCK basket cells ($VGluT3^+$CCKBCs), was recently shown to critically regulate theta oscillations and spatial information coding of place cells. Initial reports of VGluT3 expression within this subpopulation prompted speculation that $VGluT3^+$CCKBCs subserve unique computational roles based on their ability to co-release GABA and glutamate. Indeed, in contrast to Dale's principal of "one neuron, one transmitter" recent studies have described a variety of central neurons that utilize more than one classical neurotransmitter including GABA/glutamate co-releasing neurons in subcortical circuits. However, detailed investigation into the functional properties of a pure $VGluT3^+$ CCK-INT cohort, including glutamate release, is currently lacking. We initiated a developmental characterization of $VGluT3^+$ INTs using

VGluT3Cre:Ai14 reporter mice. As expected a large percentage of reported INTs have perisomatic targeting axons with cannabinoid receptor 1 (CBR1) labeled terminals, typical of CCKBCs. Surprisingly, however, the population extends beyond VGluT3$^{+}$CCKBCs to include subsets of dendrite targeting INTs. VGluT3 expression, revealed by both cell reporting and terminal VGluT3 staining, is very low at early postnatal ages and then increases through development, plateauing around P30. Preliminary electrophysiological interrogation of VGluT3Cre:Ai14 reported stratum radiatum INTs revealed basic membrane/spiking properties consistent with CCK-INTs. Moreover, paired recordings with CA1 pyramidal cells in juvenile mice revealed that GABAergic transmission from VGluT3$^{+}$CCKBCs exhibits similar unitary synaptic properties to VGluT3$^{-}$CCKBCs, including DSI and AR. Further investigations will probe for unique synaptic properties of VGluT3$^{+}$ INTs that promote participation in spatial information coding and may contribute to siezure phenotypes following loss of VGluT3.

**Authors: *J. J. COUEY**[1], B. M. HOOKS[2]
[2]Dept. of Neurobio., [1]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

**Abstract:** Primary motor cortex (M1) is required for purposeful movement and skill learning. To better understand M1 function, we aim to determine the anatomical and microcircuit basis for integration of different sources of incoming information within M1. We have previously shown that pyramidal cells in M1 receive unique innervation patterns from cortical and thalamic inputs. Here, using a combination of optogenetics and electrophysiology, we analyze the functional projections from cortical and thalamic input sources to primary motor cortex (M1) interneurons. We used parvalbumin (PV) and somatostatin (SOM) Cre-driver mouse lines to fluorescently label interneuron subpopulations and target them for whole cell patch clamp recordings. Stereotactic injections were used to express opsins selectively in axons from primary somatosensory cortex (S1) or sensory thalamus (PO). In acute brain slices, stimulation of labelled axons during whole-cell recordings from PV+ and SOM+ interneuron subpopulations revealed interneuron sub-type specific projection patterns from both S1 and PO that differ from the targeting of nearby pyramidal neurons. PV+ interneurons receive complementary patterns of input from S1 and PO. In contrast, SOM+ interneurons receive substantially different input.

These results support the hypothesis that feedforward inhibition via PV+ interneurons is recruited in a pathway specific manner. In contrast, SOM+ interneurons are potentially recruited by the local circuitry with a primary role in facilitating local competition between groups of activated pyramidal cells and PV+ interneurons.

**Abstract:** The presynaptic and postsynaptic compartments mediate neurotransmitter release and its perception via a series of complex and highly dynamic networks of protein-protein interactions. The identification of protein candidates for synapses has been a major priority since appropriate high-throughput methods were first established, with the first synaptic proteome studies published around the turn of the century. We examined synaptic proteome studies focusing on the mammalian brain from 2000 to present, which spans a period of rapid technological development and refinement in proteomics.
We combined 30 major synaptic proteomic studies (21 post synaptic and 9 presynaptic) to obtain a list of 6500 genes. We retrieved protein-protein interactions (PPIs) for the combined list of proteins and constructed the most complete PPI networks to date for presynaptic and postsynaptic compartments. We studied the network properties and identified the community structure of our pre- and post-synaptic PPI networks against a non-exhaustive set of commonly available clustering algorithms. Exploiting network based measures semi-local *centrality* and cluster *Bridgeness* we identified topologically important proteins that can simultaneously influence remote clusters in addition to their immediate locality.
We also tested the obtained network structure of the pre- and post-synaptic proteomes for enrichment of common neurological and neurodevelopmental diseases and disorders including: Schizophrenia (SCH), Alzheimer's disease (AD), Autistic Spectrum Disorder (ASD), Autistic Disorder (AUT), Bipolar Disorder (BD), Hypertension (HT), Epilepsy Syndrome (Epi),

Parkingson's Disease (PD), Frontotemporal Dementia (FD), Huntington's Disease (HD) and Intellectual Disability (ID) as defined within the Human Disease Ontology (HDO). Besides the clear links between the identified network substructures and specific diseases we found evident difference in disease susceptibility of pre- and post-synaptic compartments.

**Title:** Developmental profiling of the actin-associated protein tropomyosin at central nervous system synapses

**Authors: *T. FATH**, A. K. SUCHOWERSKA, E. C. HARDEMAN, P. W. GUNNING
Sch. of Med. Sci., Univ. of New South Wales, Sydney, Australia

**Abstract:** The actin cytoskeleton in the post-synaptic compartment of synapses is crucial to supporting synaptic maturation, structure and function. The family of tropomyosins are one of many actin-associated proteins known to regulate the postsynaptic actin cytoskeleton and are considered as gate keepers of actin filament dynamics. We have previously shown the spatial segregation to the pre- and post- synapse of different tropomyosin isoforms at central nervous system synapses, indicative of specific regulation of actin filament populations in different subcellular compartments. Here, we biochemically confirm previous reports of a segregation of Tpm1.12 to the pre-synaptic compartment and Tpm4.2 to the post-synaptic compartment. We also show that in C57Bl6 wild-type mice, there is a developmental shift in the expression of tropomyosin isoforms: as the total pool of Tpm4.2 in the brain decreases with age, there is an increase in localisation of Tpm4.2 to the post synaptic compartment in aged mice. Together these data demonstrate the instrumental role of Tpm4.2 in regulating the post synaptic actin cytoskeleton, particularly in aged mice.

**Title:** Fluorescent proteins for 2P FLIM analysis of presynaptic protein interactions

**Authors: *P. GULAKOVA**[1], D. DIETRICH[2], S. SCHOCH[1]
[1]Inst. of Neuropathology, Bonn, Germany; [2]Deaprtment of Neurosurg., Bonn, Germany

**Abstract:** Dynamic protein-protein interactions are essential for the regulation of synaptic transmission and plasticity. To understand these interactions and correlate them to functional changes it is necessary to resolve them in live neurons. 2-photon (2P) fluorescence lifetime imaging (FLIM) of Förster resonance energy transfer (FRET) is a powerful tool to study such interactions and provides the necessary temporal and spatial resolution even in native tissue. However, there are certain requirement on pairs of fluorescent proteins (FPs) to be used e.g. a high FRET efficiency and photon yield in the presynaptic compartment, sufficiently separate 2P excitability and a lifetime of the donor being ideally monoexponential and insensitive to fusion to target proteins.
Here we examined a list of cyan-yellow and red-green FP pairs (linked with a flexible linker, $SRG_4SG_4S$) for their suitability for 2P-FLIM-FRET studies in neurons. Expressing FPs in HEK293T cells proved to be inapplicable as their rapid division caused a significant fraction of immature red proteins, which did not act as acceptors and lead to a strong underestimation of FRET efficiency. This effect was not seen when transducing primary neurons with FPs and analysing FRET efficiencies at DIV 13-17.
We quantified FRET for the following FP pairs by measuring the reduction in donor lifetimes: mNeon-mRFP/TagRFP/mCherry2, TagRFP-mNeon, mEGFP-mRFP/TagRFP/mCherry2, Clover-mRuby2, mTurquoise2-Ypet/Venus/mOrange2/mNeon, mCerulean-Ypet/Venus, mTFP1-Ypet/Venus/mOrange2.
Most donors in the absence of acceptors displayed monoexponential lifetimes, while mCerulean showed a biexponential fluorescent decay. Donors fused to acceptors, in every case showed biexponential lifetimes, which for most green-red pairs could be explained by the presence of 2 fractions of pairs – one undergoing FRET and the other one not. FRET efficiencies for the tested pairs ranged from 39% to 72%, mNeon-mRFP and mTurquoise2-Ypet displayed the most pronounced FRET efficiencies being 58% and 72%, respectively. These strong FRET effects were confirmed in native neurons of hippocampal mouse brain slices after viral transduction *in*

*vivo*. Furthermore, the fluorescent properties and FRET efficiencies of these proteins were unaffected by fusion to presynaptic proteins and targeting to the presynaptic compartment. Taken together, mNeon-mRFP and mTurquoise2-YPet appeared to be highly suited for 2PFLIM-FRET studies in neurons with the former being advantageous for distinguishing changes in fluorophore distances from changes in the fraction of interacting molecules and the latter showing an outstandingly high FRET efficiency.

**Abstract:** Synaptic adhesion molecules regulate synapse development, function, and plasticity. These functions mainly involve trans-synaptic interactions and positive regulations, whereas cis interactions and negative regulation are less understood. Here we report that SALM4, a member of the SALM family of synaptic adhesion molecules, suppresses excitatory synapse development through cis inhibition of SALM3, another SALM family protein with synaptogenic activity. *Salm4*-mutant (*Salm4*$^{-/-}$) mice show increased excitatory synapse numbers in the hippocampus. SALM4 cis-interacts with SALM3, inhibits trans-synaptic SALM3 interaction with presynaptic LAR family receptor tyrosine phosphatases, and suppresses SALM3-dependent presynaptic differentiation. Importantly, deletion of Salm3 in *Salm4*$^{-/-}$ mice (*Salm3*$^{-/-}$;*Salm4*$^{-/-}$) normalizes the increased excitatory synapse number. These results suggest that SALM4 negatively regulates excitatory synapses via cis inhibition of the trans-synaptic SALM3-LAR adhesion.

**Abstract:** The composition and the state of molecular complexes are the major determinants of their function. Cryo-Electron Tomography allows high resolution, comprehensive imaging of complexes within their natural environment. However, cellular complexity and molecular heterogeneity has prevented their structural detection. We have developed a novel image processing method for detection and classification of macromolecular structures present in cellular cryo-electron tomograms. The application to tomograms of neocortical rodent synaptosomes showed that despite a large variety, many synaptic complexes fall into distinct classes. Our quantitative analysis showed that these classes posses a distinct spatial distribution at a single nanometer scale, but also that this organization is flexible. Finally, the combination of

structural features and localization of the complexes points to their molecular identity and their roles in the synaptic transmission.

**Authors: *A. M. GOMEZ**[1], L. TRAUNMÜLLER[1], P. SCHEIFFELE[2]
[1]Univ. of Basel, Basel, Switzerland; [2]Biozentrum Univ. Basel, Basel, Switzerland

**Abstract:** Neurons integrate tens of thousands of diverse inputs organized in distinct domains along their extensively branched and stereotyped dendritic tree. A synaptic adhesion code proposes to assemble complex circuits, yet a small fraction of the genome encodes for synaptic adhesion proteins. Alternative splicing bypasses the low coding power of the genome by expanding the molecular diversity required to assemble trillions of synapses into complex networks. We recently discovered that Slm2 - an RNA-binding protein - drives a highly dedicated alternative splicing program for the specification of glutamatergic synapses in the hippocampus. Remarkably, the Slm2-dependent program targeted to a devoted splice site of all three Neurexin pre-mRNAs. Here we test the idea that this Slm2-dependent synaptic specification tunes the functional integration of synaptic inputs either by uniform or clustered presentation of cell-type specific Neurexin isoforms on individual axons. By using functional imaging and electrophysiology we have mapped the distribution and strength of synaptic input coordinate with differential neurexin isoform expression.

**Title:** Paired pulse facilitation and depression of intrinsic synaptic connectivity in the claustrum of the fruit bat, Carollia perspicillata

**Authors: *R. ORMAN**[1], S. E. FOX[3], M. G. STEWART[2]
[1]Physiology&Pharmacology, [2]Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [3]Dept Physiol & Pharmacol, State Univ. of New York Downstate Med. Ctr., Brooklyn, NY

**Abstract:** Carollia perspicillata is a member of the new-world leaf-nosed bat family. Carollia's claustrum contains cells whose intrinsic excitatory circuitry is sufficient to: (1) generate single, spontaneous, synchronized burst discharges in disinhibited brain slices, (2) support activity spread along the axes where claustral cells are aligned, and (3), because of multiple axes for cell alignment, support activity spread along both the rostro-caudal and the dorso-ventral axes (Orman et al., JCN 2017 525:1459-1474) in contrast to the discrete cellular alignment shown in rats (Orman, J Physiol Sci 2015 65:533-44). We used a paired pulse paradigm to explore excitatory and inhibitory synaptic connectivity in Carollia brain slices on a 64 electrode grid. Simultaneous field potential responses were recorded throughout claustrum. Events evoked by stimuli applied to the overlying neocortex included (1) an initial brief antidromic population spike followed by (2) a population EPSP of about 5 ms duration associated with increased spiking activity, and finally (3) an IPSP of about 20 ms duration. Single conditioning pulses or short conditioning pulse trains (2-5 pulses) revealed frequency potentiation of EPSPs that persisted for 200 ms or longer. The maximal facilitation appeared to occur at about 100 ms after a conditioning pulse train. Interestingly, the population IPSP, while initially facilitated (within the first 30 ms), was subsequently depressed for periods of 200 ms or longer. The amount of depression increased as more pulses were included in the train. These results are consistent with the time course of GABA-A receptor desensitization (e.g. Jones and Westbrook, Neuron 1995 15: 181-191). Spontaneous unit activity was increased during this period of EPSP facilitation and IPSP depression. These results extend the characterization of the intrinsic connectivity of the bat claustrum. The EPSP properties closely resemble the frequency potentiation described in other brain regions, such as hippocampus (e.g. Fox and Ranck, Exp Brain Res 1981 41:399-410; Kunitake et al. Hippocampus 2004 14:986-999) and improve our understanding of the intrinsic excitatory connectivity of the bat claustrum. The properties of the synaptic circuits, both excitatory and inhibitory, highlight the richness of the set of synaptic changes available to modulate the region's intrinsic connectivity.

**Abstract:** Progesterone is required for neural development, neuroprotection, sexual differentiation and reproduction. Progesterone mediates many of these effects through its receptors, progestin receptor (PR)-A and PR-B. In the female hypothalamus, estrogens induce PR expression, which is essential for the expression of reproductive behavior. While progesterone binding to PR can facilitate lordosis in females, this behavior can also be mediated by dopamine activation of hypothalamic PR in the absence of hormone. In the present study, we sought to identify proteins involved in hormone-independent activation of PR by dopamine in the hypothalamus. Eight week old C57BL6 mice were ovariectomized, and a week later subcutaneously injected with estradiol benzoate (EB, 1 µg) to induce PR. Forty-eight hours following EB injection, mice were infused with 100 ng of SKF, a D1 receptor agonist, or vehicle into the 3$^{rd}$ ventricle. Thirty minutes after the SKF infusion, mice were sacrificed, hypothalami were collected and proteins were extracted. Protein-protein pull-down assays were done using recombinant GST-tagged mouse PR-A or PR-B in the presence or absence of R5020, a PR agonist. Isolated protein complexes from SKF- or vehicle-treated tissue that interacted with unliganded PR were analyzed by tandem mass spectrometry. We identified hypothalamic proteins that interacted with PR-A in an SKF-dependent manner, the majority of which were synaptic regulators, components of neuronal cytoskeleton and kinases. A significant number of identified proteins that interacted with unliganded PR-A were associated with regulation of energy metabolism, transcription and translation. In contrast to PR-A, unliganded PR-B did not associate with any detected hypothalamic proteins in an SKF-dependent manner, suggesting that PR-A contributes more than PR-B to the hormone-independent activation of mouse PR by dopamine, which is consistent with previous behavioral studies. The identified interactome of dopamine-activated PR provides mechanisms by which the receptor can be activated in the

absence of hormone by a ligand-independent mechanism. Additionally, the current findings offer further evidence for differential mechanisms of PR-A and PR-B action in neuronal function and behavior. Finally, these findings provide hormone-independent mechanisms of PR activation that may be involved in female reproductive health and energy homeostasis. Current studies are further exploring the dopamine-dependent PR interactome using reverse phase protein arrays and mass spectrometry-based phosphoproteomics.

**Title:** Inter-synaptic lateral diffusion of GABAA receptors shapes inhibitory synaptic currents

**Authors: *E. PETRINI**, T. RAVASENGA, E. DE LUCA, A. POLENGHI, T. NIEUS, A. BARBERIS
Inst. Italiano di Tecnologia, Genoa, Italy

**Abstract:** The lateral mobility of neurotransmitter receptors has been reported to tune synaptic signals. However, whether receptor diffusion may functionally connect two distinct synapses remains unclear. The present study provides evidence for a novel mechanism of synaptic crosstalk based on the diffusion of desensitized GABAA receptors (GABAARs) between inhibitory synapses. Indeed, by combining single particle tracking and laser photolysis of caged neurotransmitter, we demonstrate that upon synaptic activation, GABAARs can diffuse between adjacent dendritic GABAergic synapses in long-living desensitized states. As a consequence of the larger abundance of desensitized GABAA receptors at the receiving synapse, synaptic responses are transiently reduced. Glutamatergic activity (mimicked by optogenetic LiGluK2 activation) limits this inter-synaptic diffusion by trapping GABAARs at excitatory synapses. We also demonstrate that the functional cross-talk among neighboring synapses described here is calcium-dependent. Overall those data demonstrate that a given inhibitory synapse may modulate neighboring inhibitory synapses by spreading the “memory” of its recent activation. This novel form of activity-dependent hetero-synaptic interplay is likely to modulate synaptic signaling and

is expected to refine dendritic synaptic integration and enhance neuronal computational capabilities.

**Abstract:** Clinical researchers have long considered the task of localizing real-time changes in the cortical areas that handle sensory signals a difficult one, primarily due to limitations of biomedical instrumentation. The electroencephalogram (EEG), despite providing excellent temporal resolution for monitoring real-time brain signals, can only offer very limited spatial resolution of brain activities. This makes it difficult to determine the origins of brain signals, which in turn makes it challenging to pinpoint the exact cortical areas that are actively functioning. In the proof of concept for this study, EEG signals acquired from a young male subject are segmented into appropriate epochs based on a pseudorandom binary sequence. During EEG acquisition, peripheral nerve stimulation synchronized with the same pseudorandom binary sequence is applied to the immediate surface of the subject's right median nerve, enabling us to perform calculations of autocorrelation values derived from the pseudorandom binary sequence and the power spectral density of the EEG epochs. Higher autocorrelation values provide greater certainty as to the origin of the brain signals. By utilizing features of this stochastic method, we can provide close to real-time brain maps that can accurately associate ever-changing cortical activities with indications of neuroplasticity. This innovation can be utilized as a groundbreaking tool for navigated transcranial magnetic stimulation (TMS)

applications. Our study was carried out in accordance with the ethical principles for human medical experimentation as set out in the Declaration of Helsinki.

**Title:** Nmda receptor swapping during synaptic plasticity

**Authors: *D. LI**, D. V. MADISON
Mol. and Cell. Physiol., Stanford Univ., Palo Alto, CA

**Abstract:** NMDA glutamate receptors play a central role in triggering several forms of activity-dependent synaptic plasticity, including long-term potentiation (LTP) and depression (LTD). Here we show that CA3-CA3 synapses between rat hippocampal pyramidal neurons lack detectable GluN2B-containing receptors in their active postsynaptic membrane in basal conditions, but swap to having mostly GluN2B-containing receptors following the induction of either LTP or LTD. These GluN2B receptors source by diffusion from the extrasynaptic membrane, but this receptor swap requires dynamin-dependent endocytosis. This swap does not require that plasticity be successfully induced, but rather depends only on the delivery of the patterned stimulation in an NMDAR-dependent manner. Thus, this swap represents a novel form of metaplasticity, with which a synapse essentially keeps a record of previous activity, regardless of whether a change in synaptic strength occurs. As such, this NMDA receptor swap represents a potential new mechanism for storing memory traces at the synaptic level.

**Abstract:** Synaptic vesicles will spontaneously fuse at synaptic sites with this mechanism related to the $Ca^{2+}$ concentration within the presynaptic nerve terminal. We set out to examine if the occurrence of spontaneous events (minis) after a series of evoked stimulations is correlated to the frequency and duration of a stimulus train. Short-term facilitation at the neuromuscular junctions is due in part to residual $Ca^{2+}$ in the nerve terminal. However, if evoked release from high efficacy synapses result in evoked depression then the limiting factor may be the number of readily release vesicles to sense residual $Ca^{2+}$. Thus a lower frequency in occurrence of these minis may depend on the degree of the evoked synaptic depression. In addition, the frequency in occurrence of minis may also be independent of evoked events if the vesicles that give rise to the events are independent of each other. We hypothesize that the residual $Ca^{2+}$ should affect the frequency of mini occurrence. We analyzed the frequency in occurrences of minis with differing stimulating conditions using the *Drosophila* NMJ. Preliminary data with 20, 40 and 60Hz stimulation of 30 pulses indicates that the nerve terminal is able buffer the internal $Ca^{2+}$ level quickly and not impact the frequency of minis under these conditions. Various other conditions are currently being examined and will be reported on. A better understanding of these events would help to address the residue effect of nerve stimulation on synaptic transmission in various physiological conditions.

**Title:** Hp1bp3 influences neuronal excitability and cognitive function

**Authors: *S. DING**, S. NEUNER, K. O'CONNELL, C. KACZOROWSKI
The Jackson Lab., Bar Harbor, ME

**Abstract:** Recently, heterochromatin protein 1 binding protein 3 (*Hp1bp3*) was identified as a novel regulator of cognitive aging using a combination of forward genetics and a global knock-out mouse model. Through gene set enrichment analyses, we discovered that genes whose hippocampal expression correlated with that of *Hp1bp3* were significantly enriched for terms related to plasma membrane localization and for functions related to neuronal excitability. As changes in hippocampal neuronal excitability and plasticity have been posited to underlie learning and memory processes, we hypothesized *Hp1bp3* may be mediating its effects on cognitive aging via the regulation of hippocampal neuronal excitability. To test this hypothesis, we performed a targeted intrahippocampal knockdown of *Hp1bp3* in adult mice, followed by behavioral analyses and slice electrophysiology. Mice receiving shRNA for *Hp1bp3* exhibited both working and contextual fear memory deficits, demonstrating that decrease of *Hp1bp3* in the hippocampus is sufficient to induce cognitive deficits reminiscent of those observed in global knock-out mice. In addition, these mice exhibited decreased hippocampal neuronal excitability as indicated by an increase in the slow after-hyperpolarization (sAHP), providing a candidate mechanism for *Hp1bp3*-mediated changes in cognitive function. As *Hp1bp3* is known to regulate chromatin accessibility and gene expression, it is likely that *Hp1bp3* regulates the expression of critical ion channels and receptors in the plasma membrane. Ongoing work in the lab will examine this question in more detail. Finally, hippocampal sAHP plasticity in disrupted in mouse models of Alzheimer's disease, suggesting *Hp1bp3* may play a role in AD-related cognitive deficits, a possibility which will be investigated in future studies.

**Abstract:** Chemical synapses transmit information by releasing vesicles packed with neurotransmitter. Synaptic release, however, is not a reliable process, as sometimes action potentials fail to trigger the release, or vesicles are released spontaneously. Synapses employ multiple release sites to compensate for the probabilistic behavior of the release. Here we study how the number of release sites changes the rate of information transfer [1,2] at a synapse during short-term depression. The presynaptic input spike train, *X*, triggers the release at *K* independent release sites of the synapse. It is assumed that the neurotransmitter content of one released vesicle is enough to activate all the receptors on the post-synaptic site. We define an effective release process, *Z*, which is one if at least one of the *K* sites releases a vesicle and is zero otherwise (Fig. 1A). The effective release process corresponds to the EPSP that is recorded from the post-synaptic neuron. Short-term depression is incorporated into our model by assuming that each release site is inactivated after a release and recovers exponentially back to its initial release probability.

We calculate the amount of information about the presynaptic input spike train that a synapse can transfer through its *K* release sites to the post-synaptic neuron (Fig. 1B). When the number of release sites increases, the intermittent unresponsiveness of one release site is compensated by the other sites, and synaptic information transmission is facilitated. However, increasing the number of release sites augments the chance of spontaneous release as well and degrades the information transfer of the synapse. Our analysis determines the optimal number of release sites for each synapse, using the initial evoked and spontaneous release probabilities, recovery time constant and input spike rate of the synapse.

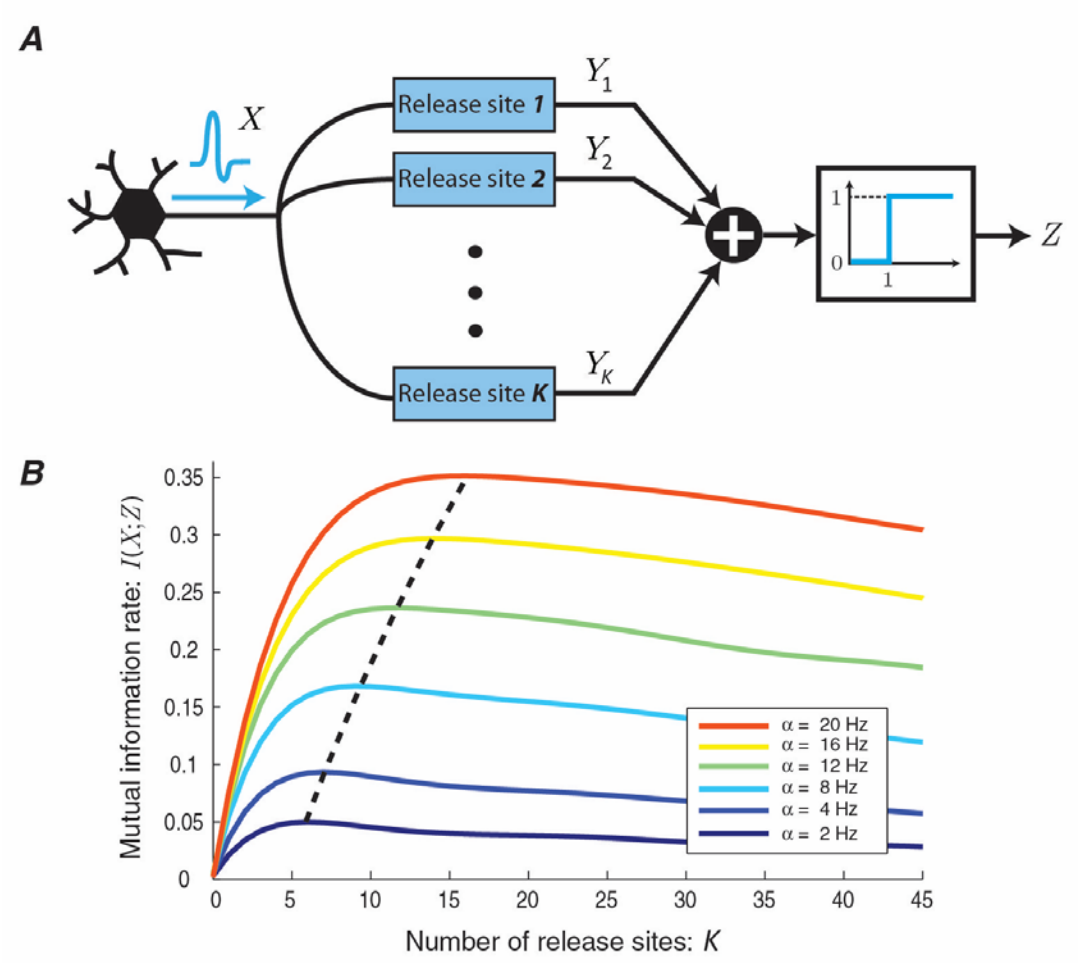

Figure1: A) Information transmission through multiple release sites of one synapse. B) Mutual information rate between the input spike train and the effective release process against the number of release sites, for different input spike rates, α. The dashed black line connects the maximum values.

**Title:** Dopaminergic effects on optogenetically activated inputs on subcortical and commissural projecting layer V medial prefrontal pyramidal neurons

**Authors: J. M. LEYRER**[1], *M. P. THOMAS[2]
[1]Univ. Of Northern Colorado, Greeley, CO; [2]Biol. Sci., Univ. of Northern Colorado, Greeley, CO

**Abstract:** The prefrontal cortex renders humans the capability of flexible behavior and mediates working memory tasks. Functionally these regions are homologous to the medial prefrontal cortex (mPFC) in the rodent. The mPFC is known to be targeted by various brain regions, including the contralateral mPFC, the amygdala, the hippocampus and the thalamus, which carry information essential for working memory tasks. However, it remains relatively unknown how information from these inputs is integrated by layer V pyramidal neurons, the major cortical output cells. Additionally, it is well established that optimal levels of dopamine within the prefrontal cortex are required for proper working memory function. In this study, we have characterized the excitatory synaptic responses of contralateral mPFC inputs onto type I (pontine projecting) and type II (commissural projecting) layer V pyramidal cells. Additionally, we identified the effects of dopamine, through both D1 receptor and D2 receptor activation, on these responses. To study isolated inputs, an optogenetic approach, using channelrhodopsin-2, was used to specifically activate commissural inputs targeting the mPFC. Using whole cell patch clamp recordings, synaptic responses were recorded from both type I and type II pyramidal cells identified with green retrobeads based on their projection patterns. A blue LED was used to elicit synaptic responses of commissural fibers expressing channelrhodopsin-2 and mCherry. Initial experiments suggest that contralateral connections onto type I cells always produce facilitating EPSPs. Additionally, D1 receptor activation increases the amplitude of EPSPs, enhances facilitation and increases the rise time and decay time of EPSPs. These results suggest that D1 receptor activation may promote persistent activity within type I cells, facilitating working memory tasks mediated by the mPFC. These experiments may lend insight into how layer V pyramidal cells integrate convergent synaptic inputs, as well as how dopamine may modulate synaptic functions that may contribute to working memory.

**Abstract:** Since Hubel and Wiesel (1963) the effects of sensory deprivation in a developing CNS has been a focus in determining critical periods and the effects on neural circuitry. The ability to temporarily enhance or depress electrical activity in sensory neurons at various stages in development provides cues in understanding the plasticity of the nervous system. Temporarily altering activity of presynaptic neurons can have effects on morphology and function of target cells subsequent to the experimental manipulations. Thus, altered neural circuits may manifest themselves in asymptomatic behaviors to standard sensory cues. We are addressing these topics in the larval Drosophila model over embryonic and larval development. In using genetic approaches, we are controlling activity in sensory systems and examining eating and locomotive behaviors as well as tactile sensory assays. In addressing the effects on neural architecture to correlate with the neural activity conditioning paradigms, sensory endings as well as projections into the CNS are being investigated. We will report on the behavioral responses to tactile stimuli throughout larval develop during various experimental manipulations. We also investigating how a previously deprived neural circuit can regain the ability for normal behavior, anatomical structure and function, providing a novel understanding of the understanding synaptic plasticity within defined neural circuits.This relates to various disease states as well as to exomedicine in the terms of development within weightless of space and as well as re-exposure to gravity.

**Title:** Rebound effect: a late onset replenishment mechanism at a fast auditory synapse

**Authors: *E. G. KRÄCHAN**, T. SCHMITT, M. FUHR, I. RÖMER, V. AUGUSTIN, E. FRIAUF
Biol., TU Kaiserslautern, Kaiserslautern, Germany

**Abstract:** Sound source localization in the mammalian auditory brainstem is achieved by processing interaural time and level differences (ILD). Synapses involved in these tasks are capable of transmitting signals in a precise and reliable manner, even during sustained high-frequency activity. They are equipped with several morphological and molecular features, e.g. inner hair cell ribbon synapses and endbulbs and calyces of Held. The lateral superior olive (LSO) is in the center of the ILD pathway and integrates excitatory signals from the ipsilateral path and inhibitory signals from the contralateral path. Although LSO inputs lack any morphological specifications, they process binaural signals in the millisecond range over sustained periods of time. Here, we assessed the synaptic response characteristics of both inhibitory, glycinergic and excitatory, glutamatergic LSO inputs to continuous (60 s) high-frequency activity (50-200 Hz). In comparison, we inserted 200 ms gaps of silence, a more physiological pattern. We performed whole-cell voltage clamp recordings at LSO neurons of juvenile (P10) and young adult (P35) mice while electrically stimulating excitatory glutamatergic inputs from the cochlear nucleus or inhibitory inputs from the medial nucleus of the trapezoid body (MNTB-LSO). Postsynaptic currents of both LSO inputs showed a frequency-dependent depression. Gaps reduced synaptic depression via replenishment of synaptic vesicles within gaps. As readout of the within-gap replenishment, we analyzed the first ePSC of each burst ($ePSC_1$) and found an unexpected increase of amplitudes after initial short-term depression (STD), which we call rebound effect. The rebound effect was present only at MNTB-LSO synapses and at frequencies >50 Hz. $ePSC_1$ amplitudes increased gradually while the subsequent ePSPCs became reciprocally smaller. The rebound began very late (~20 s), reaching a maximum that was ~25 % higher than the maximal STD levels earlier in the stimulation train. The rebound effect occurred throughout the period analyzed. It is of presynaptic origin because the quantal size was constant during the 60-s trains, which excludes postsynaptic receptor desensitization and saturation. The rebound effect strongly depended on $[Ca^{2+}]_i$ as evidenced by a shift in the onset time after lowering $[Ca^{2+}]_o$ and a strong temporal correlation with asynchronous release. The $Ca^{2+}$ buffer EGTA completely inhibited the rebound. Taken together, we found a novel replenishment mechanism, the rebound effect, at inhibitory MNTB-LSO synapses. It converts tonic responses to onset responses and may thus enable efficient computation of repetitively offered tone bursts.

**Abstract:** Mitochondrial complex I dysfunction is linked to volatile anesthetic sensitivity in nematodes, mice and children. Mice with loss of a mitochondrial complex I subunit, NDUFS4, are very hypersensitive to volatile anesthetics (VAs). Limiting NDUFS4 loss to a subset of glutamatergic neurons recapitulated the total knock-out (KO) VA hypersensitivity phenotype. Exposure to 245 µM isoflurane, which anesthetizes KOs but not controls, selectively depressed spontaneous excitatory neurotransmission in KO CA1 neurons. Here we investigated excitatory neurotransmission under conditions of high energetic demand caused by high frequency stimulation (HFS). Evoked field excitatory postsynaptic potentials (fEPSPs) were recorded from CA1 of coronal mouse brain slices. Fibers were stimulated every 30s for baseline activity and for 60min following HFS (3 trains, 100Hz, 20s between trains). In some experiments isoflurane-containing solution was superfused for 40min prior to HFS, and for the duration of the experiment. HFS-induced potentiation in KO slices within 2min post-HFS was ~120%, while control slices showed potentiation to ~160%. By 10min post-HFS, KO and control slopes of fEPSPs displayed very similar potentiation, of ~150%, which gradually decreased to ~120% at 60min. There were no differences between KO and control in the fEPSPs during HFS in the absence of isoflurane. 245 µM isoflurane exposure initially decreased slopes of fEPSPs in the KO to 40% of baseline, gradually increasing to match potentiation in control slices of about 120% over 20min. In 245 µM isoflurane the KO slices displayed much lower slopes in the first 50msec in the second and third train of HFS. 245 µM isoflurane corresponds to ~1.5 isoflurane $EC_{50}$ for the KO. We tested 1.5 isoflurane $EC_{50}$ (735 µM) in controls. Isoflurane reduced fEPSPs to ~25% of baseline at 30s post-HFS, recovering to ~80% by 15min, without further changes.

Application of an $A_1$ adenosine receptor selective antagonist partially eliminated short-term depression in control and KO slices at isoflurane concentrations corresponding to 1.5 times their respective anesthetizing concentrations. Under energetically demanding conditions, isoflurane markedly inhibited the ability of a mitochondrial mutant to recover excitatory synaptic transmission. Depression of mitochondrial function by isoflurane may limit effective neurotransmission in key circuits responsible for responses to VAs in both controls and mitochondrial mutants. Our data are consistent with VAs acting directly within mitochondria to inhibit energy production and depress excitatory transmission, most likely via inhibition of synaptic vesicle recycling.

**Abstract:** Neurons encode information in the number and frequency of action potentials they discharge. Presynaptic terminals are key elements involved in the translation of electrical signals to neurotransmitter release. However, how presynaptic terminals decode the frequency and the number of action potentials in incoming bursts through specialized calcium dynamics remains generally unknown.
To investigate how presynaptic terminals translate bursts of action potentials to generate neurotransmitter release, we combined electrophysiological measurements and high resolution presynaptic calcium imaging together with experimentally-constrained modelling of presynaptic calcium dynamics and neurotransmitter release.

We found that action potential transmission from giant mossy fiber terminals to CA3 pyramidal cells was dependent on the number of action potential in the burst, but was independent of the action potential burst average frequency. Consequently, mossy fiber terminals count the number of action potentials in bursts. This information transfer strategy relied on the amount of glutamate released from the presynaptic terminal. These experimental results could be replicated using an experimentally-constrained model of neurotransmitter release, which further revealed that action potential counting can be explained by a unique combination of structural and functional properties of mossy fibre boutons including (i) loose coupling between synaptic vesicles and voltage gated calcium channels, (ii) combined action of fast (calmodulin) and slow (calbindinD28K) endogenous calcium buffers, (iii) slow calcium removal rates and (iv) faster vesicle depletion and higher frequencies. Presynaptic calcium imaging revealed a linear summation of calcium transients during trains of action potentials at 20 Hz and 100 Hz. Our experimental and modelling results indicate that whilst synchronous glutamate release correlates with the peak calcium amplitude within local calcium microdomain at the active zone, asynchronous release depends on the global level of residual calcium in the presynaptic terminal as measured using two-photon calcium imaging.
Thus, our results argue that giant mossy fiber terminals favor a counting logic over rate or temporal coding. Such action potential counting occurs through a unique interplay between short-term facilitation through endogenous calcium buffer saturation and active replenishment of release ready vesicles.

**Title:** Voltage-sensitive dye imaging study of the input-dependent GABAergic control of the paired burst facilitation (PBF) in area CA1 of the hippocampus

**Authors: *T. TOMINAGA**, Y. TOMINAGA
Inst. of Neuroscience, Tokushima Bunri Univ., Sanuki, KAGAWA, Japan

**Abstract:** The hippocampal system uses several types of oscillatory activities. Input-specific control of the neural activities with such oscillations must make these activities meaningful in the brain. A theta burst stimulation (TBS, a train of brief 100 Hz burst stimulations repeated in 5-7 Hz) that mimics theta oscillation in the rodent hippocampal system is known to induce long-term potentiation (LTP) at area CA1 Schaffer(Sch)-pyramidale synapses. We reported that the TBS caused exaggerated action potential firing during the sequence even in the form of the pair of the brief burst stimulation [PBS; a 100 Hz burst stimulation consists of four stimuli with a 10 ms interval (a priming burst) that precedes a 170 ms interburst interval in the same 100 Hz burst stimulation (a test burst)]. A PBS applied to the Sch induced a facilitated response upon a test burst (a paired burst facilitation; PBF). The PBF can be characterized as follows: the PBF is the membrane potential events in the membrane current. The PBF accompanied the action potentiation of the E-S (EPSP-spike firing) coupling without accompanying an increase of the excitability of the postsynaptic cells while their excitability did not show any increase. Application of Gabazine (SR-95531; GABA-A receptor antagonist) abolished the short-term plastic change of the CA1 circuit caused by PBS. Hence, we hypothesized that PBF has short-term plasticity depending on the neural circuit composed of the principal neuron and interneuron(s). In the CA1 neural circuit, the GABA-A receptor acts either as a feedforward and feedback inhibition. We found that the feedforward inhibition controls the action potential firing of CA1 pyramidal cells. Since the PBF was apparent in the sub-threshold (no action potential) stimulation, we thought that the feedforward inhibition should control the PBF. To examine this possibility, we divided Schaffer collateral fibers into two groups with micro-surgery and applied stimulation into these two separate input pathways. We examined if the burst stimulation to one pathway could induce PBF in the other pathway. The PBF appeared when we delivered a burst stimulation into the same pathway. The PBF may act to control the input pathway's specific amplification for particular oscillatory activity through the network driven neural mechanisms.

**Abstract:** Activity-dependent structural and functional modulation of the synapse are tightly correlated and play an essential role in synaptic plasticity and learning/memory. Postsynaptic cAMP and GMP signaling are crucial for synaptic function, however, the role of cAMP/cGMP in structural change of the synapse remains elusive. Here, we report the role of cAMP/cGMP in bidirectional structural plasticity through interaction with their signal pathways, as well as its role in functional plasticity and related learning/memory.
Strong synaptic activation induces synapse structural enlargement called structural long-term potentiation (sLTP), reorganizing synaptic function through structural change. Using a two-photon optogenetic approach to non-invasively activate light-sensitive adenylyl cyclases at target dendritic spines in the rodent hippocampal CA1 pyramidal neurons, we showed a rapid mechanism of postsynaptic cAMP that enhances sLTP. The cAMP/PKA signal was necessary within 1 min of sLTP induction, independent of cAMP-mediated protein synthesis, and coupled with CaMKIIβ activity which controls the actin cytoskeleton in the spine structure.
In contrast, postsynaptic cGMP was involved in the depotentiation mechanism of cAMP-dependent sLTP. Pharmacological inhibition of cGMP/PKG pathway blocked the depotentiation of cAMP-dependent sLTP, suggesting a crucial inhibitory role of cGMP in cAMP-dependent sLTP. Furthermore, we found postsynaptic cGMP production using a light-sensitive guanylyl cyclase was sufficient to block the cAMP effect of structural potentiation, but not induction of sLTP. These results suggest a bidirectional regulation mechanism of structural potentiation of dendritic spines by postsynaptic cAMP and cGMP signaling pathways.
We have shown that an activity-dependent interaction of CaMKIIβ with actin is critical for controlling not only structural potentiation, but also functional LTP, which implies a tight regulation mechanism between structural and functional plasticity. By establishing the optogenetic manipulation of cAMP/cGMP at target hippocampal neurons in the living mouse brain, we will discuss novel interactive roles of cAMP/cGMP in the hippocampal synaptic potentiation and the related learning/memory.

**Title:** Effects of adenosine on parameters of short-term plasticity in mouse anterior piriform cortex

**Authors: *L. G. NOWAK**[1], S. PERRIER[2], M. GLEIZES[2], C. FONTA[2]
[1]Cerco Lab. - UMR 5549, TOULOUSE, France; [2]Brain and Cognition center, CNRS, Toulouse, France

**Abstract:** Neuronal activity in the brain is characterized by a diversity of oscillatory phenomena, some associated with the sleep/waking cycle and others with diverse behavioral and cognitive processes. Single-unit activity is often linked to the oscillatory activity recorded in the Local Field Potential. The first aim of our study was to determine whether and how different oscillatory activities affect short-term plasticity. For this purpose we used the olfactory system as a model. Indeed, during odorant stimulation, the olfactory bulb displays prominent beta and gamma oscillations. Furthermore, studies showed that the firing of mitral and tufted cells, which project to the anterior piriform cortex, is phase-locked with both beta and gamma oscillations. We examined short-term plasticity in slices of adult mouse piriform cortex maintained *in vitro* in an *in vivo*-like ACSF. In our *in vitro* study, we replaced the presynaptic neuronal firing rate by controlled and repeated electrical stimulation (trains consisting in 5 pulses, frequency between 3.125 and 100 Hz) applied to the lateral olfactory tract. Postsynaptic responses were recorded in layer 1a of the piriform cortex. Our results revealed a considerable enhancement of postsynaptic response amplitude for stimulation frequencies in the beta and gamma range. The data were fit with a phenomenological model of short-term plasticity adapted from that of Tsodyks et al. (1997). The parameters of the model indicate that the observed results can be explained by the interplay between a short-term facilitation mechanism (time constant 160 msec) and two short-term depression mechanisms, with fast (less than 20 msec on average) and slow (140 msec) recovery time constants. The second aim of our study was to examine the effect of adenosine on short-term plasticity. Indeed, at the cortical level adenosine plays a prominent role in synaptic transmission as a presynaptic inhibitory neuromodulator. In the presence of adenosine (10-1000 µM), response amplitude decreased while short-term plasticity became more dominated by facilitation. Hence facilitation compensated for decreased response amplitude in a frequency dependent manner: compensation was strongest at high frequency, up to restoring response amplitude to that measured in control conditions. The model suggested that the principal effect of adenosine was to decrease initial release probability; increased facilitation hereby ensued due to increased available resources. Altogether these results suggest that adenosine acts as a high-pass filter.

**Abstract:** Brief and sustained neuronal activity patterns can have opposite effects on synaptic strength that both require activity-regulated gene (ARG) expression. However, whether distinct patterns of activity induce different sets of ARGs is unknown. In genome-scale experiments, we reveal that a neuron's activity-pattern history can be predicted from the ARGs it expresses. Surprisingly, brief activity selectively induces a small subset of the ARG program that that corresponds precisely to the first of three temporal waves of genes induced by sustained activity. These first-wave genes are distinguished by an open chromatin state, proximity to rapidly activated enhancers, and a requirement for MAPK/ERK signaling for their induction. MAPK/ERK mediates rapid RNA polymerase recruitment to promoters, as well as enhancer RNA induction but not histone acetylation at enhancers. Thus, the same mechanisms that establish the multi-wave temporal structure of ARG induction also enable different sets of genes to be induced by distinct activity patterns.

**Abstract:** Empirical evidence from deep brain stimulation studies has shown that a variety of different parameters, including stimulation frequency and pattern influence the efficacy of the procedure. However, there is little information available regarding the long-term downstream changes evoked by such stimulation including changes in gene expression. We asked whether the temporal pattern of synaptic conditioning influences the expression of specific genes.
Acute occipital cortical slices were prepared from 10-12 week old rats, slices were cut at 300 μm and bathed in aCSF (124 NaCl, 2 KCl, 0.2 $CaCl_2$, 3.5 $MgCl_2$, 26 $NaHCO_3$, 10 D-glucose, and saturated with a 95% $O_2$-5% $CO_2$). Slices were perfused in a chamber with aCSF at 32-35 C°. A stimulating rake-electrode was positioned in the fourth layer of the primary visual cortex with a field potential (FP) recording electrode placed in layer 2/3. The slices were treated with one of four conditions: a 15 minute discontinuous (groups of stimuli separated by equal rest periods) conditioning train at 10 Hz with regular inter-stimulus intervals, a 15 minute discontinuous conditioning train at 10 Hz with stimuli having a highly irregular distribution of interstimulus intervals (Poisson distributed), a 15 minute continuous conditioning train at 100 Hz with regular inter stimulus intervals, or no stimulation (control). In all conditions, there was a 15-minute pre and post-conditioning period with stimulation at 0.1 Hz to evoke FPs. Each group was divided according to plasticity outcome (LTP -Long Term Potentiation, LTD -Long Term Depression or no change).Three hours after the conditioning, layer 2/3 above the stimulation electrode was dissected in aCSF. RNA was extracted using Bio-Rad Aurum Total RNA kit**.** Samples were processed with RNAseq. Sequences were aligned via Tophat2 and counted via HTSeq. mRNA differential expressions were tested for significance using the Benjamini-Hochberg corrected Wald Test in DESeq2. The main effect of stimulation pattern was found between the control (no stimulation) group and the group that experienced 100 Hz regular conditioning where LTD was induced by the conditioning. In those cases, six genes had significant differential expression. Fbxw7 was upregulated by 1.35 fold, Ddx10 was upregulated by 1.41 fold, Mkx was upregulated by 1.49 fold, Cass4 was upregulated by 1.51 fold, Nyap2 was upregulated by 1.50 fold, Adamsts12 was down regulated by 0.63 fold, and Fbn2 was upregulated by 1.49 fold in the 100 Hz regular LTD vs. control group. No other significant differences were found between any of the other groups. These results are considered in the context of these genes and long term synaptic plasticity.

**Title:** Compulsive methamphetamine taking under punishment increases the expression of AP1 family of transcription factors in the rat nucleus accumbens

**Authors: *M. T. MCCOY**, B. LADENHEIM, L. CONTU, M. O. JOB, B. CAMPBELL, C. A. BLACKWOOD, S. JAYANTHI, J. CADET
Mol. Neuropsychiatry Res. Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

**Abstract:** Methamphetamine is an illicit psychostimulant that is abused worldwide. Its continuous use is accompanied by many medical, neurological, and psychiatric complications. So far, however, there is no pharmacological treatment that has proven to be beneficial to this patient population. This lack of comprehensive pharmacological approaches may be related to the insufficient understanding of cellular and molecular mechanisms of methamphetamine addiction. As a first step towards identifying the molecular bases of compulsive methamphetamine taking, our laboratory has started to use footshocks as adverse consequences during methamphetamine self-administration (SA) because the definition of addiction includes the presence of negative outcomes. We use that model to measure potential changes in the expression of immediate early genes (IEGs) in the nucleus accumbens of rats during early withdrawal times from methamphetamine SA. Male Sprague-Dawley rats were trained to self-administer METH (0.1 mg/kg/injection, i.v.) or saline during twenty-one (9-hr daily access) sessions. After that time, foot-shocks were administered in increasing intensity over a period of eight sessions. We included additional control groups that were yoked for non-contingent footshocks to the rats that received methamphetamine and contingent foot-shocks. Foot-shocks caused the separation into two distinct methamphetamine SA groups: (1) shock-resistant (SR) rats that continued to press the lever for methamphetamine despite punishment and (2) shock-sensitive (SS) rats that significantly reduced their lever pressing. The rats were euthanized 2h after the last session. We then extracted RNA from the NAc, made cDNA, and ran quantitative polymerase chain reaction (PCR) to measure the expression of several IEGs including cfos, fosB, Fra1, and Fra2. We also measure the expression of cjun, junB, and junD mRNAs. SR rats showed significant increases in cfos, fosB, Fra2, and junB mRNA levels in the nucleus accumbens. Animals yoked to the SR rats showed no changes in the expression of these IEGs, indicating that these effects are specific to compulsive methamphetamine taking. These observations indicate that compulsive methamphetamine taking may be initiated activation of complex downstream targets of these IEGs. This model of self-administration associated with adverse consequences may provide greater insight into the neurobiology of methamphetamine addiction.

**Abstract:** Long-term potentiation (LTP) and long-term depression (LTD) are cellular events widely believed to underlie learning and memory. Regulation of the AMPA-type ionotropic glutamate receptor (AMPAR) levels at the synapse is crucial to postsynaptic forms of LTP and LTD of excitatory transmission. Several factors, including neurotrophins, modulate exo- and endocytosis of synaptic AMPARs, and also participate in the regulation of their gene expression. We have previously reported that the neurotrophin BDNF is a target gene of the nuclear receptor related protein 1, Nurr1, an orphan nuclear transcription factor. However, the potential role of Nurr1 on AMPAR-mediated synaptic function remains unknown. In this study, we tested whether Nurr1 transcriptional activity participates in the activity-dependent modulation of AMPARs in cultured hippocampal neurons and acute hippocampal slices. We found that Nurr1 expression is low in basal conditions, but it increases upon synaptic stimulation in mature hippocampal neurons. This increase is dependent on calcium entry through ionotropic glutamate receptors and requires the activation of the CREB-CRTC1 signaling pathway and calcineurin. In addition, Nurr1 agonists increased both BDNF and the GluA1 subunit levels in cultures, and

partially blocked LTD at CA3-CA1 synapses in hippocampal slices, suggesting that Nurr1 is involved in the activity-dependent modulation of BDNF and AMPAR-GluA1 subunit. Together, our findings indicate that Nurr1 could play a role in AMPAR plasticity associated to learning and memory events.

**Abstract:** Oxytocin (OXT) is a neuropeptide critical for regulation of social behaviors. Brain-derived neurotrophic factor (BDNF) and its receptor TrkB are highly expressed in the paraventricular hypothalamus, a key site of neuroendocrine cells secreting OXT. Transcription of *Bdnf* is controlled by several promoters, which drive expression of multiple transcripts encoding an identical protein. *Bdnf* promoter I significantly contributes to BDNF production in the hypothalamus. Female mice with selective disruption of promoter I-derived BDNF (Bdnf-e1 -/-) show impaired maternal care, reduced *Oxt* transcripts, and enhanced aggression towards foreign pups. To better understand the role of BDNF signaling in OXT neuron function, we used TRAP (translating ribosome affinity purification) and RNA sequencing (RNAseq) to examine cell-type-specific gene expression in OXT neurons from wild-type and Bdnf-e1-/- females. First, to validate our technique and identify transcripts enriched in OXT neurons, we crossed mice expressing Cre recombinase under control of the endogenous *Oxt* promoter to the RiboTag

mouse, which expresses a hemagglutinin (HA) tag on the ribosomal protein RPL22 under control of Cre. Ribosome-associated mRNAs were affinity purified with a HA antibody and characterized using high-throughput RNAseq analysis. To elucidate changes in OXT gene expression following perturbations in BDNF signaling, we used an adeno-associated viral (AAV) Ribotag approach to isolate and sequence ribosome-associated transcripts in OXT neurons from control and Bdnf-e1 -/- females with impaired maternal care. Here we report genes and gene pathways highly enriched in OXT neurons and provide a molecular profile defining the OXT neuron transcriptome. We also identify transcripts vulnerable to misregulation in OXT neurons following loss of hypothalamic BDNF signaling. These results demonstrate the molecular dissection of a sexually dimorphic hypothalamic population that governs complex social behaviors. Our findings also identify BDNF-dependent signaling pathways in OXT neurons that can be targeted to modulate social function.

**Title:** Induction of BDNF by Electroconvulsive stimulation requires the immediate early gene early growth response 3 (Egr3)

**Authors: *K. MEYERS**[1], K. K. MARBALLI[2], J. M. CAMPBELL[1], A. L. GALLITANO[3]
[2]Basic Med. Sci., [1]Univ. of Arizona - Col. of Med., Phoenix, AZ; [3]Basic Med. Sci., Univ. of Arizona, Phoenix, AZ

**Abstract:** Electroconvulsive therapy (ECT) is one of the most effective treatments for severe psychotic and mood disorders. ECT is rapid and safe, and is used as a first-line treatment for medication resistant illnesses such as psychotic depression. However, the mechanisms underlying the therapeutic efficacy of ECT remain unknown. One candidate for an important role in ECT is brain derived neurotrophic factor (BDNF), which is activated by electroconvulsive seizure (ECS). Disruption of hippocampal BDNF attenuates the effect of antidepressants, and infusion of BDNF into the hippocampus reverses depression-like behavior in rodents. But the mechanism by which neuronal activity regulates *Bdnf* expression is unclear. We hypothesized that immediate early genes, which are rapidly activated at high levels in the brain in response to ECS, may regulate neurotrophic factors, including *Bdnf*. To test this hypothesis, we conducted an

expression microarray on RNA isolated from hippocampal tissue from wildtype and *Egr3* deficient (*Egr3*-/-) male mice one hour post ECS (versus no-ECS, baseline control). Experimental results identified *Bdnf* as one of 63 differentially expressed genes in WT compared with *Egr3*-/- mice following ECS. This result was validated by quantitative RT-PCR in the RNAs used for the microarray, as well as in two independent cohorts of female *Egr3*-/- and matched WT littermate mice. *In situ* hybridization showed that ECS induced high level expression of *Bdnf* mRNA in the hippocampal dentate gyrus of WT mice one hour post ECS, with cellular distribution in the Cornu Ammonis 3 region (CA3). In contrast, no increase in *Bdnf* expression was seen in *Egr3*-/- mice. These findings support the hypothesis that *Egr3* may be required for activation, or maintenance, of *Bdnf* expression in the hippocampus in response to acute ECS. These findings suggest that the immediate early gene transcription factor *Egr3* may play an essential role in translating neuronal activity into the molecular changes that underlie the therapeutic effect of ECT.

**Abstract:** Early growth response (Egr) immediate early gene (IEG) transcription factors are crucial regulators of synaptic plasticity and are critical for memory formation. Egr family members *EGR1* and *EGR3* are associated with risk for psychiatric illnesses, including schizophrenia, and are reduced in the brains of these patients. Psychiatric disorders are accompanied by cognitive and memory deficits. In addition, brain tissue from psychiatric disorder patients show high levels of DNA damage. Recent studies have found that DNA damage induced by normal physiologic activity induces expression of IEGs such as *Egr1* in

neurons. These studies suggest that DNA double strand breaks, a form of DNA damage may serve as an “on” switch for activation of IEGs which, in turn, regulate synaptic plasticity and memory formation. However, for IEGs to be ready to respond to a subsequent stimulus, this damage must be repaired. Here we report that *Egr3* regulates genes involved in DNA repair in response to neuronal activity. In order to identify novel gene targets of EGR3 in the hippocampus, we carried out global gene expression studies using a microarray in both wild type (WT) and *Egr3-/-* male mice using a model of *Egr3* induction namely electroconvulsive seizure (ECS). Briefly male mice received no ECS/ ECS (n = 4 per group) followed by hippocampal RNA extraction and global gene expression analyses carried out using Illumina WG-6 microarray. Gene pattern and Genome studio programs were used for identifying differentially expressed genes (DEGs). Validation of candidate genes was carried out using quantitative real time PCR in both the original male cohort and an independent female cohort (n = 4-5 per group). 64 common genes identified in both programs were used for biological and functional analysis using Ingenuity pathway analysis (IPA). GADD45B (growth arrest and DNA-damage-inducible 45 beta) signaling (p = 2.04 E-05) was revealed as the top pathway in WT mice vs. *Egr3-/-* 1 hour post-ECS. A literature survey revealed at least 13 genes from the differentially expressed gene list to be involved in DNA damage response. We successfully validated 7 of these genes in the original male cohort and 3 genes in both the original male and an independent female cohort. Based on these results we hypothesize that *Egr3* regulates genes that repair or “turn off” the DNA damage “switch” that activates IEGs. Dysfunction in *Egr3* may thereby result in an accumulation of DNA damage contributing to cognitive and neurobehavioral deficits.

**Title:** Genomic identity and plasticity of cAMP-dependent genes in *Aplysia* californica

**Authors: *C. BOSTWICK**, T. P. MOROZ, A. B. KOHN, L. L. MOROZ
Neurosci., Univ. of Florida Whitney Lab. for Marine Biosci., Saint Augustine, FL

**Abstract:** The second-messenger intracellular signaling molecule cyclic adenosine monophosphate (cAMP) orchestrates a myriad of cellular processes, including long-term synaptic plasticity and memory, through its effects on the cAMP-dependent protein kinase (PKA). Several proteins and molecules involved in the initial cAMP-dependent signaling cascade have been elucidated, but less is known of the molecules “downstream” of the signaling cascade, particularly those that are recruited and activated several hours after signaling initiation. In order to gain a more comprehensive understanding of the cAMP/PKA molecular pathway, we utilized next-generation high-throughput sequencing to query the nervous cells of a classic neuroscience model, the sea hare *Aplysia californica.* We divided the Aplysia central nervous system (CNS) into individual ganglia and treated those ganglia with a cAMP-derivative (8-bromo-cAMP) for various lengths of time to activate the cellular cAMP/PKA signaling pathway. This allowed us to identify cAMP/PKA-dependent genes that are differentially expressed between the various ganglia subtypes of the Aplysia CNS as well as differential expression of cAMP/PKA-dependent genes in the same ganglia over the course of 8-bromo-cAMP treatment. We discovered hundreds of differentially expressed transcripts. These transcripts encode chromatin-remodeling enzymes, ion channels, cellular receptors, transcription factors, and regulatory kinases or phosphatases, among others. Some of the differentially expressed transcripts are “uncharacterized”, meaning their function or cellular role is currently unknown, and potentially unique to Aplysia. Among the incredible assortment of roles these uncharacterized transcripts may play are the regulation of gene expression, facilitation of protein-protein interactions, involvement in novel cell signaling, or the modification of cellular RNA after transcription. In addition to uncharacterized transcripts, we identified differentially expressed neuronal-specific long noncoding RNAs (lncRNA) that may potentially mediate previously unidentified regulatory roles within the nervous system. This comprehensive study of the genetic identity of molecules and cellular processes involved in the cAMP-dependent signaling cascade over time and across the Aplysia CNS can provide a foundation to understanding the dynamics of this crucial and ubiquitous cellular signaling pathway and its effects on long-term synaptic plasticity and memory.

**Title:** CoREST expression in the pilocarpine-induced status epilepticus in mice

**Authors: *M. E. ANDRES**[1], C. A. RIVERA[2], V. NOCHES[2]
[1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [2]Pontificia Univ. Catolica de Chile, Santiago, Chile

**Abstract:** CoREST (CoREST1, rcor1) is member of a family of transcriptional corepressors that also comprise CoREST2 (rcor2) and CoREST3 (rcor3). CoRESTs form complexes (LCH) with the histone demethylase LSD1 and deacetylases HDAC1 and HDAC2 to epigenetically modify chromatin packaging. Previously, we have shown that LCH complexes formed by the different CoREST display differential capabilities. Indeed, CoREST2 have less repression capacity and lower interaction with HDAC1/2, suggesting that CoREST2-containing LCH complexes play different functional role than CoREST1-containing LCH complexes. Several lines of evidence show that the expression of proteins forming LCH complexes is regulated by neuronal hyperexcitability. For instance, HDAC2 increases during temporal lobe epilepsy and the expression of the neuronal splice variant of LSD1 increases in the hippocampus of mice with pilocarpine-induced seizures. Since CoRESTs are platform proteins bringing HDAC1/2 and LSD1 to chromatin, we hypothesized that their expression is also regulated during hyperexcitability. To this end, we treated mice with the muscarinic cholinergic agonist pilocarpine to induce seizures in the temporal lobe of the brain. Using this model, we replicated previous data showing that the ratio between neuroLSD1 and LSD1 increases while total protein levels do not change in the hippocampus after 24 hours of seizure. Under the same conditions, CoREST1 and CoREST2 mRNA expression and proteins levels are modified in the mice hippocampus. The data were also replicated in hippocampal neurons in culture and hippocampal cell lines treated with pilocarpine. Altogether, the data indicate that CoREST1 and CoREST2 expression is regulated by hyperexcitability.

**Title:** Dynamic recruitment of CoREST proteins to neuronal chromatin

**Authors: *C. A. RIVERA**[1], V. NOCHES[2], M. E. ANDRES[3]
[1]Pontificia Univ. Católica De Chile, Santiago, Chile; [2]Biologia Celular y Mol., Pontificia Univ. Católica de Chile, santiago, Chile; [3]Biologia Celular y Mol., Pontificia Univ. Catolica De Chile, Santiago, Chile

**Abstract:** CoREST1, 2 and 3 proteins belong to a transcriptional co-repressor family that regulates neuronal gene expression in non-neuronal tissues and neural progenitors. These proteins recruit the chromatin modifying enzymes, histone demethylase LSD1 and histone deacetylases HDAC1 and HDAC2 forming the biochemically stable protein complex LCH. The best-characterized protein of this family is CoREST1, which can be recruited to chromatin by binding transcription factors or directly to the nucleosome, where the enzymatic activities of LSD1 and HDAC1/2 are required to repress gene transcription. Previous work of our laboratory has shown that the transcriptional repressor capacity of CoREST proteins is different. In addition, it has been shown that LCH subunits can be post-translationally modified disrupting the complex integrity. Together, these data support the hypothesis that the composition of the complex is post-translationally regulated. In this work, we use biochemical techniques to show that chromatin association of different subunits of the LCH complex is dynamic and can be altered in animal and cellular models of pharmacologically induced neuron hyperexcitability. In basal conditions, we observed that CoREST1 and CoREST2 are distributed in the subcellular fractions corresponding to insoluble chromatin, soluble cytoplasmic and nucleoplasmic fractions. However, CoREST3 is found only as soluble complexes in nucleosome-free fractions, suggesting a differential chromatin affinity for CoREST proteins. To induce hyperexcitability we treated hippocampal cell cultures with pilocarpine, a muscarinic cholinergic agonist, during 24 hrs. CoREST2, HDAC1 and HDAC2 were globally recruited to chromatin in hippocampal cells resulting in the modification of histone lysine acetylation and methylation. Our results indicate that each CoREST protein differentially affect the global chromatin state in terms of post-translational modifications of histones and DNAse accessible regions.

**Abstract:** In the mammalian central nervous system, each neuron receivers signals from other neurons synapses located on its cell body and dendrites. The numerous proteins in a cell must be in the right place at the right time to carry out their functions. In a manner unique among activity-regulated immediate early genes (IEGs), mRNA encoded by Arc (also known as Arg3.1) undergoes rapid transport to dendrites and local synaptic translation. From now on, arc mRNA is thought to be a natural target for nonsense-mediated mRNA decay (NMD) by virtue of its two conserved 3′-UTR introns. NMD and other related translation-dependent mRNA decay mechanisms may serve as critical brakes on protein expression that contribute to the fine spatial-temporal control of Arc synthesis. Here in our study, low basal level of Arc gene expression is also regulated by Upf1 in transcriptional- and translational-manner. Furthermore, sustained expression of Arc by reducing of Upf1 contributions to cofilin phosphorylation and abnormal neuronal outgrowth.

**Abstract:** Recent discoveries of reversible mRNA modifications have generated interest in the epitranscritptome. $N^6$methyladenosine ($m^6A$), the most abundant mammalian mRNA modification, affects almost every aspect of mRNA metabolism, including RNA splicing, export, localization, translation efficiency, and stability. Studies in cell lines have demonstrated that $m^6A$ plays a critical role in stem cell differentiation and cellular stress response. Much less is known about the role of $m^6A$ in postmitotic cells such as neurons. Interestingly, $m^6A$ brain levels remain low throughout mouse embryogenesis, but increase dramatically by adulthood. Polymorphisms in FTO (fat mass and obesity-associated protein), an $m^6A$ demethylase, have been linked to obesity, addiction, ADHD, and nucleus accumbens reactivity. Moreover, deletion of FTO increases $m^6A$ levels and alters dopaminergic signaling in mice, and a recent study has shown that fear conditioning can elevate $m^6A$ levels in prefrontal cortex while knockdown of FTO enhances memory consolidation. While these and other studies implicate the importance of $m^6A$ in brain function, no studies exist examining the consequences of $m^6A$ deficiency in animals. To prevent $m^6A$ deposition in neurons, we generated a floxed *Mettl14* allele ($M14^{f/f}$). *Mettl14* encodes an essential component of the $m^6A$ methyltransferase complex. Using the Meox2-cre germline deleter strain, we found that constitutive deletion of *Mettl14* is embryonically lethal. To circumvent this lethality, we crossed $M14^{f/f}$ mice with mice expressing Cre recombinase under direction of the Drd1 promoter (D1Rcre) to selectively delete METTL14 from striatonigral neurons. Striatonigral METTL14 deletion decreased striatal $m^6A$ levels, and transcriptome-wide $m^6A$ profiling and mRNA-seq revealed global changes in mRNA levels in the striatum. A distinct subset of downregulated mRNAs tended to encode neuronal or synaptic proteins, while upregulated mRNAs tended to encode proteins involved in metabolism and translational regulation. Behaviorally, METTL14 deletion in striatonigral neurons altered key functions of these neurons: responses to dopaminergic drugs and motor learning. The functional consequences of $m^6A$ deficiency in postmitotic neurons was further confirmed by viral-mediated neuron specific deletion of METTL13 in the dorsal striatum of adult mice.

**Title:** *In vivo* 2pFLIM imaging of experience dependent dynamics of CREB with cellular resolution

**Authors: *T. LAVIV**, P. PARRA-BUENO, R. YASUDA
Max Planck Florida Inst., Jupiter, FL

**Abstract:** A major quest in neuroscience is to decipher the remarkable dynamics of the structure and function of the brain during experience dependent plasticity. Previous studies using *in vitro* models such as LTP/LTD, have determined in exquisite details the molecular mechanisms of synaptic plasticity. However, very little is known regarding ongoing *in vivo* molecular dynamics in the brain , during learning. This is primarily due to lack of technical approach for monitoring protein dynamics *in vivo*. Furthermore, accumulative evidence have shown a prominent role for transcription and translation of new genes and proteins during learning and memory. However, it was not possible to directly measure the relationship between transcription/translation and neuronal activity. In order to try and bridge this gap, we have established an imaging based approach to enable *in vivo* 2-photon Fluorescence lifetime imaging (FLIM) measurements of protein activity in the mouse cerebral cortex. 2pFLIM is advantageous for chronic *in vivo* imaging since it does not depend on changes in fluorescence intensity, which are prominent during these experiments, and therefore allows chronic reliable measurement of bio-sensor activity in the brain. In order to measure molecular dynamics at the level of single cells, we have established and characterized a FLIM bio-sensor for nuclear CREB activity, a well-known transcription factor which plays a vital role in long term memory and synaptic plasticity. This system allows us to perform chronic FLIM based measurements of CREB activity levels in single cell resolution in cortical layer 2/3 cells. Using this technique we were able to demonstrate a dynamic increase in CREB activity during enriched sensory environment as well as during motor learning. Furthermore, exploiting recently identified RFPs suitable for FLIM, have now allowed us to perform dual-color FLIM using red-shifted biosensors alongside GCaMP6 calcium

sensor, which enables us to measure CREB dynamics along neuronal activity simultaneously in the same population of cells. Therefore, this approach provides direct access to real-time monitoring of protein signaling dynamics and neuronal activity *in vivo*. In the future, this experimental approach could be applied to a wide range of signaling molecules and brain regions, allowing dissection of the temporal dynamics of various signaling proteins in the living brain.

**Title:** Expression of the small G-protein Rem2 is transcriptionally regulated by CREB

**Authors: *H. L. PUHL, III**, D. J. LIPUT, M. D. AKBAR
NIH, Rockville, MD

**Abstract:** Rem2 is a member of the RGK subfamily of the RAS superfamily of small G-proteins. Rem2 has a more neuronal expression pattern compared to other RGK proteins and is expressed in a temporally controlled and very restricted distribution within the central and peripheral nervous systems. Rem2 has been shown to inhibit high voltage activated calcium channels and influence synaptogenesis and dendritic arborization. Aside from the regulation of Rem2 expression by calcium, not much is known about its transcriptional control. To investigate potential transcriptional elements involved in Rem2 expression we first identified several mouse neuroblastoma cell lines including Neuro2A, N1E-115, ND7/23 (rat/mouse fusion) and a pituitary tumor line ATT20 that endogenously express Rem2 mRNA (qPCR) and protein (Western blot). Rem2 expression was not detected in non-neuronal lines such as L cells and NIH3T3. Rem2 expressing cell lines were used in a dual luciferase assay to identify a 3.6 kb region upstream from the 5'UTR of the mouse Rem2 gene with promoter activity. Using a deletion approach, expression peaked with a 600bp fragment which included the 5'UTR, plateaued, and ceased within the 5'UTR, 93bp from the translational start site. Deletion or mutagenesis of several putative transcription factor binding sites (TFBS) for factors such as CREB (CRE), NFkB, Sp1 and ElkI did not alter luciferase expression levels. Surprisingly, cotransfection of a constitutively active CREB fusion protein (VP16-CREB) with the 600bp

promoter fragment reporter resulted in about a 5-fold increase in luciferase activity. This induction was observed in constructs with various TFBS mutations including several predicted CRE sites. Using qPCR, we found transfection of N1E-115 with VP16-CREB mRNA induced a 33-fold increase in Rem2 mRNA, while transfection of ND7/23 with a plasmid encoding VP16-CREB induced a 112-fold increase in Rem2 mRNA. Rem2 has been shown to express well in regions of the basal ganglia such as the striatum. We observed a time dependent increase in Rem2 mRNA measured by qPCR following exposure of primary striatal cultures to the adenylate cyclase activator forskolin. Furthermore, transfection of primary striatal cultures with VP16-CREB mRNA produced a dose dependent increase in Rem2 mRNA expression. Taken together these data suggest the expression of Rem2 is induced by CREB at the transcriptional level in cell lines and neurons. The inability of TFBS mutagenesis to affect this induction in cell lines suggests the CREB effect may be indirect. Finally, Rem2 expressing cell lines identified here will provide a useful tool to further study Rem2 function and expression.

**Abstract:** Neuroplasticity, a dynamic change in synaptic strength, is pivotal for learning and memory. At the cellular and molecular level, regulation of RNA transcription and *de novo* protein synthesis at synapses have been implicated in long-term synaptic plasticity. Cytoplasmic polyadenylation element-binding protein 3 (CPEB3) is a sequence-specific RNA binding protein that has been shown to regulate polyadenylation-induced mRNA stability in dendrites and thereby mediate synaptic plasticity. Previous studies have demonstrated that a single nucleotide polymorphism (SNP) in the intronic sequence of *CPEB3* is associated with human episodic

memory. Notably, the intronic sequence in which this allele of SNP is located has been identified in a self-cleaving ribozyme. However, how CPEB3 ribozyme affects mRNA expression in neurons remains unexplored. In this study, we investigated the role of CPEB3 ribozyme in regulating its mRNA expression in response to neuronal stimulation. Primary cortical neurons were stimulated by potassium chloride (KCl) or glutamate application, and gene expression of CPEB3 was examined at various time points. CPEB3 mRNA expression was up-regulated at two hours after glutamate stimulation, yet it was down-regulated at prolonged time points, which was correlated with the CPEB3 ribozyme expression. Similarly, membrane depolarization by KCl resulted in an up-regulation of CPEB3 mRNA and ribozyme expression at one hour compared with unstimulated cultures. Repeated KCl-induced depolarization led to a reduction in CPEB3 mRNA expression, whereas, ribozyme expression was elevated. Collectively, those results suggest that the self-cleaving CPEB3 ribozyme might regulate mRNA and protein expression of CPEB3 in neurons, and this activity-dependent induction might contribute to neuroplasticity.

**Abstract:** Monoamines, such as serotonin, dopamine, etc., play a critical role in neuronal plasticity, with alterations implicated in the development and treatment of numerous brain disorders. Although vesicular packaging of monoamines is essential for neurotransmission, recent data have demonstrated the additional presence of ‘reserve’ pools of extravesicular

monoamines in the nucleus of monoaminergic neurons; it has remained unclear, however, whether nuclear monoamines may play roles independent of neurotransmission. Serotonin has previously been shown to form covalent bonds with certain cytoplasmic proteins via transamidation by the tissue transglutaminase 2 (TGM2) enzyme, a process known as serotonylation. Since this modification alters the signaling properties of its substrates, we hypothesized that nuclear proteins may similarly be modified to control distinct aspects of their function.Here, we describe histone proteins-specifically histone H3 glutamine 5 (H3Q5ser)-as novel substrates for monoaminylation *in vivo* and have delineated, at least in part, the biophysical, biochemical and molecular functions of this novel modification in the context of neuronal development and transcriptional plasticity. Utilizing a unique combination of biochemical, genome-wide and neurobiological approaches, our data indicate that H3 serotonylation acts to facilitate binding of adjacent H3 methylation binding proteins (e.g., pre-initiation complex subunits, such as TAF3/TFIID), thereby promoting neuronal genic activation and the facilitation of neural differentiation. In sum, our data provide the first direct evidence that hydrophobic monoamines in brain contribute directly to neuronal gene expression via a novel, neurotransmission-independent epigenetic mechanism, phenomena that will likely have broad implications within the field of neuroscience and beyond.

**Abstract:** The field of neuroepigenetics has grown rapidly over the past few decades, recently implicating chromatin phenomena in the etiology of several psychiatric disorders including

major depressive disorder (MDD). While it has been demonstrated that dysregulation of histone posttranslational modifications (PTMs) may be involved in the deleterious transcriptional processes that promote physiological maladaptations in MDD, underlying mechanisms contributing to this disorder are not fully understood. While it is clear that aberrant serotonergic signaling in brain plays a critical role in the pathophysiology and treatment of MDD, data from our laboratory suggest potential alternative mechanisms of action for monoamines-so-called histone monoaminylations-whereby, for example, the presence of serotonin in the nucleus of dorsal raphe (DR) neurons may directly mediate transcriptional responses related to serotonergic plasticity and MDD. Our preliminary data indicate that histone serotonylation is significantly altered in chronically stressed rodents and postmortem DR tissues from MDD subjects, phenomena that appear to be reversed by antidepressant treatments. Furthermore, potentiation of such alterations in a rodent model of MDD (e.g. chronic social defeat stress) enhances susceptibility to stress, indicating a functional role for histone serotonylation in depressive-like behaviors.
It has also been shown that there is a unique critical window of plasticity related to serotonergic neuronal development and circuit formation in rodents occurring during postnatal periods. Pharmacological manipulation of serotonin via fluoxetine precipitates depressive phenotypes in adulthood. Such findings support the notion that susceptibility to depression in adults may result from early life alterations in serotonergic signaling, and possibly, histone serotonylation itself. We therefore are performing developmental profiles (both transcriptional and epigenomic, +/- early life fluoxetine exposures) of serotonergic neurons to assess if histone serotonylation may have a role in neuronal development/maturation in relation to later life stress susceptibility. Considering that antidepressant treatments are only effective for ~1/3 of individuals with MDD, it will be important to develop novel approaches that target histone PTMs in a cell-type specific manner in vivo to better understand their direct contributions to disease states for development of future pharmacological interventions. Thus, we are now developing novel intein-based chemical methodologies to synthesize specific histone PTMs in brain for functional behavioral assessments.

**Abstract:** Down syndrome (DS) is the most common genetic cause of intellectual disability worldwide resulting from triplication of chromosome 21 (HSA21) in humans. Despite much progress in understanding the genetics of DS, the genes encoded on HSA21 that directly contribute to intellectual disability, as well as their associated molecular mechanisms, remain incompletely understood. BRWD1 is an uncharacterized, brain enriched chromatin effector protein encoded within the DS critical region 2 on HSA21. BRWD1 is believed to act as a transcriptional activator via its chromatin interactions (i.e., 'reading' functions); however, its roles in the contexts of neurodevelopment and in DS have yet to be studied. We recently observed that Brwd1 expression is significantly elevated in brain of two rodent models of DS, as well as in neurons derived from human induced pluripotent stem cells from DS subjects. Numerous associated histone posttranslational modifications (PTMs), many of which we have demonstrated to directly interact with BRWD1, are also altered in their expression. We have further demonstrated that Brwd1 overexpression, similar to that observed in DS-like brain, via viral-mediated transduction of adult dorsal hippocampal neurons (CA1) in wildtype animals results in a) a blockade of immediate early gene responses during contextual conditioning, b) abnormalities in neural physiology and c) deficits in cognition (both contextual and spatial memory). It is therefore our working hypothesis that BRWD1 trisomy in DS brain results in aberrant interactions between BRWD1 and an altered epigenetic landscape, thereby contributing to deficits in transcriptional plasticity and cognition. Taken together, these studies will aid in our global understanding of essential neuroepigenetic processes associated with brain plasticity.

**Abstract:** Throughout neurodevelopment and into adulthood, precisely coordinated spatiotemporal regulation of chromatin conformations and accessibility dictates the complex transcriptional programs required for neuronal maturation and function. As highly specialized postmitotic cells, neurons exhibit remarkable plasticity in response to external signals-a characteristic largely mediated by activity-dependent gene expression. Currently the processes that dynamically modulate nucleosome structure at activity-dependent loci are not well understood. Recently however, our laboratory described a novel mechanistic role for histone turnover in this brain-specific form of transcriptional plasticity. We found that the H3.3 histone variant accumulates in neuronal chromatin with age, remaining highly dynamic over time. Critically, H3.3 deposition into nucleosomes is required for activity-dependent gene expression, synaptic connectivity and cognition, suggesting that H3.3 incorporation may be a key mechanism maintaining neuronal function at both the synaptic and circuit levels. We now extend these findings to investigate the role of chromatin accessibility and H3.3 dynamics in neuropsychiatric disease states such as MDD. We build on our recent finding that disrupting H3.3 incorporation into the nucleosome results in aberrant transcriptional plasticity and increased susceptibility to depressive-like behaviors in the Chronic Social Defeat Stress (CSDS) mouse model. Importantly, we expand on the translational implications of this work by integrating measures of nucleosome dynamics across human, non-human primate and rodent cohorts. This approach will allow us to examine both conserved and divergent chromatin regulation patterns across species, as well as to determine the contributions of histone dynamics to depression-like syndromes. To assess differential histone turnover in human postmortem tissues from depressed patients *vs.* normal controls, we employed 14C/12C bomb pulse dating of HPLC-purified H3.3 from brain tissues via accelerator mass spectrometry. To assess genome-wide nucleosomal deposition patterns and chromatin accessibility in human (MDD), monkey (Variable Foraging Demand) and rodent

(CSDS) models of depression, we use ATAC-seq (assay for transposase-accessible chromatin coupled to next generation sequencing) on FACS-isolated neurons and glia. The current study will greatly advance understanding of how chromatin structural regulation affects nucleosome dynamics and gene expression in the context of MDD, and may also identify novel mediators of depression for future therapeutics development.

**Abstract:** Monoamines are often regarded as chemical messengers that act on extracellular surface-bound receptors in brain. However, recent work has demonstrated that non-vesicular monoamines also reside within neuronal nuclei and have a neurotransmitter-independent, intracellular functions, where they are capable of being enzymatically (i.e., post-translationally) added to specific glutamine-containing proteins via transamidation by the tissue transglutaminase 2 (TGM2) enzyme. Indeed, we have established that histone H3 is a robust substrate for monoaminylation and that this process is directly involved in transcriptional regulation, cell type-specific differentiation programs, and psychiatric phenotypes. Therefore, we hypothesized that other, non-histone proteins may similarly be monoaminylated to regulate aspects of their function. In order to selectively isolate monoaminylated proteins from brain tissues, we developed a novel endogenous chemical tagging method to specifically immunoprecipitate (IP) dopaminylated/norepinephrinylated proteins. This approach relies on the unique catechol

chemistry of dopamine/norepinephrine (which contain two hydroxyl groups on their aromatic rings), whereby their oxidation to meta-quinones allows for the cycloaddition of a bicyclononyne (BCN) desthiobiotin-conjugated probe to endogenously catechol-modified substrates. To initially validate this approach, we demonstrated that histone H3 can readily be IP'd from tissue culture lysates after exogenous application of dopamine. In validating our probe for use in brain, we found that H3 can similarly be IP'd from mouse ventral tegmental area (VTA) nuclear extracts. Next, to identify alternative endogenously dopaminylated protein targets in brain, we probed mouse VTA nuclei using liquid chromatography mass spectrometry (LC-MS/MS). Of the several proteins identified, we have validated calcium-responsive transactivator (Crest/Ss18l1) as a target. Interestingly, Crest is a member of the neuronal-specific nBAF complex that is involved in nucleosome remodeling and contains a glutamine-rich region that has recently been implicated in amyotrophic lateral sclerosis (ALS). Future studies will assess functions for Crest monoaminylation. Furthermore, we are also examining dopaminylation of proteins in other neuronal fractions (e.g., synaptosomes) and cell types (e.g., glia), thus highlighting the overall utility of this novel method and the exciting prospects of exploring new roles for monoamines in cellular plasticity.

**Abstract:** Drug abuse is characterized by loss of control over drug intake, as well as persistent drug-seeking behaviors, despite negative consequences to both the drug abuser and those directly

affected by their behavior. Given that drug addicts continue to crave and pursue drugs of abuse following extended periods of abstinence and/or treatment indicates that there must be life-long changes that occur in brain to promote these behavioral phenotypes. Persistent changes in neuronal gene expression are known to promote physiological alterations implicated in drug addiction. More recently, cell-type and brain region specific epigenetic mechanisms have also been demonstrated to regulate transcriptional programs contributing to addiction-like behaviors; however, our understanding of how these mechanisms mediate life-long addiction remains limited. Dopaminergic neurotransmission in the central nervous system plays a critical role in psychostimulant-induced neural plasticity, with alterations in dopamine production/function being implicated in both the development and treatment of substance abuse disorders. Although packaging of dopamine by the vesicular monoamine transporter is essential for numerous aspects of reward, recent data have demonstrated the additional presence of 'reserve' pools of extravesicular monoamines in the nucleus of monoamine producing neurons. Dopamine, as well as other monoamines, has previously been shown to form covalent bonds with certain cytoplasmic proteins catalyzed by the tissue Transglutaminase 2 enzyme. Our laboratory has recently identified histone proteins as robust substrates for dopaminylation *in vivo*, specifically on histone 3 glutamine 5 (H3Q5dop). In addition, our data demonstrate that chronic withdrawal from volitional administration of extended access to cocaine in rodents results in high levels of dopamine accumulation in the nucleus of dopamine producing neurons in the ventral tegmental area (VTA), as well as altered expression of Tgm2, the H3 dopaminylase, and a robust increase in histone dopaminylation. Furthermore, we have demonstrated that inhibiting dopaminylation in VTA is sufficient to block cocaine-seeking behaviors following extended withdrawal. Taken together, these potentially paradigm-shifting studies will aid in our understanding as to how monoamines, specifically dopamine, function in brain to regulate neurotransmission independent neuronal plasticity and cocaine-mediated behaviors.

**Abstract:** A burgeoning literature suggests that mature, post-mitotic neurons can "dedifferentiate" into a pluripotent, proliferative state that may give rise to cancer stem cells and ultimately brain tumors. Diffuse intrinsic pontine glioma (DIPG) represent one universally fatal class of brain tumors that may be particularly vulnerable to neuronal dedifferentiation, as they are characterized by a proneuronal phenotype and arise at critical developmental periods when neurons are still undergoing cell fate specification. Approximately 80% of DIPG are further characterized by a methionine substitution at lysine 27 of histone H3 (K27M) that leads to inhibition of polycomb repressive complex 2 (PRC2) and loss of the H3K27 di- and tri-methylation marks that it catalyzes. Because PRC2 function is essential for neuronal fate specification, we hypothesized that loss and redistribution of K27me2-3 in the K27M context may cause maturing neurons to dedifferentiate, precipitate a cancer stem cell-like state and set the stage for later oncogenic events. Here, we used *in vitro* and *in vivo* neuronal models to interrogate the impact of K27M on chromatin dynamics, transcriptional programs, morphology and neuronal network formation. At the molecular level, we see that while histone turnover appears largely intact, there are profound global alterations in histone modification profiles that lead to a transcriptional signature suggestive of a more primitive, pluripotent state. In fact, we found that maturing neurons and DIPG are both more vulnerable to the inhibitory action of K27M on PRC2 than other cell types. Furthermore, functional and morphological hallmarks of neural network formation were markedly impaired in K27M bearing neurons, as was their ability to respond to stimulation. Together, our results suggest that K27M may force neurons into a more primitive state that then combine with later oncogenic events to produce a cancer stem cell-like state, which bears the hallmarks of universally fatal, treatment resistant DIPG.

**Title:** Evidence for presynaptic protein synthesis and its requirement to maintain neurotransmitter release at the calyx of Held nerve terminal

**Authors: M. S. SCARNATI**, *K. G. PARADISO
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

**Abstract:** Presynaptic activity requires the synthesis, localization, interaction and maintenance of thousands of proteins that are typically thought to be synthesized in the soma and transported to synapses. However, several groups have demonstrated that some postsynaptic proteins can be locally synthesized at dendritic locations far from the cell body. Local protein synthesis at presynaptic terminals has recently been shown to occur at inhibitory neurons in mammalian brains, but additional evidence has been difficult to obtain, largely due to the small size of most nerve terminals. To better address this question, we are using the calyx of Held nerve terminal, located in the medial nucleus of the trapezoid body (MNTB) in the auditory brainstem. This large, glutamatergic presynaptic terminal forms a monosynaptic, axosomatic connection to MNTB principal cells, and is involved in sound localization. The size of this nerve terminal, combined with an ability to transmit at high frequencies, and the long distance from the cell body make this nerve terminal a good choice to test for local presynaptic protein synthesis. Using fluorescent non-canonical amino acid tagging (FUNCAT) to measure newly synthesized proteins, we find that synaptic activity can produce newly synthesized presynaptic proteins in the calyx of Held nerve terminal. To determine if ribosomes are present in this presynaptic terminal, we did immunofluorescence experiments. We find evidence for 5.8s rRNA, a major component of ribosomes, in the calyx of Held nerve terminal. Next, we used a nucleic acid stain that fluoresces upon binding to RNA. These dye indicates the presence of RNA in the calyx of Held nerve terminal. This indicates that the message and machinery for local protein synthesis are present at this nerve terminal. Finally, electrical recordings of synaptic activity indicate that a reduction in firing frequency or a delay in neurotransmitter release can occur following prolonged synaptic activity in the presence of protein synthesis inhibitors. Our results indicate that local protein synthesis can occur at this nerve terminal, and it appears to be necessary to maintain high levels of presynaptic activity. These findings indicate that presynaptic protein synthesis occurs and that it can be required to maintain neurotransmitter release at high firing frequencies.

**Title:** Linking cannabinoid-1 receptor activation to presynaptically-synthesized target proteins in endocannabinoid-mediated long-term plasticity

**Authors: *H. R. MONDAY**, T. J. YOUNTS, M. E. KLEIN, B. A. JORDAN, P. E. CASTILLO
Neurosci., Albert Einstein Col. of Med., Bronx, NY

**Abstract:** The ability of synapses to undergo changes in strength underlies information storage in the brain. The necessity of local postsynaptic protein synthesis in synaptic plasticity is well-established, but the role of presynaptic protein synthesis in the adult mammalian brain remains poorly understood. Using electrophysiology, fluorescent noncanonical amino acid tagging (FUNCAT) to visualize newly synthesized proteins, and super-resolution microscopy, we recently reported that endocannabinoid-mediated long-term depression of inhibitory transmission (eCB-iLTD) in the hippocampus requires presynaptic protein synthesis. We found that eCB-iLTD is blocked by inhibiting protein synthesis in the presynaptic neuron but not by inhibiting somatic translation or trafficking along microtubules, suggesting that translation in the presynaptic neuron occurs locally. In addition, using FUNCAT in hippocampal cultures, we discovered that activation of the cannabinoid-1 receptor ($CB_1R$) promotes protein synthesis. Here, we sought to determine the signaling pathways involved downstream of the $CB_1R$ that lead to and regulate protein translation. To this end we used a combination of approaches, including pharmacology and electrophysiology in rat hippocampal slices. We found that eCB-iLTD involves signaling via the Akt-GSK3-mTOR pathway, but unexpectedly, PI3K and $G_{\beta\gamma}$ are not required. We also used FUNCAT to test whether these pathways regulate $CB_1R$-dependent enhancement of new protein synthesis. In order to assess how protein synthesis regulates neurotransmitter release, we used stable isotope labeling of amino acids in cell culture (SILAC) and mass spectrometry as a first attempt to uncover target proteins whose expression is regulated by $CB_1R$ activation. Thus, we provide direct evidence that local presynaptic translation is a highly regulated process requiring a complex network of signaling molecules. The identification of key players in this signaling pathway linking sustained activation of the $CB_1R$ to the translation machinery may be important for developing therapies for diseases characterized by disrupted eCB-mediated plasticity, including schizophrenia, autism, and addiction.

**Abstract:** New gene transcription is required to maintain long-lasting synaptic plasticity. This requirement for transcription indicates that signals from stimulated synapses must reach the nucleus, a target that is often hundreds of microns away. One such mechanism of synaptonuclear communication that is essential for long-term plasticity is the physical translocation of signaling proteins from the synapse to the nucleus. While a few dozen proteins are known to undergo activity-dependent synapse-to-nucleus translocation, little work has been done to systematically characterize the population of proteins that undergo this translocation. Here, we use several mass spectrometry-based approaches to identify proteins that undergo activity-dependent nuclear import. First, we identified cargoes of the importin β1 transport complex at the synapse. Importin β1 is a nuclear import protein that undergoes activity-dependent translocation from synapses to the nucleus in hippocampal neurons and its cargoes are likely to mediate synaptonculear communication. Mass spectrometry identified known as well as novel cargoes of importin β1 at the synapse. Next, we extracted nuclei from stimulated and unstimulated hippocampal neurons to identify proteins that exhibit activity-dependent nuclear localization. We used a strong stimulus (pilocarpine-induced seizures) and a weaker but more physiologically relevant stimulus (contextual fear conditioning). We first characterized the nuclear localization of a known synaptonuclear signaling protein, CRTC1, and are characterizing the population of syanptonuclear signaling proteins using mass spectrometry.

**Title:** Examination of stalled polysomes *In vivo* in hippocampal cultures

**Authors: *K. GINZBERG**, T. GRABER, W. SOSSIN
McGill Univ., Montreal, QC, Canada

**Abstract:** The stalled polysome model of mRNA transport in neurons describes the arrangement of mRNA cargo where the rate-limiting step of translation, initiation, occurs before transport (Graber et al, PNAS. 2013 Oct 1; 110(40): 6205-16210). The incomplete peptide is then transported to the dendrite, where, upon activation, translation recommences and protein synthesis is completed (Graber et al, 2013). Protein synthesis from stalled polysomes is necessary for metabotropic glutamate receptor mediated long term depression (mGluR-LTD) (Graber et al, 2013). In order to examine stalled polysomes in vivo in primary hippocampal cultures we have adapted Wang et al.'s (Cell. 2016 May 5;165(4):990-1001) suntagging technique (Tanenbaum et al, Cell. 2014 Oct 23; 159(3): 635-646.), which allows for real-time translation visualization using multivalent fluorescence amplification of a nascent polypeptide signal. A pre-formed GFP-ScFv molecule is expressed which binds to a simultaneously expressed nascent V4 peptide array during translation (Wang et al, 2016); the aggregation of GFP on the V4 array brings the signal above background. An ornithine decarboxylase at the C-terminus ensures the quick degradation of the construct upon translation completion; all signal is therefore derived from active sites of translation (Wang et al, 2016). We are comparing the translation dynamics of the V4 peptide to two modified V4 transcripts: one including the Arc 3'UTR and one including the Map1b 3'UTR: the 3'UTRS of Arc and Map1b mRNA transcripts have been implicated in the regulation of their localization and translation (Graber et al, 2013; Wang et al, 2016). The translation of Map1b following mGluR-LTD induction is initiation independent (Graber et al., 2013). Arc translation also increases following mGluR-LTD (Tatavarty et al, Mol Biol Cell. 2012 Mar 1; 23(5): 918-929); this translation appears to also be initiation independent, but in a manner dependent on its open reading frame and we thus do not expect to observe this effect in our reporter (Na et al, Neuron. 2016 Aug 3;91(3):561-73). We are examining the effects of the initiation inhibitor homoharingtonine (HHT) and DHPG-induced mGluR-LTD on the Map1b and Arc reporters described above. We expect increased dendritic localization of both reporters relative to the unmodified V4 transcript, and we expect signal from our Map1b reporter but not from our Arc reporter to persist in the presence of HHT. We also

expect that signal from our Map1b reporters will decrease with DHPG application regardless of HHT presence. Using these tools, we are able to further elucidate the mechanisms of stalled polysome-regulated mRNA transport.

**Title:** The role of mTORC1 effectors eIF4A1 and PDCD4 in activity dependent translation

**Authors: *I. KATS**[1], E. KLANN[2]
[1]New York Univ., New York, NY; [2]Ctr. for Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

**Abstract:** *De novo* protein synthesis has been shown to be critical for long-lasting synaptic plastisticity as well as the formation of long-term memories. In contrast, dysregulated protein synthesis plays a role sbbrant behaviors associated with autism spectrum disorder. Translation initiation, regulated by mammalian target of rapamycin 1 (mTORC1) and its effectors eIF4E and p70 S6 kinase 1 (S6K1), are relevant to both normal function and disease. Incresed expression of eukaryotic initiation factor 4E (eIF4E) or deletion of its inhibitor eukaryotic factor 4E binding protein 2 (4E-BP2) causes autistic endophenotypes in mice. Moreover deletion of while S6K1 can cause deficits in various types of memory. Inhibitors of either the interaction of eIF4E with eukaryotic initiation factor 4G (eIF4G) or the eukaryotic initiation factor 4A (eIF4A) have also been shown to affect translation in brain slices and to disrupt long-term potentiation. eIF4A1, the helicase in the cap-dependent translation initiation complex, has proven to be important for translation in cancer cells and its inhibitor PDCD4 is phosphorylated and broken down by the proteasome pathway to allow for translation and cell growth. We have begun studies to examine the role of eIF4A1 and PDCD4 in activity-dependent translation. Our preliminary data indicate that PDCD4 is regulated by neuronal activity. Moreover, PDCD4 and eIF4A1 appear to have opposing effects of dendrite complexity in neurons. These results implicate the importance of eIF4A1 and PDCD4 in activity-dependent translation and regulation of dendritic morphology suggesting that they may play a role in memory function.

**Title:** Synaptic specificity in late long-term potentiation (L-LTP) is influenced the location of polyribosomes and protein dynamics

**Authors: *H. Z. SHOUVAL**[1], M. A. HUERTAS[2], T. C. SACKTOR[3]
[1]Neurobiol & Anat, Univ. Tex Medl Schl Houston, Houston, TX; [2]Neurobio. and Anat., Univ. of Texas Med. Sch. at Houston, Houston, TX; [3]Dept Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY

**Abstract:** Memories that may last a lifetime are stored as persistent enhancement of synaptic efficacies, and the ability to preserve these over long time scales constitutes the maintenance phase of synaptic plasticity. The synaptic mechanism underlying these persistent changes, late long-term potentiation (L-LTP), depends on the state and number of specific synaptic proteins. These proteins are synthesized by polyribosomes located in dendritic shafts or inside synaptic spine's. Due to the diffusive nature of proteins in solutions, a question arises as to the possibility that proteins synthesized in one, previously stimulated, site might diffuse into a different location compromising synaptic specificity. This this is a general problem for maintenance by a bi-stable switch and applies specifically to maintenance by *PKMζ,* where evidence indicates that ongoing protein synthesis and slow degradation are essential for memory maintenance.
Previously we have shown (Aslam et al., 2009; Jalil et al., 2015) that positive feedback at the level of the translation can insure the stability of protein number after the induction of plasticity, despite diffusion and protein turnover. This approach can also account for the observed effect of kinase, and protein synthesis inhibitors in the induction of L-LTP and long-term memory. On the basis of this concept we develop a reaction-diffusion implementation of this model and investigated the conditions and limits of synapse specificity in this framework. Our results include both theoretical analysis and simulations performed using NEURON's Reaction-Diffusion (rxd) module in Python.
By exploring steady-state spatial distributions of synthesized proteins we determined the critical distance between polyribosomes at which synapse specificity is preserved and characterize how various morphological (e.g. spine neck diameter) and dynamical (e.g. degradation rate) parameters, and the location of polyribosomes, i.e. in dendrites outside of spines or inside spine heads, influence this critical separation. We also explore how the existence of immobile (or slowly diffusing) proteins in dendritic spine heads can contribute to improve synaptic specificity.

We conclude that if the protein synthesis, that is responsible for maintenance, occurs in dendritic shafts, synapse specificity as observed experimentally could not be maintained. On the other hand if protein synthesis occurs within synaptic spines, synapse specificity could feasibly be maintained by this maintenance mechanism. Therefore our model generates a strong prediction that synapses in which L-LTP has been induced should be populated with active polyribosomes.

**Title:** The RNA binding protein ZBP1 regulates neuronal migration through control of beta actin mRNA

**Authors: *J. BISWAS**[1], Z. B. KATZ[2], A. R. BUXBAUM[3], M. LOPEZ-JONES[1], R. H. SINGER[1]
[1]Anat. and Structural Biol., Albert Einstein Col. of Med., Bronx, NY; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]Neurosciences, Univ. of California San Diego, San Diego, CA

**Abstract:** During the early stages of neural patterning RNA binding proteins tightly regulate gene expression to facilitate cell survival, differentiation, and migration of neurons. Previous reports have elucidated the importance of the RNA binding protein Zipcode Binding Protein 1 (ZBP1) in RNA localization, axon guidance and directionality of cultured fibroblasts. However little has been done to elucidate its role in vivo. Here we report that ZBP1 acts as an essential component for neuronal development and migration through its role in actin regulation. Using a gene trap model we show that the expression profile of ZBP1 during development spatially and temporally coincides with regions of the brain important for the migration of newly differentiated neurons. Histopathological analyses and BrdU staining show an early cell organization deficiency in the developing neocortex and a loss of cell density in the cortical plate as well as the marginal zone of the cortex. To investigate the molecular mechanisms underlying these migration defects we focused our attention on how loss of ZBP1 may affect its best characterized target, beta actin. Our findings show that ZBP1 KO and knockdown not only affects the actin cytoskeleton and disrupts pools of F and G actin but affects actin transcription.

Taken together, our findings show that ZBP1 acts to guide persistent directionality of cells and reveals the importance of ZBP1 mediated actin RNA regulation in neural migration and survival.

**Title:** Investigating non-canonical translation in neurons

**Authors: *H. WONG**, J. LEVENGA, C. A. HOEFFER
Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO

**Abstract:** Protein synthesis is required for persistent forms of synaptic plasticity such as long-term potentiation and long-term depression, which are thought to be cellular substrates of memory. The primary pathway for protein synthesis is canonical translation, which initiates with binding of the small ribosomal subunit and associated translation initiation factors to the 5' cap of eukaryotic mRNAs. While this pathway is well-studied and known to support synaptic plasticity and memory, protein synthesis can also occur to a lesser extent through non-canonical pathways. In one mode of non-canonical translation, protein synthesis initiates from an internal ribosome entry site (IRES) in the mRNA transcript. An IRES is a complex secondary structure in the mRNA that recruits the ribosome with an alternative set of translation initiation factors. Very little is known about the contribution of this IRES-mediated mode of translation to neural function. However, a few proteins critically linked to synaptic plasticity have been reported to contain an IRES in their mRNA transcript. We hypothesized that IRES-mediated translation may play a role in the protein synthesis supporting persistent forms of synaptic plasticity. To explore this idea, we have developed bicistronic translation reporters to measure cap- and IRES-mediated protein synthesis in neurons. Using these reporters in addition to complementary approaches, we

are examining translational activity in hippocampal neurons following different stimulation and treatment conditions. These studies may provide new insight into the translation mechanisms underlying synaptic plasticity and how their dysfunction could be involved in memory disorders.

**Authors: *Y. J. YOON**[1], H. CHOI[3], R. H. SINGER[2]
[1]Anat. and Structural Biol., [2]Anat. & Structural Biol., Albert Einstein Col. of Med., Bronx, NY; [3]HHMI/Janelia Res. Campus, Ashburn, VA

**Abstract:** We have developed a ribosome intersubunit FRET assay that assesses the association of the small and large subunits of the ribosome in live cells. A pair of ribosomal proteins from each subunit were tagged with self-labeling HaloTag. The tag can be readily labeled with cell-permeable ligands conjugated to bright fluorescent dyes which allow single molecule detection. FRET was assessed using FLIM measurements to observe changes in fluorescence decay from fluorophores undergoing energy transfer. The results demonstrate that our FRET assay was able to detect clusters of assembled ribosomes within dendrites and reveal the presence of translating ribosomes or granules. An advantage of the FLIM-FRET assay is the ability to detect over time, which can reveal kinetic information about how polysomes or granules change.

**Title:** Dynamics of transcription and transport of labeled-endogenous Arc mRNA in live neurons

**Authors: *H. MOON**[1], S. DAS[2], R. H. SINGER[2,3], H. PARK[1]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Anat. & Structural Biol., Albert Einstein Col. of Med., Bronx, NY; [3]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

**Abstract:** Spatially and temporally controlled gene expression is crucial for the formation of memory. Especially, an immediate early gene Arc is known to be deeply involved in the modulation of synaptic plasticity. Upon stimulation, transcription of Arc mRNA occurs in a selected group of neurons. After transcription, Arc mRNA is transported to the desired destinations including distal parts of dendrites for local translation. These two biological phenomena, transcription and transport of Arc mRNA undoubtedly have significant roles in the memory formation. We developed Arc-PBS KI mouse for single mRNA imaging in live cells by knocking in 24 tandem arrays of PP7 binding site (PBS) in the 3′ untranslated region (3′ UTR) of the Arc gene. Using the Arc-PBS KI mouse, we investigated the dynamics of transcription and the transport of Arc mRNAs in live primary neuron cultures. First, we simultaneously imaged somatic $Ca^{2+}$ activity and Arc mRNA transcription after stimulation by bicuculline. Whereas synchronized bursts of $Ca^{2+}$ activity was induced in 100% of neurons, Arc transcription was induced only in a subpopulation of neurons during 30 min of observation after stimulation. To determine the factor governing this selection of Arc transcribing neurons, we performed immunostaining of Ser-133 residue phosphorylated CREB and single molecule FISH of Arc mRNA together. We found that neurons with higher level of CREB phosphorylation (Ser-133) has indeed higher probability of Arc transcription. We also investigated transport of Arc mRNAs along the dendrites after stimulation. Most of the Arc mRNAs were in rest phase (~88%) during one-minute observation time, and even the directed motions of Arc mRNAs were frequently interrupted by rests, similar to the previously reported behavior of β-actin mRNAs. The active movements of Arc mRNAs were bidirectional with almost equivalent occurrence of anterograde and retrograde steps and with a speed of ~1.5 μm/s in both directions. In summary, this study presents new perspectives about the dynamics of transcription and transport of endogenous Arc mRNA, which plays important roles in synaptic plasticity at the molecular level.

**Title:** A transgenic mouse for visualizing dynamics of endogenous Arc (Arg3.1) mRNA in hippocampal neurons

**Authors: *S. DAS**[1], H. MOON[2], H. PARK[2], R. H. SINGER[1,3]
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Janelia Res. Campus, Ashburn, VA

**Abstract:** Spatio-temporal control of gene expression in a neuronal network is an essential element of memory formation. The immediate early gene Arc (activity-regulated cytoskeletal associated), or Arg3.1, plays a crucial role in synaptic plasticity and memory consolidation. Arc expression is neuronal activity dependent and primarily regulated by transcription and targeting to active synapses. While most *in vivo* studies describe the spatial regulation of Arc, however, the temporal dynamics of single endogenous Arc mRNA in response to neuronal activity or LTP is not well defined. To address that, we have generated a transgenic mouse for tagging endogenous Arc gene by knocking in 24 repeats of bacteriophage-derived PP7 binding sites (PBS) into 3'UTR of Arc gene. These PBS stem-loops are bound by their cognate partner-PP7 coat protein (PCP), which are fluorescently labeled, thereby allowing visualization of active Arc loci and individual mRNAs in real-time. In hippocampal neurons from this mouse, by real-time imaging, we detect transcription from both endogenous Arc alleles, and observe transcriptional bursting in response to synchronous neuronal activity. Also, using single molecule fluorescence *in-situ*hybridization (smFISH), we can quantify the transcriptional burst from each allele, and mature Arc mRNA production with high spatial resolution. The tagging of endogenous Arc gene provides an important tool which will allow us to investigate the correlation between neuronal activity and endogenous gene transcription at single cell level with unprecedented spatio-temporal resolution.

**Abstract:** Fragile X Syndrome (FXS) model mice display distinct repetitive/perseverative behaviors that are likely striatal-based (Welch et al., 2007), but the majority of studies on synaptic dysfunction in FXS model mice have been focused on hippocampal and cortical circuits. Altered protein synthesis appears to be a common molecular anomaly that contributes to synaptic and behavioral impairments associated with autism spectrum disorder (ASD). Consistent with this idea, patients with FXS, which is caused by the lack of the RNA binding protein fragile X mental retardation protein (FMRP), have a high incidence of ASD. Increased eIF4F complex formation measured as an increase in eIF4E-eIF4G interactions has been reported in FXS model mice, which may results in altered protein synthesis that could lead to abnormal cortico-striatal synaptic function and plasticity, and aberrant behavior in FXS model mice. The mechanism for the increased eIF4E-eIF4G interactions in FXS could be due to upregulated mTORC1 signaling (Sharma et al., 2010), disruption of FMRP/CYFIP1/eIF4E complexes (Napoli et al., 2008), or a contribution of both pathways, which would result in exaggerated cap-dependent protein synthesis (Hoeffer and Klann, 2010). Our central hypothesis is that the aberrant repetitive and perseverative behaviors exhibited by FXS individuals is due to exaggerated eIF4E-mediated translation at cortico-striatal synapses. Using FUNCAT to examine de novo protein synthesis, we found that FXS mice exhibited altered protein synthesis in the striatum. We proceeded to determine whether cortico-striatal synaptic composition, function, and plasticity were altered in FXS model mice, and found that high-frequency stimulation-induced metabotropic glutamate receptor (mGluR)-dependent long-term depression (LTD) in cortical-striatal slices from FXS model mice was enhanced. These findings are consistent with previous findings in hippocampal and cortico-striatal slices from eIF4E transgenic (Santini et al., 2013) and FXS model mice (Huber et al., 2002; Hou et al., 2006). Finally, repetitive behaviors in FXS model mice were reversed by the cap-dependent translation inhibitor 4EGI-1 (Moerke et al., 2007) that selectively disrupts the interaction between translation factors eIF4E and eIF4G. Our findings are consistent with the hypothesis that enhanced cap-dependent translation via increased eIF4E-eIF4G interactions contributes to repetitive behaviors displayed by FXS model mice that are likely cortico-striatal in nature and provide critical information concerning potential therapeutic treatments for synaptic and behavioral dysfunction not only FXS, but also in ASD.

**Abstract:** Severe early life stressors increase the probability of developing psychiatric disorders later in life through modifications in neuronal circuits controlling brain monoaminergic signaling. Our previous work demonstrated that a single episode of maternal deprivation (MD, a 24hr deprivation on postnatal day 9) in rats modifies dopamine signaling from the ventral tegmental area (VTA) through changes at GABAergic synapses onto VTA dopamine neurons. These synaptic changes were reversible via in vitro histone deacetylase (HDAC) inhibition through restoration of the scaffold A-kinase anchoring protein (AKAP150) signaling that is important for $GABA_A$ receptor trafficking in VTA dopamine neurons. Our work here confirms that that MD induces epigenetic modifications at the level of histone acetylation (histone H3 hypoacetylation at lysine 9, Ac-H3K9) associated with an upregulation of HDAC2 (a class I HDAC). In vivo injection with a selective class 1 HDAC inhibitor, CI-994, was sufficient to reverse MD-induced hypoacetylation at 3hr and 24hr after the injection. Western blot analysis of AKAP150 expression through sub-cellular fractionation technique showed an increase in synaptic levels of AKAP protein in VTA tissues. Consistent with these results, we found that MD increased AKAP150 mRNA levels using in situ hybridization technique. Western blot analysis also confirmed that the protein levels of gephyrin and mature brain-derived neurotrophic factor (mBDNF) were lower after MD. On the other hand, NMDA receptor NR2B subunit expression was upregulated while NR2A protein levels were unchanged in the VTA after MD suggesting that the developmental switch of NMDA receptor composition in these young rats may be delayed. Our electrophysiological recordings of dopamine cell excitability in response to depolarizing currents showed that dopamine neurons were hyperexcitable after MD and this hyperactivity was normalized at 24hr after in vivo injection of the the HDAC inhibitor, CI-994. Behavioral analyses in the forced swim test in MD animals suggest that active coping climbing behavior was increased after MD. Future research will determine whether histone hypoacetylation occurs at gephrin and mBDNF promoters and whether a single in vivo injection of CI-994 is sufficient to reverse MD-induced epigenetic and synaptic modifications including the expression of AKAP150, gephrin, mBDNF, and NMDA receptor subunits in the VTA. Furthermore, we will investigate whether in vivo HDAC inhibition normalizes behavioral changes associated with MD.

**Title:** Activity-driven regulation of Nogo receptor 1 expression and localisation

**Authors: *A. T. BRODIN**, D. T. DOMINGUES, K. WELLFELT, L. OLSON, T. E. KARLSSON
Neurosci., Karolinska Institutet, Solna, Sweden

**Abstract:** Nogo receptor 1 (NgR1) together with multiple partners restrict plasticity during development and learning. Overexpression of NgR1 results in impaired long term memory and less elaborate dendritic trees. We and others have shown that NgR1 mRNA is downregulated by increased neural activity, and have hypothesized that this downregulation is a prerequisite for the formation of lasting memories. However, it is still unclear whether NgR1 acts presynaptically, postsynaptically, or at both locations. Further, while NgR1 mRNA is robustly downregulated by activity, it remains to be determined how this correlates to levels and locations of functional NgR1 protein. Finally, little is known about the signalling pathways from increased neuronal activity to alterations of NgR1 mRNA levels. Using primary hippocampal cell cultures, we are analysing the transcriptional and translational regulation of genes involved in Nogo-type signaling. Using several complementary techniques, we investigate how the different proteins are distributed with regard to pre- or postsynaptic localisation. We also show that altered neuronal activity significantly alters transcriptional activity of most of the investigated genes. The results

contribute to positioning the Nogo-system as a master regulatory system of activity induced structural plasticity and hence how memories are formed and maintained.

**Title:** Network state-dependent recruitment of hippocampal CA1 interneuron-selective cells in awake mice

**Authors: *L. TOPOLNIK**, V. VILLETTE, R. FRANCAVILLA
CRCHUQ-CHUL, Laval Univ., Quebec, QC, Canada

**Abstract:** In the CA1 hippocampus, type 3 interneuron-selective cells co-express vasoactive intestinal peptide (VIP) and calretinin and innervate selectively several different types of CA1 orien/alveus interneurons. Despite their potentially important role in coordination of network activity and hippocampus-dependent mnemonic processes through local circuit disinhibition, very little remains to be known about the functional organization of this cell type and its recruitment in awake animals in relation to network oscillations. To understand the functional role of IS3 cells, we performed *in vivo* two-photon calcium imaging of VIP interneuron activity in the CA1 hippocampus in combination with contralateral local field potential (LFP) recordings in head-restrained awake VIP-Cre mice running on the treadmill. During the experiment, mice showed spontaneous alternations in their behavior between locomotion periods that were associated with prominent theta oscillations and stationary states with occasional high-frequency ripple episodes. Putative IS3 cells identified *post-hoc* based on the soma properties and the expression of calretinin showed a high level of variability in somatic activity, but overall were more active during locomotion than during quiet state. Moreover, during theta oscillations associated with locomotion periods, IS3 cells often exhibited a delayed recruitment. During quiet state, these cells showed no change in somatic activity in relation to contralateral ripple episodes. Collectively, these data indicate that IS3 cells are preferentially recruited during theta-run epochs and, through timely disinhibition at different spatial domains of pyramidal cells, may facilitate the input integration and plasticity induction during animal navigation.

**Abstract:** Inhibitory interneurons of the hippocampus are critical controllers of network rhythms that are linked to learning and memory. In particular, the oriens-lacunosum/moleculare (O-LM) cell directly regulates pyramidal cell activity in the hippocampal CA1 region. Thus, it is essential to understand how the biophysical properties of O-LM cells allow them to contribute to hippocampal function. Computational modelling is needed to synthesize experimental data and generate testable hypotheses. We previously developed O-LM models to study how biophysical properties of O-LM cells affect output. However, the models were developed using morphological and electrophysiological data obtained from different O-LM cells, resulting in non-uniqueness of the fitted model parameters. We hypothesized that experimental data of O-LM cells, with matched electrophysiological and morphological data, would result in constraints in dendritic distributions of hyperpolarization-activated, mixed cation channels ($I_h$). We performed a set of whole-cell recordings from dorsal hippocampal somatostatin-positive ($SOM^+$) O-LM cells in SOM-CRE/Rosa26YFP mice, followed by biocytin fills to match their electrotonic and morphological properties. We used Neuromantic to obtain 3D morphologies of the cells that served as the foundation for new multi-compartment O-LM cell models implemented in the NEURON simulation environment. The passive properties of the resulting models were fitted using current clamp data from the same cells. Surprisingly, we found that the

specific membrane capacitance across several O-LM cells was substantially lower than the values typically reported in mammalian neurons. Finally, we fitted the distribution of $I_h$ in the models as a function of distance from the soma using the PRAXIS optimization method in NEURON, while injecting the current clamp command data obtained from the experiments directly into the soma of the models. Interestingly, we found that the models were only able to fit the recorded membrane potential of O-LM cells in response to hyperpolarizing current steps when $I_h$ was distributed onto the majority of the dendrites. The fitted passive parameters, in conjunction with the recorded total membrane conductance due to $I_h$, thus provided robust constraints on the dendritic distributions of $I_h$ in $SOM^+$ O-LM cells. These results offer insights into the electrotonic structure of O-LM cells and dendritic distribution of HCN channels that impact on synaptic integration and spiking output. These models will serve as a next generation of tightly constrained O-LM cell models that can help obtain insight into hippocampal function.

**Abstract:** Obtaining recordings from individual cells during behaviour is technically challenging. This is more so for hippocampal interneuron subtypes which represent a neuronal minority and are difficult to unambiguously identify given interneuron diversities. Interneuron specific 3 (IS3) cells, a cell type known to exclusively inhibit other inhibitory interneurons, has yet to be characterized in terms of its function *in vivo*. Our goal here is to generate *in vivo*-like states for IS3 cells using our previously developed IS3 cell models to predict inputs that they

receive *in vivo* and, in concert with experiment, to understand their functional contributions to hippocampal activity.
We know that neurons *in vivo* show more depolarized membrane potentials ($V_m$), increased $V_m$ standard deviations ($\sigma_{Vm}$), and increased irregular spiking as measured by the coefficient of variation of interspike intervals (*ISICV*) relative to those *in vitro*. We use these criteria to determine conditions under which our models can exhibit high-conductance (HC), or *in vivo*-like, states. We started with two previously developed multi-compartment models of IS3 cells, experimentally-constrained synaptic parameters, and realistic synaptic density values. The first model variant (SDprox1), possesses ion channels in the soma and proximal dendrites including A-type potassium channels ($I_A$), whereas in the second model variant (SDprox2), $I_A$ is restricted to the soma.
We perform a parameter search where we vary the full range of synapse numbers and a wide range of presynaptic spike rates (~4.4 million simulations). We find that synchronous inputs (mainly excitatory) amplify the size of the HC state parameter spaces through increased *ISICV* and $\sigma_{Vm}$ values. On dividing the parameter space into high/low pools, we find that having (i) high excitation (783-1530 synapses; 20-30 Hz) and low inhibition (4-172 synapses; 10-50 Hz), or (ii) high inhibition (176-344 synapses; 60-100 Hz) and low excitation (18-765 synapses; 5-15 Hz), shifts the parameter space away from HC regimes. Also, SDprox2 mostly generated larger numbers of HC scenarios, likely due to the SDprox1 model having dendritic $I_A$, which reduces excitability.
Thus, we have shown that common inputs, balanced excitation/inhibition, and lack of dendritic $I_A$, promote HC states in IS3 cell models. We can further reduce possible HC scenarios by excluding levels of synaptic input that would render distal dendrites unresponsive due to saturation, and examining responsiveness to rhythmic inputs. Moving forward, these models will be used in combination with experimental work to obtain an understanding of the functional roles of IS3 cells in the hippocampus.

**Title:** Properties of connections established by local and extrinsic excitatory projections on the hippocampal CA1 interneuron-specific interneurons

**Authors: *X. LUO**, R. FRANCAVILLA, L. TOPOLNIK
CHU de Quebec, Univ. Laval, Quebec, QC, Canada

**Abstract:** The information processing in cortical circuits requires a delicate balance between excitation and inhibition. In addition to the inhibitory interneurons that control the activation of pyramidal cells, there are interneuron specific (IS) interneurons that coordinate the network level of inhibition. In this study, we focused on the hippocampal CA1 Type 3 IS cells (IS3) that co-express the vasoactive intestinal peptide (VIP) and calretinin. These cells make synapses on several types of oriens/alveus (O/A) interneurons and may control the information flow through hippocampal CA1 area. However, the synaptic properties of local and extrinsic excitatory projections converging onto IS3 cells and the mechanisms of their recruitment during network activity remain unknown. Using a combination of patch-clamp whole-cell recording and electrical and optogenetic stimulation in CA1 area of acute hippocampal slices of VIP-eGFP and VIP-tdTomato mice, we examined the properties of local excitatory synapses on IS3 cells and of distant projections arriving from the median raphe (MR) nucleus. Our data showed that the excitatory postsynaptic currents (EPSCs) evoked in IS3 by activation of the temporoammonic pathway (TA) and the Schaffer collaterals (SC) had different amplitude, kinetics and temporal summation properties. In addition, both TA- and SC-EPSCs showed two components, which were mediated by the activation of AMPA and NMDA receptors, respectively. Furthermore, optogenetic activation of MR projections generated small EPSCs in some IS3 cells, consistent with sparse MR contacts on IS3 interneurons. In contrast, large-amplitude MR responses were evoked in other VIP cells located within the O/A including VIP basket cells. The MR-EPSCs were sensitive to both 5-$HT_3$ and glutamate receptor antagonists, consistent with viral targeting of both MR glutamate and 5-HT projections that innervated densely the CA1 LM and O/A layers. These data indicate that hippocampal IS3 interneurons are mostly recruited through SC- and TA-projections with distinct properties, which may be well suited for the activity-dependent coordination of hippocampal CA1 inhibition, induction of synaptic plasticity and gating of cortico-hippocampal information.

**Title:** Prolonged hyperexcitability of hippocampal mossy fibers after repetitive high frequency stimulation

**Authors: *H. KAMIYA**
Dept. of Neurobio., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan

**Abstract:** Axons are classically thought to generate action potentials at the initial segments and propagate reliably to the target cells. However, recent studies suggested that the excitability of the axons and the terminals is regulated by the preceding neuronal activity in an activity-dependent manner, due to either modulation of the intrinsic properties of ionic channels or activation of the autoreceptors on the axonal membrane. In this study, it was attempted to test whether plastic changes in the axon excitability might be induced by repetitive stimuli of the input fibers. For this purpose, large axon terminals of hippocampal mossy fibers were adopted for monitoring axon excitability. Using a loose-patch recordings, axonal spikes were monitored directly from the single mossy fiber terminals. In the resting condition without stimulation, a very few spike was detected from the single axon terminals. However, repetitive high frequency stimulation of the mossy fibers (e.g. 100 Hz for 1 s, repeated 5 times) reliably increased the frequency of axonal spikes for prolonged time. In some recordings, burst discharges followed after the spike trains during the high-frequency stimulation, suggesting that axonal excitation outlasts the stimulation period. To look for the mechanism, local perfusion of $Ca^{2+}$-free solution around the recording site was used to minimize the contribution of autoreceptor activation. Application of $Ca^{2+}$-free solution diminished these burst discharges following high-frequency stimulation. This result suggests that activation of autoreceptors on the mossy fibers and/or the terminals causes the prolonged excitation. This activity-dependent hyperexcitability of axon may serve as a candidate cellular mechanism of epileptogenesis in the hippocampus.

**Title:** Dominant role of $\alpha_1$ $Na^+/K^+$ ATPase in generating the slow afterhyperpolarization in CA1 pyramidal cells

**Authors: *M. N. TIWARI**, S. MOHAN, Y. BIALA, Y. YAARI
Dept. Of Med. Neurobio., Jerusalem, Israel

**Abstract:** The slow afterhyperpolarization (sAHP) is a key regulator of intrinsic neuronal excitability. Changes in the sAHP have been implicated in learning behaviors, in cognitive

decline in aging, and in epileptogenesis. Despite its importance, its underlying mechanisms, traditionally attributed to $Ca^{2+}$-gated $K^+$ currents (IKCa's), are still controversial. Here, we have addressed the role of $Na^+/K^+$-ATPases (NKAs) in sAHP generation in rat CA1 pyramidal cells, using sharp glass microelectrode recordings in acute hippocampal slices perfused with standard aCSF (35$^o$C) containing synaptic transmission blockers. The sAHPs size increased with the number of spikes (5-150 spikes at 50 Hz). Suppression of IKCa's with $Ni^{2+}$ and $Cd^{2+}$ (200 μM each) had no significant effect on sAHPs evoked by up to 40 spikes, and only partially reduced the sAHPs evoked by longer spike trains. The sAHPs in aCSF containing $Ni^{2+}$ and $Cd^{2+}$ were inhibited by ouabain (10 μM) and by $K^+$-free aCSF, indicating that they are generated by NKAs. The size of NKA-sAHPs was voltage-dependent, increasing with depolarization and decreasing with hyperpolarization without reversing even at -115 mV. Low ouabain concentration (1 μM), that selectively blocks $\alpha_3$-NKA isoenzymes, had only a small effect on NKA-sAHPs. We conclude that in rat CA1 pyramidal cells, NKAs are the predominant generator of the sAHP, even in the case of sAHPs evoked by short spike trains. Of the two NKA isoenzymes expressed by CA1 pyramidal cells, namely $\alpha_1$- and $\alpha_3$-NKA, the former isoenzyme plays the dominant role in sAHP generation, endowing it with a steep voltage-dependence. Thus normal and pathological changes in $\alpha_1$-NKA expression or function may affect cognitive processes by modulating the inhibitory efficacy of the sAHP.

**Title:** Activity dependent scaling of H-current in mouse CA1 OLM-interneurons

**Authors: *D. YOUSEF YENGEJ**, W. J. WADMAN
Univ. of Amsterdam, Amsterdam, Netherlands

**Abstract:** Activity driven homeostatic scaling of excitability is a well-documented way of keeping neuronal firing within working range. CA1 pyramidal neurons in the rat hippocampus adjust their excitability by upscaling hyperpolarization activated cyclic nucleotide-gated (HCN) channels in the membrane (van Welie et al., 2004; Noam, et al., 2010). H-current ($I_h$) was also found in CA1 interneurons, and while scaling of their current could have similar effects at the cellular level, the outcome at circuit level will be more complex. In this study, we investigated $I_h$ scaling in stratum Oriens-Laconusum-Moleculare (OLM) interneurons as a result of enhanced synaptic drive.
Whole cell patch-clamp recordings were performed in sagittal brain slices of 4-6 weeks old male

mice. OLM neurons were recognized based on location, morphology and high firing rate (>150 Hz). $I_h$ was quantified in voltage clamp by stepwise hyperpolarization. The voltage-dependent activation obeyed a Boltzmann function.
Alpha-Latrotoxin (LTX, 0.15 nM) was used to upregulate spontaneous synaptic release, which was confirmed by an enhanced presence of miniature post synaptic currents. As a consequence of the enhanced activation of the glutamatergic input, $I_h$ was upregulated in about 15 min. by approximately 51% (±11% SEM, n=9) in CA1 OLM-interneurons, in a way comparable to what has been described for $I_h$ upregulation in CA1 pyramidal neurons. The change was best described by amplitude scaling and did not affect the voltage dependent properties of $I_h$.
Neuronal sub-threshold resonance was measured by injecting a chirp current (0.5 - 20Hz) and recording the resulting membrane voltage response. Resonance was voltage dependent and most prominent around a membrane potential of -80 mV; it was blocked by the HCN channel blocker ZD7288 (20 µM). Preliminary results indicate that $I_h$ scaling is associated with a change in resonance in OLM interneurons: The peak frequency of the resonance shifted with $I_h$ upregulation from ~2.0 Hz to ~2.9 Hz (n=3).
We conclude that OLM interneurons present activity induced scaling of $I_h$ which modulates intrinsic excitability, firing rate and subthreshold neuronal resonance. $I_h$ modulation in OLM interneurons will affect theta frequency and power (Neymotin, et al., 2013). Disruptions of this process could result in several disorders, including epilepsy.

**Title:** Group I metabotropic glutamate receptors generate two types of intrinsic membrane oscillations in hippocampal O-LM interneurons

**Authors: G. GOVINDAIAH**[1], Y.-J. KANG[1], L. CHUNG[3], E. GARCIA-RILL[2], *S.-H. LEE[1]
[1]Neurol., [2]Ctr. for Translational Neuroscience, Dept. of Neurobio. and Developmental Sci., Univ.

of Arkansas For Med. Sci., Little Rock, AR; [3]Dept. of Neurobio., Duke Univ. Sch. of Med., Durham, NC

**Abstract:** Metabotropic glutamate receptors (mGluRs) are a family of G protein-coupled receptors, and are highly expressed in the hippocampus. Activation of hippocampal group I mGluRs (i.e., $mGluR_1$ and $mGluR_5$) is known to regulate interneuron excitability and synaptic transmission, and generate network oscillations. In addition, previous studies have shown that activation of mGluRs produced slow supra-threshold membrane oscillations (< 0.1 Hz) in oriens-lacunosum moleculare (O-LM) interneurons. The underlying mechanisms at the single cell level of gamma and slow oscillations are not fully understood. We have examined key factors in regulation of intrinsic slow and gamma oscillations by using whole-cell patch-clamp recordings from identified CA1 O-LM interneurons. Our study revealed that the selective $mGluR_{1/5}$ agonist (S)-3,5-dihydroxyphenylglycine (DHPG) induced slow intrinsic membrane oscillations (< 0.1 Hz), which consisted of membrane depolarization and repolarization phases. DHPG produced supra-threshold membrane depolarization, which was associated with gamma frequency action potentials followed by action potential-free intrinsic gamma oscillations. The voltage-gated $Na^+$ channel blocker, TTX, blocked intrinsic gamma oscillations, while DHPG-induced slow oscillations were insensitive to TTX. The slow oscillations were reduced by the $mGluR_1$-selective antagonist LY341495, and were partially blocked by the $mGluR_5$-specific antagonist MPEP. Blockade of nonselective cation-conducting transient receptor potential channels or voltage-dependent L-type $Ca^{2+}$ channels blocked the slow oscillations. Depleting intracellular $Ca^{2+}$ with BAPTA or inhibiting ryanodine receptor-sensitive internal stores with ryanodine also abolished the slow oscillations. These findings suggest that DHPG induced two types of membrane oscillations in O-LM interneurons via multiple mechanisms. Our findings suggest that the activation of group 1 mGluRs in O-LM interneurons play an important role in regulation of hippocampal network oscillations, which support key functions of the hippocampus. **Abstract:** The entorhinal cortex (EC) constitutes an important interface between the hippocampus and various regions of the neocortex. Sensory signals enter the hippocampal formation via neurons located in superficial layers of the EC. In turn, information from the hippocampus reaches the neocortex through deep layers of the EC (mainly layer V (LV)). Based on distinct molecular markers, LV of the medial entorhinal cortex (mEC) can be subdivided into layers Va and Vb. The main targets of projections from CA1 and the subiculum are Ctip2 positive pyramidal-like neurons in LVb. In contrast, Etv1 positive neurons with a characteristic horizontal basal dendritic tree located in LVa (i.e., a narrow zone adjacent to lamina dissecans) are the major source of intra-telencephalic projections. Here, we investigated the functional connectivity between CA1 and mEC LV neurons as well as the local connectivity within LV. We performed simultaneous paired patch-clamp recordings from LV neurons in acute horizontal mouse brain slices. Location and morphology of recorded neurons were confirmed by biocytin labeling and Ctip2 immunoreactivity. We found that electrical stimulation of the alveus in CA1 induced robust excitatory postsynaptic potentials (EPSPs) in identified layer Vb and Va principal neurons after a delay of ~ 4 ms, suggesting direct hippocampal input to both cell types. We found no evidence for direct synaptic connections from Vb to Va neurons (0/27 pairs). However, Va neurons were mutually interconnected with a probability of about 20% (5/26), while connectivity from Va to Vb cells was less than 5% (1/27). Additionally, we identified two types of local interneurons: fast-spiking (FS) and low-threshold spiking (LTS) interneuron. Remarkably, both types of interneurons also received monosynaptic hippocampal excitatory input as well as direct input from Va principal neurons. FS interneurons almost exclusively target Vb cells with high connectivity (4/6 pairs). Morphological analysis of principal neurons shows that all Vb cells are pyramidal shaped, while Va neurons revealed pyramidal as well as non-pyramidal forms (in 18%). The axon of both types of Va neurons exposed powerful arborizations within LV, as well as projections towards the angular bundle. Moreover, non-pyramidal Va neurons frequently send additional axonal branches towards superficial layers. We conclude that Va and Vb neurons as well as local interneurons receive direct input from CA1. Furthermore, our results indicate input-output integration by interconnected mEC LVa neurons and distinct signal processing within LV.

**Abstract:** Exploratory behavior leads to the location-specific activation of hippocampal place cells. During memory consolidation at rest, these cells are then replayed in the same firing sequences but temporally compressed. In vitro this reactivation can be observed as hippocampal local field potential events of duration 30-60 ms called sharp-wave ripple complexes (SPWs). Recent studies postulate multiple mechanisms for forming such ensembles. For instance, recurrent excitatory feedback connections within the hippocampus enable reverberating activation without external inputs. Also, patterns of convergent and divergent synaptic connectivity, activity-dependent synaptic efficacy and non-linear dendritic integration support the formation of defined spatiotemporal activity of specific cells and while silencing neighboring neurons.
Recently, we showed that in about 50 % of CA1 hippocampal pyramidal cells the axon stems from a basal dendrite (axon-carrying dendrite cells, AcD cells) rather than from the soma (nonAcD cells). AcD cells are intrinsically more excitable and generate dendritic spikes with higher probability and greater strength. Axon-carrying dendrites for their part might constitute a privileged channel for excitatory synaptic input in this subset of cortical pyramidal cells. Consequently, this anatomical feature could represent a novel mechanism for neuronal networks to selectively recruit specific neurons into transiently stable ensembles and thereby promote specificity of neuronal representation.
However, the question whether AcD cells are preferentially recruited into multi-neuronal ensembles has yet to be addressed. We employed extra- and intracellular electrophysiological recordings as well as immunofluorescent stainings in acute hippocampal mouse brain slices. Our data suggests that network input to privileged dendrites potentially circumvents strong perisomatic inhibition that affects the cell during spontaneous SPWs. Indeed, our electrophysiological recordings indicate that only AcD cells were able to fire action potentials (APs) during spontaneous SPWs. These APs showed the peculiar waveform resembling ectopically generated spikes described previously. Both AcD cells and nonAcD cells received strong hyperpolarizing inputs, preventing classical APs from being generated. On the network level AcD cells appear to be recruited into neuronal ensemble activity preferentially.

**Title:** Kv4.1 is a key player for sparse firing of mature granule cells in hippocampal dentate gyrus

**Authors: *K.-R. KIM**[1], Y. SUH[2], S.-H. LEE[3], W.-K. HO[4]
[1]Dept. of physiology, Seoul Natl. University, Col. of Med., Seoul, Korea, Republic of; [2]Dept. of Biomed. Sci., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Dept. of Physiol., Seoul, Korea, Republic of; [4]Seoul Natl. Univ. Col. Med., Seoul, Korea, Republic of

**Abstract:** The dentate gyrus (DG) hippocampal region is one of the most plastic regions where adult neurogenesis occurs. Another distinguishing characteristic of DG is sparse action potential firing. Firing of DG granule cells (DG-GCs) depends both on their synaptic connectivity and on low intrinsic excitability. However, the ion channel mechanism for low intrinsic excitability and its change during maturation are not well understood. Here, we show that Kv4.1 channels are preferentially expressed in DG-GCs among three major hippocampal regions, and its expression is increased with maturation. Functional analysis showed that blocking Kv4.1 channels with its specific antibody increased firing rates selectively in mature DG-GCs without affecting other parameters of intrinsic excitability, suggesting that Kv4.1 could in principle contribute to low intrinsic excitability in mature DG-GCs. Detailed analysis showed that Kv4.1-mediated currents in DG-GCs have distinct inactivation kinetics from A-type $K^+$ channels and a unique $Ca^{2+}$ sensitivity, in that its activity is inhibited by 10 mM BAPTA. Consistent with the specific localization of Kv4.1, its inhibition with antibody or 10 mM BAPTA have no effect in young DG-GCs or CA1 pyramidal neurons. Together, these data suggest that Kv4.1 channels act as a regulator to prevent hyperexcitability of mature granule cells. The action of Kv4.1 channels depends on the degree of intracellular $Ca^{2+}$ buffering, implicating a dynamic role of intracellular signaling in refining DG excitability.

**Title:** Retroaxonal barrage firing in neuropeptide Y interneurons in hippocampus and cerebral cortex

**Authors: *T. DEEMYAD**[1], J. LÜTHI[2], J. WINNUBST[3], N. SPRUSTON[3]
[1]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept. of Mol. Life Sci., Univ. of Zurich, Zurich, Switzerland; [3]HHMI Janelia Res. Campus, Ashburn, VA

**Abstract:** A novel form of persistent firing, originating from distal axons, has been reported previously in a subset of interneurons that contain neuropeptide Y (NPY cells) in the hippocampus CA1 area and piriform cortex (Sheffield et al. 2011, Krook-Magnuson et al. 2011 and Suzuki et al. 2014). We refer to this as retroaxonal barrage (RaB) firing, because it is generated in the distal axons of these cells (Sheffield et al. 2011). Although different subpopulations of interneurons in various brain areas express NPY, the ubiquity of such RaB firing has not been explored in them. To explore this possibility, patch clamp recordings were made from NPY interneurons in several areas of the hippocampus and neocortex. All recordings were made from parasagittal slices in mice expressing GFP under the NPY promoter and repetitive depolarization steps were used to induce RaB firing. RaB firing was observed in NPY cells in all layers of hippocampal areas CA1, CA2 and CA3. RaB firing was most frequently found in cells located near the border of SLM/SR of CA1. It was also observed in the subiculum, albeit in a lower fraction of cells (~33% of NPY cells) in this region compared to other hippocampal areas (~80%). We recorded from unlabeled interneurons in CA1, and could not induce RaB firing in any of them. In the cerebral cortex, all regions showed barrage firing (somatosensory, motor, orbitofrontal and visual cortices) with the highest percentages in the somatosensory cortex (~80%) and the lowest in the motor cortex (~67%). A large variability was observed between the duration of RaB firing in different regions, with a shorter median duration of RaB firing in the neocortex (median = 6.3 seconds) compared to the hippocampus (median = 18 seconds, Welch Two Sample t-test, $p = 0.029$). However, we could not find a significant difference between areas in the number of action potentials needed to induce RaB firing. Finally, in CA1, repeated induction of barrage firing in the same interneuron resulted in an increase in the duration of barrage firing from 5.5 s (first induction median duration) to 16.4 s on the fifth induction, but there was no change in the number of action potentials required to induce RaB firing. Together, these results suggest that barrage firing is a general phenomenon in the diverse group of NPY expressing interneurons in all hippocampal and many neocortical regions. This

finding has important implications regarding the potential functional consequences of RaB firing in cortical circuits.

**Title:** Effects of dopamine on persistent firing in layer III entorhinal cortex neurons

**Authors: *A. A. BATALLAN BURROWES**, C. A. CHAPMAN
Psychology, Concordia Univ., Montréal, QC, Canada

**Abstract:** Persistent neuronal firing in entorhinal cortex neurons that occurs following depolarizing current injection is thought to provide a potential mechanism that could contribute to short-term working memory. Persistent firing is observed during muscarinic cholinergic receptor activation following periods of induced spiking, and is dependent on activation of the calcium-activated non-specific cationic current (CAN). Persistent firing is observed for varying durations in entorhinal layer cortex layer II, III, and V cells, and firing patterns reported previously in layer III cells are robust and long-lasting. Dopamine may contribute to mechanisms of working memory in the entorhinal cortex, and has been shown to modulate up and down states in layer III entorhinal neurons. Application of dopamine to entorhinal neurons can also result in increases in intracellular calcium that could modulate activation of the CAN current and the resulting persistent firing. We therefore used whole cell recordings to assess the effects of dopamine on persistent firing in layer III neurons initiated by strong depolarizing current steps. Slices from male Long-Evans rats (3 to 7 weeks-old) were maintained in ACSF (32 °C) containing kynurenic acid (2 mM) and picrotoxin (100 µM) to block excitatory and inhibitory synaptic transmission, and 4 sec, 50-300 pA current steps were used to induce persistent firing. Persistent firing was not observed in normal ACSF, but was observed in the presence of 10 µM carbachol in 16 of 37 layer III cells. Persistent firing occurred with a mean latency of ~4 sec following current injection, was associated with a mean plateau potential of ~4 mV, and lasted for 5 to >25 sec. Addition of 1 µM dopamine in 8 cells had variable effects on persistent firing. In 4 cells, persistent firing was no longer observed following addition of dopamine. In the remaining cells, there was a non-significant reduction in the amplitude of the plateau potential,

and no consistent changes in latency, duration, and frequency of persistent firing. These results indicate variability in the ability of layer III entorhinal neurons to display persistent firing, and also indicate that dopamine may suppress persistent firing in some entorhinal layer III neurons.

**Abstract:** Despite the substantial diversity in the firing properties of individual neurons, these activity patterns are homogeneous within a well-defined types of neurons. Here we provide evidences for an exception in this generally accepted view by demonstrating markedly different firing properties within an anatomically stereotyped group of hippocampal GABAergic cells. First, using *in vitro* patch-clamp recordings, we distinguished two subgroups of CCK-expressing interneurons (CCK-IN) based on their firing patterns in response to current injections. The first group of CCK-INs (TOR cells) showed rectifying activity with delayed onset firing during sustained current injections depending on the preceding membrane voltage. The second subset of morphologically indistinguishable CCK-INs did not show state-dependent spike inhibition (non-TOR cells), but they possessed regular firing, irrespective of the membrane potential preceding the activity. Voltage-clamp recordings revealed that the state-dependent rectifying firing is correlated with the presence of an A-type $K^+$ current that activates and inactivates at negatively shifted voltages. The pharmacological sensitivity and voltage-dependence of this $K^+$-current are consistent with the properties of Kv4.3 subunit-containing channels. However, immunolocalization experiments revealed the Kv4.3 subunit at a similar levels in TOR and nonTOR CCK+ cells. Therefore, we further explored the potential underlying differences

between the two subgroups by analyzing the total RNA content of individually recorded CCK+ cells using single cell RNAseq. This analysis suggested many differences in important neuronal genes including a distinguishing marker, SATB1, whose presence was verified in TOR, but not in non-TOR cells using immunolocalization. Furthermore, the results also showed that albeit the Kv4.3 RNA can be similarly detected in TOR and non-TOR CCK-INs, the auxiliary subunits of Kv4.3 channels, the KChIPs are remarkably different. Due to the known influence of KChIPs on currents conducted through the Kv4.3 channels, their differential availability in the two CCK-IN subgroups potentially explains the measured differences in the firing properties. Finally, we explored how these different A-current properties accommodate the excitability of otherwise similar neurons for various physiologically relevant activity regimes, such as theta-modulated inputs. Our results revealed that different availability of an A-type $K^+$ conductance could render different function among anatomically similar CCK-INs.

**Title:** Changes in firing rates of CA3 place cells across sleep following a novel experience

**Authors: *E. HWAUN**[1], L. L. COLGIN[2]
[1]UT Austin, Austin, TX; [2]Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX

**Abstract:** Encoding memories of new experiences presumably requires strengthening of synaptic connections between hippocampal neurons. However, without a regulatory mechanism, the overall excitability of the hippocampal network will continue to increase as more novel information is encoded. It has been hypothesized that neural activity levels are reset during sleep in order to preserve a relatively constant level of excitability over time. Accordingly, a previous study showed that neurons in hippocampal subregion CA1 decreased their firing rates during rapid eye movement (REM) sleep (Grosmark et al., 2012). However, it remains unclear whether firing rate reductions during REM are specific to cells encoding new experiences. Moreover, memories are thought to be stored in the recurrent collateral system of CA3, yet it is unclear whether similar firing rate changes occur in CA3. To address these questions, we recorded neural

activity in CA3 as rats were exposed to a novel environment and during the subsequent night's sleep. CA3 place cells that were active in the novel environment showed firing rate reductions during REM sleep, whereas firing rates of CA3 place cells that were not active in the novel environment did not change much during REM sleep. Moreover, firing rates during sharp wave-ripples in non-REM sleep were significantly higher for CA3 cells that were active in the novel environment compared to CA3 cells that were not active in the novel environment. Also, the magnitude of firing rate decreases during REM sleep was significantly correlated with the magnitude of firing rate increases during ripples. Together, these results suggest that homeostatic regulation of neural activity levels in CA3 cells during sleep is stronger for those cells that encode memories of new experiences that occurred earlier in the day.

**Title:** The role of calcium activated potassium channels in controlling excitability of neonatal hippocampal neurons in primary cultures

**Authors: M. S. HUNSBERGER**, A. J. MONICAL, *M. MYNLIEFF
Biol. Sci., Marquette Univ., Milwaukee, WI

**Abstract:** Profound differences in excitability exist between the adult and neonatal hippocampus. These differences may be partly due to differences in the complement of potassium ($K^+$) channels expressed in adults and neonates. We examined the contributions of specific $K^+$ currents to the regulation of excitability in neonatal neurons. $K^+$ channels regulate excitability by determining speed of action potential (AP) repolarization as well as the magnitude and duration of the fast, medium, and slow afterhyperpolarizations (fAHP, mAHP, and sAHP). Whole-cell patch clamp recordings in current clamp and voltage clamp mode were performed on primary cultures of neonatal rat (P0-P10) hippocampal neurons. Cells were categorized into four general groups (basket, stellate, vertical, and pyramidal) according to the duration of their AP, the fAHP, and maximum firing rate in response to a 100 ms depolarizing pulse. Recordings were performed in the presence of nimodipine to determine the role of the L-type Calcium ($Ca^{2+}$) current in regulating excitability through activation of $Ca^{2+}$ activated $K^+$ channels and specific $K^+$

channel blockers to determine the roles of individual $K^+$ currents across cell types. Nimodipine (10 µM) blocked 66% of the sustained $K^+$ current ($I_K$; N=31), 25% of the transient $K^+$ current ($I_A$; N=25), and decreased the duration of the AP across all cell types (N=42; p=0.016). Nimodipine treatment decreased the magnitude of the fAHP in basket and stellate cells but not in the other cell types identified. This confirmed that $Ca^{2+}$ influx through L-type channels contributes to excitability in neonatal hippocampal neurons, likely due to activation of $K^+$ channels. Blockade of the large conductance BK channels with 100 nM verruculogen resulted in an attenuation of 15% of $I_K$ (N=30) and 23% of $I_A$ (n=25). Verruculogen decreased AP trains by 24% in response to a 1s pulse (N=21) and also decreased the magnitude of the mAHP after a 100 ms pulse by 14% in basket cells (N=5). Blockade of the small conductance SK channels with 1 µM apamin resulted in an attenuation of 21% of $I_K$ (N=30) and 24% of $I_A$ (N=27). These data suggest that the potassium current blocked by the L-type channel blocker, nimodipine, is likely comprised of multiple $Ca^{2+}$ activated $K^+$ currents. The effect of blockade of KCNQ channels was also tested as these channels are suggested to be both voltage gated and $Ca^{2+}$ sensitive. Blockade of KCNQ channels with 50 µM XE-991 resulted in an attenuation of 64% of $I_K$ (N=19) and 54% of $I_A$ (N=18). The larger blockade of $I_A$ by BK, SK, and KCNQ blockers when compared to blockade of L-type $Ca^{2+}$ channels suggests that other $Ca^{2+}$ channels contribute specifically to the transient portion of the $K^+$ current in these cells.

**Title:** Ionic current correlations are ubiquitous and regulated - evidence from mammalian neurons

**Authors: *J. P. GOLOWASCH**[1], T. TRAN[3], C. T. UNAL[4], L. ZABORSZKY[4], H. G. ROTSTEIN[2], A. KIRKWOOD[3]
[1]Dept Biol. Sci., [2]Dept Mathematical Sci., NJIT, Newark, NJ; [3]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [4]Ctr. for Mol. and Behavioral Neurosci., Rutgers University-Newark, Newark, NJ

**Abstract:** Ionic current levels in populations of identical neurons are extremely variable (Goldman et al. 2001; Leao et al. 2012; Liss et al. 2001; Olypher and Calabrese 2007; Ransdell et al. 2012; Swensen and Bean 2005). This poses the question of how these neurons can generate consistent activity patterns despite the variability of the current they express. It has been proposed that neurons can express different ionic currents in a co-regulated manner, which would result in the appearance of correlated ionic currents, maximal conductances or their transcripts numbers in a population of identified (identical) neurons. This has been observed in a number of neuronal cell types in several invertebrate species (Khorkova and Golowasch 2007; MacLean et al. 2003; Ransdell et al. 2013; Schulz et al. 2007; Tobin et al. 2009). However, that has typically been assumed to be an invertebrate idiosyncrasy. Evidence of their existence in vertebrates is largely indirect or anecdotal (Amendola et al. 2012; McAnelly and Zakon 2000). Nevertheless, there is persuasive theoretical work that suggests feasible mechanisms that generate these correlations (O'Leary et al. 2013; O'Leary et al. 2014), and the potential functional role of ionic current correlations (Hudson and Prinz 2010; O'Leary and Marder 2016). There is also evidence that the expression of ionic current correlations is a highly regulated phenomenon (Khorkova and Golowasch 2007), suggesting that correlations play important roles in the long-term dynamics of neuronal activity, the regulation of the robustness of this activity, or both. Here we report that ionic current correlations are widely distributed in mammalian neurons, with significant correlations between $K^+$, leak and transient inward currents in adult mouse cholinergic basal forebrain and hippocampal granule cells. We also have evidence of long-term regulation of some of these current correlations, suggesting a highly dynamic but slowly evolving interaction between the currents and their potential functional role. We conclude that the existence of correlations between ionic currents is not an invertebrate phenomenon, but a ubiquitous one among neurons.

**Abstract:** Epilepsy is the fourth most common neurological disorder, and is responsible for a greater total global burden of disease than any neurological condition except stroke or migraine. Despite considerable advances in the treatment and diagnosis of seizure disorders, our understanding of the cellular and molecular mechanisms by which epilepsy develops (epileptogenesis) remains incomplete. To elucidate mechanisms underlying epileptogenesis in humans we study the excitability of human hippocampal neurons and networks in tissue slices from specimens excised during brain surgery for the treatment of focal, pharmacoresistant epilepsy. Specifically, we characterize electrophysiological and morphological features of single neurons via whole-cell patch clamping and reconstructed biocytin-fillings as a function of cell type for different hippocampal subfields. Importantly, these measurements are performed in ex vivo hippocampal slices derived from patients with varying degrees of hippocampal sclerosis (Watson grade 1-4). A major aim of this work is to bridge the spatiotemporal scales and causally link how changes at the component level (synapses, single-neuron excitability, etc.) are reflected at the network and the observable level (such as depth LFP, EEG, ECoG, etc.) To integrate these different facets, detailed biophysical single-neuron models are developed that account for observed ephys and morphology features as well as pathology-related alterations [Druckmann et al, Front Neurosci 2007; Reimann, Anastassiou et al, Neuron, 2013]. Ultimately, these computational simulations seek to bridge the gap between single-neuron biophysics, ensemble activity and experimentally recorded signals such as the depth EEG and multi-unit activity typically measured during seizures in humans. Using experiments and computational modeling we investigate the underlying causes of seizure disorders. In particular we investigate the hypothesis of epileptogenesis in the setting of hippocampal sclerosis (i.e. with varying degrees of morphological changes) in the dentate gyrus.

**Abstract:** The hippocampus plays a critical role in learning and memory, as well as in spatial processing, which are supported by coordinated network activity, including theta and gamma oscillations. Recent evidence suggests that hippocampal subregions (e.g., CA1) can generate these oscillations at the network level, at least in part through GABAergic interneurons. However, it is unclear whether specific GABAergic interneurons generate intrinsic theta and/or gamma oscillations at the single cell level. Since major types of CA1 interneurons (i.e., parvalbumin-expressing basket cells (PVBCs), cannabinoid type 1 receptor-expressing basket cells (CB1BCs), and neurogliaform family cells) are thought to play key roles in hippocampal oscillations, we tested the hypothesis that they generate intrinsic oscillations at the single cell level. We performed whole-cell patch-clamp recordings of GABAergic interneurons in the CA1 region of the mouse hippocampus in the presence of excitatory and inhibitory synaptic blockers to identify spontaneous intrinsic membrane potential oscillations. The majority of PVBCs (81%), but not the other interneuronal subtypes, produced intrinsic gamma oscillations if the membrane potential remained above -45 mV. By contrast, both CB1BCs and neurogliaform family cells, as well as the remaining PVBCs (19%) produced intrinsic theta/alpha, but not gamma, oscillations. These oscillations were blocked by persistent sodium current blockers (i.e., tetrodotoxin or riluzole). These data demonstrate that the three major types of hippocampal interneurons produce distinct frequency bands of intrinsic membrane oscillations. These findings support the possibility that intrinsic oscillatory properties of these interneuronal subtypes are key mechanisms of hippocampal theta and gamma oscillations at the network level, and suggest that specific interneuronal subtypes play different functional roles in hippocampal information processing. This work was supported by the College of Medicine, University of Arkansas for Medical Sciences (startup funding to S.-H.L.), and a Center for Translational Neuroscience award from the IDeA program at NIGMS, P30 GM110702.

**Abstract:** It was reported that spatial (place) and non-spatial (odor) information are integrated at hippocampal dentate gyrus in the brain. The dentate gyrus is a gate for memory association among cortexes. The granule cells (GCs) in hippocampal dentate gyrus receives two inputs from entorhinal cortex. Spatial information is delivered from medial entorhinal cortex to the medial dendrite (MD) through the medial perforant path (MPP). On the other hand, non-spatial information is delivered from lateral entorhinal cortex to the distal dendrite (DD) through the lateral perforant path (LPP). In addition, it was reported that 4-8Hz (theta rhythms) and 20-40Hz (gamma rhythms) oscillations were observed in the MPP and LPP in the rat brain during the odor discrimination task, respectively.To investigate the interaction of those two inputs, the frequency responses of GCs for the input with spatial information and non-spatial information were measured at 10-40 Hz of input frequency in rat hippocampal slices. During experiments, NMDA-receptors antagonist D-APV was applied to prevent from inducing the synaptic plasticity by frequency stimuli. In addition, inhibitory inputs were blocked by picrotoxin, GABAergic receptor antagonist. As the experimental result, GCs responses for successive inputs on DD sustained, suggesting a rate coding, and that 1md on is transient, suggesting a temporal coding.In addition, Multi-compartment GC with dynamic synapses model (Tsodkys et al. 1988) was developed using NEURON simulator and the model was fixed by parameter fitting for the physiological data. Regular burst inputs and random pulses were applied to MD and DD synapses, respectively. As the computational experimental result, the sensitivity for burst inputs to MD alone did not show a clear temporal pattern. In addition, as 20 Hz random pulses were simultaneously applied to DD, the GC activity was facilitated and the high temporal pattern sensitivity was observed. Moreover, as random pulse inputs were simultaneously applied to DD at 30-50 Hz, the GC activity was more facilitated. So that, the pattern discrimination was broad. Our results suggest that around 20Hz of DD inputs is suitable to enhance and tune the temporal-pattern of burst inputs to MD.

**Title:** JC virus propagation is potentiated by glial replication & is accelerated by demyelination-associated glial proliferation

**Authors: *C. LI**[1], J. BATES[1], S. J. SHANZ[1], M. S. WINDREM[1], S. A. GOLDMAN[1,2]
[1]URMC, Rochester, NY; [2]Univ. of Copenhagen, Copenhagen, Denmark

**Abstract:** Progressive multifocal leukoencephalopathy (PML) is a devastating demyelinating infection in the central nervous system (CNS) of immunosuppressed individuals, mediated by the gliotropic polyomavirus JCV. We recently found that JCV replicated primarily in mitotic human glial progenitors and astrocytes, with oligodendrocyte death occurring through T antigen-mediated apoptosis rather than lysis. This observation raised the possibility that JCV infection might be potentiated by astrocytic replication, and hence accelerated in the setting of mitotic gliogenesis. To test this hypothesis, we first tagged dividing human astrocytes in vitro with bromodeoxyuridine (BrdU), then infected them with JCV MAD1 and confirmed that proliferating human astrocytes were more supportive for JC viral propagation, as early T antigen expression appeared both in $BrdU^+$ and $BrdU^-$ host cells, but the late VP1 antigen, whose expression indicates viral replication, only appeared in $BrdU^+$ cells at day 5 post-infection. Similarly, 5'-ethinyl 2'-deoxyuridine (EdU) labeling revealed more mitotic astrocytes among JCV-infected cells than among matched uninfected cells. In vitro scratch assays combining with MAD1 infection revealed that viral propagation was accelerated in the wound region, compared with regions distant to the scratch, tracking the increased glial proliferation rate in the wound area. On that basis, we next assessed the dependence of JCV infection upon local glial proliferation in vivo, using human glial chimeric mice subjected to cuprizone challenge. To this end, we established chimeras by engrafting human induced pluripotent stem cell (hiPSC)-derived glial progenitor cells (GPCs) into neonatal $rag1^{-/-}$ immune deficient C57B1/6 mice, and then injecting MAD1 JCV into the brains of these animals as adults, resulting in their active infection. The chimeras were then challenged with cuprizone diet (0.2% w/w, for 16w or 20w), which resulted in both demyelination and a proliferative response by the resident human glial cells.

Immunostaining for T antigen and VP1 revealed that JCV propagation was significantly accelerated in these mice. These results suggest that JCV propagation in PML may be potentiated by glial DNA replication, and that the accentuated glial cell division attending acute demyelination might provide an especially favorable environment for JCV propagation and hence PML progression. These data would argue for the aggressive prevention of new demyelinating events in patients at risk for PML. More broadly, this study expands our understanding on JC virus propagation and provides a model by which to further assess the pathogenesis and treatment of PML.

**Title:** A highly expanded IgA B-cell in the cerebrospinal fluid of a multiple sclerosis patient

**Authors: *J. LIN**, A. LIANG, A. FINNEY-STABLE, S. SADIQ
Tisch MS Res. Cntr NY, New York, NY

**Abstract: Introduction:** The effectiveness of B-cell targeted therapy in multiple sclerosis (MS) has rejuvenated interest in B-cells and the potential roles they may play in the pathogenesis of MS. MS B-cell interest has traditionally been due to the presence of cerebrospinal fluid (CSF) IgG oligoclonal bands, a diagnostic marker for MS. Recently, IgM antibodies have been reported as a potential indicator of clinical isolated syndrome conversion to MS and/or future disease severity. The association of IgA isotype B-cells or antibodies with MS however, has been lacking. We report here the presence of a highly expanded IgA isotype B-cell in the CSF of a clinically definite MS patient.
**Methods:** Twelve mL of CSF was obtained via lumbar puncture. Cells from CSF were centrifuged and stained for CD19 and CD138. Ninety six single cells were sorted via FACS for CD19 or CD138 positivity. Gene specific primers for immunoglobulin heavy and light chains were used for reverse transcription. Nested PCRs were performed to amplify the variable region and a small portion of the constant region. Sequencing yielded the variable region as well as identified the immunoglobulin isotype. ELISAs for protein levels were performed according to standard procedures.
**Results:** PCR and subsequent sequencing of the 96 single cell sorted CD19+ or CD138+ B-cells

yielded 67 heavy chain sequences with the following breakdown via isotypes: 40 IgA, 19 IgM, and 8 IgG. Variable region sequence analysis show 38 of the 40 IgA sequences shares identical CDR3 regions. This highly expanded IgA clone made up 56.7% of the sequenced identified CD19+ or CD138+ B-cells. The sequenced light chains also show this clonal expansion and also serve as a contamination check (identical CDR3 heavy chains also had identical CDR3 light chains). Albumin levels did not show blood brain barrier permeability out of normal range (CSF/Serum ratio of 3.8, normal at <9). CSF IgA levels was high at 7.7 µg/ml (normal at <2.3 µg/mL).
**Conclusion:** We report here an atypical MS CSF patient where the predominant B-cell detected in his CSF is a highly expanded CD19 or CD138 positive B-cell with an IgA isotype. Analysis using total amounts of CSF IgA as well as albumin levels in the CSF and serum is suggestive of intrathecal synthesis. Further research is being conducted to ascertain the specificity of this antibody and its relevance to disease pathogenesis.

**Abstract:** Multiple Sclerosis (MS) results in visual cortex (VC) dysfunction, even in the absence of ophthalmic pathologies. The precise mechanism of this dysfunction remains elusive. Our previous studies have shown an association between white-matter microstructure (WMMS) insult and reduced Blood-Oxygen-Level-Dependent (BOLD) signal in the VC of MS patients when compared to healthy controls. However, the physiological basis of the reduction in VC BOLD signal observed in MS remains unknown. We hypothesized that WMMS destruction affects communication between neurons and cerebral vasculature (ie., neurovascular coupling) and in turn, disrupts neural function. In this study, we sought to isolate the origin of MS-related

BOLD changes by comparing various components of the hemodynamic response function, blood-flow and oxygen metabolic constituents using dual-echo calibrated functional MRI (cfMRI). We conducted a case-control study comparing relapsing-remitting MS patients diagnosed by McDonald criteria with matched healthy controls. Participants were scanned using a 3T MRI scanner. We utilized a dual-echo pulse sequence that permitted near-simultaneous measurement of cerebral blood flow (CBF) and BOLD signal. In the scanner, participants performed a hypercapnia inhalation challenge while being scanned. They subsequently performed a block designed visual task. During the visual task, participants responded via bilateral button-press whenever a fixation cross at center-screen changed in luminance; during stimulation blocks, flickering checkerboards were presented at 6Hz.Individual data were preprocessed and convolved to obtain functional regions of interest (ROI). BOLD and CBF time series were obtained from these ROIs. Cerebral metabolic rate of utilization of oxygen ($CMRO_2$) was calculated using the deoxyhemoglobin dilution model. Whereas healthy controls exhibited stimulation-induced BOLD signal increases that were sustained across the block, MS patients exhibited stimulation-induced BOLD signal increases that declined across the block. Estimated maximum blood-oxygenation (the factor M) was higher in MS patients than healthy controls. During stimulation, increases in CBF and $CMRO_2$ were lower in MS patients than healthy controls. These results support the hypothesis that MS-related neural pathology arises more from neural and glial deficits than from vascular deficits and suggest that reduced neural metabolism plays a key role in MS-related reduction in neurovascular coupling.

**Abstract:** Multiple Sclerosis (MS) leads to motor cortex (MC) dysfunction and this has been attributed to decreased alertness and fatigue. The neural-vascular coupling system, composed of cerebral blood vessels, glial cells, and neurons coherently function to maintain effective neural function. Previously, we have found reduced blood-oxygen-level dependent (BOLD) signal in the motor cortex of MS patients. However, the relative contributions of each neural-vascular component to reduced BOLD signal remain unknown. We performed a cross-sectional study comparing relapsing-remitting MS patients with healthy controls. All subjects who met the inclusion criteria were scanned using a 3T MRI scanner with a dual-echo calibrated functional MRI (cfMRI) sequence which provided near-simultaneous measures for both cerebral blood flow (CBF) and BOLD signal. During imaging, subjects performed a motor task which required bilateral button presses in time with a 2Hz auditory cue. An additional hypercapnia gas challenge involving inhalation of room air (4 min) and 5% $CO_2$ (6 min) permitted measures of cerebral metabolic rate of oxygen utilization ($CMRO_2$). Data were preprocessed and analyzed using the general linear model to obtain functional regions of interest (ROI). Percent signal change was obtained for each measure in these ROIs. During active blocks, MS patients displayed an initial rise in CBF followed by a gradual decline, whereas healthy controls exhibited a similar initial rise and a subsequent sustained plateau. CBF decreased in MS patients but BOLD signal was not different from healthy controls, suggesting lower $CMRO_2$ in MS patients. Estimated maximum blood-oxygenation (the factor M) was higher in MS patients than healthy controls. These results suggest progressive uncoupling between glial cells, neurons, and blood vessels with persistent stimulation of the motor cortex.

**Abstract:** The hemodynamic response function (HRF), a model of brain blood-flow changes in response to neural activity, arises from communication between neurons and the vasculature that supplies these neurons by means of glial cell intermediaries. Disruption of such communication might have consequences for cognition and performance. In demyelinating diseases, particularly Multiple Sclerosis (MS), white-matter microstructure is damaged, and performance is impaired. White-matter damage compromises the ability of neurons to adequately convey their metabolic needs, resulting in insufficient oxygen and nutrient perfusion. In this study, we isolated the components of the HRF that could quantify the extent to which damaged white matter affects neural-vascular coupling, and possibly cognitive symptoms experienced by MS sufferers. Twenty-eight relapsing-remitting MS patients and 23 healthy controls matched on age, sex, and education were scanned on a 3T MRI scanner (TE = 30 ms, TR = 2000 ms, 39 4-mm transverse slices, no gap, in-plane resolution 3.43 × 3.43 $mm^2$, 70$^o$ flip angle, 64 × 64 matrix). During scanning, participants performed (1) a simple button-press task, in which they responded via bilateral button-press whenever a flickering checkerboard appeared, and (2) an fMRI-adapted version of the WAIS Symbol Digit Modalities Task, in which they indicated via button-press whether a probe digit-symbol pair matched a corresponding pair in a key of 9 digit-symbol pairs. HRFs were modeled from visual, motor, and prefrontal brain regions during both tasks using piecewise linear-B spline functions, an approach that minimized assumptions regarding HRF shape that may not be valid for diseased populations. These functions were then characterized using several shape metrics. Group differences in peak amplitude (visual $p < 0.02$, motor $p < 0.04$, prefrontal $p < 0.01$), time-to-peak (prefrontal $p < 0.02$), full-width-at-half-maximum (motor $p < 0.05$), and area-under-curve (prefrontal $p < 0.01$) indicated significantly different HRF shapes between controls and patients. Relationships between processing speed task performance and both time-to-peak ($p < 0.004$) and area-under-curve ($p < 0.001$) were also observed. These results support the hypothesis that dysfunction of the neural-vascular communication system disrupts the nutrient delivery vital to intact neural functioning. They also support the hypothesis that pathological alterations to white-matter microstructure underlie MS-related cognitive performance deficits.

**Title:** Restoring vision in a mouse model of optic nerve demyelination through transplantation of iPSC-derived oligodendrocyte precursor cells

**Authors: *M. M. STANDIFORD**[1], K. MIRCHIA[2], E. TRIPLET[2], C. L. HOWE[2]
[1]Mayo Grad. Sch., Rochester, MN; [2]Neurol., Mayo Clin., Rochester, MN

**Abstract:** In the United States, more than 400,000 people suffer from multiple sclerosis (MS). Often the first symptom patients will experience is optic neuritis. Optic neuritis is acute inflammation of the optic nerve and is associated with pain, temporary loss of vision, and chronic demyelination. Nearly 80% of MS patients will experience optic neuritis over the course of the disease and even patients without a clinical history of optic neuritis exhibit poor visual function. In order to restore visual function in these patients, the optic nerve axons must be protected and the myelin sheath repaired in order to reestablish high-speed, coordinated conduction of impulses. While there are a number of immunomodulatory therapeutics available, no therapies are currently approved for remyelination. Unlike the rest of the central nervous system, the optic nerve is uniquely accessible for drug delivery or cell transplantation using current clinical practices. Because the remyelinating capacity of endogenous oligodendrocyte precursor cells (OPCs) diminishes overtime in MS patients, we aimed to determine if transplantation of OPCs was a viable remyelination therapy in the optic nerve. We transplanted OPCs derived from induced pluripotent stem cells (iPSC) via intravitreal injection into our novel cuprizone-induced mouse model of optic nerve demyelination. These chronically demyelinated mice show both histological aberrations and visual defects. We find that following OPC transplant mice exhibit restoration of histological abnormalities and functional recovery as measured by normalization of visual evoked potentials. Herein, we show that transplantation of OPCs into the optic nerve is a viable therapeutic strategy for optic nerve demyelination.

**Title:** Conditional knockout of DARS2 results in white matter atrophy and neurobehavioral changes in mice

**Authors: *C. L. NEMETH**[1,2], S. N. TOMLINSON[1], C. F. MURRAY[1], C. TIFFANY[1], M. V. JOHNSTON[1,2], A. TRIFUNOVIC[3], A. FATEMI[2]
[1]Dept of Neurol., Kennedy Krieger Inst., Baltimore, MD; [2]Neurol., Johns Hopkins Univ., Baltimore, MD; [3]CECAD Res. Centre, Inst. for Mitochondrial Dis. and Aging, Univ. of Cologne, Cologne, Germany

**Abstract:** Leukoencephalopathy with brain stem and spinal cord involvement and lactate elevation (LBSL) is caused by mutations in DARS2, a gene encoding the mitochondrial enzyme aspartyl-tRNA synthetase. LBSL results in a rare, progressive, neurological disease that manifests as white matter signal abnormalities in the cerebral white matter and spinal cord, as well as slowly progressive dorsal column spasticity, dysarthria, and ataxia. To date, no animal model recapitulates disease pathology and no treatment exists. Previous attempts to develop an animal model of LBSL through the complete or conditional neuronal knock-out of Dars2 have been unsuccessful. Here, to mimic the clinical presentation in white matter, we developed a conditional knock-out of DARS2 using Cre-lox recombination in PDGFRα-expressing oligodendrocyte precursors. PDGFR$\alpha^{Cre+}$;Dars2$^{fl/fl}$ animals show a slight progressive behavioral phenotype with a reduction in both locomotor activity and rearing in open field over time, consistent with slowly progressive ataxia seen in LBSL. Preliminary data from these animals also suggests a reduction in oligodendrocyte transcription factor (Olig2)-expressing cells per area in the corpus callosum and an overall reduction in corpus callosum area relative to age-matched control littermates, consistent with white matter abnormalities observed in the clinic. This novel mouse model has the potential to elucidate mechanisms of LBSL and may allow for translation to clinical discoveries for the treatment of LBSL.

**Title:** Targeting protease activated receptor 1 improves CNS myelin regeneration

**Authors: *C. CHOI**[1,2], P. STARSKI[1,3], G. WALTERS[1], A. PAULSEN[1], I. A. SCARISBRICK[1,2,3]
[1]Dept. of Physical Med. and Rehabil., Mayo Clin., Rochester, MN; [2]Dept. of Physiol. and Biomed. Engin., Rehabil. Med. Res. Center, Mayo Clin., Rochester, MN; [3]Grad. Sch. of Biomed. Sci., Neurobio. of Dis. Program Mayo Clin., Rochester, MN

**Abstract:** Protease activated receptors (PARs) are a unique G-protein coupled receptor (GPCR) family, being activated by proteolytic cleavage within their extracellular domain to reveal a new amino-terminus that binds to the second extracellular loop to elicit intracellular signaling. PAR activating enzymes are known to be present in the intact central nervous system (CNS) and can also be elevated upon extravasation or after secretion by infiltrating immune cells in cases of neurological injury and disease. Despite this knowledge, little is currently understood regarding the consequences of CNS PAR activation or whether these receptors can be targeted to promote repair. Previous research in our laboratory has shown that several secreted serine proteases are highly enriched in white matter of individuals with demyelinating conditions, such as multiple sclerosis, or after spinal cord injury. In addition, we recently reported that PAR1 exhibits peak expression levels in the murine spinal cord at birth and that genetic deletion of PAR1 results in an accelerated pattern of spinal cord myelination, including higher levels of proteolipid protein at term and MBP levels in adulthood (Yoon et al., 2015). Collectively these data suggested that PAR1 is a key regulator of myelination and here we tested the hypothesis that PAR1 also regulates the process of remyelination. This hypothesis was investigated by determining whether genetic deletion of PAR1 impacts myelin regeneration in the lysolecithin model of focal demyelination. We accomplished this by systematic quantification of the amount of remyelination, astrogliosis, and inflammation in the spinal cord of adult male wild type or PAR1 knockout mice at 14 or 30 days after lysolecithin injection. PAR1 knockout mice showed improvements in the number of remyelinated axons compared to their wild type littermates 14 days after lysolecithin-mediated demyelination. Enhancements in myelin regeneration were

paralleled by increased numbers of both Olig2 and CC-1 positive oligodendrocytes and decreased numbers of Isolectin B positive microglia/monocytes at sites of myelin repair. These findings suggest that PAR1 is an essential rheostat of myelin generation and regeneration, such that inhibition of PAR1 may be a useful target to accelerate myelin repair in the adult CNS.

**Title:** Reduced myelin sheath thickness in aged forebrain-specific CTGF knockout mice

**Authors: *H.-C. CHANG**[1], L.-J. LEE[1,2,3]
[1]Grad. Inst. of Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

**Abstract:** In the nervous system, connective tissue growth factor (CTGF) is expressed in the cortical subplate, but its function is still unclear. In order to clarify the role of CTGF in the subplate, forebrain-specific *Ctgf* knockout (Fb*Ctgf* KO) mice were generated. In the present study, we characterized the phenotypes of aged mutant mice. Twenty one months old Fb*Ctgf* KO mice have equivalent weight and locomotor activity compared with age-matched control mice. In a series of behavioral tests, both control and Fb*Ctgf* KO mice showed similar emotion performances in open field test, elevated plus maze test and forced swimming test. In learning and memory tests, no significant difference was observed between control and Fb*Ctgf* KO mice in novel object recognition test and Y-maze test. It has been report that CTGF takes part in the maturation of oligodendrocytes and myelin formation, but whether CTGF participate in the maintenance of myelin structure is unknown. In the cerebral cortex, the expression of myelin basic protein was not altered in Fb*Ctgf* KO mice while the number of mature oligodendrocyte in white matters was also not changed. However, the thickness of myelin sheath in Fb*Ctgf* KO mice was thinner than control mice, whereas the axonal diameter was comparable between controls and mutants. Our results suggest a role of subplate-derived CTGF in the maintenance of myelin structure.

**Title:** Modulating molecular chaperones improves demyelinating neuropathy in the MPZ-RAF mouse model

**Authors: *X. ZHANG**[1], B. S. J. BLAGG[2], R. T. DOBROWSKY[1]
[1]Pharmacol. and Toxicology, [2]Medicinal Chem., Univ. of Kansas, Lawrence, KS

**Abstract:** Demyelinating neuropathies result from Schwann cell (SC) dedifferentiation upon loss of axonal contact or injury. Recent evidence suggests that c-jun is critical in promoting Schwann cell dedifferentiation. Elevated c-jun levels have been detected in a variety of human neuropathies suggesting that it may be a potential target for preventing or slowing the demyelination process. We previously demonstrated that modulation of heat shock protein 90 (Hsp90) with a small molecule Hsp90 modulator called KU-32 decreased c-jun expression and prevented demyelination in SC-neuronal co-cultures in a heat shock protein 70 (Hsp70)-dependent manner. In the current study, we utilized a transgenic mouse model (MPZ-Raf) in which injection of tamoxifen (TMX) leads to activation of the Raf-MAPK kinase pathway specifically in SCs. Elevated SC MAPK activity increased c-jun expression, demyelination and subsequent motor dysfunction. With this model, we sought to determine whether modulating heat shock proteins with KU-596, a third generation Hsp90 modulator, is sufficient to ameliorate the motor neuropathy that develops in these mice. Treating MPZ-Raf mice with KU-596 reduced the induction of c-jun but had no effect on the extent of MAPK activity. Drug treatment improved motor performance, delayed the onset of rear-limb paresis and ameliorated the extent of peripheral nerve demyelination in both prevention and intervention studies. Hsp70 was necessary for the neuroprotective efficacy of KU-596 since MPZ-Raf×Hsp70KO mice did not respond to KU-596 treatment. KU-596 is currently in Phase 1 clinical trials and our data indicate that modulating heat shock proteins may provide a novel therapeutic approach to attenuate c-jun induced demyelinating neuropathies in humans.

**Title:** Lipid biochemistry probed with Nile Red spectral microscopy reveals novel features during cuprizone demyelination and remyelination

**Authors: *W. TEO**[1], A. V. CAPRARIELLO[2], M. MORGAN[1], P. K. STYS[3]
[1]Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada; [2]Clin. Neurosciences, [3]Clin. Neurosci., Univ. of Calgary, Calgary, AB, Canada

**Abstract:** Myelin is a lipid-rich spiral wrapping of axons that facilitates rapid saltatory conduction. Although myelin is predominantly lipid (70-85% w/w), a lack of methods for studying lipids in tissue sections has hindered our understanding of changes in intact and pathological myelin. Using the solvatochromic lipophilic fluorescent dye Nile Red (NR), whose fluorescence spectral profiles change with biochemical alterations in the local tissue environment, we report a number of novel tissue defects in the cuprizone (CPZ) animal model of de/re-myelination, particularly at early time points, below the threshold for detection by conventional methods. After only a single week of CPZ treatment, well before overt demyelination, lipids in the corpus callosum (CC) exhibited distinct biochemical changes, preceding overt demyelination. Accumulation of intense lipid droplets between the lateral CC and hippocampal white matter provided further evidence of early lipid pathology. At 2 weeks of CPZ, a time point also lacking overt histological defects, active myelin change reported by NR spectral shifts around the lateral ventricles was seen together with lipid droplet accumulation. Further, focal lesions of lipid loss were identified in grey and white matter, with no correlates by standard immunohistochemistry (MBP, IBA-1), suggesting that NR lipid histochemistry was more sensitive to early pathological changes than conventional protein immunohistochemistry. At week 3 of CPZ, when demyelination is known to occur, lipids continued to exhibit even more abnormal signatures with further accumulation of lipid droplets in demyelinated areas. After 6 weeks of CPZ + 4 weeks recovery, re-myelination was robust but NR showed that regenerated myelin was biochemically abnormal, exhibiting features of early 1 week CPZ signatures. CONCLUSION: solvatochromic properties of NR coupled with spectral microscopy represent a powerful new tool for detecting very early and subtle myelin damage, likely reflecting lipid biochemical changes. This method is more sensitive than conventional techniques such as myelin stains and immunohistochemistry. Furthermore, NR microscopy suggests that remyelination, at

least in the CPZ model, is aberrant, which may have implications for delayed degeneration which has been reported in this model.

**Title:** Antisense oligonucleotide therapy elicits rapid, sustained pathology reversal in a mouse model of Alexander disease

**Authors: *B. POWERS**[1], T. HAGEMANN[2], C. MAZUR[1], E. SWAYZE[1], A. MESSING[2]
[1]Neurosci. Drug Discovery, Ionis Pharmaceuticals, Carlsbad, CA; [2]Waisman Ctr. and Dept. of Comparative Biosci., Univ. of Wisconsin-Madison, Madison, WI

**Abstract:** Alexander disease (AxD) is a fatal leukodystrophy caused by autosomal dominant missense mutations in the gene for glial fibrillary acidic protein (GFAP). Mutations cause GFAP to accumulate above a toxic threshold and aggregate with other proteins into intra-astrocytic inclusions called Rosenthal fibers (RFs), the pathological hallmark of the disease. Seizures, megalocephaly and developmental delay occur in early-onset patients, while late-onset patients instead exhibit bulbar signs, spasticity, and ataxia. AxD knock-in mice carry point mutations in mouse *Gfap* that are orthologous to patient mutations and exhibit spontaneous, pronounced GFAP overexpression and RFs. We investigated the therapeutic potential of antisense oligonucleotides (ASOs) to reduce mouse GFAP expression and reverse disease pathology in knock-in mice. We administered a single intracerebroventricular (ICV) bolus injection of an ASO targeting GFAP in 8 week old mice that exhibit marked GFAP overexpression and RF burden. We observed up to 99% GFAP mRNA reduction in the CNS one week post-ICV. GFAP protein was reduced to WT levels by 4 weeks post-ICV and continued to decline between 4-8 weeks. RF burden was reduced 2 weeks post-ICV and completely reversed by 4 weeks after ASO administration. Markers of microglial activation/recruitment (Aif1 mRNA) and oxidative stress (Nqo1 mRNA) markedly declined to nearly WT levels by 1 and 2 weeks post-ICV, respectively. GFAP suppression and complete pathology reversal continued out to 16 weeks. In conclusion, ASOs targeting GFAP show great promise as a therapeutic strategy to achieve rapid and sustained reversal of AxD pathology.

**Title:** IL-37 exerts therapeutic effects in experimental autoimmune encephalomyelitis

**Authors: *A. SÁNCHEZ FERNÁNDEZ**[1], C. DINARELLO[2,3], R. LÓPEZ-VALES[1]
[1]Cell Biology, Immunol. and Physiol., Univ. Autonoma De Barcelona, Bellaterra, Spain; [2]Div. of Infectious Dis., Univ. of Colorado Denver, Aurora, CO; [3]Dept. of Med., Radboud Univ. Med. Ctr., Nijmegen, Netherlands

**Abstract:** Multiple sclerosis (MS) is a chronic, autoimmune and degenerative disorder that causes central nervous system demyelination and axonal injury. MS affects 2.5 million people worldwide and it is highly disabling. Although its ethology remains elusive, several lines of evidence support the concept that autoimmunity plays the major role in disease pathogenesis. The current treatments for MS are unable to prevent disease progression. Interleukin 37 (IL-37), one of the eleven members of the IL-1 family, is known to broadly reduce innate inflammation as well as acquired immunity. IL-37 has demonstrated to mediate significant resistance against several inflammatory challenges, including after spinal cord injury. Thus, based on its protective and anti-inflammatory properties, we hypothesized that IL-37 could mitigate the neurological deficits in MS.
Since IL-37 is not present in the mouse, in the present study, we induced experimental autoimmune encephalomyelitis (EAE) in transgenic mice expressing the human form of IL-37

(hIL-37tg) or in wildtype littermates. Mice were immunized subcutaneously with myelin oligodendrocyte glycoprotein 35-55 peptide emulsified in complete Freund's adjuvant containing *Mycobacterium tuberculosis.* Immediately after the immunization and 48h later, mice were intraperitoneally injected with pertussis toxin.
We firstly assessed the changes in mRNA levels of IL-37 during the course of the disease. Real time PCR experiments revealed that IL-37 transcripts were barely detected in the spinal cord of unimmunized and immunized mice at the onset of EAE. However, strong induction of IL-37 (~7 fold increased) was observed at the peak and progression phase of the disease. We then evaluated whether IL-37 attenuated the clinical signs of the disease. We found that transgenic expression of IL-37 did not delay the onset of the disease, but markedly reduced neurological deficits. Moreover, histological analysis revealed that IL-37 conferred protection against myelin loss. Taking together, this study presents novel data indicating that IL-37 may have therapeutic potential for the treatment of MS.

**Title:** *In vitro* derivation of oligodendrocyte precursors from neural progenitors harbored in the adult bone marrow - implications for remyelination therapy

**Authors: *D. K.-Y. SHUM**, Y. P. TSUI, K. L. K. WU, Y. S. CHAN
Sch. of Biomedic. Sci., Fac. Med., Univ. Hong Kong, Hong Kong, China

**Abstract:** Loss of myelin due either to congenital abnormalities or traumatic injuries impacts on conduction of nerve impulses, causing neurological deficits. Our recent success with a strategy that enriches and expands the neural progenitor subpopulation among adult samples of bone marrow stromal cells provided impetus for pursuit of bone marrow-derived neural progenitors (BM-NPs) as source for deriving oligodendrocyte precursors (OPs) for use in transplantation and remyelination. Cultures of rat BM-NPs treated with supplements of β-heregulin, PDGF-AA and bFGF fostered the derivation of oligodendrocyte precursors in 3 weeks. These BM-OPs were positive for the OP markers, NG2, Olig2, PDGFRα and Sox10. The BM-OPs were then

subjected to *in vitro* myelination assay in co-cultures with purified DRG neurons. In 2 weeks, BM-OPs matured into oligodendrocytes and extended myelin basic protein-positive processes along multiple neurites. The BM-OPs were further transplanted into the corpus callosum of myelin-deficient, juvenile Shiverer mice. Mature oligodendrocytes and ultrastructure of compact myelin were identifiable in the corpus callosum in 6 weeks. Our findings indicate BMSCs as a possible source of oligodendrocyte precursors for CNS remyelination therapy.

**Title:** Serum enkephalin levels correspond to disease severity in EAE

**Authors: *P. J. MCLAUGHLIN**, M. D. LUDWIG, I. S. ZAGON
Dept Neural & Behav Sci., Penn State Univ. Coll Med., Hershey, PA

**Abstract:** Experimental autoimmune encephalomyelitis (EAE), an animal model for multiple sclerosis presents with increased levels of cellular proliferation within the immune system (T and B lymphocytes) and central nervous system (astrocytes and glia). Opioid growth factor (OGF), is an endogenous opioid chemically termed [$Met^5$]-enkephalin. Systemic injections of OGF in models of chronic progressive EAE or relapsing-remitting EAE beginning either at the time of immunization or following established disease have demonstrated substantial reductions in clinical disease, relapses, and numbers of activated astrocytes, glial/macrophages, and demyelination. In this study, serum OGF levels were monitored throughout the course of progressive EAE and correlated to clinical behavior, activity in an open field, and sensitivity. C57Bl/6J mice were immunized with myelin-oligodendrocytic glycoprotein and treated daily with either OGF or saline. Clinical behavior was monitored daily, and locomotor activity and thermal sensitivity were measured periodically. Blood samples were collected periodically and enkephalin (OGF) levels measured by ELISA (MyBiosource). Peak disease scores for saline-injected EAE mice reached a mean of 5.7 (scale 1-10) on day 18, in comparison to a peak clinical score of 2.5 for OGF-treated EAE-mice. Serum OGF levels in EAE mice between 8 and 128 pg/ml over the course of disease in comparison to normal, non-diseased mice with stable OGF levels averaging 149 pg/ml. Exogenous OGF therapy increased serum levels in EAE mice corresponding to markedly reduced disease severity, increased open field behavior and decreased hot-plate sensitivity. These data suggest that there is a dysregulation of endogenous OGF in the

disease state and that treatment with exogenous OGF restores serum enkephalins to normal. Thus, the relatively non-invasive measure of serum OGF may be a useful marker for disease progression and therapeutic response.

**Title:** Methionine metabolism is altered in multiple sclerosis

**Authors: *F. MIR**[1], Z. BALIC[2], J. JIAN[1], S. A. SADIQ[1]
[1]Tisch MS Res. Ctr. of NY, New York, NY; [2]Tisch MS Res. Ctr. of NY, NEW YORK, NY

**Abstract:** Methionine is an essential amino acid which is critical for a number of metabolic processes such as protein synthesis, methylation, sulfur metabolism, redox regulation, and signal transduction. Methionine is highly susceptible to oxidation in vivo and the principal product of methionine oxidation is methionine sulfoxide (MetSO). Proteins lose their biological activity when specific methionine residues are oxidized to MetSO. In the current study we investigated the involvement of methionine oxidation in the pathophysiology of multiple sclerosis (MS). Cerebrospinal fluid (CSF) was obtained from MS patients (n=120) and age- and sex-matched controls (n=30) with informed consent under an IRB-approved protocol. Methionine metabolites were quantified by mass spectrometry (AbsoluteIDQ p180, Biocrates, Austria). Methionine sulfoxide levels were found to more than two fold elevated in the CSF of MS patients as compared to the controls (p=0.017). Interestingly this increase in MetSO was more pronounced in the progressive MS patients (p=0.0003) and more modest in the relapsing remitting MS patients (p=0.02) as compared to the control population. The MetSO/Met ratio also increased in the MS cohort. These results were further confirmed by an ELISA using an anti- MetSO antibody in an independent cohort of MS patients. In a parallel study using experimental autoimmune encephalomyelitis (EAE), we found MetSO levels to be increased in the brain and spinal cord lysates of mice during disease peak. This was accompanied by a concomitant decrease in the methionine sulfoxide reductase levels. Taken together these results indicate a dysregulation of methionine metabolism during MS and may have effects on DNA methylation, myelin gene expression and anti-oxidant levels contributing to the pathophysiology of MS.

**Authors: C. L. NEMETH**[1], B. TURK[2], C. F. MURRAY[2], *C. TIFFANY[2], O. GOK[3], A. SHARMA[3], S. KAMBHAMPATI[3], R. RAMIREDDY[3], A. B. MOSER[2], P. A. WATKINS[2], R. M. KANNAN[3], S. KANNAN[4], A. FATEMI[5]
[1]KennedyKrieger Institute/Lipid Lab., Baltimore, MD; [2]Kennedy Krieger Inst., Baltimore, MD; [3]Ctr. for Nanomedicine at the Wilmer Eye Inst., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Anesthesiol. and Critical Care Med., [5]Neurol., Johns Hopkins Univ., Baltimore, MD

**Abstract:** X-linked adrenoleukodystrophy (X-ALD) is a neurodegenerative disorder due to defects in the peroxisomal membrane transporter protein, ABCD1, with variable phenotypes ranging from a rapidly progressive, inflammatory cerebral demyelination (cerebral ALD) in young boys and adult men to the chronic slowly progressive adult onset adrenomyeloneuropathy (AMN) affecting men and women. Hallmark pathophysiology includes accumulation of very long chain fatty acids (VLCFA), increased oxidative stress, and progressive axonopathy, with little to no genotype-phenotype correlation. Furthermore, X-ALD phenotypic variability complicates prognosis and treatment. Allogeneic hematopoietic cell transplantation is effective in early stages of cerebral ALD but not in other forms and no other effective interventions exist. Recent advancements in dendrimer nanoparticle therapeutics provide platforms in which dendrimer-drug conjugates enable targeted and intracellular slow release of drugs requiring fewer treatments at lower drug concentrations. One such drug, 4-Phenylbutyrate (4PBA) has been shown to increase expression of ABCD2 and proliferation of peroxisomes in models of X-ALD; however, with a half-life of less than one hour, 4PBA requires frequent high dosages, precluding its utility in the clinic. Previously, we have demonstrated specific uptake of PAMAM dendrimer-drug conjugates in spinal cord neurons of the ABCD1 knockout mouse as well as within patient-derived primary macrophages and fibroblasts. Here, we demonstrate efficacy of 4PBA conjugated to dendrimer in both of these cell types to significantly alter biochemical and inflammatory abnormalities. In macrophages derived from ALD and AMN patient peripheral

blood monocytes, a 6h stimulation of 30 μM VLCFA leads to significant release of TNF ($p$ = 0.009, compared to unstimulated cells) and pretreatment with D-4PBA prevents these increases (30 μM D-4PBA, $p$ = 0.0018; 100 μM D-4PBA, $p$ = 0.002; 300 μM D-4PBA, $p$ = 0.002). Furthermore, treatment with 3 or 10 μM D-4PBA increases enzyme activity of SOD1, an important anti-oxidant regulator of cell death ($p$ = 0.0142 and $p$ = 0.0174, respectively). Similarly, in another in vitro model of ALD and AMN patient derived fibroblasts, reductions of VLCFA (C26:0 and C26/C22) were detected after a 16-day exposure to 30 μM (AMN $p$ = 0.017) or 100 μM D-4PBA (ALD $p$ = 0.026; AMN $p$ = 0.0006). Together, these data support feasibility and efficacy of low dose and versatile nanoparticle therapy to reduce ALD-related disease burden in patient derived cells and sets the stage for new therapeutic opportunities for complex diseases such as X-ALD.

**Title:** Cerebrospinal fluid IgA levels correlate with disease activity in patients with multiple sclerosis; A novel finding

**Authors: A. LIANG**, A. FINNEY-STABLE, J. LIN, *S. A. SADIQ
Tisch MS Res. Ctr., New York, NY

**Abstract: Background:** Cerebrospinal fluid (CSF) IgG oligoclonal bands is a diagnostic biomarker of multiple sclerosis (MS) and a majority of these patients have IgG indexes above normal range (N <0. 7), an indicator of intrathecal IgG production. Recent literature also suggests a presence of CSF IgMs in patients with more severe forms of MS. We have previously shown that CSF fetuin-A levels has been linked to inflammatory disease activity. To further elucidate the role of B-cells in MS and associated disease activity, we investigated the presence

of IgGs, IgMs, and IgAs, and tested for correlations with CSF fetuin-A levels.
**Methods:** In a continuing study, CSF and serum samples from 30 MS patients were analyzed by ELISA to calculate indexes for IgGs, IgMs, IgAs, and albumin. Testing for previously reported biomarkers of disease activity, CSF was further analyzed by ELISA for fetuin-A, and osteopontin. Significant correlations were determined by a non-parametric Spearman test using the statistical program GraphPad Prism.
**Results:** CSF fetuin-A levels significantly correlated with CSF IgAs ($r = 0.5755$, $p = 0.0009$). Further analyses showed that CSF fetuin-A levels also significantly correlated IgA index ($r = 0.4434$, $p = 0.0205$). No correlations were found with IgG indexes, IgM indexes, and osteopontin.
**Conclusion:** We have identified a subset of MS patients with high CSF IgA levels that has not been reported in previous literature. Further investigation is required to elucidate the role of IgAs in the B-cell response for MS. In addition, high CSF IgA levels were an indicator of intrathecal IgA production and does not support a presence of a blood brain barrier breakdown. Unlike IgGs and IgMs, IgAs appears to correlate with disease activity, as demonstrated with its positive correlation to CSF fetuin-A levels. Future studies should be performed to determine if intrathecal IgA production decreases post-treatment in MS patients.

**Authors: B. R. BARNES**[1], W. E. DECOTEAU[2,3], J. E. BUCKLEITNER[2], T. A. BEDARD[2], S. C. HENEGAN[2], E. M. NEEDHAM[2], J. A. ROBINSON[2], M. M. GARDNER[3], *A. Y. ESTEVEZ[1], J. S. ERLICHMAN[2], K. L. HECKMAN[1]
[1]Biol., [2]Neurosci., [3]Psych., St. Lawrence Univ., Canton, NY

**Abstract:** Antioxidants are potential therapeutic agents for multiple sclerosis due to their ability to neutralize reactive oxygen species generated during pathogenesis, though this potential has not yet been convincingly translated to clinical use. Previously we have shown 2 nm cerium oxide nanoparticles (CeNPs) dampened the severity of experimental autoimmune encephalomyelitis (EAE) and improved motor function in EAE mice when delivered intravenously (ACS Nano 2013 7 (12), 10582-10596). Here we explore the efficacy of delivering CeNPs delivered subcutaneously in the murine EAE model. CeNP treatment began 7 days after disease induction,

a time when demyelination was underway. Doses ranging from 5-20 mg/kg/week significantly reduced clinical severity compared to controls. In addition, motor performance, assessed by hanging wire and rotarod, where also significantly improved in CeNP treated animals. A dose-dependent effect was apparent in the hanging wire task but not the rotarod or clinical severity suggesting that we were close to a ceiling effect with respect to biological activity at this dose regimen. These findings demonstrate that subcutaneously delivered CeNPs are effective at mitigating disease progression in the EAE model and that the minimum effective dosing will likely be lower than 5 mg/kg/week in this model.

**Abstract:** Remyelination of the CNS is the default pathway following demyelination in practically all myelin disorders. Remyelination is a prominent feature in multiple sclerosis, at least early in the disease, but eventually lessens and fails with time. To-date, the weight of evidence identifies the oligodendrocyte progenitor cell (OPC), which is found both in developing and mature white matter, as the source of remyelinating oligodendrocytes. In contrast, the adult oligodendrocyte (OL) is thought to be incapable of playing a role in remyelination, despite certain *in vitro* data that suggests that these cells may in fact be able to re-ensheath axons. We have explored this question using a novel model of demyelination and remyelination known as FIDID (feline irradiated diet induced demyelination). In this disorder, there is extensive vacuolation of myelin in the spinal cord that leads to scattered but frequent demyelination, with demyelinated axons adjacent to axons with surviving, mature myelin sheaths. At the same time, in these areas, thinly remyelinated axons are present. To explore the cellular milieu underlying this array of myelin changes, we first asked if OL cell death occurred as a cause of the demyelination. TUNEL labeling showed that there was little to no cell death and pyknotic cells were rarely seen on light microscopy or EM, hence adult OLs appear to survive and are adjacent to scattered demyelinated axons. We then identified individual OLs on EM and found cells that had processes extending both to mature and thin myelin sheaths. We interpret this finding as demonstrating that surviving OLs have processes to both mature and immature (thinly myelinated) internodes. Furthermore, we confirmed these observations by tracing the cell processes of single OLs using 3-D reconstruction (Renovo Neural, Inc.). We propose that in this model, the adult OL can play an important role in the remyelination, especially in the lateral and ventral columns of the spinal cord. The difference between the outcome here and those studies where the OPC is the ‘dominant’ cell, may be due to differences in the pathologic milieu. The data presented here however, suggest that the adult OL, perhaps surprisingly, may be a contributor to myelin repair in certain myelin disorders.

**Title:** Effects of intrathecal delivery of primary and secondary progressive MS cerebrospinal fluid on motor function and CNS pathology

**Authors: *J. K. WONG**, N. J. KUNG, S. A. SADIQ
Tisch MS Res. Ctr. of New York, New York, NY

**Abstract:** Multiple sclerosis (MS) is characterized by inflammatory demyelination, astrogliosis and axonal loss in the CNS. Most patients present with relapsing-remitting MS (RRMS) then eventually enter a phase of disease progression termed secondary progressive MS (SPMS). However, approximately 10-15% of patients have primary progressive multiple sclerosis (PPMS), which is characterized by unremitting disease progression from disease onset. Although PPMS and SPMS patients both experience continuous neurological decline, there are differences in their lesion distribution and extent of inflammation. It remains unclear whether the pathophysiological mechanisms contributing to clinical progression in PPMS and SPMS are the same.

Here, we investigated whether intrathecal delivery of cerebrospinal fluid (CSF) obtained from PPMS and SPMS patients would have similar effects on behavior and CNS pathology in mice. Mice underwent laminectomies at cervical levels 4 and 5 to expose the underlying spinal cord and CSF was injected under the dura mater into the subarachnoid space. Control animals were injected with saline or CSF from healthy donors. Functional deficits were assessed by evaluating forelimb reaching, gripping and tail rigidity at various time points following intrathecal CSF delivery. Mice injected with PPMS CSF displayed significantly higher behavioral deficit scores than control animals, as well as SPMS CSF-injected mice. Mice injected with SPMS CSF did not show functional impairments and scores were not statistically different from controls. Mice were perfused at 1 day post injection (DPI), 3 DPI, and 7 DPI. Brains and spinal cords were post-fixed overnight in 4% paraformaldehyde, cryoprotected in 30% sucrose, then cryosectioned for histological analyses. Spinal cords from mice injected with PPMS CSF exhibited evidence of astrogliosis at all time points, as revealed by significantly increased GFAP immunostaining in the dorsal white matter. However, astrogliosis was not observed in mice injected with SPMS CSF. Similarly, a significant increase in immunostaining intensity for SMI-32, a marker of

axonal damage, was observed in mice injected with PPMS CSF, but not SPMS CSF. In contrast, Iba1 immunostaining was similar in all groups, suggesting that microglia do not play a major role in contributing to deficits and pathology observed in PPMS CSF-injected mice. No group differences in GFAP and Iba1 immunostaining were observed in the corpus callosum and hippocampus, indicating that the effects of PPMS CSF remain localized at the site of delivery. The induction of behavioral deficits and spinal cord pathology appears to be unique to PPMS CSF, not SPMS CSF.

**Abstract:** Enhancing CNS remyelination represents an attractive therapeutic strategy for demyelinating diseases such as multiple sclerosis. As CNS myelination requires a myriad of cell interactions and communications, functional cell-based systems that recapitulate this process are necessary for screening non-neurotoxic small molecules that capable of promoting myelin repair. Here we describe a cerebral myelinating aggregate culture system that closely mimics *in vivo* myelination and retains axon-glial interactions and our results from screening 2460 pharmaceutical compounds. The neural aggregate culture system was generated from E15.5 mouse forebrains, composed primarily progenitors of neurons, astrocytes and oligodendrocytes, and were maintained in a serum-free medium for up to 4 weeks in Matrigel-coated 96-well plates. Radial growth of axons was robust after 1-2 days in culture (DIV) and extensive axonal networks were formed around 2 weeks *in vitro*. Glial progenitors migrated out of aggregates and gradually differentiated into astrocytes and axon-ensheathing oligodendrocytes, thereby establishing a 2.5D culture platform that provides suitable cellular environment for *in vivo* applicable drug screening. To develop quantitative high-throughput *in vitro* assays that enable

assessment of myelination and morphological changes of oligodendrocytes, we used an ImageXpress Micro XLS system to track oligodendrocyte differentiation over time in aggregate cultures prepared from transgenic mice expressing the membrane-anchored green fluorescent protein (mEGFP) under the promoter of 2′-3′-cyclic nucleotide 3′-phosphodiesterase (CNP1). CNP-mEGFP mice allowed us to visualize mature/myelinating cells and myelin along the axon. We identified multiple molecules that significantly enhance myelination and oligodendrocyte differentiation in the aggregate cultures and further validated the results using organotypic brain slices. After considering chemical structures, we chose 5 compounds that could permeate the blood brain barrier and tested their effects on remyelination using the lysolecithin-induced corpus callosum de/remyelination mouse model. We are currently analyzing the *in vivo* effects of the identified compounds on remyelination.

**Abstract:** Clonally expanded CD8+ T cells outnumber their CD4+ counterparts in MS lesions yet their role in disease pathogenesis and the relevant target antigen(s) remain unknown. We posited that CNS CD8+ T cells are specific for neuronal antigen and may participate in axon or neuron injury in multiple sclerosis—thereby contributing to cumulative disability. We have previously shown in a viral mouse model of multiple sclerosis that perforin-competent CD8+ T cells are necessary and sufficient to cause axon injury in the context of overt demyelination. Furthermore, we showed that in vitro OT-1 T cells can cause perforin-dependent axon injury to neurons presenting the immunodominant SIINFEKL epitope in the context of MHC class I following treatment with interferon gamma. Here we further demonstrate that in addition to

interferon gamma treatment, demyelination is sufficient to drive neuronal expression of MHC class I genes as well as antigen processing genes, leading to recruitment of activated CD8+ T cells that are specific for axonally targeted neo-antigens, and that these CNS-recruited CD8+ T cells contribute to elimination of antigen-expressing axons. These findings support a role for autoreactive CD8+ T cells in the axonal injury that underlies progression in multiple sclerosis. Future studies are aimed at identifying patients with pathogenic anti-axonal CD8+ T cells who may be responsive to targeted immunotherapy.

**Abstract:** Alzheimer’s disease (AD) is the leading cause of dementia in the elderly with currently no disease-altering therapy. The ε4 allele of the apolipoprotein E (*APOE*) gene is the strongest genetic risk factor for late-onset AD among its three polymorphic alleles (ε2, ε3 and ε4). ApoE4 promotes Aβ aggregation and deposition and is associated with impaired brain lipid homeostasis, glucose metabolism, vascular functions and increased neuroinflammation. Thus, understanding the pathobiology of apoE4 represents a great opportunity to both uncover mechanisms underlying AD risk and also explore new strategies for AD therapy. ApoE is abundantly expressed in the brain and in periphery. In fact, apoE concentration in plasma is about 10 times higher than that in the cerebral spinal fluid. As peripheral apoE, produced mainly by the liver, is separated from brain apoE by the blood-brain barrier (BBB), it is not clear whether and how peripheral apoE affects the function of the central nervous system (CNS) and AD pathogenesis. To address this, we have developed novel mouse models expressing human apoE3 or apoE4 in an inducible, cell type-specific manner. After breeding to albumin-Cre (Alb-Cre) mice which drive apoE expression specifically in the liver, we have generated human apoE3 and apoE4 liver-specific mouse models in the background of murine *Apoe*-KO. Here, we demonstrated that expression of apoE3 in the periphery enhanced synaptic activity and cognition,

whereas expression of apoE4 did the opposite. In addition, peripherally-expressed apoE isoforms differentially affect cerebrovascular integrity and functions, as well as neuroinflammation. Together, our results demonstrate that peripheral expression of apoE isoforms differentially regulates CNS functions. Our findings provide novel mechanistic insights into the pathobiology of apoE4 in AD, and have implications in designing new therapeutic strategies targeting apoE to treat AD.

**Abstract:** Although the microbiome is emerging as a modulator of the human condition, the role of the microbiome in Alzheimer's disease (AD) is unclear. The *APOE4* genotype is the greatest genetic risk factor for AD and yet has been associated improved gastrointestinal recovery after insult in human and murine studies. These observations lead us to hypothesize that *APOE* genotype impacts the gut microbiome. To assess this hypothesis, we compared 16S ribosomal RNA gene amplicon-based microbiome profiles in EFAD mice, homozygous for *APOE2, APOE3, or APOE4* with both carriers and non-carriers of the 5xFAD mutations at 4 and 6 months of age. Ordination (principal coordinate analyses) of the multivariate data revealed that combining carriers and non-carriers, *APOE* genotype is associated with distinct microbiome profiles, with *APOE3* intermediate between *APOE2* and *APOE4*. Comparisons of the underlying bacterial differences showed that the relative abundance of multiple bacterial families were significantly altered in a step-wise fashion from *APOE4* to *APOE3* to *APOE2*, including bacteria from the family Ruminococcaceae (Clostridia) which were highest with *APOE2*. Bacteria from

this family can be induced by resistant starch diets, and are key for digesting resistant starch to increase short chain fatty acid levels. In summary, we report that the *APOE* genotype is correlated with specific gut microbiome profiles in a murine model, though the mechanism of action is not yet understood. The effect of sex, FAD carrier status and age are important modulators of *APOE* effects and will be investigated, clarifying the potential for translational impact of these data. As well, these data will be strengthened if replicated in other murine model organisms and humans.

**Authors: *B. ZHOU**, Y.-W. A. HUANG, M. WERNIG, T. C. SUDHOF
Stanford Univ., Stanford, CA

**Abstract:** Apolipoprotein E (ApoE) ApoE4 allele has been identified as the leading risk factor for Alzheimer’s disease (AD). In our previous work, we have shown that ApoE secreted by glia stimulates neuronal APP transcription and Aβ production, with an ApoE4 > ApoE3 > ApoE2 potency rank order, through a non-canonical MAP-kinase pathway (DLK->MKK7->ERK1/2). Here via the human induced neuronal cell co-culturing with MEF system, we found that ApoE also stimulates transcription of synaptic genes and promotes miniature EPSC frequency, with the same potency order of ApoE4>ApoE3>ApoE2. Further mechanism studies indicate that this stimulation is through the same MAP-kinase pathway, but independent from the increased APP transcription.

**Title:** Reversing apoE4 lipidation deficiency with a clinically tested HDL mimetic peptide

**Authors: *D. S. CHERNICK**[1], D. A. HOTTMAN[2], A. GRAM[2], L. LI[1,2]
[1]Pharmacol., [2]Exptl. and Clin. Pharmacol., Univ. of Minnesota, Minneapolis, MN

**Abstract:** Human apolipoprotein E (apoE) exists in three isoforms; the apoE ε4 allele is the primary genetic risk factor for late-onset Alzheimer's disease (AD), while apoE ε2 is protective in AD, and apoE ε3 is neutral. ApoE in the brain is produced and secreted primarily by astrocytes, and binds lipids to form high-density lipoprotein (HDL)-like particles in the interstitial and cerebrospinal fluid. Although the mechanisms by which apoE4 affects the development of AD are not completely understood, compelling evidence indicates that the pathogenic effects of apoE4 are mediated by lipid-related pathways. Compared with the more common apoE3 isoform, apoE4 exhibits deficiency in lipidation and formation of HDL in the brain, whereas apoE2 is lipidated most effectively. ApoE directly interacts with amyloid-β (Aβ), and the level and lipidation state of apoE affects Aβ aggregation and clearance pathways. We have found that a clinically tested 18-aa HDL mimetic peptide, 4F, increases the secretion and lipidation of apoE from primary murine astrocytes. The current study aims to determine whether treatment with 4F can reverse the lipidation deficiency of apoE4. Using immortalized mouse astrocytes expressing the human apoE2, apoE3, and apoE4, respectively, we found that 4F treatment promotes lipidation of all human apoE isoforms. Experiments are underway to determine whether 4F enacts these same effects in primary astrocytes from human apoE isoform (apoE2, apoE3, and apoE4)-targeted replacement (TR) mice. We are also investigating whether treatment with 4F enhances apoE lipidation *in vivo* and mitigates amyloid pathology and memory deficits in mouse models of AD. Our goal is to harness the lipidation power of the HDL-mimetic peptide to reverse apoE4 lipidation deficiency and reduce the risk of AD.

**Title:** Regulation of apolipoprotein E expression and secretion in astrocytes

**Authors: *E. DRESSELHAUS**[1], G. RAMASWAMY[2]
[1]Intrnl. Med., Pfizer, Cambridge, MA; [2]Intrnl. Med. Res. Unit, Pfizer Inc, Cambridge, MA

**Abstract:** Apolipoprotein E (ApoE) is a key lipid transport protein expressed in several cell types and in the brain is predominantly expressed in astrocytes. In the brain it plays critical roles in neuronal repair, synaptogenesis, and clearance of toxic Aβ. Human apoE has three common isoforms, which show a genotype dependent effect on age and risk for late onset and sporadic forms of AD (apoE4>apoE3>apoE2). Despite its association with AD, regulation of apoE in astrocytes is still largely unknown. Currently known mechanism for astrocytic apoE regulation involves nuclear receptors such as liver X receptor (LXR) and retinoid X receptor (RXR). A small molecule phenotypic screen with annotated chemical libraries including Pfizer's chemogenomics library identified three classes of compounds that increased astrocytic apoE secretion: LXR agonists, RXR agonists, and class I HDAC inhibitors. However, the molecular mechanism by which HDAC inhibition leads to apoE secretion is not known. The goal of this project is to delineate the differences in the molecular mechanism by which these three classes of compounds regulate astrocytic apoE. In a human astrocytoma cell line, a time and dose dependent increase in APOE gene expression was observed using both qPCR and RNAseq following cell treatment with the pan-LXR agonist T0901317, the RXR agonist Bexarotene, or the pan-class I HDAC inhibitor MS-275. An increase in gene expression of other genes involved in APOE regulation was also observed, including ABCA1 and LXRα, but not LXRβ. In a co-treatment study, the effects of T0901317 and MS-275 appear to be synergistic for the expression and secretion of APOE but not for other genes tested. Differences in gene expression and cofactor recruitment following treatment with the mentioned compounds can give clues to how APOE expression and secretion is regulated in astrocytes and other cell types.

**Title:** Changes in the synaptic proteome in Alzheimer's disease indicate a role for Clusterin and ApoE in synapse degeneration

**Authors: *R. J. JACKSON**[1], A. G. HERRMANN[1], M. LLAVERO[2], C. HENSTRIDGE[1], D. J. LAMONT[3], T. M. WISHART[2], T. L. SPIRES-JONES[1]
[1]Ctr. for Cognitive and Neural Systems, [2]Univ. of Edinburgh, Edinburgh, United Kingdom; [3]'FingerPrints' Proteomics Facility, Dundee, United Kingdom

**Abstract:** Of the main pathological features of Alzheimer's disease (AD), synapse loss is the greatest correlate of clinical cognitive decline, and this synapse loss is thought to be central to disease pathogenesis. Although most cases of AD are not directly heritable, genetic risk factors have been identified, the strongest of which is the epsilon 4 isoform of Apolipoprotein E (ApoE4). The ApoE4 allele increases not only the chance of developing AD compared to the more common ApoE3 allele but also increases the rate of cognitive decline seen within the disease. The related Apolipoprotein J or clusterin has also been genetically linked to AD in genome-wide association studies. However, the mechanisms by which AD causes synaptic degeneration and the role that ApoE and Clusterin play in that degeneration remains unclear. Proteomic analysis of synaptoneurosomes isolated from 25 control and 30 Alzheimer's disease patients with known APOE genotypes have indicated that 241 proteins were changed in the AD synapse samples compared to control. Clusterin was found to be significantly upregulated the AD synapse compared with control synapses (fold change 1.63, $p<0.001$). This upregulation was further increased in AD individuals with an ApoE4 genotype compared to those with an ApoE3 genotype (fold change 1.25, $p<0.01$). Fluorescent western blot confirmed this finding in independent cases. Analysis of human post-mortem tissue by array tomography indicates that Clusterin localizes to both the pre and post synaptic densities in a disease and ApoE genotype dependent manner. Array tomography also indicates that clusterin colocalizes with oligomeric Aβ and ApoE protein at the synapse in a disease and ApoE genotype dependent manner, highlighting a potential link between these proteins in synaptic toxicity.
This study investigates the interaction of Clusterin and ApoE at the synapse in post-mortem tissue and shows an ApoE4 genotype dependent increase in the amount of Clusterin at the synapse of AD individuals.

**Abstract:** Alzheimer's disease (AD) is a neurodegenerative process characterized, in part, by an accumulation of the beta-amyloid (Aβ) protein in the brain and cerebrovasculature. Mounting evidence suggests the excessive accumulation of Aβ in the AD brain is not due to aberrant Aβ production, but the result of impaired Aβ clearance mechanisms. One explanation for the attenuated clearance in AD is dysfunctional Aβ transport at the blood-brain barrier (BBB). The BBB transporter primarily responsible for the brain-to-blood elimination of Aβ is the low density lipoprotein receptor-related protein 1 (LRP1). While LRP1 interacts with an array of ligands, one of the more closely associated is apolipoprotein E (apoE). Previously, we examined the effects of apoE on the proteolytic shedding of LRP1 to its non-functional soluble form. Our results indicate an inverse relationship between LRP1 shedding and Aβ transit across the BBB, one that is apoE isoform-specific. To elucidate the mechanisms driving these observations, we examined the interactions between apoE and a known LRP1 sheddase, matrix metallopeptidase 9 (MMP-9). In a cell-free assay, MMP9 activity was significantly attenuated by apoE in an isoform-specific manner (apoE2>apoE3>apoE4). In apoE4 animals, treatment with an MMP9 inhibitor, SB-3CT, resulted in a significant reduction in brain LRP1 shedding and increased Aβ clearance from the brain to the periphery. Our findings indicate apoE4 is less effective in modulating MMP9 activity and LRP1 shedding than the other apoE isoforms. These studies show that MMP9 modulation can facilitate Aβ removal from the brain, which may provide a novel approach to the treatment of AD, particularly for individuals with an apoE4 genotype.

**Title:** ApoE isoforms differentially regulates cleavage and secretion of BDNF

**Authors: *A. SEN**[1], T. J. NELSON[2]
[1]Blanchette Rockefeller Neurosciences Inst., West Virginia Univ., Morgantown, WV;
[2]Blanchette Rockefeller Neurosciences Inst., Morgantown, WV

**Abstract:** Apolipoprotein E4 (ApoE4) is a major genetic risk factor for sporadic or late onset Alzheimer's disease (AD). BDNF is decreased by 3 to 4-fold in the brains of AD patients at autopsy. ApoE4 mice also have reduced brain-derived neurotrophic factor (BDNF) levels. However, there have been no reports relating the different ApoE isoforms or AD to differential regulation of BDNF. Here we report that in the hippocampal regions of AD patients pro-BDNF expression showed a 40% decrease compared to that expression in the hippocampi of age-matched control patients. We further report that ApoE isoforms differentially regulate maturation and secretion of BDNF from primary human astrocytes. After 24 hours, ApoE3 treated astrocytes secreted 1.75- fold higher pro-BDNF than ApoE2-treated astrocytes, and ApoE2-treated astrocytes secreted 3-fold more mature-BDNF (m-BDNF) than ApoE3-treated astrocytes. In contrast, ApoE4-treated cells secreted negligible amounts of m-BDNF or pro-BDNF. ApoE2 increased the level of intracellular pre-pro BDNF by 19.04 ± 6.68 %, while ApoE4 reduced the pre-pro BDNF by 21.61 ± 5.9 % compared to untreated cells. Similar results were also seen in ApoE2, ApoE3 or ApoE4 treated cells at 4 hr. Together, these results indicate that an ApoE2 or ApoE3 mediated positive regulation of BDNF may be protective while ApoE4 related defects in BDNF processing could lead to AD pathophysiology. These interactions of the ApoE isoforms with BDNF may help explain the increased risk of AD associated with the ApoE4 isoform.

**Abstract:** Apolipoprotein E (*APOE*) gene is the strongest genetic risk factor for sporadic, late-onset Alzheimer's disease (AD). The ε4 allele of human apoE (apoE4) slows amyloid-β (Aβ) clearance (Castellano et al., 2011) and induces Aβ fibril aggregation (Ma et al., 1994). Previous work has shown that a monoclonal antibody against murine apoE decreased plaque load when administered intraperitoneally to a mouse model of amyloidosis when given either before (Kim et al., 2012) or after (Liao et al, 2014) the onset of plaque deposition. Our current study aimed to further investigate the therapeutic effects of apoE antibodies. We hypothesized that certain anti-apoE antibodies that specifically bind apoE would reduce amyloid pathology via a microglial-mediated mechanism. We initially characterized different anti-apoE antibodies and selected an antibody for further *in vivo* experiments based on its overall binding properties to apoE. In a 6-week treatment regimen, antibody administration to 2-month APPPS1-21/apoE4 mice (n=10-13/group) at 50 mg/kg/week reduced Aβ plaque load ($p<0.05$, one-way ANOVA, Tukey post-hoc test). Following acute administration of anti-apoE antibodies (50 mg/kg, 4 injections every 3 days), we detected an increase in plaque-associated staining with the microglial marker CD45 in the antibody-treated mice ($p<0.05$). These results suggest that binding of the anti-apoE antibody may trigger the active recruitment of microglia to plaques. Anti-apoE antibodies may serve as a viable therapeutic strategy for targeting Aβ plaques in AD.

**Title:** Differential effects of human and mouse apolipoprotein E on the metabolism and aggregation of amyloid-β peptides

**Authors: *A. KOKAWA**, Y. OHNO, T. HASHIMOTO, T. IWATSUBO
The Univ. of Tokyo, Tokyo, Japan

**Abstract:** Alzheimer's disease (AD) is the most common neurodegenerative disease causing dementia, and massive deposition of amyloid-β peptide (Aβ) as senile plaques in the brain is the pathological hallmark of AD. Apolipoprotein E (apoE) plays an important role in the lipid transport in the brain. There are three common alleles of the human *APOE* gene (*ε2*, *ε3*, and *ε4*), which give rise to differences at one or two amino acid sequence positions of the protein products. Among *APOE* genes, *APOE ε4* allele is the major genetic risk factor for AD, whereas it is still unknown how apoE impacts the Aβ metabolism in the brain. Mouse apoE protein shares ~70% homology with human apoE. To compare the effects of human apoE on Aβ metabolism in the brain with those of mouse apoE, we examined APP transgenic mice (APPswe/PS1deltaE9 line) and those crossed with human apoE3 knock-in mice (APP mice and APP/apoE3 KI mice, respectively). First, we immunostained cortices of 9-month-old APP or APP/apoE3 KI mice with an anti-Aβ or anti-apoE antibodies and found that the Aβ burden in APP/apoE3 KI mice was significantly lower than that in APP mice. We observed co-deposition of human apoE3 or mouse apoE with Aβ in the plaques. We next performed *in vivo* microdialysis in 3-month-old APP or APP/apoE3 KI mice to assess the Aβ metabolism in the hippocampal interstitial fluid (ISF). After measuring the baseline concentration of ISF Aβ, we perfused a γ-secretase inhibitor into the hippocampus and sequentially collected the ISF samples to analyze the half-life of Aβ in the brain. The concentration and the half-life period of ISF Aβ in the hippocampus of APP mice and APP/apoE3 KI mice were at similar levels. In addition, the levels of lipidated apoE in the Tris-soluble fraction of the brain of APP/apoE3 KI mice was comparable with that in APP mice as determined by gel filtration analysis. Finally, we conducted *in vitro* ThioflavinT (ThT) binding assays to examine the effects of human or mouse apoE on the fibrillization of Aβ. Synthetic Aβ42 was incubated alone, or in the presence of recombinant human apoE3 or mouse apoE, and then the formation of Aβ fibrils were assayed by ThT. In comparison with the incubation of Aβ alone, coincubation with human apoE3 delayed the start of Aβ fibril formation. Notably, mouse

apoE was less effective in inhibiting the Aβ fibril formation than human apoE3. In conclusion, our data suggest that human apoE3 suppresses Aβ fibril formation more strongly than mouse apoE. This may explain the lesser Aβ deposition in APP/apoE3 KI mice compared with APP mice.

**Abstract:** One of the hallmarks of Alzheimer's disease is the presence of extracellular diffuse and fibrillar amyloid plaques predominantly consisting of the amyloid-β (Aβ) peptide. Activated microglia cluster around Aβ plaques, although the physiological mechanism facilitating microglial clustering is still poorly understood. The formation of Aβ plaques within the brain parenchyma is influenced both by the concentration of monomeric forms of Aβ in the interstitial fluid and by other proteins in the brain, perhaps most notably apolipoprotein E (apoE). ApoE has previously been shown to influence the rate of Aβ clearance from the brain interstitial fluid in an isoform-dependent manner, and to influence the kinetics of amyloid formation in vitro. Both of these characteristics likely contribute to apoE-dependent effects on Aβ plaque formation in vivo. In addition to influencing Aβ metabolism, increasing evidence suggests that apoE expression may influence the microglial response in the context of neurodegenerative disease. ApoE is strongly upregulated by microglia in the context of Aβ pathology and ApoE has been shown to bind to the microglial receptor, TREM2, which has been implicated in regulating microglial response to amyloid plaques. Although chronic microglial activation is hypothesized to result in neurotoxic inflammatory signaling, recent studies found that plaque-associated microgliosis was negatively correlated with the degree of neuritic dystrophy around plaques, suggesting a potential protective role for microglia, at least in responding to amyloid plaques.

The effect of apoE expression in amyloid mouse models on the glial response to amyloid pathology is not currently understood. In this study, we characterize the impact that apoE has on amyloid pathology and the innate immune response in the APPPS1ΔE9 and APPPS1-21 amyloid mouse models. We find that Apoe KO mice exhibited reduced fibrillar plaque deposition and altered regional distribution of plaque pathology within the hippocampus, consistent with previous studies. However, the fibrillar plaques that were present in Apoe KO mice exhibited a striking reduction in plaque compaction and hyperspectral fluorescent imaging using luminescent conjugated oligothiophenes identified distinct Aβ morphotypes in Apoe KO mice. We also observed a significant reduction in plaque-associated microgliosis and activated microglial gene expression in Apoe KO mice, along with significant increases in dystrophic neurites. Our results suggest that apart from influencing Aβ plaque formation, apoE facilitates plaque-associated microgliosis and limits plaque-associated neuronal toxicity.

**Abstract:** Lipoproteins secreted from glial cells have important roles in lipid metabolism and transport of the central nervous system (CNS). Apolipoprotein (apo) E is a major apo in the CNS. It has been known that apo E-containing glial lipoproteins not only supply lipids to neurons but also cholesterol in apo E-containing glial lipoproteins promotes synaptogenesis in CNS neurons. We have reported that apo E-containing glial lipoproteins stimulate axon growth of retinal ganglion cells and protect retinal ganglion cells from apoptosis induced by trophic factor-withdrawal via low density lipoprotein receptor-related protein 1 (LRP1). It has also been shown that alpha2-macroglobulin (a2M), which is known as an LRP1 ligand, is increased in aqueous humor of glaucoma patients. Here, we demonstrate that apo E-containing lipoproteins

prevent retinal damage induced by intravitreal injection of *N*-methyl-D-aspartate in rats and decrease a secretion of a2M from primary cultured retinal glia. The protective effect of apo E-containing lipoproteins against excitotoxicity in primary cultured retinal ganglion cells was interfered with a2M, but exogenous treatment of the lipoproteins overcame the interference. Administration of apo E-containing lipoproteins into culture medium decreased mRNA and protein levels of a2M in a receptor-mediated manner in primary cultured retinal glia. These findings suggest a potential therapeutic strategy of apo E-containing lipoproteins or LRP1 agonists by reducing a2M levels in the retinal glia as treatments for neurodegenerative disorders of the retina, such as glaucoma.

**Abstract:** The apolipoprotein ApoE4 allele is the most important genetic risk factor for Alzheimer’s disease (AD), whereas the ApoE2 allele is protective. How ApoE influences AD pathogenesis, however, remains unclear. Using homogeneous populations of pure human neurons derived from ES cells, we show that ApoE binding to neuronal ApoE-receptors activates MAP-kinase signaling via dual leucine-zipper kinase independent of cholesterol, which in turn promotes synaptogenesis by stimulating transcription of synaptic genes and of APP. Strikingly, ApoE4 activated MAP-kinase signaling significantly more and ApoE2 significantly less potently than ApoE3. CRISPRi-mapping of the APP promoter showed that ApoE activated APP transcription via an AP-1-binding site. Stimulation of APP synthesis by ApoE significantly increased Aβ production, again with a rank potency order of ApoE4>ApoE3>ApoE2. Our data suggest that ApoE4 may predispose to AD by inducing a small chronic increase in neuronal MAP-kinase signaling, APP production, and Aβ synthesis, and that interference with ApoE-stimulated APP transcription may delay AD pathogenesis.

**Title:** Abeta42 oligomers impair NMDA receptors function: A model for studying the early synaptic alterations following Alzheimer’s disease onset

**Authors: *A. MARCANTONI**, M. CERULLO, P. BUXEDA, V. CARABELLI, E. CARBONE
Univ. of Turin, Torino, Italy

**Abstract:** We have recently defined the mechanisms of calcium dyshomeostasis induced by Abeta42 showing that, while Abeta42 stimulates $Ca^{2+}$ release from ryanodine receptors (RyRs), it inhibits $Ca^{2+}$ entry through voltage gated $Ca^{2+}$ channels (VGCCs) and NMDA receptors (NMDARs)[1]. It is known that NMDARs are important for controlling neuronal plasticity, learning and memory processes and that these brain functions are altered during aging [2] as well as in AD [3]. These previous observations have suggested a more detailed study of the effects of Abeta42 on NMDARs activated currents. Patch clamp experiments revealed that the average inward current carried by NMDARs previously activated by the selective agonist NMDA (50 µM) was significantly decreased by Abeta42 oligomers (from 352.3±52.7 pA (n=31) to 117.3±15.4 (n=23)). By comparing the dose response curves obtained by increasing the NMDA concentration from 2 to 300 µM and fitted by the Hill equation, we did not observe any change induced by Abeta42 administration ($K_d$ and n values were 17.3±3.3 and 1.4±0.4 in control vs 16.5±3.3 1.5±0.4 in the presence ofAbeta42). We concluded that Abeta42 does not affect the ligand-receptor binding process. We next estimated the unitary current and the number of NMDARs from variance analysis [4] observing that Abeta42 decreases the total number of NMDARs without altering their conductance. By performing calcium imaging experiments we quantified the total amount of intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) before and after exposure of neurons to Abeta42. We observed that NMDA administration induced an 8-fold increase of $[Ca^{2+}]_i$ and that, in good agreement with that observed in patch clamp experiments, Abeta42 almost halved this effect. Further experiments revealed that $Ca^{2+}$ entry through NMDARs is accompanied by $Ca^{2+}$ release from the stores. When we focused on the role of RyRs we observed that the overall amount of $[Ca^{2+}]_i$ increase measured after NMDA administration was half-dependent by RyRs and that Abeta42, despite increasing the amount of $Ca^{2+}$ released by RyRs[1] and decreasing the number of NMDARs, did not change this proportion. We concluded that Abeta42 impairs NMDARs function and that this may occur during the early stages of AD onset.

The development of selective modulators of these receptors may be useful for developing effective therapies that could enhance the quality of life of AD patients.

**Abstract:** The hippocampus plays a critical role in learning and memory processes. Its correct performance relies on excitatory/inhibitory synaptic transmission balance. Neuronal hyperexcitabillity in the hippocampus is one of the most distinctive hallmarks in early stages of Alzheimer’s disease (AD). This imbalance may emerge from inhibitory neurotransmission impairments, rather than an increase in excitatory activity, and has been related to the network dysfunction observed at those early stages of the disease. G-protein gated inwardly-rectifying potassium (GirK) channels induce neurons to hyperpolarize, thus acting as restrictors of the neuronal excitation excess. As we have previously shown *in vitro*, amyloid-$\beta$ (A$\beta$) peptides, which have a causal role as the main neurotoxic in AD pathogenesis, disrupt GirK channels at

the molecular and synaptic levels. In this work we have examined the role of GirK channels in an *in vivo* murine model of AD. We aimed to analyse the relationship between GirK channels and the hippocampal dysfunction developed in amyloid-$\beta$ pathology. In order to reach that objective, we performed acute intracerebroventricular injections of A$\beta_{1\text{-}42}$ peptide in fully alert behaving mice to create a non-transgenic model of AD. The effect of said injections was studied: 1) at the synaptic level, by using I/O and PPF protocols in CA3-CA1 synapse, 2) at the circuit and network levels, by studying oscillatory properties of CA1 region and LTP induction in CA3-CA1 synapse and 3) at the behavioral level, on learning and memory capabilities during an object recognition test, which depends on CA3-CA1 synapse performance. Our data suggest that GirK channels are necessary for normal hippocampal activity at synaptic, neural network and behavioral levels. An imbalance on GirK activity results on excitability, LTP and learning abnormalities. Interestingly, we found that an increase in GirK activity on A$\beta$-injected mice restores hippocampal excitability levels increased by the amyloid peptide in the CA3-CA1 pathway, and therefore counteracts hippocampal synaptic plasticity, network oscillatory activity, and memory deficits induced by A$\beta$. Taken together, our results support the assertion that corrections focused on the prevention of network hyperexcitability, for example by increasing GirK channels activity, would provide new therapeutic approaches for AD pathogenesis. GirK channels modulation emerges as a promising tool to improve AD related memory deterioration and underlying network signaling and synaptic neurotransmission aberrations.

**Title:** Early disruption of parvalbumin expression and perineuronal nets in the hippocampus of the Tg2576 mouse model of Alzheimer's disease

**Authors: V. CATTAUD**, C. BEZZINA, C. REY, C. LEJARDS, L. DAHAN, *L. VERRET
CRCA CNRS Toulouse, Toulouse, France

**Abstract:** Alzheimer's disease (AD) results in deterioration of cognitive functions linked to abnormal patterns of brain activity. Our recent findings indicate that transgenic mouse lines resembling key features of AD have impaired parvalbumin(PV)-expressing inhibitory fast-spiking interneuron function, which can be linked to network hypersynchrony, aberrant oscillatory activity, and memory deficits. In the mature brain, PV cells are often associated with a specific form of extracellular matrix, the perineuronal net (PNN). Indeed, PNN are appearing around PV cells at critical period of cortical maturation and are ensuring the stabilization of existing synapses. Moreover, loss of PNN in the hippocampus is often associated with aberrant hippocampal plasticity and function.
Thus, we wondered whether modifications of PNN around PV cells could participate to aberrant brain network activities observed in AD mice. To address this question, we performed stainings for PV and PNN in the hippocampus of 3, 6 and 13-month-old Tg2576 and non-transgenic (NTg) mice. Our data show a deficit of PV+ and/or PNN+ cells as young as 3-month-old in the CA1, CA2, and CA3 of Tg2576 mice, and a disruption of PNN before PV+ cells decrease. This is suggesting that PV+ cell plasticity is an early event in the course of the pathology of this AD mouse model.
We also tested whether the long-lasting beneficial effect of transient enriched environment (EE) can be sustained by a change in PV cell plasticity. To do so, Tg2576 and NTg mice were transiently exposed to EE between 3 and 5.5 months of age that has proven long-lasting effect on memory functions in this mouse line. We observed a rescue of PV cell number in the hippocampus of Tg2576 mice following transient EE, suggesting that the beneficial behavioral effect of environmental stimulations might be sustained by improving the basal activity of PV cells rather than by restoring their PNNs.

**Abstract:** Cell cycle re-entry, followed by hyperploidization of differentiated neurons, and synaptic failure are two known events taking place at the earliest stages of Alzheimer's disease (AD), but their functional connection remains unexplored. To address this question, we used differentiated cortical neurons that were forced to reactivate the cell cycle by SV40 large T antigen (TAg) expression, evidenced by an 80% of BrdU incorporation in NeuN+ neurons two days after transfection together with an increase of DNA content. We show that cell cycle re-entry specifically leads to reduced spontaneous electrical activity and diminished spike generation in cortical neurons. This is followed by delayed non-apoptotic cell death independent on oxidative stress. We also show that membrane depolarization by KCl partially rescues TAg-dependent neuronal death even though electrical capacity of TAg-transfected neurons remains reduced, thus suggesting that the survival of AD-associated hyperploid neurons may depend on their insertion in active neuronal circuits. Our results indicate that cell cycle reentry in neurons may actively participate in the AD etiology.

**Abstract:** The synaptic activity in the hippocampus and PFC is important for cognitive functions. Synaptic dysfunction is a distinctive neural alternation in the early stages of dementia and related to the progression of clinical symptoms. Epidemiological studies have shown that

Diabetes Mellitus (DM) is a risk factor for dementia, and the progression of cognitive impairment is accelerated by DM. Alteration in neural insulin signaling may be associated with pathogenesis of DM-related cognitive impairment. However, the mechanism of the interaction between neural insulin signaling and synaptic dysfunction is largely unknown. Our recent work showed that activated hippocampal insulin signaling correlates with cognitive impairment in the physiological type 2 diabetes model (DIO: Diet Induced Obesity) mice. Furthermore, we found that insulin signaling components are localized not only in cytoplasm but also in the postsynaptic density (PSD), and synaptic insulin signaling is upregulated in both the hippocampus and prefrontal cortex (PFC) of DIO mice. Finally, we confirmed that DIO mice exhibited impaired working memory via hippocampus and PFC network in the reversal Water T-maze test. Thus, these results suggested that DM-induced upregulation of synaptic insulin signaling may facilitate hippocampus and PFC dependent cognitive impairment.

**Abstract:** Alzheimer's disease (AD) is the most common age-related neurodegenerative disorder. At least two types of AD can be distinguished: sporadic AD (SAD) of unknown etiology, which accounts for most cases, and genetically encoded familial AD (FAD), which affects up to 5% of all of the patients. The most widely accepted risk factor for developing Alzheimer’s disease is age. It has been shown that during brain ageing, subtle but sustained changes in calcium homeostasis occur.
Store-operated calcium entry (SOCE) is the major $Ca^{2+}$ influx pathway in non-excitable cells.

However, recent body of evidence indicates that SOCE plays an important role in brain neurons. SOCE is a process by which the depletion of $Ca^{2+}$ from the endoplasmic reticulum (ER) causes an influx of $Ca^{2+}$ from the extracellular space to replenish the intracellular stores. STIM1 and STIM2 are calcium ER sensors mediating the process of SOCE by interacting with the ion channels in the cell membrane - ORAIs. Our group showed that the cytoplasmic resting $Ca^{2+}$ level in primary rat cortical neurons can be modulated by overexpression of STIM proteins. We also detected an enhanced magnitude of $Ca^{2+}$ influx during SOCE in human lymphocytes from SAD patients.
The objective of our research is to understand how elevated basal $Ca^{2+}$ level in neurons contributes to neurodegeneration. We have already obtained transgenic mice with elevated gene expression of STIM1, STIM2 or ORAI1 specifically in brain neurons. In one of our recent papers we described the line overexpressing STIM1 [FVB\NJ-Tg(STIM1)Ibd], which exhibited impairments in long term depression and behavior. Using neuronal calcium fluorescent imaging combined with electrophysiology and behavioral tests we now analyze phenotype of the mice lines overexpressing STIM2 or ORAI1. We have found that FVB\NJ-Tg(STIM2)Ibd lines exhibit anxiety - related changes in behavior but no alternations in synaptic plasticity in CA3-CA1 hippocampal projection, wheareas FVB\NJ-Tg(ORAI1)Ibd mice demonstrate changes in the distribution of miniature excitatory postsynaptic currents (mEPSCs) amplitudes. The obtained lines can be suitable models for further analysis of the hypothesis that brain dysfunction during ageing is induced by changes in $Ca^{2+}$ homeostasis.

**Title:** Age-dependent changes in the synaptic regulator arc (activity-dependent cytoskeleton-associated protein) in the hippocampal formation of mice

**Authors: *A. KHAN**[1,2], K.-C. LEE[1], H.-Y. WANG[1,2]
[1]Dept Physiol, Pharmacol & Neurosci, CUNY Sch. of Med., New York, NY; [2]Biol., The Grad. Center, City Univ. of New York, New York, NY

**Abstract:** Introduction: Activity-dependent cytoskeleton-associated protein (Arc) is a postsynaptic, neuron specific protein. Arc is a prominent regulator of synaptic plasticity and homeostasis (Korb and Finkbeiner, 2011). Specifically, Arc is involved in AMPA receptor endocytosis and late phase LTP consolidation at the dendrite. NMDA receptor activation drives up Arc expression to promote remodeling of the dendritic spine via its direct and indirect interactions with dendritic spine proteins such as cofilin and the actin cytoskeleton. Given that synaptic activity is reduced in an age-dependent manner and markedly deteriorated in Alzheimer's disease (AD), we propose the hypothesis that basal and activity-driven Arc expression are altered during normal aging and in AD pathogenic progression. To this end, we investigated Arc expression under non-stimulated (basal) and NMDA/Glycine stimulated conditions in hippocampal formation (HF) from 3-, 6-, 10- and 15-month old wild-type (WT) and 3x transgenic (Tg) AD mice. Methods: A well-established, ex-vivo stimulation method (Wang, H.-Y., J. Neurosci, 9: 9773-9784, 2012) was used to assess Arc levels in response to Kreb's Ringer (control) and NMDA/glycine. Arc in the solubilized HF slices was isolated by immunoprecipitation with anti-Arc antibodies and determined using western blotting. Simultaneously, β-actin purified by anti-actin antibody was used as the immunoprecipitation/loading control. Results: Basal Arc expression is elevated in 3xTg AD mice at 6-month of age. NMDA/glycine-stimulated Arc expression is reduced in 3X Tg AD mice of all ages and in WT > 10 months of age. Conclusions: Our data suggest that activity-driven Arc expression is a sensitive indicator for assessing the magnitude of synaptic dysfunction during both the aging process and, more significantly, AD pathogenesis.

**Title:** Amyloid-β induces dendritic degeneration by altering Rho kinase (ROCK) signaling in Alzheimer's disease

**Authors: *B. W. HENDERSON**, J. H. HERSKOWITZ
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

**Abstract:** Current estimates project that there are approximately 5.4 million Americans affected by Alzheimer's disease (AD). Cognitive decline is a clinical hallmark of AD, while accumulation of amyloid-β (Aβ) is a pathological hallmark. Aβ accumulates prior to synapse loss in AD, and synapse loss correlates more strongly with cognitive decline than classical pathologic hallmarks. Yet, there are few therapeutic strategies that target synapse loss as a mechanism to delay or prevent cognitive decline in AD. RhoA, a Rho GTPase family member, and its primary downstream effectors, the Rho-associated coiled-coil containing protein kinases (ROCK) 1 and ROCK2, are potent regulators of actin dynamics, influencing neuronal morphology and synaptic plasticity. Our previous work demonstrated that ROCK1 and ROCK2 protein levels are increased in mild cognitive impairment due to AD (MCI) and AD cases, and that Aβ activates the RhoA/ROCK pathway. We show that Aβ induces dendritic spine degeneration in primary hippocampal neurons, but treatment with Fasudil, a clinically available pan-ROCK inhibitor, prevents Aβ-induced spine loss. Moreover, we define how pharmacologic or genetic manipulation of ROCKs interacts with Aβ's negative impact on dendritic spine physiology in hippocampal neurons. Using three-dimensional modeling of dendritic structure, we define isoform-specific effects of ROCKs on dendritic spine density and morphology. Our findings highlight key role for ROCKs in dendritic degeneration and continue to support a notion for ROCK inhibition as a viable treatment for cognitive decline in AD progression.

**Title:** In diabetic rats, insulin within the hippocampus increased

**Authors: *A. S. SHINGO**[1], S. KITO[2], T. MURASE[1]
[1]Okinaka Mem. Inst. For Med. Res., Minato-Ku, Tokyo, Japan; [2]Shonan Hosp., Kanagawa, Japan

**Abstract:** Hitherto, we have clarified the mechanism of the cognitive decline in intracerebroventricularly streptozotocin-injected rats (STZ-3V rats). These rats showed impaired spatial memories and decreased immunoreactivities for hippocampal pCREB, AKT, IDE and SST together with increased immunoreactivity for Ab protein. They are considered a model of Alzheimer's disease. Furthermore, we demonstrated the immediate recovery from cognitive impairments in STZ-3V rats following one shot intracerebral injection of insulin detemir. Based on these results, we proceeded to study how cognitive dysfunction in type 2 diabetes is related to intracerebral insulin signalling and measured the amount of insulin within the hippocampus. The

new-born Wistar strain rats were prepared for type 2 diabetes mellitus (DM2T) by intraperitoneal injection of streptozotocin 2-3 days after birth. After the 4-week-old rats were imposed for Morris water maze test, immnohistochemical staining for insulin-signalling-related substances along with amyloid beta (Ab) protein were done. The insulin within the hippocampus was quantitatively assayed by ELISA.The DM2T rats showed impaired spatial memories and decreased immunoreactivities for hippocampal pCREB, AKT, IDE and SST along with increased immunoreactivity for Ab protein exactly as observed in STZ-3V rats. Insulin within the hippocampus was increased compared to the hippocampus in control rats contrary to our initial expectation of brain insulin deficiency in diabetes. It was concluded that there was the insulin resistance in DM2T hippocampus which leads to cognitive impairments accompanied by Alzheimer's disease-like cerebral changes.

**Abstract:** Approximately 30-50% of individuals who come to autopsy without dementia have high levels of Alzheimer's disease (AD) pathology. These cases are proposed to represent individuals who are resilient to dementia, but how cognitively normal older individuals with AD pathophysiology withstand the development of dementia has remained one of the most pivotal, unanswered questions in the field. Here we used innovative, highly optimized three-dimensional modeling of dendritic spines to analyze synapse populations from controls, cognitively normal individuals with high AD pathology, and AD dementia cases. Our analysis shows that dendritic spines undergo unique structural remodeling exclusively in patients with high AD pathology but no cognitive impairment. Samples included postmortem human prefrontal cortex tissue from age-matched pathology-free controls, controls with high levels of AD pathology (CAD), and

late-onset AD cases. Methods included Golgi-Cox technique, brightfield imaging, three-dimensional digital reconstruction and morphological analysis of dendritic spines. We compared the density of dendritic spines within layers II and III pyramidal neuron dendrites in Brodmann Area 46 dorsolateral prefrontal cortex, a key area of working memory, using the Golgi-Cox technique in control, CAD, and AD cases. We developed a method to digitally trace impregnated dendrites from brightfield microscopy images, enabling accurate three-dimensional reconstruction of dendritic structure. Analysis of spine morphology revealed unique structural remodeling of synapses exclusively in CAD cases compared to controls or AD. These results bridge gaps to link non-human primate models of age-related memory loss with human dementia. Our findings support the hypothesis that spine plasticity is a mechanism of cognitive resilience that protects older individuals with AD pathophysiology from developing dementia and highlight structural plasticity as a substrate for therapeutic intervention to delay dementia onset during the preclinical phase of AD.

**Abstract:** Alzheimer’s disease (AD) is neurodegenerative disorder characterized by progressive cognitive impairment and aberrant behavior. Although amyloid β-peptide (Aβ) accumulation is a diagnostic criterion for AD, it has become evident that neuronal circuits can resist and/or compensate for Aβ cytotoxicity as demonstrated by cognitively intact individuals with extensive Aβ deposits, and transgenic mice that accumulate massive amounts of Aβ but no neuronal death. Mitochondrial impairment is implicated as an early event in AD pathogenesis. We recently reported that the mitochondrial protein deacetylase SIRT3 protects neurons against excitotoxic and metabolic stress by mechanisms involving enhanced removal of mitochondrial superoxide and inhibition of apoptosis (*Cell Metab.* 2016; 23:128-142). Here we report that AD patients exhibit a marked reduction in SIRT3 levels in vulnerable, but not in minimally vulnerable, brain regions suggesting a potential role for diminished SIRT3 in AD pathogenesis. Because it has

been known since the early 1990s that Aβ renders neurons vulnerable to excitotoxicity (*J Neurosci.* 1992; 12:376-389), and AD patients have an increased incidence of seizures, we asked whether SIRT3 might stabilize neuronal network activity and thereby enable normal cognition even as Aβ accumulates. To this end, we are evaluating behavioral phenotypes and cellular and molecular alterations in brain neuronal networks in $SIRT3^{-/-}$ mice and APP/PS1 double mutant transgenic mice with a SIRT3 haploinsufficiency. We find that SIRT3 is required for adaptation of hippocampal and amygdala neuronal network activity (up-regulation of GABAergic tone) to bioenergetic/excitatory challenges (intermittent food deprivation and exposure to picrotoxin) in non-AD mice. While APP/PS1 AD mice have a propensity to develop seizures, APP/PS1 SIRT3+/- mice exhibit severe seizures and die between the ages of 3 and 6 months. We are determining whether APP/PS1 SIRT3+/- mice have accelerated behavioral and neuropathological phenotypes, and whether increasing SIRT3 expression in hippocampal neurons using AAV-mediated gene therapy will ameliorate neuronal network abnormalities and cognitive impairment in APP/PS1 AD mice. **Title:** Altered cortical and hippocampal excitability in TgF344-AD rats modeling Alzheimer’s disease pathology

**Authors: *M. STOILJKOVIC**, C. KELLEY, B. STUTZ, T. L. HORVATH, M. HAJÓS
Yale Univ. Sch. of Med., New Haven, CT

**Abstract:** Current neurophysiological findings suggest that accumulation of amyloid-β (Aβ) and hyperphosphorylated tau in the brain disrupt synaptic function in hippocampal-cortical neuronal networks leading to impairment in cognitive and affective functions in Alzheimer’s disease (AD). Available therapies in clinical practice have limited efficacy and do not affect AD progression, while development of new drugs with disease-modifying potential has proven a challenge due in large part to the lack of highly predictive animal models and assays. In the present study we recorded neural activity in TgF344-AD rats, a recently developed transgenic model with a full array of AD pathological features, including age-dependent accumulation and deposition of Aβ, tauopathy, apoptotic neuronal loss, and cognitive impairment (Cohen et al., 2013). Under urethane anesthesia, TgF344-AD rats showed significant age-dependent decline in brainstem-elicited hippocampal theta oscillation and decreased theta-phase-gamma amplitude

coupling comparing to their age-matched WT counterparts. In freely-moving condition, hippocampal and cortical recordings also demonstrated altered neuronal activities. Both the power of hippocampal theta oscillation and gamma power during sharp-wave ripples were significantly lower in TgF344-AD rats. Additionally, these rats showed impaired coherence in both intercortical and hippocampal-cortical network dynamics. Cortical EEG also revealed higher neuronal excitability with increased incidence of paroxysmal hypersynchronous high-voltage spindles, which occur during awake, behaviorally quiescent state. Furthermore, TgF344-AD rats demonstrated impairments in sensory processing, having diminished auditory gating and 40-Hz auditory evoked steady-state response in the auditory cortex. Subsequent analyses of these rats showed accumulation of hyperphosphorylated tau in basal forebrain cholinergic and GABAergic neurons which innervate both the hippocampus and cortex. Also, lower expression of synaptophysin and tenascin-C in hippocampal neurons was present, along with increased levels of key inflammatory cytokines. The observed differences in hippocampal and cortical neurophysiological activity, alterations in synaptic function, and higher inflammatory tone in TgF344-AD rats, which mirror several abnormalities described in AD patients, may be used as promising markers to monitor therapies influencing disease progression.

**Title:** Opposing effects of Aβ42 on cholinergic synaptic activity and a role for synaptic homeostasis

**Authors: *E. HAHM**, R. Y. NAGARAJA, R. TOOKER, S. TSUNODA
Dept Biomed. Sci., Colorado State Univ., Fort Collins, CO

**Abstract:** The generation of β-amyloid (Aβ) peptides in the brain is a primary event leading to Alzheimer’s disease (AD). The toxic Aβ42 species has many effects, including the alteration of neural activity. Interestingly, reported changes include both increases and decreases in neural activity. We find that human Aβ42 induces an increase in cholinergic synaptic activity in *Drosophila*, which is followed by synaptic depression, a sequence of events that parallels

suggested changes in cholinergic activity in mammals. We show that the early increase in synaptic activity is likely due to extracellular Aβ42 acting on pre-synaptic α7 nAChRs, and that increasing synaptic activity can induce a homeostatic decrease in activity at later stages. Conversely, countering the early increase in synaptic activity in Aβ42-expressing cultures prevents the induction of later synaptic depression. Our findings support the hypothesis that endogenous synaptic homeostasis mechanisms are likely to play a key role in the progressive effects of Aβ42 on neurons.

**Title:** Intracellular Abeta oligomers increase AMPA neurotransmission by pre and postsynaptic actions

**Authors: *L. G. AGUAYO**[1], C. PETERS[2], J. GONZALEZ[2], N. O. RIFFO[2], B. MUÑOZ[2], E. J. FERNANDEZ[2]
[2]Physiol., [1]Univ. Concepcion, Concepcion, Chile

**Abstract:** Introduction
The current dogma of the amyloid cascade supports the conclusion that Aβ interaction with extracellular components of the neuronal membrane initiates neurotoxicity. However, the effect that intracellular Aβ may have on neuronal functions has still not been extensively examined. The presence of intraneuronal Aβ aggregates has been correlated with neuronal death in transgenic mice models, and neurons undergoing degeneration in 5xTg-AD mice showed intracellular amyloid deposits. In this study, we examined the effects of intracellular Aβ oligomers (Aβo) on mice hippocampal neurons from slices and in tissue culture.
Results
Electrophysiological recordings were done using the whole-cell variation of the patch clamp technique in presence of an external solution containing high NaCl and 10 HEPES (pH 7.4). The internal solution consisted of high KCl, ATP-Na2, BAPTA and Aβo oligomers or fibers (5-1000 nM). The holding potential was -60 mV and currents were acquired at 50 μs intervals. $A\beta_{1-42}$ and $A\beta_{1-40}$ were dissolved in HFIP (10 mg/ml) and stored in aliquots at -20ºC. In order to form Aβo,

the samples were stirred at 500 rpm using a Teflon-coated micro-stir bar for 24-48 h at ~22°C and stored at 4°C until required.
The effects of intracellular Aβo were studied on the amplitude, frequency and time course of miniature synaptic currents. Under control conditions, the average frequency of synaptic currents was approximately 0.15±0.02 Hz and increased to 0.67±0.1 Hz after application of 5 nM of Aβ oligomers (5 min). With higher concentrations (50 nM), the effect was faster and larger supporting a concentration dependent effect. Application of denatured Aβ and DMSO did not produce any affects on the frequency of synaptic currents. The effect of Aβ was more selective for oligomers since application of different concentrations of fibrillar Aβ was less active, affecting the frequency of synaptic currents only when applied at 1 μM (0.55±0.2 Hz). The effects of Aβo were more extensive on AMPA-mediated neurotransmission than in $GABA_A$-mediated. The properties of the action potential and the value of the resting membrane potentials were unchanged by the intracellular perfusion of Aβo.
Conclusion
The data showed that low concentrations of intracellular Aβo had a profound effect on synaptic transmission. The effect was more evident on excitatory neurotransmission affecting pre and postsynaptic mechanisms.

**Title:** The acylated tripeptide Arg-Glu-Arg enhances hippocampal LTP and can reverse LTP deficits produced by $Abeta_{25-35}$

**Authors: *K. D. PARFITT**[1], S. F. WAKE[2], J. C. NECARSULMER[2], V. SRINIVASAN[2], I. SOLOMON[2], K. M. KNOX[2], S. A. CRAWFORD[2], D. J. O'LEARY[3], W. C. ABRAHAM[4]
[1]Dept of Neurosci., Claremont, CA; [2]Dept of Neurosci., [3]Dept of Chem., Pomona Col., Claremont, CA; [4]Psychology, Univ. of Otago, Dunedin, New Zealand

**Abstract:** Secreted APPα (sAPPα), a 612-residue protein derived from amyloid precursor protein, has neurotrophic and neuroprotective properties and enhances hippocampal long term potentiation (LTP) *in vivo* and *in vitro*. Few of the cellular mechanisms of action of sAPPa are known, but a tripeptide sequence within sAPPa—arginine-glutamate-arginine (RER)—has been

proposed as an active region of the protein that enhances memory in a passive-avoidance task in chicks. This tripeptide corresponds to a growth-promoting region of the external domain of APP (amino acids 328-330), can be administered peripherally and seems to cross the blood brain barrier in chicks. We examined the ability of congeners of sAPPα's RER motif, in an acylated and diastereomeric form (Ac-rER), to mimic the LTP-enhancing effects of full-length sAPPα observed previously in rat and mouse hippocampus. First we tested the ability of Ac-rER to enhance LTP induced by mild theta burst stimulation (TBS). Hippocampal slices were prepared from adult male C57Bl/6N mice and allowed to recover for 2 h. Baseline field excitatory postsynaptic potentials (EPSPs) were evoked in area CA1 by electrical stimulation of the Schaffer collateral/commissural pathway, and recorded in stratum radiatum. Application of mild theta-burst stimulation (TBS, 5 trains (5 Hz) of 5 pulses (100 Hz)) induced post-titanic potentiation (PTP) but not LTP in untreated slices. In contrast, when applied 25 min before, during and following the mild TBS, Ac-rER (10 nM) facilitated both PTP and LTP compared to controls (responses 1h post-TBS = 139 ± 4.3 % vs 108 ± 3.1% of baseline; N = 9 and 8, respectively; $p<0.01$). Ac-rER was more effective than the non-diastereomeric peptide (Ac-RER) in enhancing LTP; in the presence of Ac-RER, LTP was 119 ± 6.4 % of baseline. Neither of these tripeptides, nor the randomly selected control Ac-IFR tripeptide, were found to alter baseline synaptic transmission or paired pulse facilitation. To determine whether sAPPα has metaplastic properties, we washed the Ac-rER (10 nM, 30 min) out of the bath for 30 min prior to TBS. Under these conditions, LTP was 125 ± 4% of baseline (vs 108 ± 5% in controls; $p<0.01$). We also examined whether Ac-rER can ameliorate $A\beta_{25-35}$-induced deficits in LTP induced by 3 X TBS (10 trains (5 Hz) of 5 pulses (100 Hz)). Treatment of slices with Ac-rER prior to and during application of $A\beta_{25-35}$ (200 nM) prevented the deficits in LTP observed in the presence of $A\beta_{25-35}$ alone. These results suggest that this acylated diastereomeric tripeptide shares similar plasticity-enhancing properties of sAPPα and has the potential to reverse the deficits in synaptic plasticity seen in Alzheimer's disease.

**Abstract:** Alzheimer's disease (AD) is the main cause of dementia, accounting for 60-80% of all cases. During the course of the disease, three main neuropathological alterations occur: cerebral atrophy, intracellular neurofibrillary tangles and extracellular amyloid plaques. Early loss of episodic memory in AD patients is closely associated with the progressive degeneration of medial temporal lobe structures, including the hippocampal formation and adjacent cortex. In addition, neurofibrilar tangles are first observed in the transentorhinal (TEC), entorhinal cortex and hippocampal CA1 field. Synapse loss has also been reported, but relatively few detailed studies have been performed using electron microscopy. This is important because elucidation of the changes that affect synapses is crucial for better understanding the pathogenic mechanisms underlying AD. Brain tissue from 5 AD patients and 6 control subjects with no neurological alterations were used in this study. These human brain samples had less than 3h postmortem delays. A 3D ultrastructural analysis of the neuropil in layer II of the TEC and superficial pyramidal layer of the medial CA1 was performed. We used an instrument that combines a high-resolution field-emission SEM column with a focused gallium ion beam (FIB), which mills the sample surface on a nanometer scale. The sequential and automated use of FIB milling and SEM imaging allows us to obtain large image stacks that represent a three-dimensional sample. Customized analysis software was used for the reconstruction of synapses, which allowed their number, morphology (surface area of the synaptic apposition surface) and spatial distribution to be calculated. These spatial and morphological data are of great interest in terms of synaptic function. Our preliminary results show that the total number of synapses per volume in AD patients was lower than in controls, both in CA1 and TEC. However, we have not found differences in the morphology of the synapses in AD patients compared with control subjects. Furthermore, the spatial organization of synapses showed a nearly random 3D distribution, regardless of the subject group and the region analyzed. In conclusion, these data show a decrease in the density of synapses in these brain regions in AD patients but both the spatial distribution and size of the synapses remain unchanged. Further studies will be performed to extend these observations to other brain areas of AD patients and to try to elucidate the functional consequences of these synaptic changes.

**Title:** Sigma-1 receptor and sex specificity in a mouse model of Alzheimer's disease

**Authors: *M. A. SNYDER**[1], K. MCCANN[2], E. HRISTOVA[2], R. BERGERON[1,2]
[1]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [2]Univ. of Ottawa, Ottawa, ON, Canada

**Abstract: Background:** Studies suggest that nearly 2/3 of Alzheimer's disease (AD) patients are women and that they have a faster disease progression than men. Despite this clinical profile, only a small fraction of research includes animals of both sexes and even fewer examine data for potential sex differences. With no cure and few treatments available for AD, novel therapeutic targets are desperately needed. One protein of interest is the sigma-1 receptor (Sig1R) which has roles in regulating $Ca^{2+}$ homeostasis, synaptic transmission, cognition, and is modulated by sex hormones. Sig1R agonists are neuroprotective and anti-amnesic in AD models making it a target for intervention. Further, Sig1R binding sites are decreased in post-mortem AD brains and a Sig1R gene polymorphism is a risk factor for AD. Therefore, Sig1R loss could contribute to AD progression. Our research focuses on how amyloid beta (Aβ) induces changes in neuronal $Ca^{2+}$ signaling and causes synaptic dysfunction in the hippocampus. We also evaluate how Sig1R loss contributes to the deficits in AD. **Methods:** We used the well-characterized $A\beta_{25-35}$ infusion AD model, as this paradigm recapitulates the process of sporadic AD. $A\beta_{25-35}$ was infused, *i.c.v.*, into brains of adult male and ovariectomized female wild-type (WT) or Sig1R knockout (KO) mice. Using electrophysiological recording and western blot, we examined Aβ-induced changes to synaptic transmission and synaptic proteins. **Results:** We found that female mice infused with $A\beta_{25-35}$ had an increased post-burst afterhyperpolarization, a paradigm used as a proxy for changes in $Ca^{2+}$ homeostasis. They also had an increased facilitation in response to trains of stimuli. Interestingly, Aβ-infused male mice did not show these changes. Instead, Aβ-infused male mice had alterations in their AMPA/NMDA ratio which was not found in female WT mice but was present in female Sig1RKO mice. Despite these Aβ-induced sex differences in hippocampal function, both male and female Aβ-treated mice had reduced magnitude of long-term potentiation. Surprisingly, Sig1R loss did not exacerbate most Aβ-induced deficits. However, uninfused aged Sig1RKO male and female mice had increased levels of $A\beta_{1-42}$ in their cortex compared to WT mice, suggesting Sig1R loss may interact with aging to increase AD pathology. **Conclusions:** Our data suggest that the mechanistic action of Aβ differs between male and female mice. Understanding how Aβ impacts synaptic function and $Ca^{2+}$ homeostasis

within the male and female hippocampus differently could explain the faster disease progression in females and lead to sex-specific therapeutic intervention.

**Title:** Cargo-specific dynamics of neuronal intracellular transport (NIT)

**Authors:** ***M. FEOLE**, V. M. POZO DEVOTO, M. CARNA, V. LACOVICH, K. TEXLOVA, G. STOKIN
Intl. Clin. Res. Ctr. FNUSA-ICRC, Brno, Czech Republic

**Abstract:** The neuronal intracellular transport (NIT) is a highly regulated process, involving several proteins that regulate the trafficking of molecules. Transported proteins are involved in several processes such as synaptic plasticity, neurotransmission, cell morphology, differentiation, cell-cell interaction, degradation and damage signaling. This is particularly relevant during aging when changes in energy metabolism together with oxidative stress, erode the axonal structure and function. Intriguingly, several neurodegenerative disorders, in particular those associated with aging, such as Alzheimer’s disease, exhibit significant axonal pathology including impairments in transport. However, the mechanisms underlying axonal pathology remain poorly elucidated. We aim to characterize transport dynamics of specific cargoes analyzing differences in directionality (anterograde vs retrograde), localization (soma, dendrites, axon) and velocity (fast or slow). For this study a well characterized neuronal culture differentiated from human Neural Stem Cells was used to investigate transport of different cargoes. NIT was investigated using differently transported GFP coupled cargoes, and assessed by live imaging with a confocal microscope. In addition to identify different neuronal compartments immunocytochemistry was performed after imaging. A detailed characterization of transport dynamics from typical proteins (Synaptophysin, BDNF, PSD95, Neurofilaments, etc.) present in different neuronal compartments was obtained. This characterization includes dynamics parameters such as mean velocity, proportion of anterograde/retrograde/stationary movement, segmental velocity, average run length, pauses, and reversions. Preliminary results compared to already elucidated APP transport showed different velocities of various retrograde/anterograde associated cargoes along

the different neuronal compartment. Further experiments will shed light on the intricate NIT network and ultimately provide critical knowledge and its involvement in the pathophysiology of neurodegenerative disorders.

**Title:** L-3-n-butylphthalide rescues hippocampal synaptic failure and attenuates neuropathology in aged app/ps1 mouse model of alzheimer’s disease

**Authors: *Y. PENG**
Inst. of Materia Medica, Beijing city, China

**Abstract:** Alzheimer’s disease (AD) is an age-related and irreversibly progressive neurodegenerative disorder that occurs gradually and results in memory, behavior and personality changes. Our previous studies showed that L-3-n-butylphthalide (L-NBP), an extract from seeds of Apium graveolens Linn (Chinese celery), improved cognitive ability in animal models of cerebral ischemia, vascular dementia and AD. It is well known that cognitive deficit of AD is caused by synaptic dysfunction. In this study, we investigated the effect of L-NBP on hippocampal synaptic function in aged APP/PS1 AD transgenic mice and related mechanisms. Eighteen-month-old APP/PS1 transgenic (Tg) mice were administered 15 mg/kg L-NBP by oral gavage for 3 months. Synaptic morphology and the thickness of post-synaptic density (PSD) in hippocampal neurons were investigated by electron microscope. The dendritic spines, Aβ plaques and glia activation were detected by staining. The expressions of synapse-related proteins were observed by western blotting. The results showed that L-NBP treatment significantly increased the number of synapses and apical dendriticthorns and the thickness of PSD, increased the expression levels of synapse-associated proteins including PSD95, synaptophysin (SYN), β-catenin and GSK-3β, and attenuated Aβ plaques and neuroinflammatory responses in aged APP/PS1 Tg mice. It indicated that L-NBP might restore synaptic and spine function in aged APP Tg mice through inhibiting Aβ plaques deposition and neuroinflammtory response. Wnt/β-catenin signaling pathway might be involved in L-NBP-related restoration of synaptic function.

**Abstract:** One of the pathological hallmarks of Alzheimer’s disease is the deposition of amyloid plaques due to the accumulation of extracellular amyloid-beta (Aβ) peptides. Emerging evidence suggests that the soluble oligomeric form of Aβ is a synaptotoxic agent that mediates the impairment of synaptic functions and disrupts neuronal circuit activities. Meanwhile, hyperactivation of neuronal activity contributes to the overproduction of Aβ. We previously demonstrated that a G protein-coupled receptor, melanocortin 4 receptor (MC4R) is critical for hippocampal synaptic plasticity. Importantly, deregulation of hippocampal MC4R signaling results in the impairment of synaptic plasticity, i.e., long-term potentiation, in Alzheimer’s disease. Suppression of postsynaptic MC4R in the hippocampus exacerbates long-term potentiation deficit in APP/PS1 mice, a transgenic mouse model of Alzheimer’s disease, whereas restoration of MC4R signaling alleviates this hippocampal synaptic plasticity impairment. Here, we demonstrated that specific activation of MC4R results in reduced amyloid pathology. Specifically, intracerebroventricular delivery of the MC4R agonist D-Tyr MTII into the brains of APP/PS1 mice significantly reduced Aβ content. It is interesting to examine whether MC4R signaling reduces Aβ pathology is dependent on the restoration of synaptic functions and circuit activity. Together, our findings suggest that activation of hippocampal MC4R signaling may be a

therapeutic approach for Alzheimer's disease, as indicated by its beneficial effects on impaired synaptic functions and Alzheimer's disease-like pathology.

**Abstract:** β-secretase (BACE1), the rate-limit enzyme of Aβ production, is significantly elevated in the cortex and hippocampus with Alzheimer's disease (AD) brain, which is often accompanied by hyperactive neurons. However, it remains unknown whether elevated BACE1 activity contributes to the hyperactivity of neurons in the AD brain. $GABA_A$ receptor, in general, produces inhibitory currents to prevent neurons from over excitability. We hypothesize that elevated BACE1 activity causes dysfunction of $GABA_A$ receptor, which in turn, leads to hyperactivity of neurons in the AD brain. We used multiple techniques, including co-IP, western blotting, and patch-clamp to address whether BACE1 suppressed the expression and functions of $GABA_A$ receptors. Our preliminary results showed that BACE1 significantly decreased expression level and whole-cell currents of $GABA_A$ receptors in HEK293T cells, suggesting BACE1 modulated $GABA_A$ receptors in vitro. We also used the newly developed mouse model BACE1 transgenic mice in our lab: hubc-BACE1 (HUBC) and also BACE1 knock-out mouse ($BACE^{-/-}$) to investigate whether BACE1 inhibited $GABA_A$ receptor currents in hippocampal neurons in acute brain slices. We found that both phasic and tonic currents of $GABA_A$ receptors were significantly decreased in the dentate gyrus granule cells of HUBC mice and, on the contratry, increased $GABA_A$ receptors were identified in that of $BACE1^{-/-}$ mice. The finding suggested that BACE1 modulated expression and/or functions of $GABA_A$ receptors in vivo. Moreover, we used the Barnes Maze test, to study whether elevated BACE1 activity in mice impaired learning and memory. Compared to wildtype mice, HUBC mice showed decreased long-term potentiation (LTP) in the perforant pathway and impaired spatial memory, suggesting elevated BACE1 impaired cognitive functions.

In summary, our results show that elevated BACE1 activity may be critically involved in hyperexcitation and cognitive impairments in AD by directly inhibiting GABAergic system functions. This would be the first time to identify the regulatory effects of BACE1 on synaptic plasticity and will provide a new potential therapeutic target for AD.

**Abstract:** Alzheimer’s disease (AD) progression is associated with the spread of tau pathological aggregates within the brain in a highly reproducible pattern that is used to stage the disease. We have shown that extracellular tau oligomers are cytotoxic to neurons, inhibit long-term potentiation and impair memory formation in mice. Tau oligomers have also been shown to transmit tau pathology to neighboring neurons by seeding tau misfolding and aggregation. Our small molecule approach aims to inhibit intracellular tau oligomer formation to reduce toxicity and to inhibit the spread of tau pathology, whereas other approaches have focused on using immunotherapy to block the extracellular transmission of tau pathology without addressing the continual formation of new tau oligomer seeds within neurons.
We have developed novel assays to select and optimize small molecules inhibiting tau self-association into oligomers to block the aggregation pathway at its start which differentiates our approach from tau fibril formation inhibitor programs. Our proprietary small molecule leads were designed, prepared and optimized to have CNS drug-like properties. Pharmacokinetic studies were performed in mice and showed both good exposure and half-life in the brain. An optimized compound from our lead series was selected for in vivo evaluation in a 5-day toxicity

study in mice at 100 mg/kg p.o. and no adverse events were observed.
A blinded efficacy study was performed in the htau model, best representing the development of tau pathology in AD. Male and female mice (n=100) were separated into four groups and treated for four months starting at three months of age with vehicle, 10 mg/kg, 40 mg/kg or 100 mg/kg of the lead compound milled into feed. All mice survived until the study end point and did not show any adverse events or an inability to thrive. For example, mice in all treatment groups gained weight at the same rates. At the end of the period, mice were sacrificed and their brains collected for histological and biochemical analyses that are in progress. The primary endpoint for the study is statistically significant reduction in insoluble tau, and the secondary endpoints are dose dependent reduction in tau aggregates, reduction in soluble tau, and reduction in phosphorylated tau. The findings of this study will be presented in due course.

**Authors: *M. HEBRON**, M. PEYTON, X. LIU, X. GAO, R. WANG, I. LONSKAYA, C. MOUSSA
Georgetown Univ., Washington, DC

**Abstract:** The role of cell surface tyrosine kinase collagen-activated receptors known as discoidin domain receptors (DDR1/2) is unknown in neurodegenerative diseases. We detect up-regulation in the expression level of DDRs in post-mortem Alzheimer and Parkinson brains. It is currently unknown whether regulation of DDRs that modulate many cellular functions is beneficial or detrimental in neurodegeneration. We used lentiviral gene transfer to knockdown DDR1/2 in models of Alzheimer's and Parkinson's disease and determined the effects of DDR receptor level on accumulation of α-synuclein, tau and β-amyloid. We found that DDR knockdown reduces the levels of these proteins and prevents cell loss. DDR knockdown alters brain immunity and significantly reduces the level of triggering receptor expressed on myeloid cells (TREM)-2 and microglia. We used a novel compound called LCB-03-0110 that inhibits DDRs and found significantly reduced levels of neurotoxic proteins, decreased cell death and behavioral improvement in neurodegeneration models. These studies suggest that DDR inhibition is a novel target to clear neurotoxic proteins and reduce inflammation in neurodegeneration. LCB-03-0110 is a pharmacological candidate to treat neurodegenerative diseases.

**Authors: *M. MORIN**[1], E. SHER[2], M. P. JOHNSON[1]
[1]Neurosci. Discovery Res., Eli Lilly and Co., Indianapolis, IN; [2]Neurosci. Discovery Res., Eli Lilly and Co., Windlesham, United Kingdom

**Abstract:** Activation of Glucagon-Like Peptide receptors (GLP-1r), critical for glucose metabolism, has been shown to have neuro-protective and anti-inflammatory properties *in vitro* and *in vivo*. In several preclinical models of Alzheimer's disease, peripheral administration of a

GLP-1r agonist has been reported to reduce abnormal neuropathology and improve the cognitive and motor deficits that occur in these models (Brain Research 1634:158-170; Neuromol Med 15:102-114). The exact mechanism by which this occurs is currently unknown, as existing GLP-1r agonists are all large molecule proteins with a theoretically limited ability to cross the blood brain barrier (BBB). In these experiments, an *ex vivo* autoradiography assay was developed to assess the central exposure of peripherally administered GLP-1 receptor agonists in mice. Autoradiography with [$^{125}$I] GLP-1(7-36) was used to determine GLP1-receptor distribution in C57Bl/6 mouse brain and several peripheral tissues under equilibrium conditions. Consistent with the literature, GLP-1(7-36) binding was widely distributed throughout the brain, with the highest levels seen in the lateral septum, habenula and dentate gyrus of the hippocampus. Moderate levels were present in several hypothalamic nuclei (arcuate nucleus, lateral hypothalamus) and the pretectal nucleus of the thalamus. The highest level of GLP-1(7-36) binding in the assessed peripheral tissues was found in the lung. For the *ex vivo* assay, the lateral septal area of the brain and one peripheral tissue (lung) were assessed following subcutaneous dosing of a GLP-1r agonist, liraglutide. Liraglutide (1mg/kg) significantly displaced the [$^{125}$I] GLP-1(7-36) binding in the lung at 2 and 6 hours (63 and 90% inhibition, respectively). However, there was no inhibition of the GLP-1r binding in the lateral septum of the brain. These results may indicative that the neuro-protective effects of GLP-1 agonists are due to an indirect action of GLP-1 activation on neurons, local activation of GLP-1r in a discreet brain region that was not quantified or a low percent occupancy with central GLP-1 receptors that is less than the level of detection of the assay.

**Abstract:** Gamma power has been shown to be altered in several neurological diseases, including Alzheimer's disease. Previous work from our lab showed a reduction in gamma power (with a unimodal distribution around 40 Hz) in the 5XFAD mouse model, in young amyloid pre-depositing mice. Using a non-invasive 40 Hz light flicker, we were able to entrain gamma oscillations in the visual cortex, and observed a transformation in microglial morphology and reduction in amyloid load. Here, we investigated whether stimulation of other sensory modalities at 40 Hz, such as auditory, can have an effect on Alzheimer's-like pathology. We applied a 40 Hz auditory stimulation, and observed markedly reduced amyloid load and tau phosphorylation as well as microglia activation in both the auditory cortex and hippocampus. Our data demonstrates a non-invasive strategy to ameliorate AD-like pathology in regions additional to the primary sensory cortex in several AD mouse models.

**Title:** Inosine improve cognition in aged rats- Possible antioxidant and anti-inflammatory mechanism

**Authors: *P. RUHAL**, D. DHINGRA
Guru Jambheshwar Univ. of Sci. and Technol., Hisar, India

**Abstract:** Aging is characterized by progressive decline in physiological functions due to maladaptation of synaptic processes that eventually results in aberrant perception, cognitive dysfunction and neurodegeneration. This deterioration is due to the formation of engrams in the brain and one of that is the "oxidative stress" which occurs due to imbalance between the generation of free radicals and antioxidant enzyme activity. As the population is aging, the incidence of age-related neurodegenerative diseases, such as Alzheimer's disease, is growing. In

the present study, we investigated the effect of inosine (50, 100 and 200 mg/kg; i.p.) in 18 months old middle-aged male rats. Inosine was administered to rats for 14 successive days. Donepezil (1mg/kg; i.p.), an acetylcholinesterase inhibitor was used as a standard drug. Behavioural models were used to evaluate the effect of drugs on learning and memory of rats. After behavioural studies, animals were sacrificed for the preparation of cytoplasmic fractions of hippocampus and pre-frontal cortex for the quantification of acetylcholinesterase activity, oxidative stress parameters, proinflammatory marker i.e. TNF-α, IL-6 and histopathological examinations. Inosine significantly improved learning and memory of rats when tested in behavioural models. Further, inosine significantly reduced the oxidative stress markers and improved antioxidant enzyme activities (i.e. SOD and GSH). However, no significant difference in AChEs activity was observed in inosine treated groups in comparison to aged control rats. Further, TNF-α and IL-6 level were found to be ameliorated in ICV-STZ-treated rats after the treatment of inosine in a dose dependent manner. Histopathological evaluation showed that inosine treated aged rats has less number of pyknotic neurons as compared to aged control rats. **Conclusion:** Inosine significantly improved learning and memory of rats possibly through its dual effect i.e. antioxidant as well as anti-inflammatory effect and improvement of neuronal survival in hippocampal CA-1 region of middle-aged rats. However, additional study is needed to further explore the downstream signalling pathways involved in the neuroprotective effect of inosine in aged animals.

**Title:** Histone Deacetylase inhibitor, sodium butyrate, exerts neuroprotective actions in intracerebroventricular streptozotocin induced biochemical abnormalities in rats

**Authors: *S. SHARMA**, R. TALIYAN
Birla Inst. of Technol. and Science, Pilani, Pilani, India

**Abstract: Background** Alzheimer’s disease (AD) is the leading cause of dementia and is characterized by progressive loss of memory and other cognitive functions. Both neuro-inflammation and oxidative stress have been reported to be elevated in AD. Recently, reduced histone acetylation along with elevated expression and activity of histone deacetylases (HDACs) has also been reported in various preclinical and clinical studies of AD. Thus, the present study was undertaken to determine the therapeutic potential of HDAC inhibitor, Sodium butyrate (NaB) in Intracerebroventricular-Streptozotocin (ICV-STZ) induced sporadic Alzheimer's

disease (sAD) in rats.
**Methods** Adult Male Wistar rats (250-350g) were infused with STZ twice (3 mg/kg ICV) on alternate days (day 1 and day 3) using following coordinates: 0.8 mm posterior to bregma; 1.5 mm lateral to sagittal suture; 3.6 mm ventral from the surface of the brain. The ICV-STZ treated rats received either vehicle (0.9%w/v NaCl) or NaB (150 and 300mg/kg, i.p.) for a period of 21 days. Thereafter the animals were sacrificed; brains were removed and used for biochemical and histological studies.
**Results** The ICV-STZ administration results in significant elevation of oxidative-nitrosative stress (malondialdehyde and nitrite levels), reduction in antioxidant enzyme level (reduced glutathione), increase of pro-inflammatory marker (Tumour necrosis factor-α) in hippocampus homogenates as compared to vehicle treated animals. In addition, ICV-STZ administration results in reduced level of global histone H3 acetylation and brain derived neurotrophic factor (BDNF) in hippocampus brain homogenate. In contrast, NaB treatment significantly and dose dependently attenuated the oxidative-nitrosative stress and neuro-inflammatory markers in ICV-STZ treated rats. Further, NaB treatment augments the histone H3 acetylation and BDNF levels in ICV-STZ treated rats. Moreover, the neuroprotective effects of NaB were further confirmed by increased neuronal count in hippocampus regions during histological studies.
**Conclusion** The neuroprotective effects of NaB may be due to its ability to attenuate inflammatory markers or its antioxidant potential. Moreover, based upon these results, it could be suggested that HDAC inhibitors might exert neuroprotective actions by increasing H3 acetylation and subsequently BDNF levels.

**Title:** Effects of metformin in combination with voluntary exercise in a female transgenic mouse model of Alzheimer's Disease

**Authors: A. JALDI**, F. BELLO, T. SMITH, T. FALEGAN, *J. S. ALLARD
Physiol. and Biophysics, Howard Univ. Col. of Med., Washington, DC

**Abstract:** Type-2 diabetes (T2DM) presents a 1.5 to 2-fold increased risk for Alzheimer’s disease (AD). Researchers are focused on the role of neuronal insulin resistance as a potential cause. If true, then insulin-sensitizing agents may be effective therapies for both peripheral and

central insulin resistance. Both metformin treatment and aerobic exercise have powerful anti-diabetic effects, including insulin-sensitization. The overall goal of this study is to understand the impact and mechanisms by which metformin treatment and voluntary exercise affect brain function, neuronal insulin signaling and the progression of neurodegenerative disease. Using the APP/PS1 mouse model of AD, the effects of metformin and exercise therapy separately, alone and in conjunction are compared. Metformin intake was approximated at a daily dose of 70 mg/kg body weight for one year and animals had free access to an in-cage running wheel. AD pathology in the adult mouse brain, including inflammation and amyloid beta plaque deposition are analyzed, as well as glucose metabolism. These results provide new information on the effects of metformin in combination with exercise on AD-like pathology.

**Abstract:** The overall health beneficial effects of extra virgin olive oil (EVOO) phenolic components are well established. Our previous data have shown the protection of oleuropein aglycone (OLE) against protein/peptide aggregation *in vitro* and in TgCRND8 mice, a transgenic model of Aβ deposition. A protective action of the oral intake of a mix of polyphenols present in olive mill waste water was also shown. Here we extended our previous investigations on the neuroprotective, antinflammatory and antioxidant power of EVOO polyphenols by investigating the effects on cognitive functions, brain amyloid deposits, neuroinflammation and oxidative stress in TgCRND8 mice following diet supplementation with hydroxytyrosol (HT), a major polyphenol in olive oil and the main metabolite of oleuropein aglycone.
4-month-old Tg mice (n=6/group/genotype, equally divided for sex) were used for treatment. The animals were fed for 8 weeks with a modified low-fat (5.0%) AIN-76A diet (10 g/day per mouse) supplemented with HT (50 mg/kg of diet). The animals were divided into four different

groups: i) Tg mice fed with low-fat diet as such (untreated Tg mice); ii) Tg mice fed with the same diet supplemented with HT (HT-fed Tg mice); iii) wt mice fed with low-fat diet as such (untreated wt mice); iv) wt mice fed with the same diet supplemented with HT (HT-fed wt mice). Behavioral performance was evaluated by means of Morris Water Maze, step down inhibitory avoidance and object recognition tests. Neuropathological investigations were carried out by immunohistochemistry and western blotting analysis. We found that dietary supplementation with HT significantly improves cognitive performances of Tg mice respect to untreated Tg mice. Similar to data reported for OLE, we found that HT administration to these mice triggers autophagy in the cortex and reduces the accumulation of amyloid aggregates of Aβ42 and its pyroglutamylated 3–42 derivative (pE3-Aβ) in the cortex and hippocampus, as compared to untreated Tg mice. HT administration also affected the inflammatory response in the hippocampal areas, as shown by the reduced astrocytes activation and TNF-α mRNA levels. These results support HT neuroprotection *in vivo* against Aβ toxicity and its involvement in the beneficial effects of the Mediterranean diet for Alzheimer‘s disease prevention.

**Title:** Modulation of IGF-1R ameliorates Alzheimer's disease phenotype in a transgenic mouse model

**Authors:** *M. SOHRABI, ***M. SOHRABI**, G. D. MANOCHA, C. COMBS
Biomed. Sci., Univ. of North Dakota, Grand Forks, ND

**Abstract:** Alzheimer’s disease (AD) is characterized by extracellular amyloid β (Aβ) peptide accumulation and intracellular neurofibrillary tangles. Aging is a major risk factor for development of this progressive neurodegenerative disorder. Insulin like growth factor-1 (IGF-1), upon binding to its receptor (IGF-1R), regulates growth, development, aging, and lifespan. However, the contribution of this growth factor to age-related AD pathology and progression is highly controversial. Based on our previous work, APP/PS1 double transgenic mice demonstrated a decrease in brain IGF-1 levels when they were crossed with Ames dwarf mice (df/df). Subsequently, a reduction in gliosis, Aβ plaque deposition, and Aβ 1-40/42 concentrations were observed in this mouse model. This correlation supported the hypothesis

that IGF-1 may contribute to progression of disease. To better assess the role of IGF-1 in AD, 9-10 month-old male littermate control wild type and APP/PS1 mice were randomly divided into 3 treatment groups including control (untreated), vehicle (DMSO), and picropodophyllin (PPP), a potent, selective, competitive, and reversible IGF-1R inhibitor. The brain penetrant, specific inhibitor was dissolved in DMSO and given to the drug-treated mice via ip. injection of 1mg/kg/day. Mice were sacrificed after 7 days of daily injection and the brains and spleens were collected to quantify histologic and biochemical changes. The PPP-treated APP/PS1 mice demonstrated attenuated pro-inflammatory cytokine levels in the temporal cortex including IL-6 and IL-1β. Additionally, insoluble Aβ 1-40, soluble, and insoluble Aβ 1-42 levels, microgliosis, protein phosphotyrosine, and APP levels were reduced due to drug treatment. Our data suggests IGF-1R signaling is associated with disease progression in this mouse model. More importantly, modulation of the IGF-1R signaling pathway in the brain, even in aged animals, is sufficient to reverse disease phenotype. This suggests that small molecule therapy targeting the IGF-1R pathway is viable for late stage disease treatment.

**Abstract:** Accumulation of oligomeric forms of the amyloid beta peptide (AβOs) in specific regions of the brain is thought to be a central cause of synapse damage/loss and cognitive decline in Alzheimer’s disease (DA). Nevertheless, despite being a topic of extensive study, the mechanisms by which AβOs build-up occurs is still a matter of intense debate. The proteasome, the main degradation machinery in the cell, appears to be a central player in AβOs clearance. Further, although there are conflicting results in the literature, it has been reported that Aβ inhibits the proteasome, possibly by binding to the proteasome's catalytic subunits. Here, we report that AβOs at low concentrations inhibit the proteasome in (1) hippocampal neuronal

cultures, (2) synaptosomes extracted from the hippocampi of AβOs-i.c.v.-injected mice and (3) when directly applied to isolated synaptosomes. These results corroborate other studies in the literature regarding proteasome inhibition by Aβ, point to AβOs as a high-affinity proteasome inhibitor, and show that AβOs-mediated proteasome inhibition is even more prominent on synapses. Proteasome inhibition, thus, may be a key event in AD pathology by enabling AβOs levels to rise, setting the stage for neurodegeneration to occur.

**Title:** Intranasal delivery of Aβ oligomers impairs memory in mice

**Authors: *D. C. MEJIDO**, K. G. N. FERREIRA, H. M. MELO, F. G. DE FELICE
Inst. of Med. Biochem. Leopoldo de Meis, Federal Univ. of Rio De Janeiro - UFRJ, Rio de Janeiro, Brazil

**Abstract:** Alzheimer's disease (AD) is a neurodegenerative disorder that progressively impairs memory and cognitive functions. Since its first description, myriad studies have been conducted to characterize the complex pathophysiology of this disease, now recognized as the most common type of dementia. AD was initially associated with deposition of fibrillar forms of the amyloid β peptide (Aβ) on the neuronal extracellular surface, as well as the intracellular aggregation of tau protein in neurofibrillary tangles. However, recent evidence support that small soluble Aβ oligomers (AβOs) are central to neurodegeneration in AD. Dysfunctions in synaptic plasticity that lead to memory impairment and culminate in neuronal loss are specifically associated with the neurotoxicity of soluble oligomers. Still, investigators of AD neuropathology often rely on transgenic animal models that do not reflect the direct effects of AβOs, nor resemble the sporadic cases of the disease. Our group has previously validated AD experimental models based on intracerebroventricular (i.c.v.) injection of synthetic AβOs in mice and non-human primates, and applied them to evaluate both synaptic plasticity and memory deficits, as well as the association of metabolic dysfunctions with AD. Investigating the mechanisms by which oligomers affect brain insulin signaling, we demonstrated that AβOs can inhibit insulin receptor substrate (IRS-1) and internalize its receptor in the mouse brain. However, the i.c.v. route for AβO administration imposes some limitations, not being adequate for multiple injections in chronic regimens, nor being easily performed, demanding constant user training and complete anesthesia of the animals. To address these problems and possible biases, here we

propose an alternative approach for AβO administration, using an intranasal (IN) route, which has been considered a promising technique for direct delivery of peptides to the central nervous system, bypassing the blood-brain barrier. We now show that IN delivery of AβOs (500 pmols) in mice significantly impairs short term memory in an object recognition test paradigm, 24 hours, 7 or 21 days after a single administration. These preliminary findings suggest that IN delivery of AβOs produce the same behavioral impacts observed with the well-established i.c.v paradigm. Importantly, same animals impaired by IN oligomers exhibited a trend of decrease in synapse associated proteins PSD-95 and synaptophysin. Therefore, IN delivery of AβOs holds promise as a novel and improved approach for modelling AD in mice; the first to allow the isolated study of AβO toxicity in the brain in a non-invasive manner.

**Abstract:** Parkinson’s disease (PD) is classically characterized by debilitatingmotor symptoms, which are preceded by a number of non-motor symptoms including olfactory deficits, anxiety, depression and cognitive impairment. Aggregation of α-synuclein (alfa-syn), ultimately giving

rise to formation of Lewy bodies in dopaminergic neurons, is thought to play a central role in PDpathology. However, whether amyloid fibrils or pre-fibrillar soluble oligomersof alfa-syn are the main neurotoxic species in PD remains controversial. Here, we investigated the impact of a single intracerebroventricular (i.c.v.) infusion of α-syn oligomers (alfa-SYOs) on motor and non-motor symptoms of PD in mice. alfa-SYOs induced olfactory dysfunction, and decreased dopamine levels and numbers of TH-positive cells in the olfactory bulb, 4 and 8 days post infusion (dpi), respectively. The olfactory deficit persisted until 45 dpi, at which time point olfactory bulb dopamine levels had returned to control levels. alfa-SYO-infused mice had no deficit in object recognition memory, but showed increased anxiety-like behavior 20 dpi. Finally, administration of alfa-SYOs induced late motor impairment and reduction in TH-levels and dopamine content in the striatum 45 dpi. In conclusion, i.c.v. infusion of alfa-SYOs recapitulated PD-associated motor and non-motor symptoms in a temporal sequence similar to that seen in PD patients. Results point to alfa-syn oligomers as the proximal neurotoxins responsible for early non-motor and motor deficits in PD, and suggest that the i.c.v. infusion model characterized here may comprise a useful tool for identification of novel therapeutic targets and for drug screening approaches for PD

**Abstract:** Alzheimer´s disease (AD) is the main cause of dementia worldwide. Although the prevalence of AD is increasing, there is no effective therapy to treat this neurodegenerative disease. Considerable evidence indicates that soluble oligomers of the amyloid-beta peptide (AβOs), which accumulate in AD brains, are implicated in early synaptic dysfunction and memory impairment in AD. Previously, we have reported that exposure of primary hippocampal neurons to AβOs induces internalization of dendritic insulin receptors (IR) (De Felice et al., 2009, PNAS) and inhibition of insulin receptor substrate-1 (IRS-1) (Bomfim et al., JCI, 2012), inducing neuronal insulin resistance. Insulin plays important roles in neuronal survival, learning and memory, and its possible beneficial effects have been tested in clinical trials for AD. Although insulin appears to improve cognition in control individuals and in early stages of AD, protective effects were not readily observed in late stages of the disease. Possible explanations for this include the removal of IRs from the neural surface instigated by oligomers, and blockade of IR-mediated signaling by AβO-induced IRS-1 inhibition. We have now investigated whether insulin-like growth factor 1 (IGF-1) could be utilized to circumvent IR signaling blockade and to promote alternative activation of insulin-related pathways, thus protecting neurons from AβO-induced damage. We first found that exposure to AβOs did not affect surface levels of IGF-1 receptor in hippocampal neuronal cultures. To test our hypothesis, we employed a recombinant adenoviral vector (Rad-IGF-1) to induce over-expression of IGF-1 in hippocampal cultures for two weeks prior to exposure to AβOs (500 nM). Cultures were then evaluated for neuronal binding of AβOs, synaptic integrity, and neuronal oxidative stress (production of reactive oxygen species, ROS). Interestingly, despite only a slight decrease in AβO binding to neurons, viral-mediated expression of IGF-1 prevented AβO-induced dendritic spine loss and excessive ROS production. Next, we performed intracerebroventricular (i.c.v.) injection of Rad-IGF-1 in Swiss mice two weeks prior to i.c.v. infusion of AβOs, a model we have implemented to study the *in vivo* impact of AβOs (Figueiredo et al., 2012, J. Neurosci.). Interestingly, brain expression of IGF-1 protected against memory impairment induced by AβOs, as assessed using the novel object recognition test. Results suggest that RAd-IGF-1 gene therapy could be a promising strategy to protect neuronal damage and memory impairment induced by AβOs.

**Abstract:** Recent studies have indicated that irisin, an exercise-induced myokine first identified as a regulator of adipocyte metabolism, may play important roles in brain function. Irisin was reported to stimulate hippocampal BDNF expression, which, in turn, promotes neuronal survival, synaptic plasticity and memory. However, the mechanisms underlying brain actions of irisin are still unclear. Decrease levels of brain-derived neurotrophic factor (BDNF) and abnormal activation of the unfolded protein response (UPR) have been described to play important roles inducing brain dysfunction in Alzheimer’s disease and other neurodegenerative diseases. Here, we have produced recombinant irisin to test its ability in modulating these signaling pathways. Primary hippocampal cultures were treated with irisin, followed by quantification of the expression of BDNF and of genes related to the UPR. We found that irisin significantly increased BDNF and reduced UPR-related gene expression (ATF4 and CHOP) in hippocampal neurons. Our results support the notion that irisin has neuromodulatory effects in the hippocampus, which could be of relevance to learning and memory processes.

**Title:** The saturated fatty acid palmitate induces cognitive impairment in mice

**Authors: *H. M. DE MELO**, S. FERREIRA, F. G. DE FELICE
Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil

**Abstract:** Obesity is a chronic epidemic disease that affects an increasing number of individuals worldwide and constitutes the most important risk factor for the development of type 2 diabetes mellitus. Obese and type 2 diabetes mellitus humans present structural changes in the brain and cognitive dysfunction. The increase of saturated fatty acids, such as palmitate, in the circulation has been shown to be relevant in the pathogenesis and development of obesity. Brain palmitate uptake is increased in obese patients, and positively correlated with age. Here, we aimed to evaluate the impact of palmitate in the hippocampus, a brain region key for learning and memory. Using *in vivo* intracerebroventricular (icv) injections of palmitate in male Swiss mice, we observed that palmitate induces cognitive impairment in novel object recognition, novel location recognition, step-down inhibitory avoidance and Barnes maze tasks. By using non-radioactive puromycin incorporation assays, we further observed that palmitate attenuates *de novo* protein synthesis in hippocampal slices. Among these proteins, we highlight the reduction of synaptophysin, an important synaptic anchoring protein. Our results imply excessive palmitate levels in the brain as a likely mechanism explaining cognitive impairment in obesity and type 2 diabetes mellitus. Thus, strategies aimed to prevent increased circulating free fatty acids, such as a healthier lifestyle and food, may prevent palmitate-associated effects in obesity, contributing to better cognitive performance and healthy aging.

**Abstract:** Sepsis survivors frequently develop late cognitive impairment. Because little is known of the mechanisms driving this post-septic memory dysfunction, there are no current effective approaches to prevent or treat it. Here, we subjected mice to severe sepsis induced by cecal ligation and puncture (CLP) and evaluated the sepsis-surviving animals in the open field, novel object recognition (NOR), and step-down inhibitory avoidance (IA) task at different times after surgery. Post-septic mice (30 days post-surgery) failed in the NOR and IA tests but exhibited normal performance when re-evaluated 45 days after surgery. Cognitive impairment in post-septic mice was accompanied by reduced hippocampal levels of proteins involved in synaptic plasticity, including synaptophysin, cAMP response element-binding protein (CREB), CREB phosphorylated at serine residue 133 (CREBpSer133), and GluA1 phosphorylated at serine residue 845 (GluA1pSer845). Expression of tumor necrosis factor α (TNF-α) was increased and brain insulin signaling was disrupted, as indicated by increased hippocampal IRS-1 phosphorylation at serine 636 (IRS-1pSer636) and decreased phosphorylation of IRS-1 at tyrosine 465 (IRS-1pTyr465), in the hippocampus 30 days after CLP. Phosphorylation of Akt at serine 473 (AktpSer473) and of GSK3 at serine 9 (GSK3βpSer9) were also decreased in hippocampi of post-septic animals, further indicating that brain insulin signaling is disrupted by sepsis. We also treated post-septic mice with liraglutide, a GLP-1 receptor agonist with insulinotropic activity, or TDZD-8, a GSK3β inhibitor, which rescued NOR memory. In conclusion, these results establish that hippocampal inflammation and disrupted insulin signaling are induced by sepsis and are linked to late memory impairment in sepsis survivors.

**Abstract:** It is increasingly recognized that sleep disturbances and Alzheimer's disease (AD) share a bidirectional relationship. AD patients exhibit sleep problems and alterations in the regulation of circadian rhythms; conversely, poor quality of sleep increases the risk of development of AD. The aim of the current study was to determine whether chronic sleep restriction potentiates the brain impact of amyloid-β oligomers (AβOs), toxins that build up in AD brains and are thought to underlie synapse damage and memory impairment. We further investigated whether alterations in levels of pro-inflammatory mediators could play a role in memory impairment in sleep-restricted male mice. We found that a single intracerebroventricular (i.c.v.) infusion of AβOs disturbed sleep pattern in mice. Conversely, chronically sleep-restricted mice exhibited higher brain expression of pro-inflammatory mediators, reductions in levels of pre- and post-synaptic marker proteins, and exhibited increased susceptibility to the impact of i.c.v. infusion of a sub-toxic dose of AβOs (1 pmol) on performance in the novel object

recognition memory task. Sleep-restricted mice further exhibited an increase in brain TNF-α levels in response to AβOs. Interestingly, memory impairment in sleep-restricted AβO-infused mice was prevented by treatment with the TNF-α neutralizing monoclonal antibody, infliximab. Results substantiate the notion of a dual relationship between sleep and AD, whereby AβOs disrupt sleep/wake patterns and chronic sleep restriction increases brain vulnerability to AβOs, and point to a key role of brain inflammation in increased susceptibility to AβOs in sleep-restricted mice.

**Abstract:** Alzheimer’s disease (AD) is a devastating neurodegenerative disease and is characterized by β-amyloid (Aβ) plaques in the brain. At the present, there is still no approved drug with a proven disease-modifying effect. Sesame seed (*Sesame indicum*) has long been known as a natural healthy food in Southeast Asian countries. Many evidences suggested that sesame lignans including sesamin, sesamolin, and sesamol obtained from sesame seed possess antioxidative property. To test whether these sesame lignans exhibit benefit effects in AD, the transgenic *Caenorhabditis elegans* (*C. elegans*) model of Aβ toxicity was utilized. The purpose of this study was to investigate the protective effect of sesame lignans against Aβ toxicity. Among tested compounds, sesamin and sesamolin significantly delayed Aβ-induced paralysis and therefore significantly reduced Aβ toxicity. Moreover, sesamin and sesamolin significantly improved Aβ-induced defect in chemotaxis behavior and reversed the defect back to normal. However, we found that only sesamin but not sesamolin extended lifespan in *C. elegans*. These results suggest the potential of sesame lignans as a source for the development of anti-Alzheimer’s drug and it is worth doing further investigation of the relationship of lignans structure and their anti-Aβ toxicity activity.

**Title:** Antibodies targeting truncated Asp421 tau protein clear human Alzheimer's tau and prevent its toxicity in primary neuronal and mixed cortical cultures

**Authors:** ***S. R. MODAK**, E. M. SIGURDSSON
Neurosci. and Physiol., New York Univ. Sch. of Med., New York, NY

**Abstract:** Cleavage at aspartate in position 421 (Asp421) of the tau protein is a hallmark feature of tau pathology in Alzheimer's disease (AD) and related tauopathies. This truncated form of the protein is postulated to have a role in their pathogenesis by promoting seeding at an early stage, although others suggest that it appears at a later stage. Various tau immunotherapies are currently in clinical trials but this epitope has received limited attention. We previously reported that two Asp421 targeting monoclonal antibodies (mAbs) clear AD derived paired helical filament (PHF)-enriched tau intracellularly when the mAb is added after PHF has been internalized (Modak SR et al, SFN 2015, 579.14). Here, we co-treated primary neurons (PN) or mixed cortical culture (MC) from transgenic tauopathy mice (JNPL3) with these same mAbs or IgG1 control and PHF (both at 10 μg/ml). The purpose of the co-administration was to primarily focus on the benefits of their direct extracellular interaction. Subsequently, western blots were conducted at different time points (24 h, 48 h, 72 h and 96 h) with various markers. Maximal effects of PHF and mAbs were observed at 96 h. The two mAbs, 5G2 and 1G11 have differing affinity for the free Asp421 epitope, $10^{-9}$ vs. $10^{-6}$ M, respectively. PHF was toxic in both culture models based on levels of NeuN, which is a neuronal marker (PN: 49%-, MC: 53% reduction at 96 h), and this toxicity was completely prevented by the higher affinity mAb, 5G2, in both models ($p<0.001$), whereas control IgG1 had no effect. The lower affinity mAb, 1G11 had less pronounced effect in blocking PHF toxicity (PN: 44%-, MC: 24% reduction at 96 h, $p<0.0001$ vs 0.001). For 5G2, this was associated with clearance of total tau (PN: 93%-, MC: 91% reduction at 96 h, compared to PHF+IgG1 control, $p<0.0001$ for both) and phospho-tau (PN: underway, MC: 95% reduction at 96 h, $p<0.0001$). The 1G11 mAb was less effective and cleared total tau only in PN (48% at 96 h, $p<0.0001$) and did not clear phospho-tau in MC (PN analysis is underway). Analysis of Iba1 levels in MC as a marker of microgliosis revealed dramatic increase

in Iba1 over time in PHF treated culture (1083% over untreated cells at 96 h, $p<0.0001$), which was completely prevented by 5G2 ($p<0.0001$) but only slightly by 1G11 (862% over untreated cells, $p<0.0001$). However, the 1G11-mediated reduction in microgliosis was significant compared to the PHF-treated culture (19%, $p<0.0001$). In conclusion, this study clearly illustrates the therapeutic potential of the higher affinity mAb, 5G2, in targeting the pathological Asp421 tau epitope, derived from human AD brain, to prevent its toxicity and associated microgliosis, as well as to enhance tau and phospho-tau clearance.

**Title:** Partial humanization alters antibody charge and impairs primarily intracellular- but to some extent extracellular efficacy in targeting pathological tau protein

**Authors: *E. E. CONGDON**[1], J. CHUKWU[2], D. UJLA[1], D. B. SHAMIR[1], H. B. R. SAIT[1], X. KONG[3], E. M. SIGURDSSON[4]
[1]Neurosci. and Physiol., [2]Mol. Biophysics, [3]Biochemistry, Mol. Pharmacol., [4]Neurosci. and Physiology, and Psychiatry, New York Univ. Sch. of Med., New York, NY

**Abstract:** Maximizing tau antibody (Ab) efficacy may require Abs that target tau both extra- and intracellularly. Previously, we simulated these situations by treating primary neuronal cultures in two ways. PHF tau enriched from Alzheimer’s brain and tau Ab were added either together (PHF+Ab) or Ab 24 h after PHF (PHF→Ab). In the former approach, the tau and Ab primarily interact extracellularly. In the latter approach, Ab uptake is required for efficacy in preventing

PHF-induced toxicity and pathology. Ab uptake into neurons depends on multiple factors including their charge as indicated by their isoelectric point (IEP). In the first set of experiments, we assessed efficacy of three Abs: 1B9 (P-Thr 212/P-Ser214; IEP=8.0); 2C11 (P-Ser262; IEP=7.8) and; Tau-5 (210-244; IEP=5.1), in the dosing methods described. Although the Abs showed efficacy under the extracellular PHF+Ab condition, they were ineffective in the PHF→Ab paradigm. These differences could be explained by their limited neuronal uptake. Confocal imaging and western blots analysis showed that all three had significantly less neuronal uptake than 4E6, an Ab known to be efficacious under both conditions ($p \leq 0.0001$ for all). However, their epitope differences complicate interpretation of their efficacy profile. To address this issue, we compared efficacy of mouse 4E6 (IEP=6.5) and its partially humanized derivative, h4E6 (IEP=9.6), in the two assays. PHF alone induced toxicity (85% increase in LDH and 94% decrease in NeuN, $p \leq 0.05$, 0.001 compared to control), and increased total and phospho-tau (p-tau) levels (6.7-fold and 5.1-fold control) in the remaining neurons. In both the PHF+Ab and PHF→Ab dosing paradigms, unmodified 4E6 prevented this toxicity based on NeuN as well as total and p-tau ($p \leq 0.0001$ for all), and resulted in values comparable to untreated control. The change in 4E6's IEP with humanization was accompanied by a loss of efficacy in the PHF→Ab paradigm (86% loss of NeuN as well as 3.9- and 4-fold increase in total and p-tau in the remaining neurons). In the PHF+Ab paradigm, the h4E6 retained efficacy in preventing increases in tau levels (0.49-fold above and 0.2-fold below untreated control for total and p-tau, $p \leq 0.01$, 0.002) but was not as effective as m4E6 in preventing toxicity (61% NeuN loss compared to 94% for PHF alone; $p \leq 0.01$). These results show that neuronal uptake of tau Abs improves their efficacy. As importantly, because uptake is to a large extent governed by charge, Ab humanization may greatly affect its efficacy, irrespective of its binding to the target. Finally, the humanization may affect extracellular efficacy because of subtle changes to its target binding site.

**Title:** Therapeutic potential of an anti-tau single chain variable antibody fragment assessed in *Drosophila* models of tauopathy

**Authors: *S. KRISHNASWAMY**[1], H. D. RYOO[2], E. M. SIGURDSSON[3]
[1]Neurosci. and Physiol., [2]Cell Biol., [3]Neurosci. and Physiology, and Psychiatry, New York Univ. Sch. of Med., New York, NY

**Abstract:** We have identified numerous single chain variable fragments (scFv) of tau antibodies from phage display libraries derived from monoclonal tau antibody hybridomas. We subsequently characterized further one of these scFv and showed its promise as an imaging diagnostic agent to identify tauopathies in live animals (Krishnaswamy S et al, J Neurosci Dec 10, 2014).
Here, we examined its therapeutic potential in two transgenic (tg) *Drosophila* tauopathy models that express wild-type human tau (htau) or the familial human tauopathy mutation R406W. All the flies expressed the transgene specifically in neurons (elav-Gal4 promoter). scFv expressing flies were crossed with the tauopathy flies, the number of hatched flies were counted, and their survival curve determined. Overall, the survival curves were very significantly different (log-rank test, $p<0.0001$). Control flies with the neuronal promoter survived the longest. On the other hand, tg R406W flies had the shortest live span, which was greatly prolonged by co-expressing the anti-tau scFv ($p=0.0004$). Likewise, tg htau flies had a moderately short live span, which was prolonged by co-expressing the anti-tau scFv ($p=0.09$). In addition, the tau transgenes led to developmental toxicity, which was prevented by the scFv, based on the number (n) of hatched progeny that are expressing tau transgenes in comparison with the predicted mendelian ratio of those flies: Control (n=48); tg htau (n=18); scFv-htau (n=55), tg R406W (n=7); scFv-R406W (n=35). We are currently examining various tau fractions in these flies at different time points to clarify the mechanism of this pronounced therapeutic effect.
In summary, these findings support the therapeutic potential of anti-tau scFv and the use of *Drosophila* models for such screening.

**Title:** SCF+G-CSF synergistically increases amyloid beta removal by bone marrow-derived monocytes

**Authors: *L.-R. ZHAO**[1], B. LI[2]
[1]SUNY Upstate Med. Univ., Syracuse, NY; [2]Neurol., LSUHSC-S, Shreveport, LA

**Abstract:** Alzheimer's disease is a rapidly growing health problem worldwide. Impairments in Aβ clearance play a key role in Alzheimer's disease development and progression. Stem cell factor (SCF) and granulocyte-colony stimulating factor (G-CSF), the two essential hematopoietic growth factors, have been demonstrated their synergistic efficacy in hematopoietic stem cell mobilization. Here we have determined the synergistic effectiveness of SCF+G-CSF in Aβ clearance by bone marrow-derived monocytes/macrophages (BMDMMs) through both *in vivo* and *in vitro* approaches. Male APP/PS1 mice (10 month old) were randomized to receive 12- day injections (s.c.) of either vehicle solution, SCF (200μg/kg), G-CSF (50μg/kg), or SCF+G-CSF. Age-matched wild-type (WT) mice served as normal controls. We observed that only SCF+G-CSF-treated APP/PS1 mice showed a long-term and stable recovery in spatial learning and memory that was examined by a water maze 3 and 7 months after treatment. SCF+G-CSF treatment also synergistically reduced the Aβ load in the brain 8 months after treatment. In addition, we also found that the recruitment of BMDMMs ($Iba1^+$ cells) and the association of the BMDMMs with Aβ plaques in the brains of APP/PS1 mice were increased by SCF+G-CSF one day after the final injection. The *in vitro* data further confirmed that SCF+G-CSF synergistically enhanced uptake of aggregated Aβ by BMDMMs in a dose- and time-dependent manner. These findings reveal that the combination of SCF and G-CSF treatment leads to a synergistic and long-term therapeutic effects in cognitive improvement and Aβ clearance in a mouse model of cerebral amyloidosis. Promoting Aβ removal by BMDMMs plays a critical role in SCF+G-CSF-enhanced Aβ clearance. This study provides new insights into the contribution of

hematopoietic growth factors in restricting the progression of Alzheimer's disease. This study was supported by the National Institute On Aging of the National Institutes of Health in the United States (R01AG051674).

**Title:** AAV9-mediated Cdk5 inhibitory peptide reverses pathological changes and behavioral deficits in the AD model mice

**Authors: *Y. HU**[1], Y. HE[2], S. PAN[3], M. XU[3], R. HE[3], W. HUANG[3], P. SONG[3], J. HUANG[4], H. ZHANG[5]
[1]Dept. of Neurol., Nanfang Hosp., Guangzhou, China; [2]Nanfang Hosp., Guagnzhou, China; [3]Nanfang Hosp., Guangzhou, China; [4]421 Hosp., Guagnzhou, China; [5]Depts Behav Med. & Psych, Pharm, West Virginia Univ. Hlth. Sci. Ctr., Morgantown, WV

**Abstract:** Cdk5, binding to and activated by p35, phosphorylates multiple substrates and plays an essential role in the development and function of the central neuron system. However, proteolytic production of p25 from p35 under stress conditions leads to inappropriate activation of Cdk5 and contributes to hyperphosphorylation of tau and other substrates related to the pathogenesis of Alzheimer's disease (AD). Selective inhibition of aberrant Cdk5 activity via genetic overexpression of Cdk5 inhibitory peptide (CIP) reduces pathological changes and prevents brain atrophy and memory loss in p25-transgenic mice. In the present study, we delivered AAV9-GFP-CIP into brain cells via intracerebroventricular infusion in APP/PSEN1 double transgenic mice at 3-month-old, after the occurrence of β amyloid (Aβ) aggregation and hyperphosphorylation of tau. Three months treatment of AAV9-GFP-CIP reduced pathological changes including tau hyperphosphorylation, Aβ deposit, astrocytosis and microgliosis, which were correlated with the reversal of memory loss and anxiety-like behavior observed in APP/PS1 mice. Neuroprotection effect of AAV9-GFP-CIP lasted to additional seven months, which was the endpoint of the study. These findings provide a novel strategy to selectively targeting Cdk5 for treatment of AD.

**Abstract:** Motor function is a means for human and other animals to interact with the surroundings. In the absence of pathology, motor functions are usually coordinated, efficiently, and effortlessly. However, disease or injury can compromise the speed, accuracy, efficiency, and flexibility of motor function execution. This makes it possible that the motor function changes could reflect or even predict the pathological changes. Currently, many motor functions have been listed among the important criteria for diagnosis, such as gait for spinal cord injury rehabilitation evaluation, and reaching and grasping for stroke pathological assessment. However, most of the current motor-function-based diagnosis has three major disadvantages: 1) the overall motor function in healthy subjects or experimental animals is not quantitatively characterized; 2) current motor function analysis methods are not sensitive enough for pre-clinical or progressive changes; 3) the analysis features are usually empirically derived, not suited for diseases that are not well characterized. In this study, we established a mathematical model that automatically tracks locomotion pattern through supportive vector machine in an Alzheimer's disease mouse model (J20). Our results show that our model can select locomotion

kinematic features that accurately (87.10% accuracy) detect and classify the J20 mouse from their wildtype littermates.

**Title:** Novel partial mitochondrial complex i inhibitors as disease-modifying therapy for Alzheimer’s disease

**Authors: *S. TRUSHIN**
Neurol., Mayo Clin., Rochester, MN

**Abstract:** Key words: mitochondrial complex I, Alzheimer’s Disease, drug discovery
Alzheimer’s Disease (AD) has no effective treatments, and recent clinical trials focused on prevention of amyloid beta (Aβ) production have consistently failed. Alternative approaches are urgently needed. We recently demonstrated that modulation of mitochondrial function with a small molecule tricyclic pyrone compound CP2 prevents the development of cognitive and behavior phenotypes in multiple transgenic mouse models of familial AD. Target identification conducted using low-mass molecular dynamic simulations, pull-down and competitive binding assays, multiple biochemistry and enzymatic approaches revealed that CP2 competes with the flavin mononucleotide (FMN) for binding to the redox center of mitochondrial complex I (MCI) *partially* reducing its activity (EBioMedicine, 2015, PMID 26086035). Here, we describe new classes of compounds small molecule inhibitors of FMN site of MCI including a novel lead compound NSMC00594 developed using rational design and extensive structure-activity relationship studies. In cellular assays, novel MCI inhibitors protect against Aβ toxicity in MC65 Tet On/Off cellular model of AD, mildly inhibit MCI activity decreasing NAD+/NADH ratio with minimal toxicity in primary mouse embryonic neurons. Binding of the lead compound NSMC00594 to the FMN site of MCI was confirmed using a pulldown and competitive binding assays, and surface plasmon resonance technology. Chronic administration of NSMC00594 to APP/PS1 and non-transgenic mice via drinking water over 8 months did not affect the development in the progeny and had no detectable toxicity or side effects at 2x of therapeutic dose. NSMC00594 has good oral bioavailability and penetrates the blood brain barrier. Pre-symptomatic treatment of APP/PS1 mice with NSMC00594 resulted in cognitive protection after

6 months of chronic oral administration. Mechanistic studies demonstrate that MCI inhibitors induce mitochondrial biogenesis, enhance cellular energetics, induce a protection against oxidative stress and engage other mechanisms that intersect with the pathways involved in longevity and health extension. Our studies present the evidence that modulation of MCI activity by the novel partial MCI inhibitors averts cognitive decline in Alzheimer's Disease representing novel therapeutic approach.

**Abstract:** Alzheimer's disease (AD) is the leading cause of dementia with an estimated global prevalence of 24 million individuals. Incidences of this disease are expected to double every 20 years emphasizing an urgent need for a development of disease modifying therapeutic strategies. A substantial body of clinical evidence has framed AD in the context of metabolic dysfunction and its pathophysiological importance to disease progression, suggesting that modulation of cellular energetics could represent new therapeutic approach. In our previous research, we have demonstrated that modulation of mitochondrial complex I activity using a tricyclic pyrone compound CP2 is effective in clearing both amyloid beta (Aβ) and phosphorylated Tau, augmenting mitochondrial bioenergetics, promoting resistance to oxidative stress and restoring mitochondrial transport, levels of BDNF and synaptic proteins in presymptomatic APP/PS1

mice. In parallel, these mice demonstrated an improved cognitive and behavioral phenotype over their untreated littermates.
In our current study, we tested whether CP2 treatment could halt the disease progression in symptomatic APP/PS1 mice. We also evaluated treatment efficacy based on multiple parameters informative of healthy aging in chronologically aged non-transgenic (NTG) littermates. Both APP/PS1 and NTG mice displayed improved cognitive and motor performance following chronic CP2 treatment over 13 months compared to untreated counterparts. CP2-treated mice displayed reduced levels of inflammation and senescent cells, and APP/PS1 mice had reduced levels of soluble Aβ. We defined the molecular mechanism underpinning this improvement by assessing biochemical pathways involved in the mechanisms of longevity, mitochondrial bioenergetics/signaling, neurotransmitter trafficking, and oxidative stress using multiple techniques and systems biology approaches. Our results suggest that modulation of mitochondrial complex I activity with small molecules represents a promising therapeutic approach to ameliorate AD and promote healthy aging.

**Abstract:** The general amyloid interaction motif (GAIM) derived from the M13 phage tip protein g3p binds a wide variety of amyloids in a conformation-dependent manner. Dimeric GAIM-Ig-fusions robustly bind and remodel Aβ42 amyloid and tau fibers. In transgenic models of AD and tauopathy, GAIM-fusion treatment reduces Aβ plaque load, phospho-tau levels and improves cognition. In this study, we explored the mechanism of GAIM-mediated remodeling of amyloids by mutagenesis. Using this data, we designed next generation Ig-fusions which in addition to showing improved binding potency to multiple amyloid aggregates, have reduced potential for immunogenicity after removal of potential T-cell epitopes.

Data obtained from H/D exchange NMR studies, GAIM-peptide-based inhibition assays and computational modeling was used for targeted mutagenesis of the GAIM scaffold. Stable, high expressing variants were then screened for binding to Aβ42 and Tau-K18 fibers using SPR and binding ELISA assays. High binding variants were further screened for Aβ42 fiber remodeling as well as tau and α-synuclein transmission inhibition activities. An independent mutagenesis program was carried out to sequentially eliminate potential T-cell epitopes of GAIM.
GAIM-Ig-fusions identified in the screen with increased amyloid binding and remodeling activity fall into two main categories: 1) variants with reduced interdomain interaction of N1 and N2 domains of GAIM and 2) alterations of specific residues facing the interdomain groove of N1 and N2 domains. Binding specificity depends on the stability of both domains and the melting temperature for domain separation. Over-stabilizing of N1 or N2 domains leads to reduced binding activity, while destabilizing of the domains leads to increased non-specific binding. The data elucidated a novel mechanism for amyloid binding of GAIM mediated by residues facing the interdomain groove of N1 and N2 domains. We hypothesize progressive binding and rearrangement of GAIM β-strands enables GAIM to bind to and remodel amyloids into non-fibrous and non-pathogenic aggregates.
GAIM-Ig-fusions represent a novel class of therapeutics to treat protein misfolding disorders. This study presents recent discoveries in the structure-activity relationship of GAIM and potential candidates with improved *in vivo* efficacy for reducing the accumulation of amyloid plaque and the spread of intracellular tau tangles.

**Abstract:** PDE2A, which plays a role in the regulation of intraneural cGMP and CMP in the brain, is mainly expressed in the areas involved in emotion, perception, concentration, learning and memory. It is assumed to play an important role in CNS disorders such as depression and anxiety. PDE2A inhibitors are being investigated for treatment of cognitive impairment in Alzheimer's disease. We have developed a preclinical model in dogs to evaluate the activity of PDE2A inhibitors in the brain. A needle guide is placed in the skull of the dogs to sample CSF directly from the lateral ventricle in conscious animals. cGMP in CSF is used as a biomarker for functional activity following PDE2A inhibition. Repeated sampling enables the longitudinal follow up of cGMP in the CSF. Clear dose related increases in cGMP are seen after administration of PDE2A inhibitors. This model enables the ranking of compounds preclinically for in vivo activity, setting of safety margins and human dose prediction. Since it is not possible to sample the lateral ventricle in humans and to address the potential use of cGMP in CSF as a biomarker in clinical trials, we evaluated the effect of a PDE2A inhibitor on cGMP in CSF sampled more downstream. The cisterna magna was chosen as sampling site since lumbar CSF sampling in dogs is more difficult compared to humans. We found that cGMP concentrations in CSF sampled from the cisterna magna were much lower than in the lateral ventricle. Compared to the dog own baseline values, a dose related increase in cGMP was seen after dosing a PDE2A inhibitor. However, increases in cGMP in CSF compared to baseline were also seen in some vehicle dosed dogs. A more extensive longitudinal follow up of untreated and vehicle dosed dogs is required to have an idea on the fluctuations of cGMP in the cisterna magna and address the potential value of cGMP as a biomarker for PDE2A inhibition in the brain in humans.

**Abstract:** Compelling evidence indicates that Type 2 Diabetes (T2D) and Alzheimer's Disease (AD) may possibly share a common pathological origin, but the underlying mechanisms remain poorly understood. T2D is a known risk factor for AD, while insulin resistance (hallmark of T2D) has been extensively documented in AD patients and insulin has an important role in learning and memory.We developed a mouse model (AtENPP1Tg mouse) that recapitulates typical characteristics of human metabolic syndrome and insulin resistance, which presents also brain dysfunction, specifically in hippocampus, thus offering a unique chance to explore which mechanistic pathways connect diabetes with AD.Interestingly, the pool of mesenchymal stem cells (MSCs) in many organs, included adipose tissue, of diabetic patients, is significantly reduced, as well as their role in regeneration is dramatically reduced. We hypothesize the existence of an axis between adipose tissue and CNS, in which adipose tissue-residing-MSCs deliver messages to CNS. When adipose tissue becomes insulin resistant, the amount of MSCs reduces, hence the adipose tissue-brain axis is impaired resulting in both peripheral and brain insulin resistance.Therefore, in order to investigate this relationship, we injected via subcutaneous route, human umbilical cord-derived Wharton's Jelly (WJ) mesenchymal stem cells (MSCs), directly into the adipose tissue, thus reestablishing the cross-talking between peripheral organs and brain. First, we evaluated blood glucose levels in transgenic transplanted mice compared to not -transplanted; then, we assessed the LTP response in hippocampus between the two groups; finally, we investigated if insulin signaling was restored in synaptosomes isolated from both transplanted and not-transplanted mice.It is conceivable that these beneficial effects are mediated by MSC-derived exosomes, delivered to CNS from the periphery, therefore the replenishment of MSCs may restore insulin signaling both in periphery and CNS, thus reestablishing adipose tissue-brain cross-talking.

**Abstract:** Alzheimer's disease (AD) is the most common neurodegenerative disorder characterized by progressive impairment of memory and cognition. At the cellular level, AD patients exhibit cerebral accumulation of extracellular amyloid plaques, composed of amyloid-beta and intraneuronal neurofibrillary tangles, formed of phosphorylated tau. It has become an international public health epidemic with an enormous psychological and economical impact in society with an urgent need for novel treatments. Previous data suggest that release of amyloid-beta and tau is dependent on neuronal activity. Furthermore, oligomers of amyloid-beta disrupt glutamate transporter, leading to spill over to extrasynaptic space, local activation of NMDA receptors and inhibition of long-term potentiation. We hypothesized that modulation of glutamatergic systems, via enhancement of the major glutamate transporter EAAT2, could be beneficial in an Alzheimer's disease mouse model (5xFAD). The 5xFAD mice carry 3 of the autosomal dominant human APP mutations and 2 of the presenilin mutations and develop amyloid plaques. In this study, Riluzole, a glutamate modulator that has been shown to increase EAAT2 expression, was used to treat 5xFAD mice from 1 to 6 months of age. Memory performance was then tested in the Y-maze test, a spatial memory task dependent on the hippocampus. 5xFAD mice treated with riluzole showed prevention in spatial memory decline in comparison to 5xFAD mice treated with water and performed at the same level as age-matched wild-type mice. We are currently performing biochemical and RNA-sequencing analysis in these samples to investigate the underlying molecular mechanisms of the behavioral rescue in this amyloid mouse model and evaluating if it is also associated to genes related to neuroplasticity and neural communication as we have published in an aging model before.

**Abstract:** The beta1-adrenergic receptor (ADRB1) is a promising therapeutic target involved in the cognitive deficits and pathological features associated with Alzheimer's disease (AD). Evidence indicates that ADRB1 plays an important role in regulating neuroinflammatory processes, and activation of ADRB1 may produce neuroprotective effects in neuroinflammatory diseases. Novel small molecule modulators of ADRB1, engineered to be highly brain permeable and functionally selective for the G-protein with partial agonistic activity, could have tremendous value both as pharmacological tools and potential lead molecules for further preclinical development.
Xamoterol is a highly selective partial agonist of ADRB1. However, its therapeutic utility as a CNS drug is limited due to its poor oral bioavailability and brain penetration. As part of our program to discover functionally selective partial agonists of ADRB1 that have potential therapeutic value for AD and neuroinflammatory disorders, we have explored the structure-activity relationship of xamoterol derivatives. Our medicinal chemistry effort led to the discovery of a series of compounds. As functionally selective agonists of ADRB1, these compounds produce partial agonistic activity on G-protein signaling with $EC_{50}$ values in the low nanomolar range, but engage very little beta-arrestin recruitment compared to the unbiased agonist isoproterenol. The compounds also inhibit the tumor necrosis factor α (TNFα) response induced by lipopolysaccharide (LPS) both *in vitro* and *in vivo*, and show high brain penetration. The newly identified, functionally selective partial agonists of ADRB1 are invaluable research tools to study mechanisms of G-protein coupled receptor signal transduction.

**Abstract: Introduction:** Limited therapeutic effects of current Alzheimer (AD) treatments highlight the need for new research approaches. Drugs that simultaneously target different aspects of AD could provide therapeutic benefits. Targeting the endocannabinoid system could be such an approach. Endocannabinoid signaling has been demonstrated to be involved in memory formation, motor control, inflammation & oxidative stress. Several *in vitro* studies showed that cannabinoids reduce Aβ-induced neurotoxicity as well as cell death & facilitate neurogenesis. Recently, it could be demonstrated that cannabinoids stimulate the removal of intraneuronal Aβ *in vitro*. The aim of the study was to investigate the multi-faceted therapeutic potential of Tetrahydrocannabinol (THC). For the first time the neuroprotective properties of THC were studied *in vivo using* Tg4-42 mice. These mice expressing Abeta4-42 develop severe hippocampal neuron loss & memory deficits.
**Material & Methods:** Five months old male & female Tg4-42 Alzheimer mice were treated daily with Tetrahydrocannabinol (20mg/kg) for six weeks. Sex and age-matched control Tg4-42 mice treated with the Vehicle solution (5% ethanol, 5% Tween80 in 0,9% sodium chloride solution) were used a control group. Behavior tests were performed assessing memory, motor functions & anxiety (Rotarod, Novel Object Recognition, Elevated-Plus-Maze, Dark/Light & Water Maze). Design-based Stereology will be used to analyze neuron loss in Tg4-42.
**Results & Discussion:** THC-treatment ameliorates motor performance in Tg4-42. Treated mice showed a significantly better performance on the Rota Rod compared to control mice. Recognition memory in the novel object recognition task was improved in THC-treated Tg4-42. Furthermore, THC-treatment caused alterations in the anxiety behavior. In addition, the effects of THC on spatial reference memory will be presented as well as the effects on neuron loss in the CA1 region of the hippocampus. In conclusion, the present study shows that chronic THC

treatment can be therapeutic beneficial for several altered parameters in AD including motor deficits, anxiety & memory. Our findings reinforce a cannabis-based medicine as a potential therapy against AD.

**Title:** Voluntary exercise increases ganglion cell survival in retinas of 5xFAD mice

**Authors: *O. MANOUCHEHRIAN**[1,2], M. SVENSSON[3], T. DEIERBORG[3], L. TAYLOR[2]
[2]Dep of Ophthalmology, [1]Inst. for Clin. Sci., Lund, Sweden; [3]Exptl. Neuroinflam. Lab., Dept. of Exptl. Med. Sci., Lund, Sweden

**Abstract:** Retinal ganglion cell (RGC) loss is a feature of the early stages of Alzheimer's disease (AD), although the mechanism behind this phenomenon has yet to be fully elucidated. Recent studies of experimental AD models suggest that amyloid precursor protein and amyloid-beta (Aβ) deposition may contribute to RGC degeneration. The Aβ load in the brain of familial Alzheimer's disease (FAD) mice has been found to be ameliorated with voluntary exercise. Here, we investigate if the effect of voluntary exercise extends to ganglion cell survival and retinal Aβ load in 5xFAD mice.
From 2 months of age, 5xFAD mice were voluntarily exercised for 6 months (n = 12) or kept sedentary (n = 14) and compared to age-matched wildtype controls (n = 6).
Immunohistochemistry was used to quantify Aβ deposition (Aβ), ganglion cell survival (NeuN and RBPMS) and glial reactivity (Iba1 and GFAP).
We found that both 5xFAD groups displayed significantly elevated Aβ load in the ganglion cell layer, and fewer RGC's compared to wildtype controls. However, exercised 5xFAD mice displayed a significantly increased RGC survival ($p>0.0001$) compared to sedentary 5xFAD counterparts, despite no significant difference in Aβ load. The RGC rescue effect of exercise was on average 45% (95% CI = 28%, 62%) using RBPMS and 24% (95% CI = 13%, 34%) using NeuN. No significant differences with regards to glial reactivity (GFAP and Iba1) were observed

between any of the three groups.
In support of previous studies showing potential positive role of exercise in AD, as well as visual abnormalities in AD patients and animals, we found a substantial loss of RGCs in 5xFAD mice, which was significantly reduced through voluntary exercise.

**Title:** Determination of sigma-2 receptor densities in rat cortical neurons, astrocytes and microglia

**Authors: *C. ZENG**, C. WENG, B. P. LIEBERMAN, J. L. MIKITSH, T. A. METZ, R. H. MACH
Radiology Dept., Univ. of Pennsylvania Perelman Sch. of Medi, Philadelphia, PA

**Abstract:** Sigma-2 ligands have been shown to displace beta amyloid (Aβ) oligomer binding to synaptic puncta, prevent and reverse Aβ oligomer-induced synapse loss in primary neuronal cultures, and reverse memory loss in transgenic mouse models of Alzheimer's disease (AD). In order to understand the mechanism of sigma-2 ligands as potential therapeutics, it is necessary to determine the sigma-2 receptor density in different brain cell types. In the current study, primary rat cortical neurons, astrocytes and microglia were cultured and harvested. Sigma-2 receptor densities were determined by receptor binding assay using [$^{125}$I]RHM-4 and [$^{3}$H]DTG. By using [$^{3}$H]DTG our results show that sigma-2 densities in neurons, astrocytes and microglia are 2311 ± 291.5, 2366 ± 185.1, 2835 ± 244.9 (fmol/mg), respectively. Kd values are 82.66 ± 20.58, 52.01 ± 0.90, 43.40 ± 9.04 (nM), respectively. By using [$^{125}$I]RHM-4, our data show that sigma-2 densities in neurons, astrocytes and microglia are 1596 ± 45.6, 1766 ± 40.4, 1637 ± 16.5 (fmol/mg), respectively. Kd values are 1.20 ± 0.10, 0.84 ± 0.06, 0.99 ± 0.03 (nM), respectively. Cell uptake studies of [$^{125}$I]RHM-4 in neurons and astrocytes were also performed. The data show that cell uptake percentages of [$^{125}$I]RHM-4 input are comparable in neurons and astrocytes. These data show that sigma-2 receptors are expressed in rat cortical neurons, astrocytes, and microglia at similar levels, and the binding activities of sigma-2 ligands to neurons and astrocytes are similar. These results imply that sigma-2 ligands reverse Aβ oligomer-induced memory loss possibly by acting upon multiple brain cell types.

**Abstract:** Alzheimer’s disease (AD) is characterized by a progressive loss of plasticity and memory functions, further leading to neuronal loss and dementia. Epigenetic changes, including histone acetylation, have emerged as important contributors of AD pathophysiology. In the adult brain, histone acetylation is associated with activity-regulated transcriptional changes required for synaptic plasticity and memory. In an attempt to re-establish a proper acetylation chromatin landscape and transcriptional programs, a series of studies has tested HDAC inhibition as

therapeutic option and found a protective effect of several HDAC inhibitors in different AD mouse models. As an alternative to HDAC inhibitors, targeting CBP/p300 acetyltransferases that play important roles in neuronal plasticity and cognition has been proposed as new therapeutic strategy in memory associated disorders. We have produced the first permeant HAT activator molecule targeting the CBP/p300 proteins, CSP-TTK21, that acetylates nuclear chromatin in mice brain and improves spatial memory (Chatterjee et al., J Neurosci., 2013; Patent: WO2013160885A1). Here, we demonstrate that deficient synaptic plasticity (dendritic spine formation, LTD) and long term spatial memory can be restored by a treatment with CSP-TTK21 in an AD-like Tau pathology mouse model (THY-Tau22 mice). Using genome wide screenings (ChIP-seq), we showed that CSP-TTK21 restores the down-regulated H2B acetylome in the hippocampus of THY-Tau22 mice, especially at super-enhancer -regulated genes (enriched in H3K27ac). Upon learning, CSP-TTK21 re-established part of the learning-induced hippocampal transcriptome, consisting in the induction of immediate early genes (egr-1, cFos, Arc...) and the down-regulation of neuronal identity genes bearing the H3K27ac/H2Bac signature. This study is the first to provide *in vivo* proof-of-concept evidence that direct activation of CBP/p300 HAT with CSP-TTK21 efficiently and selectively reverses epigenetic, transcriptional, synaptic plasticity, and behavioral deficits associated to AD lesions. We think that our study opens up a new therapeutic avenue to the development of drugs that modulate the epigenome with HAT activators, as a potent alternative to HDAC inhibitors. Restoring neural circuits for the treatment of Alzheimer's disease is a major challenge and the possibility to reinstate some plasticity at a late stage in the diseased brain of AD patients may delay the patient’s decline and improve the patient’s condition and dependency.

**Title:** An FDA-approved drug as a therapeutic agent to upregulate PICALM

**Authors: *S. A. BAZZI**, K. KISLER, A. R. NELSON, A. P. SAGARE, Z. ZHAO, B. V. ZLOKOVIC
Biophysics and Physiology, Zilkha Neurogenetic Inst., USC, Los Angeles, CA

**Abstract:** Picalm, phosphatidylinositol binding clathrin assembly protein, is a known genetic risk factor in Alzheimer's disease (AD). In healthy mice and humans, Picalm is highly expressed in brain endothelial cells, is involved in clathrin-mediated endocytosis and trafficking, and clearance of amyloid from the brain across the blood-brain barrier. However, in AD Picalm brain endothelial levels are reduced. Using a Picalm deficient mouse model, we have previously shown that Picalm reduction leads to reduced amyloid clearance from brain and exacerbation of amyloid pathology, which could be reversed by increasing Picalm endothelial expression. Thus, therapeutic strategies that upregulate Picalm expression in the vasculature could lead to novel advancements in AD treatment. Currently, no therapeutic treatment targeting Picalm regulation in AD exists, and existing treatments to ameliorate or slow the progression of AD have met with little or no success. To identify a possible Picalm therapeutic treatment, we developed a luciferase reporter assay and screened a library of 2000 FDA-approved drugs. Secondary screening of the identified hits yielded a compound capable of elevating Picalm mRNA and protein levels in vitro by 1.5-3 fold in a human endothelial cell line. Similarly, the compound increased Picalm protein levels in vivo in the brain endothelium of a Picalm-deficient mouse model compared to vehicle treated littermates. In addition to Picalm upregulation, we found this compound also upregulates low density lipoprotein receptor related protein 1 (LRP1), a key protein involved in clearance of amyloid from brain, but does not affect key elements of the clathrin-mediated endocytosis machinery. Together this data indicates that Picalm upregulation could be a promising new therapeutic technique for AD.

**Abstract:** Considerable evidence suggests that pathologies occurring before the appearance of amyloid plaques and tangles may have a role in Alzheimer's disease (AD) progression. As oxidative stress is an early occurrence in neurodegeneration, we focus on this pathology as a potential mediator of AD pathology. Dysfunctional mitochondria are a likely a source of reactive species that contribute to increased stress. To further understand mitochondria-mediated oxidative stress, we took advantage of a novel mitochondria-targeted antioxidant mitoquinone mesylate (MitoQ). We previously published data showing that MitoQ treatment of young 3xTg-AD mice prior to pathology development prevents oxidative stress, memory loss and several other AD-like pathologies present in this animal model. To answer the question of whether this same antioxidant treatment would be effective during a later stage in disease progression, we began treatment of mice at 12 months of age. Mice were supplied MitoQ (100 μM) continuously in drinking water for 5 months. Following treatment, mice underwent behavioral assessment and brain tissue was harvested for biochemical assays. Morris Water Maze training, a measure of spatial memory retention, showed that mice treated with MitoQ learned spatial cues an average of 3 days before littermate controls. Additionally, mice treated with MitoQ retained spatial memory better than littermate controls in both short and long-term memory retention task. Sensorimotor deficiencies and escape motivation from the water maze were evaluated and did not prove to be significantly different between treatment groups. In support of our behavioral data, MitoQ also altered several AD-like pathologies in this animal model. Synaptophysin, a marker for synapse loss, was significantly increased in MitoQ treated animals compared to littermate controls. In contrast, indicators of oxidative stress and neurodegeneration, such as nitrotyrosine and astrogliosis were significantly reduced. Additionally, caspase-3 activity and subsequent tau pathology were also both significantly reduced with treatment. Lipidomic studies revealed that MitoQ treatment caused significant changes in oxidation and fatty acid alterations in the blood and elevated levels of stearic acid in hippocampal tissue. Our studies support evidence that mitochondrial dysfunction and the subsequent oxidative stress are key mediators in AD progression and also highlight the potential of mitochondria-targeted antioxidants for AD therapeutics.

**Title:** Arginine-rich beta-sheet breaker peptides as potential tau protein aggregation inhibitors

**Authors: *K. RALHAN**, V. GURU KRISHNAKUMAR, S. GUPTA
Biol. Engin., IIT Gandhinagar, Gandhinagar, India

**Abstract:** Microtubule Associated Protein (MAP) Tau is a neuronal protein responsible for stabilizing the axonal microtubules. However, in Alzheimer's disease, tau undergoes several post-translational modifications (PTMs) and self-assembles to form insoluble intercellular aggregates. *In vitro* aggregation of the tau protein can be halted by using inhibitors from various classes of molecules including small molecules, peptide-based fragments, and peptidomimetics. As the in-vitro aggregation of full-length tau occurs over 4-6 days, time taken for an inhibitor assay will be on the order of few weeks thus considerably delaying the initial screening. In the present study, we have used Ac-VQIVYK (PHF6) a tau-derived hexapeptide which is the most aggregation-prone fragment of tau protein as a proxy to screen inhibitors for full-length tau protein. Using experimental and computational approaches, we have rationally designed an Arginine-rich amyloid inhibiting/remodelling peptide-based fragment which can tackle PHF6 aggregation. Short peptides have not found much traction as inhibitors of protein aggregation owing to poor cell internalisation resulting in low potency. To overcome this problem, previously researchers have traditionally grafted or appended the peptide fragments in a stable cell permeable scaffold. In our hybrid peptide design, we have grafted the inhibitor peptide to Arg ($R_n$) stretch which has the property of breaking beta sheets. Arginine is a known kosmotropic which can destabilise proteins. Also, arginine-rich peptides have the advantage of acting as a signal peptide for cell internalisation. Since tau aggregation happens intracellularly, it is important for an inhibitor to internalise into the cell. Thioflavin T (ThT) based aggregation inhibition assay using PHF6 as the substrate revealed that a critical length of Arg stretch is required for the inhibitory peptide to act as a beta-sheet breaker. In combination with fluorescence microscopy and ThT assay, we show that $R_6$ and $R_8$ peptides can inhibit PHF6 aggregation. Furthermore, we wanted to check the ability of the $R_6$ peptide to disassemble preformed PHF6 fibrils. Using molecular dynamics simulations, we show that $R_6$ hybrid peptide can bring morphological changes to the PHF6 fibrils which result in loosely packed beta sheets in comparison to control simulations. These results are useful not only in identifying a potential tau aggregation inhibitor but also in devising a targeted design strategy for modifying aggregation of other amyloidogenic proteins.

**Abstract:** Among the neuronal populations that degenerate in Alzheimer's disease (AD), cholinergic loss most closely correlates with declines in synaptic number and cognitive function. Nerve growth factor (NGF) has been shown to promote neuronal survival and synaptic plasticity of cholinergic neurons, and thereby represents a promising therapy for AD. However, therapeutic efficacy of NGF is limited by its inability to cross the blood-brain barrier (BBB), its short half-life, and adverse effects triggered by NGF activation of p75 receptor in the absence of tropomyosin receptor kinase A (TrkA). Here, we use MRI-guided focused ultrasound (MRIgFUS) for non-invasive, transient and localized BBB opening, to facilitate delivery of a high affinity TrkA-specific ligand in targeted regions. We aim to promote cholinergic function by targeted delivery of a TrkA agonist using MRIgFUS. We used a transgenic (Tg) mouse model of AD with deficits related to cholinergic transmission. Briefly, Tg mice and non-Tg littermates were injected intravenously with a TrkA agonist and MRIgFUS applied to brain regions where TrkA is expressed. Expression of TrkA signaling and key downstream effectors were quantified for mRNA, protein and phosphorylation. We observed an increase in TrkA phosphorylation and downstream signaling activation after treatment. Expression of cholinergic markers were also detected and compared after treatment. These results demonstrate the therapeutic efficacy of a TrkA-specific agonist combined with MRIgFUS delivery in a mouse model of AD.

**Abstract:** Alzheimer's disease (AD) is a progressively debilitating neurodegenerative disorder affecting nearly 50 million individuals worldwide. Epidemiological and clinical studies have pointed to positive benefits of various lifestyle factors in lowering the risk of cognitive impairments and pathological changes in the brain seen in AD. One such lifestyle factor, cardiovascular exercise, has particularly demonstrated its ability to mitigate cognitive and behavioral impairments and reduce AD pathology in both human and animal studies. Information is lacking, however, in regards to the daily amount, timing of onset, and duration of exercise that produces optimal effects. Here, utilizing the Tg2576 mouse, a model of parenchymal amyloid pathology and cognitive impairment, we sought to understand the effects of different amounts of cardiovascular exercise intervention, through daily access to a running wheel, on more advanced stage disease. This study is the first to determine the benefits of different doses [0h, 1h, 3h, and 12h running wheel access] of long-term exercise intervention from 14 to 18 months of age in Tg2576 mice and in age-matched wild-type (WT) mice. The 1h and 3h running groups exhibited higher intensity patterns of running compared to the 12h groups. Behavioral analyses include Barnes maze, Y maze for spontaneous alternation, novel object recognition, radial arm maze, open field, light/dark box, marble burying/digging, Crawley's three chamber paradigm for social interaction, rotarod, and wire hang. Baseline impairments were found in the Tg2576 mice compared to wild type mice, and preliminary analyses revealed diverse patterns of effects of different doses of exercise in Tg2576 mice versus the WT mice. Analysis of exercise effects on measures of AD pathology, immune response and physiology will also be presented.

**Abstract:** Alzheimer’s disease (AD) is a progressive degenerative disorder that currently remains extremely disabling. Recent work has shown that deep brain stimulation (DBS) has promising effects in AD patients. In parallel to the clinical trials, we investigated the impact of chronic DBS in 3xTg mice, a well-established animal model of AD. AD mice were assigned to control (Cont), non-stimulation (NS) and stimulation (DBS) groups, along with age matched wild type controls (WT-Cont). Bilateral electrodes were implanted in the entorhinal cortex to deliver chronic high frequency stimulation for 25 days. Animals were tested in memory behavioral tasks, with post-mortem measurements of AD pathological markers. We found that chronic DBS in AD mice normalized their impaired performance in the Morris water maze task to that of the WT group in the 1-hour probe test. In the novel object and novel place preference tasks, AD-DBS mice spent more time at the novel object and novice location compared to AD-NS mice. These cognitive improvements in AD-DBS mice were associated with DBS induced increased neurogenesis in the dentate gyrus, a significant reduction in β-amyloid plaques, a reduction in CA-1 cellular Aβ42 levels, decreased cortical total-tau and *p*-tau, along with decreased hippocampal total-tau. Overall, we show that chronic DBS of the entorhinal cortex in AD mice improves both memory and AD specific pathological markers. These results support further testing of DBS as a potential treatment in AD patients.

**Abstract:** The recombinant C-terminal fragment of the tetanus toxin (Hc-TeTx) is a nontoxic peptide of the tetanus toxin that has been shown to exert neuroprotection in excitotoxic models *in vitro* and *in vivo*. The $A\beta_{25-35}$ peptide induce cholinotoxic effects on the *magnocellular nucleus* (NBM), in addition to produced deterioration of the learning and spatial memory processes. The aim of this work was to evaluate the neuroprotective effect of the Hc-TeTx fragment on astrocytosis and cholinergic markers in rats injured with the $A\beta_{25-35}$ peptide into NBM. Male Wistar rats were used and five experimental groups were formed: 1) intact, 2) $A\beta_{35-25}$ [2μg / 2μL], 3) Hc-TeTx [2μM / 2μL], 4) $A\beta_{25-35}$ [2μg / 2μL] and 5) Hc-TeTx + $A\beta_{25-35}$. Each treatments were administered bilaterally by stereotactic surgery into NBM (AP: -0.6, L: ± 2.7, P: -6.5). Thirty two days post-lesion were euthanasia performed on animals to extract the brains and evaluate astrocytosis (immunohistochemistry for GFAP protein), vesicular acetylcholine transporter expression (VAChT) (western blot) and acetylcholinesterase activity (AChE) (Ellman´s method) in the NBM, the frontal cortex (FCx) and the temporal cortex (TCx). The results show that administration of the $A\beta_{25-35}$ peptide increases the expression of GFAP in NBM (87 %), FCx (154 %) and TCx (89 %) respect to the intact group. However, the Hc-TeTx + $A\beta_{25-35}$ group decreases the number of GFAP-immunoreactive cells in NBM (60%), FCx (97%) and TCx (80%) respect to the $A\beta_{25-35}$ group. Nevertheless, when evaluating VAChT expression in each experimental group, the $A\beta_{25-35}$ group showed a decrease in VAChT expression in the NBM (42 %), FCx (68 %) and TCx (50 %) respect to the intact group. On the other hand, the Hc-TeTx + $A\beta_{25-35}$ group increases the expression of the VAChT in the NBM (35%), the FCx (70%) and the TCx (31%) respect to the group $A\beta_{25-35}$. Finally, when evaluating AChE activity, the $A\beta_{25-35}$ group was found to decrease the AChE activity in the FCx (34%) and TCx (44%) in relation to the $A\beta_{35-25}$ group. When the Hc-TeTx + $A\beta_{25-35}$ group was evaluated, was observed a re-establishment of AChE activity in the FCx (43%) and TCx (26%) respect to the $A\beta_{25-35}$ group. These findings suggest that the Hc-TeTx fragment regulate the astrocytes number and improves long-term cholinergic communication in rats injured with the $A\beta_{25-35}$ peptide.

**Title:** The protein kinase C-epsilon (PKC-ε) activator 8-[2-(2-pentylcyclopropylmethyl)-cyclopropyl]-octanoic acid (DCP-LA) improves learning and memory, synaptic density and hippocampal neuronal health in a ferrous-amyloid-buthionine (FAB) rat model of Alzheimer's disease

**Authors: R. F. CANDIA**[1], R. B. KNOWLES[2], *C. R. MCKITTRICK[2]
[1]Neurosci., [2]Biol., Drew Univ., Madison, NJ

**Abstract:** Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by progressive memory loss and hippocampal neurodegeneration. It is estimated to affect nearly 47 million people worldwide, and its prevalence is expected to triple within 35 years. Within the last decade, 99.6% of drugs targeting this disease have failed in clinical trials, and those few that have succeeded have mild effects, at best. Recently, protein kinase C-epsilon (PKC-ε), a serine/threonine kinase, has become a target for drug development for AD. This kinase has been shown to play a role in critical processes related to AD pathology, including neurite outgrowth, synaptogenesis, and long-term potentiation. The linoleic acid derivative 8-[2-(2-pentylcyclopropylmethyl)-cyclopropyl]-octanoic acid (DCP-LA) specifically activates PKC-ε and has been shown to be beneficial for cognitive and molecular pathology in transgenic models of AD. Since transgenic models have many issues when it comes to the drug development process, we have tested the therapeutic potential of DCP-LA in the ferrous-amyloid-buthionine (FAB) rat model, which is a pharmacological AD model that focuses on the role of oxidative stress in the molecular pathology of the disease.
We assessed the effects of DCP-LA on learning, memory, neuronal health, and synaptic density. Male rats received FAB or saline vehicle i.c.v. for 4 weeks via osmotic minipump infusion. There was a decrease in performance for FAB rats in both the learning and memory tasks in the Morris water maze. A single administration of DCP-LA (3mg/kg, i.p.) 24h before water maze training restored performance on both tasks to the level of control animals. Immunostaining for the neuronal marker NeuN was used to determine neuronal health in the hippocampus. There was significant neurodegeneration observed in the CA1, CA3, and dentate gyrus regions of FAB rats compared to all other groups. DCP-LA treatment partially restored the density of healthy neurons, but not to back control levels in the CA1 and CA3. Synaptic density in the hippocampus

was assessed using immunostaining for the synaptic marker synaptophysin. FAB rats exhibited significant loss of synaptic density in all three hippocampal regions tested, which was restored to control levels by DCP-LA treatment.
Together, these data suggest that DCP-LA treatment is able to reverse learning and memory deficits and improve neuronal and synaptic health in a pharmacological rat model of Alzheimer's disease. This suggests that DCP-LA has potential to be used in the human disease, although more research is required to determine key safety data, such as systemic toxicity, optimal dosages, and treatment windows.

**Abstract:** The neurovascular unit (NVU) is composed of endothelium, pericytes, vascular smooth muscle cells, glia and neurons. The NVU modulates blood-brain barrier (BBB) integrity as well as cerebral blood flow (CBF). Clinical evidence and animal studies have implicated BBB dysfunction in several CNS disorders including Alzheimer's disease (AD), cerebral amyloid angiopathy and vascular dementia. Emerging evidence suggests that cerebrovascular dysfunction contributes to cognitive impairment and actually precedes typical biomarkers of AD. Cyclophilin A (CypA) is an abundant isomerase that also plays a role in the initiation of inflammatory processes. Increases in the extracellular pool of CypA (eCypA) have been reported in vasculopathies such as hypertension, myocardial infarction and diabetes. CypA is also present in cerebrospinal fluid of APOE4 carriers and preclinical data in APOE4 transgenic mice showed that elevated CypA damages the BBB. The goal of this study was to provide evidence that eCypA is a relevant target in AD. Using a novel assay to assess CypA levels, we found that plasma cypA is highly elevated in AD patient plasma, a finding that was reproduced in two separate cohorts. We also utilized an amyloid mouse model of AD to investigate the role eCypA in the reduced neurovascular coupling reported in these animals. Here, we show that a two-week treatment with an eCypA inhibitor restored the CBF response to whisker stimulation in AD

transgenic mice. Together, these data indicate that targeting eCypA to promote NVU function may be a therapeutic avenue for improvement of cerebrovascular dysfunction in AD.

**Abstract:** Brains from AD patients have been shown to exhibit accumulation of ceramide, a bioactive lipid critical for the cellular secretion of exosomes. One major source of ceramide is through the hydrolysis of sphingomyelin catalyzed by neutral sphingomyelinase 2 (nSMase2). Even though transient ceramide increases through nSMase2 plays a role in normal function, chronic upregulation of ceramide has been associated with the pathogenesis of several neurodegenerative disorders including AD, HIV-associated neurocognitive disorders and

multiple sclerosis. Two recent *in vivo* studies carried out by independent laboratories and using different AD models showed that pharmacologic and genetic inhibition of nSMase2 resulted in strong efficacy end points. In one study, GW4869, a prototype nSMase2 inhibitor, inhibited tau propagation from the cortex to the hippocampus in a rapid tau propagation mouse model. In the other, nSMase2-deficient 5XFAD mice compared to wild-type mice exhibited reduced brain exosomes, ceramide levels, tau phosphorylation and improved cognition in a fear-conditioned learning task. While nSMase2 is emerging as an important player in AD etiology, the current armamentarium of nSMase2 inhibitors is inadequate to develop treatments. Currently available inhibitors exhibit low potency ($IC_{50}$'s in µM level), poor solubility, and/or limited brain penetration. In order to address these limitations, we developed a fluorescence-based assay using human recombinant nSMase2 and conducted high throughput screening. Identified hits were optimized using an iterative testing funnel where compounds are evaluated for human nSMase2 inhibitory potency, functional inhibition of exosome release in primary glial cells, cellular permeability, metabolic stability, *in vivo* pharmacokinetics, including brain penetration, and target selectivity. Our early hit optimization effort resulted in MS882, a potent nSMase2 inhibitor ($IC_{50}$=300 nM), able to dose-dependently inhibit exosome release in primary glial cells ($EC_{50}$=1 µM), which was stable in both mouse and human liver microsomes and exhibited a good pharmacokinetic profile, including brain penetration (concentration in brain at 2 h following systemic dosing was >5-fold higher than its nSMase2 $IC_{50}$). MS882 also showed good selectivity over two related enzymes - alkaline phosphatase and acid sphingomyelinase. MS882 is currently being evaluated for efficacy *in vivo*. nSMase2 is a novel therapeutic target that is mechanistically distinct from previous efforts in AD treatment with the potential of addressing disease progression that exploits a newly discovered chemical series of drug-like inhibitors.

**Title:** A novel, small-molecule activator of glutamate transporter EAAT2 translation delays disease progression in a tauopathy model of Alzheimer's disease

**Authors: *J. B. FOSTER**[1], F. ZHAO[1], K. HODGETTS[2], C.-L. G. LIN[1]
[1]Neurosci., The Ohio State Univ., Columbus, OH; [2]Neurol., Brigham and Women's Hospital/Harvard Med. Sch., Boston, MA

**Abstract:** Alzheimer’s disease (AD) is a progressive neurological disease characterized by glutamate dyshomeostasis, amyloid-β plaques, tau-tangles, and progressive loss of cognitive functions. Current therapeutics are limited in efficacy and only provide temporary, palliative care. Therefore, there is need to develop novel therapeutics that can substantially slow or reverse disease progression. Glutamatergic transmission and synaptic concentration are elevated in AD patients. This can lead to synaptotoxicity, amyloid-β deposition, and hyperphosphorylated-tau accumulation of which each can create a feedforward loop where glutamate release is further stimulated exacerbating neuronal damage. Excitatory amino acid transporter 2 (EAAT2) is responsible for clearing glutamate from the synaptic cleft and preventing excitotoxicity. However, many AD patients have reduced expression of EAAT2. We have developed a small-molecule compound series that is capable of increasing EAAT2 expression through a translational induction and previously shown that it has profound efficacy in an amyloid-β AD model. However, tau pathology is also involved in AD. Here, we evaluated the efficacy of an advanced compound in rTg4510 mice that exclusively exhibit tau pathology. We hypothesized that long-term compound treatment will delay disease progression and improve synaptic integrity. rTg4510 mice were treated with LDN/OSU-215111 (10 mg/kg P.O.) beginning at age 2 months and were treated until 4 or 8 months of age. Four-month old compound-treated rTg4510 mice performed significantly better in cognitive tasks (novel object recognition/T-maze), a working memory test (Y-maze), and showed significantly reduced hyper-exploratory behavior. Even at 8 months of age, treated rTg4510 mice appeared to perform better in the Barnes maze and novel object recognition task as well as reduced hyper-exploratory behavior. Consistent with 8-month behavioral data, hippocampal long-term potentiation (LTP) in compound-treated rTg4510 mice was significantly increased. Biochemically, at both time points, treatment partially normalized EAAT2 protein levels and preserved synaptic integrity. This study suggests that modulation of EAAT2 expression is a viable therapeutic for the treatment of AD.

**Abstract:** Objectives
In the last decade intranasal administration (INA) of stem cells was proven to be an efficacious non-invasive delivery, targeting and treatment method in preclinical models of brain disorders including Parkinson's disease, stroke, neonatal ischemia, glioma, multiple sclerosis and others. Our previous study demonstrated that intranasal mesenchymal stem cells (MSC) are successfully delivered to the brain in a double transgenic Alzheimers mouse model. However, the therapeutic efficacy of MSCs after INA and the comparison of INA vs. intracerebral transplantation (ICT) remained unexplored.
Methods
Mouse eGFP-MSCs were administered either stereotactically into the hippocampus or given intranasally to 6-month old 3xTg-AD mice. Memory deficit was monitored one week prior and 3 weeks after MSCs transplantation by forced choice alternation T-maze. Tracking of administered stem cells was analyzed immunohistochemically using eGFP antibody in the brains of mice. Brain homogenates were analyzed for the presence of soluble Amyloid beta fragments and synaptophysin as a presynaptic marker.
Results Spatial memory was improved by both ICT and INA of MSCs over the entire time of testing. The Western Blot analysis also showed equal efficacy of INA and ICT of MSCs to increase synaptophysin expression. In contrast, INA of MSCs was more efficacious in decreasing soluble Amyloid beta fragments and in delivery as well as survival of the administered cells in the cortex and hippocampus of 3xTg-AD mice.
Conclusions
In a view of the invasiveness of surgical transplantation and consequently low survival of transplanted cells due to the strong inflammatory response to intracerebral injection, the successful establishment of non-invasive INA methods allowing for repeated cell administration and avoiding inflammation provides an improved strategy for cell-based therapy of central nervous system disorders. Our data strongly support the value of intranasal administration as an efficacious non-invasive method of delivery, targeting and treatment, providing better and sustained survival of stem cells with repeated administration and allowing for the full therapeutic potential of stem cells in the central nervous system.

**Abstract:** The pathological hallmarks of Alzheimer's disease (AD) are characterized by clumps of aggregated beta-amyloid (Aβ) ("plaques") and tau ("tangles"), which along with their monomeric forms are thought to be pathologically benign. Sporadic or templated misfolding of these monomeric proteins initiates an oligomerization process to generate intermediate transient oligomeric species that display a multitude of neurotoxic and synaptotoxic effects. We have identified a novel druggable target known as the Common Conformational Motiff (CCM) which is an abnormal protein shape shared by both Aβ and tau that can be exploited to prevent their misfolding and oligomerization. Using the CCM model, a library of 11.8 million compounds was filtered for CNS properties and screened in silico against CCM leading to 3,082 hits. Through hit to lead and lead optimization efforts, we have discovered a novel class of brain-penetrant small molecule entities capable of preventing oligomerization of both beta-amyloid and tau. Efficacy of lead compounds was measured in a variety of biochemical in vitro assays. The structural effect of compounds on tau was measured by time resolved hydrogen-deuterium exchange electrospray ionization mass spectrometry (TRESI-HDX). In vitro absorption-distribution-metabolism-excretion-toxicity (ADMET) data along with mouse pharmacokinetics/ bioavailability (plasma and brain) was collected. Levels of Aβ oligomers were measured in APP/PS1 mouse interstitial fluid by repeated sampling through microdialysis. Levels of tau oligomers in homogenized cortex of the rTg4510 mice were measured by FRET-biosensor cells (tau RD P301S-CFP/YFP). Lead compounds showed anti-oligomerization activity against both Aβ and tau and correlate with structural changes induced in phosphorylated tau. This class of molecules has optimal drug like properties, demonstrating favorable in vitro ADMET, high brain

penetrance and oral bioavailability, and benign in a 44-receptor panel test. A lead compound TRV 301 demonstrates dose dependant reduction of both Aβ and tau oligomers in vivo. In conclusions, we have developed a new class of compounds capable of inhibiting oligomerization of both beta-amyloid and tau proteins. Our small molecules have appropriate pharmacokinetic profiles, able to reach the target tissue, and have demonstrated efficacy in animal models of both Aβ and tau pathologies.

**Title:** Targeted brain BRICHOS domain delivery using focused ultrasound-induced blood-brain barrier opening > the treatment of Alzheimer’s disease

**Authors: *C. J. SIERRA SANCHEZ**[1], L. GALAN ACOSTA[3], J. PRESTO[3], P. NILSSON[3], J. JOHANSSON[3], E. E. KONOFAGOU[1,2]
[1]Biomed. Engin., [2]Radiology, Columbia Univ., New York, NY; [3]Neurobio., Karolinska Institutet, Huddinge, Sweden

**Abstract:** The BRICHOS domain is encoded in more than 10 human genes associated with cancer, dementia (BRI2/ITM2b) and amyloid lung disease (proSP-C). Studies have shown that

overexpression of proSP-C or Bri2-BRICHOS delays fibril formation and toxicity of amyloid-β peptide (Aβ) *in vitro* and *in vivo*, which plays a central role in the development of Aβ amyloid plaques, one hallmark of Alzheimer´s disease (AD). BRICHOS domain thus has the potential for treating this disease. It has been revealed, *in vivo*, that overexpression of proSP-C or Bri2-BRICHOS proteins delayed Aβ42 fibril formation in the brain and improved lifespan and locomotor function in *Drosophila* flies. However, in wild-type mice, after intravenous administration, a limited amount of Bri2-BRICHOS was detected in the brain parenchyma, most likely due to a poor passage through the blood-brain barrier (BBB). Therefore the main objective of this study is to increase the BRICHOS domain delivery rate in a safe and non-invasive way, being currently focused ultrasound (FUS)-induced BBB opening the sole technique to achieve noninvasive, transient, and localized brain drug delivery.
In this study, a single-element FUS transducer (center frequency 1.5 MHz) and a pulse-echo transducer (center frequency 10 MHz), used for passive cavitation detection, confocally mounted at the center of the FUS transducer, were used. A pulsed FUS (pulse length 6.56 ms; pulse repetition frequency 5 Hz; duration 2 min; acoustic pressure 450 kPa) was targeted, in the presence of lipid microbubbles, transcranially *in vivo* to the left hippocampus of the mouse brains for trans-BBB delivery of BRICHOS domain. Mice were kept 2 hours after sonication to allow the BRICHOS domain to diffuse to the parenchyma, and then they were sacrificed for assessing the delivery by *ex vivo* immunohistochemistry (IHC) for proSP-C or Bri2 BRICHOS using a primary rabbit anti-surfactant protein-C antibody and permanent Alkaline Phosphatase red for developing the stains. Also, the neuronal marker NeuN was used for assaying possible neuronal BRICHOS uptake. BBB opening was confirmed *in vivo* by $T_1$-w magnetic resonance imaging. The overall brain histology was evaluated by hematoxylin & eosin staining for microscopic damage.
Successfully targeted brain BRICHOS domain delivery was achieved in 6 out of 10 cases. Notably, IHC showed selective uptake of BRICHOS by a specific subset of neurons in the FUS targeted hippocampus section. Microhemorrhages were observed only in two cases. This study indicates that FUS is a safe methodology for targeted brain BRICHOS domain delivery, with a potential promising application in the treatment of AD pathology.

**Abstract:** Alzheimer ’s disease (AD) is being called a silver tsunami due to the phenomenal increase in number of AD patients and the economic burden it imposes. As per Alzheimer's Association, AD poses a burden of 818 billion US$ and it is suggested that there are about 46.8 million patients worldwide. Many countries, like India, who contribute a big chunk of human population, do not even have the baseline database on the number AD (or dementia) patients. Since several decades now, the most accepted hypothesis for AD with real translation impact is the amyloid beta hypothesis. This hypothesis is well accepted mostly due to work of several investigators including Glenner & Wong, 1984, Beyreuther & Masters, 1991; Hardy & Allsop, 1991; Selkoe, 1991; Hardy & Higgins, 1992.Several pathways are known, several database exist but a cure is elusive. Historically, molecules from plant have contributed a lot to drug development. In our current study we have screened medicinal plants of Uttarakhand, India for BACE inhibitor, which is component of amyloid hypothesis. Several workers have worked on phyto-chemicals but our hypothesis was to identify a fraction of medicinal plant which would have several components instead of single phyto-moiety. The rationale for this thinking was that sometimes a group of phyto-components show better results than a single moiety. This study was done in three parts. First, medicinal plants were listed and a bioinformatics based screening using iGEMDOCK software was carried out. This screening shortlisted about 20 phyto-constituents. On the basis of rationals, pilot experiments were carried out with crude extract of 8 medicinal plants as per Mancini et. al., 2000. Extract of one medicinal plant, *P. kurroa* could inhibit BACE activity. A fresh extract of this medicinal plant was prepared with higher amount of starting material. BACE activity was monitored by fluorescent substrate kit (Abcam ab65357). Here we present our data to confirm that extract of *P. kurroa* can inhibit BACE activity better than known controls *in-vitro*.

**Abstract:** The β amyloid is generated by sequential cleavage of amyloid precursor protein (APP) by β-secretase (BACE1) and γ-secretase, and plays a central role in Alzheimer's disease (AD) pathogenesis. BACE1 is the rate-limiting enzyme for the amyloidogenic APP processing. Despite much research, the modifications of BACE1 related to β-secretase activity in AD process remain unclear. In the present study, we discovered a novel phosphorylation site of BACE1, which was detected by a specific antibody recognizing phosphorylated threonine (Thr) 252 site of BACE1. The phosphorylated BACE1 was found increased in hippocampus and cortex of an AD transgenic mouse model (5XFAD) at 1.5 months old, at which Aβ generation was increased. Further, we designed and constituted plasmids carrying $BACE1^{WT\text{-}GFP}$, $BACE1^{T252A\text{-}GFP}$ (Thr252 was replaced by alanine, resulting in deficiency of threonine phosphorylation), $BACE1^{T252D\text{-}GFP}$ (Thr252 was replaced by aspartic acid, resulting in mimics phosphorylation of threonine), respectively, and performed overexpression study in 293APPsw cells, which is a cell line stably overexpressing APPsw mutant, to investigate the function of the phosphorylated BACE1 in Aβ production. As expected, $BACE1^{WT\text{-}GFP}$ and $BACE1^{T252D\text{-}GFP}$ overexpression promoted Aβ generation in the cell line, while $BACE1^{T252A\text{-}GFP}$ had no this effect, suggesting that the phosphorylation site of BACE1 is associated with its β-secretase activity. Intriguingly, further study revealed that the β-cleavage function of BACE1 in 5XFAD/$BACE1^{-/-}$ mice was rescued by stereotactic injection of lenti-$BACE1^{WT\text{-}GFP}$ in hippocampus, but not by lenti-$BACE1^{T252A\text{-}GFP}$, implying that the phosphorylated BACE1 at Thr 252 site can determine the β-secretase activity of BACE1 in AD brain. In conclusion, the study provide a new insight into amyloidogenic APP processing and AD therapeutic implications.

**Title:** Alteration of gene expression in brain tissue samples from living Parkinson's disease patients

**Authors: *S. M. BENOIT**[1], H. XU[2], S. SCHMID[3], R. ALEXANDROVA[4], G. KAUR[4], B. THIRUVAHINDRAPURAM[4], M. O. HEBB[5]
[1]Neurosci., [2]Clin. Neurolog. Sci., [3]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada; [4]The Ctr. for Applied Genomcis, The Hosp. for Sick Children, Toronto, ON, Canada; [5]Clin. Neurolog. Sci., Western Univ., London, ON, Canada

**Abstract: Introduction:** Differential gene expression in the central nervous system (CNS) of living Parkinson's disease (PD) patients has not been previously reported and may offer critical biomarkers to define pathogenic mechanisms, new therapeutic targets, early diagnosis and disease progression. The current objective was to examine the transcriptome for gene expression alterations using RNA isolated from brain specimens in living PD and control patients. **Methods:** Total RNA was extracted from cortical biopsies in 6 patients with PD and 6 healthy controls and sequenced on the Illumina HiSeq 2500 platform using a stranded paired-end protocol. Reads, totaling approximately 90 million per sample, were trimmed to remove adapters and low quality bases, then aligned to the human genome (Hg19) using TopHat (v.1.8). Raw counts were generated using HTSeq (v.0.6.1p2); and analyzed for differential expression using edgeR (v.3.8.6). Pathway enrichment analysis was performed using the analysis tools from the Gene Ontology Consortium (http://www.geneontology.org/). **Results:** At an FDR threshold of <0.05, 763 differentially expressed genes were identified, with 347 upregulated and 416 downregulated in PD. Twenty-five of these genes had >4-fold change in expression. Genes commonly associated with or known to cause monogenic PD, such as SNCA, Parkin, PINK1 and LRRK2 showed no differential expression. The expression of Glial-derived neurotrophic factor, a potent neuroprotective and putative therapeutic agent, was significantly reduced in PD samples. Matrix-metallopeptidase 9, which has been positively linked to PD in single nucleotide polymorphism studies, and Interleukin-10, an anti-inflammatory cytokine with a highly polymorphic promoter also associated with PD, were also among several dysregulated genes with experimental associations to neurodegenerative disease. Further, pathway analysis showed enrichment of immune and inflammatory response processes, lending further evidence to findings of dysregulation of inflammatory processes in PD. **Conclusions:** To our knowledge this is the first demonstration of differential CNS gene expression in living PD patients. Alterations in gene expression in approximately 4% of the detected genes offer a wealth of data with potential to identify genetic biomarkers that may facilitate diagnosis and treatment for PD and other neurodegenerative diseases.

**Abstract:** Parkinson’s disease (PD) is the second most common neurodegenerative disorder and is characterized by the degeneration of certain neuronal populations in the central and peripheral nervous system. Although there is no therapy to halt or delay neurodegeneration, there are pharmacological or surgical approaches that treat the symptoms and improve the patients’ quality of life. To counteract striatal dopamine deficiency and treat PD symptoms the most effective drug is levodopa (L-DOPA). L-DOPA is the precursor of dopamine and its administration enhances striatal dopamine levels. However, chronic treatment with L-DOPA triggers other motor complications, including dyskinesia and motor fluctuations. L-DOPA-induced dyskinesia (LID) is one of the most disabling problems for PD patients. Currently there is no method to predict which PD patient will develop LID, whether it will be an early or a late LID onset or whether LIDs will be severe and incapacitating. One strategy to identify possible molecular markers to predict L-DOPA treatment outcome involves the screening of single-nucleotide polymorphisms (SNP) in crucial signaling pathways associated to PD pathogenesis. mTOR signaling is one of these pathways. Genetic variations in the mTOR pathway could explain the differential sensitivity to L-DOPA in PD patients. For this reason, here we investigated potential associations between genetic variations in the genes of the mTOR pathway and the onset and

severity of LIDs in patients with PD. We selected 64 SNPs from 57 genes in the mTOR pathway. After microarray genotyping we filtered out SNPs, resulting in the final number of 54 SNPs that were included in the association analysis of single SNPs or their combinations. The whole cohort of study consisted in 1,819 subjects including 898 PD cases and 921 unrelated healthy controls. A total of 401 of the 898 PD cases had complete L-DOPA treatment and LID data registered in their clinical histories. Genotypic associations were computed using the SNPStats software and combinations of SNPs and epistatic combinations were calculated using the SNPsyn and the MDR softwares. Here, we found new associations between the early appearance and the severity of LIDs with SNPs in components of the mTOR pathway. We have detected both single SNPs associations and epistatic interactions of SNPs that could predict the appearance or severity of LIDs. The results in this study will be used to design a diagnostics test to predict PD patients susceptibility to develop early LID onset and LID severity, with the overall goal to prevent/delay LID appearance and therefore, to improve PD patients' quality of life.

**Title:** Parkinson's disease associated alterations in the DNA modifications, 5-methylcytosine and 5-hydroxymethylcytosine

**Authors: *A. I. BERNSTEIN**, S. VANOEVEREN
Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI

**Abstract:** Parkinson's disease (PD) is the second most common neurodegenerative disease in the US. Pathological hallmarks of PD include the degeneration of the nigrostriatal dopaminergic pathway and other monoaminergic regions and the formation of Lewy bodies, abnormal cytoplasmic inclusions. While a small percentage (5-10%) of PD cases are monogenically inherited, the large majority of cases of PD are sporadic. Etiology of sporadic PD is thought to involve a combination of and interaction between both genetic and environmental factors. It is possible that these genetic and environmental factors converge upon the epigenome. Epigenetic modulations could imprint dynamic environmental experiences on the genome, resulting in stable alterations in phenotype. In fact, recent work suggests a role for regulation of the

epigenome in PD. For example, aberrant gene methylation of PD-associated genes has been observed in post-mortem PD brains. In addition, expression of α-synuclein has been shown be regulated by promoter methylation and α-synuclein sequesters the DNA methyltransferase DNMT1 away from the nucleus, resulting in DNA hypomethylation. Therefore, we hypothesized that specific alterations in DNA modifications are associated with PD and that these changes alter gene expression in disease relevant gene networks, thereby increasing susceptibility to PD. To test this, we profiled the DNA modifications, 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC), and the transcriptome in human postmortem brain tissue from mid-stage PD patients, late-stage PD patients and controls. To capture changes that may occur prior to the onset of pathology, we profiled both cingulate and parietal cortex, as these regions show pathology in mid and late stage disease, respectively. Previous epigenome-wide association studies for PD have not incorporated 5hmC or correlated epigenetic changes to transcriptional changes. DNA modifications were profiled using the Illumina EPIC array, paired with bisulfite and oxidative bisulfite conversion for detection of 5mC and 5hmC, respectively. The transcriptome was profiled by RNA-Seq. We identified differentially methylated and hydroxymethylated regions associated with PD diagnosis and disease stage and incorporated this data with gene expression data from RNA-Seq. In addition, we incorporated known disease associated SNPs. Network analysis of these genes implicates specific gene networks in the etiology of PD and identifies novel mechanisms of epigenetic regulation in PD.

**Title:** DNA methylation, gene expression and splicing analysis for Parkinson’s disease blood biomarker discovery

**Authors: *A. R. HENDERSON-SMITH**[1], B. MEECHOOVET[1], A. L. SINIARD[1], E. DRIVER-DUNCKLEY[2], T. DUNCKLEY[3], M. J. HUENTELMAN[1]
[1]Translational Genomics Res. Inst., Phoenix, AZ; [2]Mayo Clin., Scottsdale, AZ; [3]Biodesign at Arizona State Univ., Tempe, AZ

**Abstract:** Parkinson’s disease (PD) is a progressive neurodegenerative disorder, diagnosed only at an advanced disease stage, by a series of motor deficits that manifest over years or decades. Aberrant epigenetic modifications, including hypomethylation of α-synuclein in PD, exist across a range of diseases, from cancer to schizophrenia, and are non-invasively detectable in many body fluids and blood tissue as markers of disease.
We aimed to characterize DNA methylation and gene expression patterns in blood from PD patients and matched healthy controls to identify disease-specific biomarkers that may be used to aid earlier, more accurate disease diagnosis and tracking of disease progression.
Whole-blood samples were collected from PD patients and healthy controls, one for DNA methylation detection and one for mRNA sequencing. DNA methylation sites were probed with the Illumina Infinium HumanMethylation450 BeadChips. We used the Illumina HiSeq2000 platform for mRNA sequencing and performed separate and integrated analyses of differential expression and DNA methylation.
PD methylation profiles are readily distinguishable from healthy controls, even in whole blood DNA samples. Differential expression analyses of mRNA-seq data identified global changes in gene regulation, including overall gene expression levels and expression levels of specific transcript splice variants. Combined methylation quantitative trait loci analyses (meQTL) identified cis-acting meQTLs associated with differential expression of proximal loci.
Establishing clear patterns of altered disease-specific DNA methylation, RNA expression and processing, and meQTL analyses from whole blood, a non-invasive tissue collection option, provides increased promise for the development of a molecular biomarker for PD with sufficient sensitivity and specificity to aid in the diagnosis and tracking of this disorder.

**Abstract:** Accumulation of misfolded proteins in the brain is the main pathological hallmark of neurodegenerative diseases, including Parkinson's disease (PD), suggesting that inadequate clearance of aggregation-prone proteins plays an important role in the disease pathogenesis. Studies on the rare inherited forms of PD have highlighted disturbed alpha-synuclein (aSyn) clearance through the autophagy-lysosomal pathway (ALP) as a key mechanism leading to PD. In order to characterize the putative underlying genetic mechanisms leading to ALP dysfunction in PD, we performed comprehensive analysis of genetic variants in ALP genes in PD patients. The study included 70 PD patients and 25 healthy control subjects. Genetic variants were ascertained using the custom LYSOGENE targeted next-generation sequencing (NGS) panel, containing a comprehensive set of 440 ALP related genes, as well as genes previously implicated in familial forms of PD. In order to assess the technical variability, we analyzed the samples using the SureSelect (Agilent) and Nextera Custom Enrichment (Illumina) library preparation kits. We identified a significant number of ALP gene variants among PD patients when compared to control subjects, with 815 variants pertaining to 290 genes present exclusively in PD patients. These variants were involved in over 50 biological processes, with the greatest enrichment observed in categories of lysosome organization, organic substance transport, abnormal myelination and sphingolipid metabolism. In contrast, variants found exclusively in healthy subjects were not related to specific biological pathways. Based on the NGS data, we selected genes ARSD, GALC, IDUA and LRBA with the most over-represented genetic variants in PD patients and investigated their effects on lysosomal impairment, aSyn accumulation and neurotoxicity using the neuroblastoma SH-SY5Y cell lines stably expressing human alpha-synuclein. The results were compared to the effects of the knock-down of a known lysosome-related gene, ATP13A2, which causes a rare autosomal recessive form of juvenile-onset atypical Parkinson disease (PARK9). Our knock-down experiments confirmed the link between lysosomal impairment and aSyn accumulation. In total, our results strongly suggest that specific variants in ALP genes may contribute to lysosomal dysfunction in PD. Furthermore, these genetic variants may modulate aSyn clearance, thus promoting the PD pathology.

**Abstract:** Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by debilitating motor symptoms and affects 1.5-2% of individuals over the age of 60. The pathophysiology of PD, characterized by loss of dopaminergic neurons in the *substantia nigra* and accumulation of alpha-synuclein immunoreactive protein aggregates has long been associated with neuroinflammation. The NLRP3 inflammasome is a catalytic multiprotein complex capable of initiating inflammation in response to non-pathogenic cellular stress. Our ongoing studies, and reports by others, support a role for *NLRP3* in PD-associated neuroinflammation and neurodegeneration; elevated NLRP3 is also observed in the central nervous system of patients with Alzheimer's disease. We observed increased NLRP3 expression levels in dopaminergic neurons in post-mortem tissues from PD patients, and recently identified genetic variations in *NLRP3* by interrogating exome sequencing data obtained from the ongoing Parkinson's Progression Markers Initiative. One *NLRP3* variant, single nucleotide polymorphism (SNP) rs7525979, was found to be associated with a decreased risk of classical PD. The SNP could also differentiate patients with classical PD from patients with a form of non-classical parkinsonism identified clinically as "scans without evidence of dopaminergic deficit (SWEDD)." Synonymous SNPs, like *NLRP3* variant rs7525979, occupy the third codon position and do not impact the amino acid sequence. Although still poorly understood, it is thought that dysregulation at the level of translation, likely resulting from tRNA availability, mRNA stability, mRNA structure, and/or mRNA splicing, impacts the protein life cycle at levels ranging from translation efficiency to proteosomal degradation. Having identified the synonymous *NLRP3* SNP rs7525979 to be significantly associated with a reduced risk of PD, we conducted mechanistic studies to determine how rs7525979 may confer resistance to the disease. We assessed the impact of the synonymous SNP on properties of NLRP3 protein and found that the presence of the SNP increased protein half-life in association with reduced solubility and alterations in ubiquitination. We also characterized the impact of rs7525979 on the NLRP3 interactome using LC/MS techniques and found that the presence of the SNP resulted in differential interactions with key mediators of protein translation, folding, and degradation. Findings from these studies highlight the potential of synonymous SNPs to impact proteins and

provide a foundation for studies to determine whether modification of inflammasome function can impact the progression of PD.

**Abstract:** Histone acetylation is an epigenetic process involved in gene expression and cell survival, and is regulated by histone acetyltransferases (HATs) and histone deacetylases (HDACs). Histone acetylation imbalance is believed to play a pathogenic role in neurodegenerative diseases, including Parkinson’s disease (PD). Dysregulation in histone acetylation has been reported to occur in select brain regions including the midbrain region associated with PD. Whether the region of the basal forebrain (BF) containing the cholinergic neurons that projects to the entire cortical mantle, which plays a role in memory and attention and undergoes selective degeneration in patients with PD, displays histone dysregulation remains unknown. Here, we determined whether histone acetylation alterations occur in PD patients with (PPD) and without dementia. Protein levels of HDACs, the enzymes involved in chromatin condensation and gene transcript repression, were examined in the cholinergic BF in subjects with a pre-mortem clinical diagnosis of non-cognitive-motor impairment (NCMI, n=12), PD (n=10) and PDD (n=12) using quantitative immunoblotting. Western blot analysis revealed that HDAC1 levels in the BF were significantly upregulated in PD and PDD compared to NCMI subjects ($p = 0.001$), but not different between PD and PDD. Conversely, levels of HDAC2,

HDAC3, HDAC4 and HDAC6 were stable across the clinical groups examined. Furthermore, HDAC1 values correlated negatively with age of disease onset ($r=-0.6$, $p < 0.05$) and positively with disease duration ($r=-0.6$, $p < 0.05$) in both PD and PDD. These data suggest that HDAC1 levels are increased in the BF region containing cholinergic neurons in PD and PDD and, may play critical role in BF cholinergic neuronal degeneration in PD subjects with and without dementia.

**Abstract:** Progressive degeneration of dopaminergic (DA) neurons underlies the pathology of Parkinson’s disease. Understanding the progressive degeneration process is fundamental in the understanding of the pathology, identification of disease biomarkers, as well as the designing of therapeutic targets for intervention. However, defining the progressive events of molecular changes in the small number of affected DA neurons is challenging, and can be significantly confounded by cell type heterogeneity in the surrounding region and even among different types of DA neurons. The relatively small number of DA neurons also limits the throughput of biochemical and molecular analysis. Here we examined the process of DA neuron degeneration using single-cell transcriptomics analysis.A major challenge for single-cell transcriptomics is to obtain consistent single-cell information from complex tissue with limited technical variation. We compared two approaches: single-cell RNA-seq (scRNA-seq) and single-nuclei RNA-seq (snRNA-set). First, we used a mouse model with Dat promoter-driven expression of H2b-GFP as

a genetic marker to identify DA neurons by nuclear expression of GFP. Given the high correlation of average gene expression between single nuclei and of single cells, we found that the snRNA-seq from adult tissue seemed to have minimal technical variability, and is therefore the preferred approach. Using the snRNA data acquisition that we established, several hundred DA neurons have been profiled from normal adult mice to study the physiological variation of gene expression profiles in the population of DA neurons. In contrast to the common belief of the existence of distinct types of DA neurons, we found a rather gradual change in transcriptomic profiles. Using known markers of region-specific DA neurons, we observed a segregation of transcriptomes from principal components analysis that reflected a spatial transition from the Ventral Tegmental Area (VTA) to Substantia Nigra Compacta (SNC). This analysis highlights the resolution of our approach and the lack of bias towards artificial segregation with preselected markers, providing a platform for investigating the molecular basis of why SNC DA neurons are selectively sensitive to neurotoxins. To investigate the degeneration of DA neurons in pathological conditions, we have collected a few thousand cells from different time points after MPTP treatment in adult mice. We hope that additional analysis and validation will reveal the holistic transcriptomic landscape underlying degeneration, allowing for the identification of new biomarkers as well as novel pharmaceutical targets for disease intervention.

**Title:** Impaired temporal working memory in early stages of Parkinson's disease and atypical parkinsonism

**Authors: *Z. YE**[1], J. MA[2], S. MA[1]
[1]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [2]Dept. of Neurol., Xuanwu Hosp., Beijing, China

**Abstract: Background:** The ability to arrange thoughts and actions in an appropriate temporal order is fundamental to complex behavior from speech production to action planning. Deficits in temporal working memory (WM) have been observed in Parkinson’s disease (PD) and other brain disorders in both verbal and nonverbal behaviors. This study tested two hypotheses: (a) that the manipulation of temporal order is selectively impaired but the maintenance of temporal order

is intact in medicated nondemented patients with PD or atypical parkinsonism (APS); (b) that dopamine does not improve the manipulation of temporal order in PD patients. **Methods:** Participants were 41 nondemented patients with mild-to-moderate PD (23 females, age 53-76 yrs, education 13.1 yrs, H-Y 1-3, UPDRS III 22.1), 13 nondemented patients with APS (5 females, age 52-77 yrs, education 13.8 yrs, H-Y 1-3, UPDRS III 22.6; including Parkinson dystonia syndrome N=9, multiple system atrophy N=2, progressive supranuclear palsy N= 1, corticobasal degeneration N=1, dementia with Lewy bodies N=1) and 33 matched healthy elderly adults (20 females, age 53-76 yrs, education 13.2 yrs). All patients were on their regular antiparkinson medications. PD patients were further separated according to their ON (N=19, levodopa equivalent daily dose, LEDD 368.6mg) and OFF periods (N=22, LEDD 328.8mg). APS patients were not separated because they did not respond as well to dopaminergic agents. Each participant underwent a digit forward test, in which participants recalled randomly presented digits in their order of presentation (maintenance only), and a digit ordering test, in which participants had to recall randomly presented digits in ascending order (reordering, manipulation). **Results:** Preliminary analysis on test scores (max. 12 for both tests) revealed a main effect of Test ($F=72.9$, $p<0.001$) and an interaction of Test and Group ($F=6.7$, $p<0.01$). Namely, all groups showed a behavioral cost of reordering (ordering<forward). Compared with healthy control subjects, both PD and APS patients performed worse in the digit ordering test, but not in the digit forward test . Further analysis compared PD patients in ON and OFF periods and revealed similar behavioral costs . The cost of reordering was not correlated with LEDD or levodopa actual dose. **Conclusion:** Our findings suggest that the manipulation of temporal order was selectively impaired in PD and APS, but the maintenance were well preserved. More importantly, dopamine may have limited effects on temporal WM. This study is still going on and we will present data from an even larger sample of PD and APS patients during the conference.

**Abstract: Objective:** To investigate potential interactions between microglial activation and amyloid-β in the brain using positron emission tomography (PET) in Parkinson's disease (PD) with normal and impaired cognitive function. **Background:** Microglia, activated due to neuroinflammation, may play an important role in disease development and progression. A more rapid cognitive decline has been linked to higher amounts of beta-amyloid. Amyloid- β may promote microglial activation and further disease progression. **Methods:** We included 17 PD patients, 11 PD patients with mild cognitive impairment (MCI) and 11 healthy controls (HCs) to assess the impact of amyloid-β in the brain with [$^{11}$C] Pittsburgh compound B (PIB) on microglial activation using the translocator protein 18-kDa (TSPO) radioligand [$^{18}$F]-FEPPA. PIB distribution volume ratio (DVR) was measured in cortical and subcortical regions. A DVR of 1.2 was set to divide each brain region into PIB-positive or PIB-negative. FEPPA total distribution volume ($V_T$) values were compared for each brain region to evaluate the effect of PIB positivity while adjusting for TSPO rs6971 polymorphism (which is implicated in differential binding affinity). **Results:** Preliminary analyzes revealed a significant main effect of PIB positivity in the striatum ($F_{(2, 32)}$= 5.9, p = 0.006). Besides the striatum (p=.019), the dorsolateral (p=.012) and prefrontal cortex (p=.002) as well as the temporal (p=.004) and frontal lobe (p=.006) showed a significant interaction effect. In these regions, the PD-MCI group had significantly higher FEPPA $V_T$ if PIB-positive. In the frontal lobe, this difference was also seen in the PD group (p=.011). Further, PIB-positive PD-MCI patients showed significantly higher FEPPA $V_T$ than PIB-positive HCs in the striatum (p=.019), temporal (p=.012) and frontal lobe (p=.031) as well as significantly higher $V_T$ than PIB-positive PDs in the striatum (p=.028), prefrontal cortex (p=.004) and temporal lobe (p=.011). **Conclusions:** Our results indicate an interaction between amyloid-β and microglial activation in PD. Further investigations are necessary to evaluate if microglia activation affects disease progression or develops as a protective response.

**Title:** Hemispheric-specific neuropsychological tests in stage I early-onset Parkinson's disease (EOPD) as a predictor for disease progression

**Authors:** *K. M. LE[1], ***K. M. LE**[1], B. MULLEN[1], K. VENKITESWARAN[1], M. SUBRAMANIAN[1], S. RAVI[2], D. WAGNER[1], S. SWAMINATHAN[1], K. ANANTHAKRISHNAN[1], M. IBRAHIMI[1], J.-L. WANG[1], P. ESLINGER[1], T. SUBRAMANIAN[1]
[1]Neurol., Penn State Col. of Med., Hershey, PA; [2]Neurol. and Neural and Behavioral Sci., Pennsylvania State Univ. Col. of Med., Hershey, PA

**Abstract:** Idiopathic Parkinson's disease (PD) begins in vast majority of patients with unilateral symptoms (Hoehn Yahr Stage I). There is a latent period of an average of 5 years before such patients advance to stage II disease (bilateral Parkinsonism). Most stage I disease patients do not have any evidence of cognitive decline in routine standardized tests. However, sophisticated neuropsychological testing has reviewed subclinical mild deficits. We tested whether hemispheric-weighted neuropsychological tests can differentiate between stage I PD versus stage II PD and predict disease progression. We enrolled 54 subjects in stage I EOPD (age >40 and <60), who are left hemisphere dominant on language functions, verified by right-handedness (Edinburgh handedness scale >0.7), not moderately depressed (BDI-II < 23), and who lack signs of mild cognitive impairment (MOCA >26). The standard mental rotation test(MRT) was administered along with a verbal fluency (VF), mirror tracing, California verbal learning test, tactile performance test, picture vocabulary (PV), design fluency, and visual reproduction every 3-6 months until they reach stage II of the disease as clinically defined by the UPDRS motor sub-scores of bilateral definitive presence of tremor, bradykinesia and rigidity. Most subjects were medication naïve at their first visit and had an overnight drug washout in the practically defined (off) period for their UPDRS assessments. Our results show that there was a distinct difference in MRT score between male and female subjects as suspected from the literature ($p=0.041$). However in both sexes the MRT score were lower than historical controls' data. In right-handed EOPD men with disease onset on the left side of the body , MRT scores were substantially lower than in EOPD male subjects who had symptom onset on the right side of the body ($p=0.064$). Further, upon repeated testing, subjects who developed symptoms in the postural instability and gait domains on the UPDRS part-III had lower MRT scores in both sexes, regardless of the body side of motor symptoms. Dopaminergic treatment did not influence MRT scores. In the PV task, male right onset and left onset did not exhibit a difference in test scores.

However, female right onset did worse than their left onset cohort (p = 0.131). In the DF task, there was no notable difference between the two cohorts for the first 2 conditions, however in the third condition, both female and male left onset subjects did worse than their right onset counterparts (p =0.141 male, p = 0.113 female). These findings suggest that these hemisphere-weighted tests can be a powerful predictor of disease progression in EOPD.

**Title:** Handwriting and effector independence in individuals with Parkinson's disease

**Authors: D. L. OLIVEIRA**, R. GIMENEZ, R. B. S. C. GARBUS, C. C. G. ALONSO, R. C. MARINHO, S. M. S. F. FREITAS, *R. S. PIRES
Univ. Cidade De São Paulo, Sao Paulo, Brazil

**Abstract:** Parkinson's disease (PD) is a neurodegenerative disorder that promotes tremor, rigidity, bradykinesia, postural instability and micrographia. Micrographia has recently contributed to the diagnosis of the disease. However, the mechanisms underlying micrographia remain to be investigated. Therefore, our aim was to investigate handwriting through the effector independence of individuals with PD. A cross-sectional study was carried out with PD individuals (n = 14, 9 females and 5 males, aged 52 to 82 years) in Hoehn and Yahr stages I to III with micrographia identified by Unified Parkinson's Disease Assessment Scale (UPDRS, item 8), right-handed, according to the Edinburgh inventory. Participants in the control group (n = 14) were matched with respect to gender and age. The individuals wrote the letter "l" 8 times (8 loops) with the right and left hands, with the normal and altered grips. Five trials were performed in each condition and the order was randomized across condition. The experiments and data analyzes were made with a digitizing table, a computer and "Movalyzer Neuroscript" program. The sampling rate was 100 Hz. The “x” and “y” coordinate data were filtered using the low-pass Fourier Fast Transform (FFT) filter of 12 Hz. The unit of analysis was the stroke (segment between two points characterized by crossing zero at velocity). We performed analysis of variance (ANOVA) for repeated measures for comparison between different effectors and groups, involving the following dependent variables: absolute size and absolute mean velocity. Post-hoc analyzes with Bonferroni adjustment were used when appropriate. The alpha value was maintained at 0.05. Our data revealed that PD individuals had the absolute size smaller than the

control group in all task conditions, hand [F (1; 26) = 6.102, p = 0.020, ηp² = 0.190], grip [F (1 ; 26) = 9602, p = 0.005, ηp² = 0.270] and group [F (1; 26) = 4.099 p = 0.05, ηp² = 0.136]. In relation to the absolute mean velocity, PD individuals were slower than the control group [F (1; 26) = 4,742 p = 0.04, ηp² = 0.154], characterizing bradykinesia. Thus, our data revealed that micrographia is present in PD individuals, independently of the effector used, suggesting that the disfunction is more associated with central control (central nervous system) than peripheral components (muscle rigidity).

Hospital, Linkou Med. Ctr., Tao-Yuan, Taiwan; [6]Dept. of Physical Therapy, Col. of Hlth. Sci., Kaohsiung Med. Univ., Kaohsiung, Taiwan; [7]Dept. of Physical Med. and Rehabil., Kaohsiung Med. Univ. Hosp., Kaohsiun, Taiwan

**Abstract:** Reduced locomotion automatization is one of the important sign for Basal Ganglia disorder which could explain the Freezing of gait (FOG) for people with Parkinson Disease (PD). In early stage of PD, the de-automatization might be compensated by switching the level of cognitive control for non-freezing patients. This study hypothesized that de-automatization could be detected in early stage non-freezing PD patients in dual task condition while the cognitive resource is competed. Methods: Sixteen individuals with diagnosed PD and 15 healthy controls were recruited. The subjects in PD group were non-freezers with the Modified Hoehn & Yahr between 1 to 2.5. Subjects walked in an instrumented pressure mat at a self-select speed in both single and dual task conditions. In the dual task walking test, a calculation dual task was

provided during walking. The gait speed, step length and the cognitive performance (accuracy, and reaction time) were analyzed for both single and dual task conditions. Results: In terms of cognitive performance, the composite score of accuracy and reaction time were lower in PD group than in control group only during the dual task condition (p=.018). In terms of gait performance, the PD group showed slower gait speed and shorter step length during both single and dual task conditions (p,.05). Conclusion: The cognitive performance in the dual task condition could be an indicator of de-automatization in early stage of PD before FOG developed. Factors other than de-automatization, such as poor balance and postural control, could also explain the decreased gait performance in non-freezing PD patients.

**Title:** Biophysical properties of the hyperdirect pathway necessary to match clinical cortical evoked potentials from subthalamic deep brain stimulation

**Authors: *K. GUNALAN**, C. C. MCINTYRE
Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

**Abstract:** Deep brain stimulation (DBS) of the subthalamic region is an established clinical therapy for the treatment of late stage Parkinson’s disease. Direct stimulation of the hyperdirect pathway, which consists of a special subset of corticofugal axons originating from layer V pyramidal neurons that send an axon collateral to the subthalamic nucleus (STN), has been extensively linked to therapeutic benefit in experimental studies. One experimental measurement used to evaluate hyperdirect activation is the recording of cortical evoked potentials generated by subthalamic DBS. In humans, these evoked potentials have a very fast component (R1) that

occurs ~1 ms after the stimulus pulse, as well as a slower component (R2) that reaches its peak in ~5 ms. R1 is typically assumed to arise from antidromic invasion of the hyperdirect layer V pyramidal neurons, while R2 is assumed to arise from intracortical synaptic activity. To address these assumptions, we used a detailed patient-specific DBS model of hyperdirect pathway activation. We reconstructed the hyperdirect pathway using tractography from diffusion-weighted images. Each of the 1000 streamlines were then modeled as a multi-compartment cable structure. The voltage distribution generated by the DBS electrode was calculated using a finite element method, this voltage distribution was used to stimulate the model axons, and the response of the axons to DBS was quantified. The model system allowed us to evaluate conduction times from activation of the hyperdirect collaterals in the STN to arrival of the action potentials in cortex. We compared the conduction times for small (5.7 μm), medium (10.0 μm), and large (15.0 μm) diameter corticofugal axons. Only the 15.0 μm models could generate a R1 that coincided with clinical measurements of ~1 ms, but histological measurements suggest that axons of that size are extremely rare in the internal capsule. Given the expected diameter distribution of the hyperdirect pathway, R1 and R2 may actually represent a combined continuum of antidromic invasion of cortex, where the experimentally recorded waveform is the result of interacting field potentials generated by neurons with small, medium, and large diameter axons.

**Title:** Differences in neural activity during motor imagery in people with Parkinson disease with and without freezing of gait

**Authors: *P. S. MYERS**, M. E. MCNEELY, G. M. EARHART
Program in Physical Therapy, Washington Univ. Sch. of Med., Saint Louis, MO

**Abstract: Background:** Gait is impaired in people with PD, especially those with freezing of gait (FoG), and exercise improves gait speed. Neural mechanisms behind exercise-induced gait benefits remain unclear in PD with (FoG+) and without (FoG-) FoG. Motor imagery (MI) and motor execution neural networks overlap, and MI has been used with neuroimaging to understand mechanisms contributing to motor behaviors. Activity in the cerebellum (CBLM) may differentiate FoG+ and FoG- given differences in connectivity with other brain regions. Motor regions such as primary motor (M1) and premotor (PMC) cortices may also differentially change with exercise in FoG+ and FoG-.
**Methods:** We examined neural activity during MI before (pre) and after (post) an exercise program. Participants underwent pre and post MRI scans and motor (MDS-UPDRS-III) and gait testing "off" medication. Functional scans had 4 tasks intermixed: MI of forward gait (MI-FWD), MI of backward gait (MI-BWD), MI of standing (MI-SD), and rest. Participants walked across a GAITRite mat FWD and BWD to assess gait speed. Self-reported freezing was used to separate FoG+ (n=14) and FoG- (n=27). MRI data were processed with BrainVoyager QX. Regions of interest were traced by hand for bilateral CBLM, M1, and PMC. We extracted beta weights for each task from each region and normalized to rest. Pre and post gait speed ($\alpha<.05$) and beta weights (Bonferroni corrected $\alpha<.012$) were compared with RM-ANOVAs.
**Results:** FWD ($p=.035$) and BWD ($p<.001$) gait speed increased from pre to post. FWD was always faster than BWD ($p<.001$), and BWD increased more than FWD speed ($p=.004$). For the CBLM, M1, and PMC, MI-SD had lower activity compared to MI-FWD and MI-BWD ($p\leq.003$) at pre and post. There were no significant effects of group, time, nor interactions in any of the three regions of interest.
**Conclusions:** Despite similar responses to exercise for gait, neural activity did not change with exercise in FoG+ and FoG- in any of our selected regions of interest. Neural activity also did not differ between FoG+ and FoG-. The significant differences seen between the three imagined conditions may suggest that MI of static tasks such as standing do not recruit motor imagery networks in the same way as MI of dynamic tasks such as walking. Future analyses will examine more targeted cerebellar regions. This will provide an in depth look at neural activity within the cerebellum between static and dynamic MI tasks as well as in response to exercise.

Ctr., Ramat Gan, Israel; [4]Neurol., Hippokration Hosp., Thessaloniki, Greece; [5]Dept. of Occup. Therapy, Univ. of Haifa, Haifa, Israel; [6]3rd Dept. of Neurol., Univ. of Thessaloniki, Thessaloniki, Greece

**Abstract:** *Background:* Motor and non-motor symptoms of people with various types of disabilities affect their ability to use computers. Although they consider the use of computers as an important part of their everyday life, they face many operational difficulties. *Objective:* The purpose of the study was to evaluate the importance of computer use as perceived by patients with Parkinson's disease (PD) and Spinal Cord Injury (SCI), as well as by their caregivers. *Design/Methods:* Fifty PD individuals, (mean age: 59.1±8.05 years) and eighteen SCI patients (mean age: 45.4± 15.5 years) were included in the study. Patients' working habits with the computer were explored by means of a structured interview. Using the most pertinent data from this interview we designed a quantitative scale, focused on the contribution of the computer to various aspects of social life (CCSL). The questionnaire consisted of nine items, each scoring from 1 (not important) to 5 (very important). Then, twenty PD caregivers and fourteen SCI caregivers were interviewed using the same questionnaire as the patients, adapted for completion by proxy. *Statistical Analysis:* Reliability of the CCSL scale was assessed by means of Cronbach's alpha coefficient. Caregivers' scale scores were compared to those of their patients by means of the t test for independent samples. *Results:* A mean 13.6±9.1 and 20.5±9.1 years of computer experience, and a mean daily use of 3.9±2.4 and 5±3.4 hours, were reported for PD and SCI patients respectively. As for reliability analysis for the scale, Cronbach's alpha was 0.76 and 0.85 and item to total score correlations ranged from 0.224 to 0.649, and from 0.17 to 0.8 for PD and SCI CCSL scales, respectively. The mean (± SD) CCSL scale total score was 22.7±6.9 and 23.11±8.4 for PD and SCI patients, respectively. Single items that scored high for all were relevant to 'education' and 'work and employment'. PD patients also showed a high 'interpersonal interaction' score while SCI patients showed a high 'autonomy and self-determination' score. Caregivers' mean scores on the CCSL scale were similar to those of the patients (PD: *p=0.324*, *SCI: p=0.9*). *Conclusions:* Our preliminary results show that PD and SCI patients, and their caregivers, regard computer use as an important tool for a productive life. This information is important for the development of innovating technologies that may assist patients to overcome specific operational difficulties.

**Abstract:** Neurotrophic factors as potential candidates for ALS therapeutics have previously been studied in the context of attempts to slow disease progression but for a variety of reasons, failed to show adequate efficacy in ALS patients. Previous studies in Parkinson's Disease (PD) models have shown promise with the use of recombinant adeno-associated virus serotype-2 (rAAV2)-neurturin (NRTN) [AAV2-NRTN] to provide neuroprotection and behavioral improvements in preclinical models which subsequently resulted in several clinical studies in patients with PD. Given that this neurotrophic compound has not been studied in the context of ALS, nor has this been combined with this focal gene therapy approach for the directed delivery of AAV2-NRTN into the cervical spinal cord, we conducted a study of AAV2-NRTN to assess the preclinical safety, tolerability, biodistribution, and efficacy of this compound in a preclinical ALS mouse model. $SOD1^{G93A}$ mice were tested in four large cohorts (n=22-25): AAV2-NRTN ($1.44x10^{11}$ vg/animal, "high dose"); AAV2-NRTN ($3.6x10^{10}$ vg/animal, "low dose"); formulation buffer (FB) vehicle control; naïve $SOD1^{G93A}$ control littermates. Behavioral grip strength testing was performed twice weekly until end stage of the disease. Immunohistochemical analyses were performed to look for variations in motor neuron (MN) numbers. Behavioral analyses showed a trend towards a more gradual weakening of the forelimb strength during disease course in both "high" and "low" dose animals when compared with both FB and naïve control animals. However, this did not translate to an extension in overall survival. There was a neuroprotective effect on the number of cervical MNs during the symptomatic phase of disease in both AAV2-NRTN animal groups, but by end stage, MN numbers in the cervical

region were not significantly different between the two dosing groups. This suggests that there is evidence for neuroprotection stemming from the targeting of neurturin to cervical MNs. As expected, this neuroprotection was found to be focal and did not spread beyond the immediate region of injection. Overall, there were no increases in morbidity, no changes in serum chemistries or blood counts and no cases of drug-related mortality. These data combined suggest that AAV2-NRTN is well tolerated in SOD1$^{G93A}$ mice, is able to be effectively expressed in cervical spinal MNs, has a focal biodistribution in the spinal cord, is not found outside of the target area, and shows neuroprotection and behavioral efficacy during the symptomatic phase of disease. Because there is a broad clinical experience for this compound, these data provide further evidence to support its study in ALS patients.

**Abstract:** Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease that causes degeneration of motor neurons of the spinal cord and cortex. To fully understand the molecular mechanisms that establish selective vulnerability of these cells in ALS, we must determine how the disease progresses in these cells relative to other unaffected cell types. To accomplish this, our group has profiled gene expression changes in a vulnerable spinal-projecting population and a non-vulnerable pyramidal neuron population during disease progression in the cortex of the SOD1-G93A mouse model of familial ALS. By expressing a GFP-tagged ribosomal subunit specifically in each cell type, we isolated actively translated mRNAs from our cells of interest using Translating Ribosome Affinity Purification (TRAP). We compared cell type specific gene expression profiles between wild-type (WT) and SOD1-G93A mice to understand disease mechanisms by identifying molecular pathways that were up- or down-regulated in the two cell-types. Additionally, we compared the baseline gene expression profiles of the two cell types in WT mice to determine what makes the two cell-types inherently different. When these data were combined, we found that vulnerable spinal-projecting neurons show gene expression changes more typically associated with degenerating neurons, whereas non-vulnerable neurons display contrasting changes that could underlie mechanisms of resistance to SOD1-G93A. To determine if our mouse pyramidal neuron populations and the gene expression changes we observe in them are representative of human motor cortex and ALS, we identified markers for both neuronal types that are shared across mouse and human. Staining human tissue for these markers alongside proteins that are altered in SOD1-G93A mice allows us to establish the disease-relevance of our TRAP findings. We have established an approach for studying molecular changes that occur in vulnerable cells during disease by taking into account the underlying unique biological characteristics of those cells. This approach will allow us to understand how neurodegenerative diseases differentially affect specific neuron populations.

**Title:** Investigating the role of amyloid precursor like protein-2 in motor neuron disease

**Authors: *P. H. TRUONG**, G. D. CICCOTOSTO, P. J. CROUCH, R. CAPPAI
Dept. of Pathology, The Univ. of Melbourne, Melbourne, Australia

**Abstract:** Motor neuron disease (MND), the most common form of which is amyotrophic lateral sclerosis, is a human neurodegenerative disorder characterized by progressive destruction of motor neurons in the central nervous system, muscle atrophy, paralysis and ultimately death. Although the majority of MND cases are of sporadic origin, 10-15% of MND cases are familial, commonly involving the genetic mutations in the Cu/Zn superoxide dismutase (SOD1) gene. Transgenic mouse models over-expressing the human mutant forms of SOD1 that recapitulate the pathological symptoms seen in MND patients are widely used to study MND. Despite intensive research to understand the molecular mechanisms of this disease, the cause and modulation of MND remains unclear. The Amyloid Precursor Protein (APP) is highly expressed in the brain and its expression is increased in the mutant SOD1 transgenic mouse model and in MND patients (Koistinen et al., 2006). Deletion of the APP gene in a transgenic SOD1 mouse model significantly slowed disease progression (Bryson et al., 2012). This suggests targeting APP protein expression could modulate disease outcomes in MND. APP is part of a gene family that includes the amyloid precursor-like protein 1 (APLP1) and amyloid precursor-like protein 2 (APLP2) genes. We have investigated the role of APLP2 in MND. Expression studies found a significant increase in the expression of APLP2 protein in brain of the $SOD1^{G37R}$ transgenic mouse model. To characterize how APLP2 gene expression can modulate disease outcomes in MND we crossed the $SOD1^{G37R}$ mouse with APLP2 knockout mouse model to generate $SOD1^{G37R}$ $APLP2^{+/-}$ and $SOD1^{G37R}$ $APLP2^{-/-}$ lines. Female $SOD1^{G37R}$ $APLP2^{+/-}$ mice exhibited a significantly reduced life span, an earlier onset and accelerated progression of disease, as compared to $SOD1^{G37R}$ $APLP2^{+/+}$ mice. By contrast, female $SOD1^{G37R}$ $APLP2^{-/-}$ mice had a significantly delayed disease progression and improved survival. Taken together, our results demonstrate there are gender related differences in the SOD1 mouse model, and this is affected by APLP2 expression. These data add further support for a modulatory role by the amyloid precursor protein family in MND, and identify the APP-family as an important target for further investigation into the cause and regulation of MND.

**Title:** Characterization of transgenic mice expressing ALS-associated CHCHD10-R15L

**Authors: *É. RYAN**[1], J. YAN[2], H.-X. DENG[2], T. SIDDIQUE[2]
[2]The Ken & Ruth Davee Dept. of Neurol., [1]Northwestern Univ., Chicago, IL

**Abstract:** Coiled-Coil-Helix-Coiled-Coil-Helix Domain Containing 10 (CHCHD10) is a nuclear gene that encodes for a protein of unknown function that is enriched in mitochondria. We, and others, have identified mutations in CHCHD10 in a variety of degenerative diseases including, but not limited to, amyotrophic lateral sclerosis (ALS) and mitochondrial myopathy. Using the approach of whole exome sequencing, we identified an R15L missense mutation in CHCHD10 in individuals from a large, multi-generational familial ALS pedigree. The mutation was subsequently identified in four additional families. In an effort to better understand the pathogenic mechanism of this mutation, we engineered transgenic mouse models expressing either the wild type or mutant variants of human CHCHD10. Pathological, biochemical and behavioral characterization of these mouse lines has provided insight into the possible disease processes involved. Severe axonal pathology is apparent in a diverse range of neurons throughout the central nervous system in CHCHD10-R15L transgenic mice. The pathology is first evident around 60 days of age, yet the mice survive well beyond this. Although the CHCHD10-R15L transgenic mice have an abbreviated lifespan compared to controls, they perform comparably in motor behavior tasks up to the point of death. The cause of death is currently under investigation. Preliminary biochemical studies indicate that this mutation does not impair targeting of CHCHD10 protein to mitochondria or the efficiency of action of the electron transport chain. This novel mouse model supports the hypothesis that the R15L mutation impacts upon normal central nervous system functioning, as evident by the presence of axonal pathology. The mechanism by which the pathology manifests a behavioral deficit requires further investigation.

**Title:** Differential onset of behavioral and electrophysiological symptoms in the rNLS8 (hTDP-43ΔNLS) mouse model of TDP-43 pathology

**Authors: *P. T. LEACH**[1], M. SHPOKAYTE[2], A. SHEEHY[2], B. J. FARLEY[2], J. AMACKER[2], A. MCCAMPBELL[2], H. M. ARNOLD[2]
[1]Neurol., [2]Neurol. Res., Biogen, Cambridge, MA

**Abstract:** While specific mutations in TDP-43 (transactive response DNA binding protein 43 kDa, TARDBP) only account for 3-5% of ALS patients, TDP-43 pathology is present in the majority of ALS and FTD patients. Nearly all (97%) of Amyotrophic Lateral Sclerosis (ALS) patients exhibit ubiquinated cytoplasmic TDP-43 inclusions, despite this protein's typical nuclear localization, and nearly half (45%) of frontotemporal dementia (FTD) patients exhibit a similar TDP-43 pathology. Thus, a better understanding of this protein and its related pathology is critical to ALS research. The rNLS8 mouse model of TDP-43 pathology conditionally expresses a mutated version of hTDP-43 that lacks the nuclear location signal (ΔNLS), causing a reduction in endogenous mTDP-43 in the nucleus and instead forms cytoplasmic inclusions of hTDP-43 similar to those observed in human ALS patients. This mouse model has previously been shown to exhibit striking deficits in rotarod performance and an increased prevalence of hind-limb clasping, along with deficits in compound muscle action potential (CMAP) assessed in the gastrocnemius muscle. In the current study we confirmed these behavioral phenotypes and extended them to other behavioral and electrophysiological endpoints. Within five days of the initiation of the conditional expression of hTDP-43ΔNLS, rotarod deficits were evident, while a hind limb clasping response did not emerge until much later, about two weeks after onset of the disease model. We observed CMAP deficits in the tibialis anterior muscle, which supports the previous findings in the gastrocnemius muscle, but this deficit did not appear until three weeks after the onset of the disease model. Despite the dramatically decreased rotarod performance, these mice were observed to be hyperactive in an open field starting around 2 weeks, and remained so for up to 5 weeks, following the onset of abnormal gene expression. To our knowledge, this is the first time that hyperactivity has been reported in the rNLS8 TDP-43 mouse model of ALS, and it seems to be in contrast to the loss of coordination observed in the rotarod test. This finding is reminiscent of the long-standing debate in the ALS research field over whether physical activity is positively correlated with an increase in the risk of developing ALS symptoms. More research is needed to demonstrate if there is a causal relationship to this effect.

**Title:** Spinal muscular atrophy with respiratory distress: New CRISPR-based models and the search for a genetic modifier of disease

**Authors: *P. MARTIN**, A. H. HICKS, J. E. STAUFFER, D. G. SCHROEDER, G. A. COX
Cox Lab., Jackson Lab., Bar Harbor, ME

**Abstract:** Spinal Muscular Atrophy with Respiratory Distress (SMARD1) is a lethal autosomal recessive infantile disease, characterized by the loss of motor neurons leading to muscular atrophy, weakness of the truck and limbs and diaphragmatic weakness. Mutations in a DNA/RNA 5' to 3' helicase, *Ighmbp2*, have been shown to cause SMARD1 and more recently Charcot-Marie-Tooth disease (CMT), a less severe disease characterized by progressive motor and sensory polyneuropathy. Currently there is only one mouse model to study mutations in *Ighmbp2*, the neuromuscular degeneration ($nmd^{2J}$) mouse, which carries a hypomorphic splicing mutation which reduces wild-type protein expression. A genetic modifier region from CAST/EiJ ($Mnm^{C}$) has been mapped to Chromosome 13 and found to suppress the disease. This region contains one protein-coding gene *Zfp322a* as well as a number of tRNAs. We have created new *Ighmbp2* mutant alleles, through the use of CRISPR-CAS9 technologies, that display significant phenotypic variation relative to the $nmd^{2J}$ allele. Characterization of these models has identified two very severe models that fail to survive more than a day or two after birth, one early-onset model that typically lives 2-3 weeks and one mild disease model that may more closely resemble CMT. Not only do these mice have a reduction in lifespan, but they also have a significant reduction in motor neurons as well as increase muscular atrophy. Our characterization of these new models suggest that they recapitulate the phenotypic variation seen in the human patients and can aid in understanding the endogenous functions of *Ighmbp2*. We also aim to identify what specifically in the CAST-derived congenic modifier region ($Mnm^{C}$) is driving suppression by utilizing a CRISPR strategy to knock out each gene in turn to determine which are responsible for modulating disease severity. Our preliminary evidence suggests that *Zfp322a* null mice are viable as homozygotes and we are crossing them with our $nmd^{2J}$ mice to determine if the modifier region still suppresses disease. By identifying the modifier, we may indicate which cellular pathways *Ighmbp2* works in. The creation and characterization of these novel alleles and interrogation of the $Mnm^{C}$ region, broadens our knowledge of the function of *Ighmbp2* in the motor neurons and may allow us to identify potential therapeutic strategies.

**Abstract:** Mutations in the nuclear matrix protein Matrin 3 are associated with amyotrophic lateral sclerosis (ALS) and distal myopathy with vocal cord and pharyngeal weakness. Previously, we generated and characterized transgenic mice expressing wild-type human Matrin 3 under the mouse prion promoter (PrP-$^{WT}$MATR3). These mice develop a phenotype of hindlimb paresis or paralysis with hindlimb and forelimb muscle atrophy. Pathological analysis of the gastrocnemius and bicep of phenotypic mice showed a striking presence of vacuoles, nuclear chains, rounded fibers, and an increase in Matrin 3 immunoreactive internal nuclei in the fibers. Upon further analysis, we found that both distal and proximal muscles of the hindlimb (soleus, tibialis anterior, and quadriceps) and forelimb muscles (triceps and extensor carpi radialis) show similar pathology including vacuoles and rounded fibers. Although there appeared to be no increase in Matrin 3 protein levels in the spinal cord of the PrP-$^{WT}$MATR3 mice, spinal cords of phenotypic mice showed increased gliosis and individual neurons appeared to have higher MATR3 levels and/or with cytoplasmic immunostaining of Matrin 3. We have now generated equivalent PrP-MATR3 mice that express the F115C mutant Matrin associated with ALS (PrP-$^{F115C}$MATR3). By two months of age, most PrP-$^{F115C}$MATR3 mice develop similar muscle pathology to the PrP-$^{WT}$MATR3 mice, including the robust presence of vacuoles; however, only a few PrP-$^{F115C}$MATR3 mice with this pathology develop motor dysfunction. These data indicate that the muscular pathology, per se, is not directly causative for the motor

phenotype and suggests that defects in the spinal cord or neuromuscular junction are more likely the source of the motor phenotype. These potential deficits are currently being assessed in both PrP-$^{WT}$MATR3 and mutant PrP-$^{F115C}$MATR3 transgenic mice. Understanding the origin of the phenotype disparity across these mouse lines may provide insight on disease mechanism and/or the normal role of Matrin 3.

**Title:** TRPV4-mediated motor impairment, aberrant calcium signaling, and disrupted mitochondrial axonal transport in a *Drosophila* model of CMT2C

**Authors: *B. WOOLUMS**[1], M. TABUCHI[2], H. SUNG[2], J. M. SULLIVAN[2], B. MCCRAY[2], C. MAMAH[2], M. YANG[2], M. N. WU[2], C. J. SUMNER[2], T. E. LLOYD[2]

**Abstract:** Dominant missense mutations in the gene encoding the cation channel transient receptor *vanilloid*, family member 4 (TRPV4) cause inherited neuropathies including Charcot-Marie-Tooth disease 2C (CMT2C). *in vitro*, mutations in TRPV4 that cause CMT2C cause a gain of TRPV4 channel function and increased intracellular calcium which subsequently leads to cellular toxicity. However, the mechanisms by which CMT2C mutations in TRPV4 lead to neuronal dysfunction *in vivo* remain poorly understood. We generated transgenic *Drosophila* that express either wild-type or a CMT2C causing TRPV4 mutant (TRPV4$^{R269C}$) to assess the effect of TRPV4$^{R269C}$ on neuron function *in vivo.* Selective expression of TRPV4$^{R269C}$ in *Drosophila* CCAP neurons ($N_{CCAP}$) results in a failure of *Drosophila* wing expansion that is blocked by genetically inactivating the channel pore, demonstrating the requirement of channel function in mediating this phenotype. Perforated patch clamp analysis of $N_{CCAP}$ reveals that TRPV4$^{R269C}$ causes a calcium-dependent increase in $N_{CCAP}$ neuronal excitability. This hyperexcitability is restored to control levels by application of a TRPV4 selective antagonist. High level expression of TRPV4$^{R269C}$ causes synaptic and dendritic degeneration, both of which are rescued genetically by inactivating the channel pore or pharmacologically by feeding larvae a TRPV4 selective antagonist. We conducted a genetic screen in $N_{CCAP}$ and found that CaMKII knockdown potently

suppresses the TRPV4$^{R269C}$ mediated wing expansion phenotype and selectively rescues degeneration of synapses but not dendrites. We also find that TRPV4$^{R269C}$, but not controls, disrupts mitochondrial transport in axons by increasing the number of stationary mitochondria. We have also found that induction of TRPV4$^{R269C}$ expression after eclosion causes progressive motor impairment, suggesting TRPV4$^{R269C}$ can cause a progressive neuropathy that is independent of any developmental processes TRPV4$^{R269C}$ may disrupt. Our data demonstrate that TRPV4$^{R269C}$ causes a progressive neuropathy in our *Drosophila* model of CMT2C likely through elevated neuronal intracellular calcium which disrupts mitochondrial transport and mediates neurodegeneration through compartment-specific calcium-mediated signaling pathways. These findings support further investigation of TRPV4 antagonists as potential therapeutics for the treatment of CMT2C.

**Abstract:** A GGGGCC hexanucleotide repeat expansion (G4C2 HRE) in an intron of the C9orf72 gene has been identified as the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). One of the pathological hallmarks of C9-ALS is the presence of cytoplasmic protein aggregates colocalized with the autophagy receptor

p62/SQSTM1. Interestingly, mutations in p62/SQSTM1 are also a rare genetic cause of ALS through an unclear mechanism. In a Drosophila model of C9-ALS expressing $(G4C2)_{30}$, we have found that p62 is upregulated and forms large aggregates in motor neurons. p62 plays a key role in autophagy by binding ubiquitinated proteins and delivering them to the autophagosome for degradation via the lysosome. Surprisingly, we find that knockdown of p62 rescues degeneration in the fly eye and in motor neurons. Immunofluorescence and western blot analysis of autophagy and lysosome markers demonstrates an expansion of lysosomes and a decrease of delivery to and digestion of autophagic cargo in the lysosome. Using electron microscopy of the *Drosophila* eye we observe a remarkable accumulation of expanded multilamellar bodies and autolysosomes that precedes neurodegeneration. Because we have also found that nucleocytoplasmic transport is disrupted in $(G4C2)_{30}$ flies, we are investigating the relationship between defects in protein degradation and nucleocytoplasmic transport disruption. We propose that C9orf72-HRE expression causes dysregulation of protein folding and degradation leading to cytotoxic protein aggregation, and that this is rescued by aggregate clearance through genetic and pharmacological upregulation of chaperones, autophagy, and the ubiquitin-proteasome system. This study suggests that drugs targeting proteostasis pathways may have therapeutic potential for C9orf72-mediated ALS and FTD.

**Abstract:** Ubiquilin2 belongs to ubiquitin like protein family and regulates protein degradation through ubiquitin proteasome system (UPS). Mutations impair protein degradation and lead to abnormal protein aggregations and neuronal loses. The $UBQLN^{P497H}$ transgenic mice developed

neuronal pathology, characterized by ubiquilin2/ubiquitin/P62 positive inclusions in the brain. Mutant ubiquilin2 impairs proteasome function by a gain of function mechanism yet to be determined. Methods: Use CRISPR/Cas9 system to introduce mouse P511H mutation which is equivalent to human P497H mutation into mouse genome. Mice tissues were collected undergo pathological analysis. Results: We established three different mice strains: ubiquilin2 KI mouse introduced P511H/human P497H mutant; the in-frame deletion of mouse I512-V552/human I498-V538 which removed PXX domain ranging from P491-G526; and 1bp deletion resulted a truncated protein I498Mfs*7 with no PXX and UBA domain. The founders were 11 months old with no obvious motor phenotypes. Three $100^{\pm}$-day old progenies from ubiquilin2 KI mice tissues were underwent pathological analysis. The hippocampus region displayed small ubiquilin2 positive aggregates with similar pattern as the reported ubiquilin2 transgenic mice, but were much less extensive. Other regions of brain showed similar staining pattern. The ubiquilin2 positive aggregates were also positive for P62, but not ubiquitin. Antibodies against 26s proteasome subunits, 19s regulatory particle (ADRM1) and 20s enzymatic core particle (PSMA3), were positive. The KI transgenic mice expressed mouse ubiquilin2 protein at comparable level as the non-transgenic mouse detected by Western blot. Discussion/conclusions: The milder pathological changes in the KI mouse models may be caused by lower protein level associated with CRISPR/Cas9 system, but may better mimic human condition than the old system. Further studies with the other two mice strains with deletion of PXX and UBA domains shall provide more insight into the mechanism of neuropathy. Furthermore introduce a UBL point mutation to abolish proteasome binding domain will narrow the proteasome dysfunction into precise functional domain.

**Abstract:** Non-motor neuron-related pathology is a feature of amyotrophic lateral sclerosis (ALS), both in patients and in animal models. There is emerging evidence that sensory systems, i.e. olfaction and vision, are affected in humans. Here we asked whether such sensory neuropathology is recapitulated in the superoxide dismutase 1 (SOD1-G93A) mouse model of ALS. Human SOD1-related vacuolization as pathology marker was assessed in olfaction and vision pathways from pre-symptomatic and symptomatic disease stages using immunohistochemistry, and compared to wild type. In both, the olfactory bulb and retina, vacuolization started around postnatal day 60, and vacuole sizes increased until disease end-stage. Notably, vacuolization was largely restricted to the external plexiform layer of the olfactory bulb and to the inner plexiform layer of the retina. In both layers, hSOD1-immunoreactive vacuoles localized to dendrites of excitatory neurons. Downstream olfaction and vision pathway fiber tracts and relay stations did not display obvious vacuolization. Finally, on a morphological level, there was no evidence for an activation of astrocytes and microglia in the two affected areas. Thus, we identified a new pathology hallmark in SOD1-G93A ALS mice, i.e. a glutamatergic sensory neuron dendropathy restricted to olfactory bulb mitral cells and retinal ganglionic cells.

**Abstract:** A hexanucleotide repeat expansion in the C9orf72 gene has been shown to be the most frequent cause of ALS. Neurotoxicity is believed to be mediated by either (or a combination of) RNA toxicity, DPR toxicity or loss of function of the C9orf72 protein. The aim of this study was to develop an *in vivo* zebrafish model to investigate these mechanisms, and more specifically to disentangle RNA toxicity and DPR toxicity. Injection of repeat RNA as well as some DPR constructs (in particular GR and PR) into zebrafish oocytes induced a motor neuronal phenotype at 30 hours post fertilization. Using dot blot, Western blot and ELISA, generation of significant amounts of DPRs in fish injected with repeat RNA was excluded. Moreover, synergistic toxicity between low (not toxic) levels of the different DPRs was excluded. Additionally, interrupted repeat RNA constructs which are unable to generate DPRs were found to be neurotoxic as well. Hence, toxicity of repeat RNA seems to be mediated by direct RNA toxicity, independent of DPR toxicity. To investigate the mechanism of this RNA toxicity we tested whether overexpression of three RNA binding proteins (Pur-alpha, HNRNPA1 and HNRNPH1), that have been shown to be able to bind repeat RNA, could alleviate this toxicity. Interestingly, Pur-alpha indeed prevented RNA toxicity, whereas it had no effect on DPR toxicity. This protective effect relied on both its glycine-rich and PUR2 domain. The PUR2 domain was found to be responsible for induction of p62 levels. Interestingly, overexpression of p62 equally protected against RNA toxicity. Deletion of the glycine-rich domain, being a low complexity domain, was found to perturb the regulatory effect of Pur-alpha on stress granules. In conclusion, we show that neurotoxicity of C9orf72 repeat expansion is mediated, at least in part, by direct RNA toxicity, independent of DPR toxicity. We show that the RNA binding protein Pur-alpha as well as the autophagy related protein p62 prevent this RNA toxicity, relating RNA toxicity to perturbations in autophagy and stress granules.

**Title:** *In vivo* imaging of axonal transport in a *Drosophila* model of c9-als

**Authors: *H. SUNG**, T. LLOYD
Johns Hopkins Univ. Schl. Med., Baltimore, MD

**Abstract:** Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder characterized by preferential death of motor neurons in the brain and spinal cord. Although the majority of ALS cases are sporadic, a $G_4C_2$ hexanucleotide repeat expansion (HRE) in *C9orf72* is the most common inherited cause of ALS (C9-ALS). Since ALS displays selective vulnerability of motor neurons with early evidence of distal axonopathy, we hypothesize that disruption of axonal transport by $G_4C_2$ HRE may be a critical factor in C9-ALS motor neuronal degeneration. Here, we investigated the axonal transport of different organelles, including mitochondria, dense core vesicles (DCVs) and autophagic vacuoles (AVs) in *Drosophila* expressing 30 $G_4C_2$ repeats. For *in vivo* imaging, we monitored motor axons from intact 3$^{rd}$ instar larvae, and obtained time-lapse images by using laser scanning confocal microscopy within 10 minutes of larval dissection. We found that expression of the $G_4C_2$ HRE reduces the number of axonal AVs and retrograde movements of autophagosomes, while the movements of DCVs in motor axons were not altered. These results suggest that organelle-specific disruption of axonal transport of autophagosomes may occur in C9-ALS, and further implicate protein quality control disruption, resulting in protein aggregate formation and/or autolysosomal dysfunction, in this disease.

**Title:** Gene-environment interactions in amyotrophic lateral sclerosis

**Authors: *R. SHER**[1], S. KWOK[2], E. LOVEJOY[2], T. LAVIN[2], S. POWERS[3], M. KRUGER[2]
[1]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY; [2]Univ. of Maine, Orono, ME; [3]The Ohio State Univ., Columbus, OH

**Abstract: Background:** The scientific consensus is that gene-environment interactions are key for the development and progression of ALS, but how either toxicants or genes lead to a disease mechanism is currently unknown. A suite of environmental neurotoxicants has been associated with ALS, with evidence indicating that early developmental exposures to neurotoxins can have consequences for neurotoxicity later in life. Early defects in neural circuitry have also been found to be associated with late-onset neurological disorders, including both cognitive and degenerative diseases. By determining cellular pathways involved in modifying neurological defects we hope to gain a better understanding of the root causes of this disorder.
**Objectives:** Our research aims to study the intersection of genetics and environmental neurotoxins on both developmental motor neuron defects and on adult-onset disease in a zebrafish model of ALS.
**Methods:** We have determined the impact of embryonic exposure to environmentally relevant doses (0-25µg/L) of the ALS-associated cyanobacterial neurotoxin Beta-methylamino-L-alanine on neurodevelopmental defects in mutant SOD1-ALS zebrafish, and on consequences for adult motor function.
**Results:** (1) Tg-SOD1-G93R zebrafish exhibit significantly shorter 30hpf motor neurons at medium doses (10µg/L BMAA) but Tg-SOD1-WT overexpressing embryos are not impacted at all. (2) Five-month old Tg-SOD1-G93R fish (embryonically exposed to BMAA) show decreased ability to swim against water current, with increasing embryonic BMAA dose having a negative impact on swimming ability. In contrast, Tg-SOD1-WT fish exhibit an increased swimming ability with increasing BMAA dose. (3) Five month Tg-SOD1-G93R fish also show increasing fatigue when repeatedly challenged in the water current, while Tg-SOD1-WT fish do not exhibit any change in swimming over repeated challenges.
**Discussion:** Our results indicate that genetic and environmental insults combine to facilitate neurological dysfunction in ALS, and that overexpression of wt-SOD1 may have protective effects against neurotoxin damage. The defects seen in early neurodevelopment are mirrored at 5 months of age in the ability of fish to swim against a current and to fatigue with repeated swimming challenges. Establishing these links between exposure and adult motor neuron disease increases the power of the zebrafish model for toxicological and drug screens.

**Title:** Transcriptome analysis of corticospinal motor neurons that lack Alsin function

**Authors: *M. GAUTAM**[1], L. A. LABOISSONNIERE[3], M. KANDPAL[2], M. C. SCHULTZ[1], Y. BI[2], J. M. TRIMARCHI[3], R. V. DAVULURI[2], P. H. ÖZDINLER[1]
[1]Neurol., [2]Preventive Medicine-Health and Biomed. Informatics, Northwestern Univ., Chicago, IL; [3]Dept. of Genetics, Develop. and Cell Biol., Iowa State Univ., Ames, IA

**Abstract:** Corticospinal motor neurons (CSMN) are unique in their ability to collect and integrate signals from different regions of the cerebral cortex and relay that information to the spinal cord targets. Thus, they play an important role for the initiation and modulation of voluntary movement. CSMN degeneration has been central in hereditary spastic paraplegia (HSP), primary lateral sclerosis (PLS) and in amyotrophic lateral sclerosis (ALS). Mutations in various genes result in motor neuron vulnerability, progressive degeneration, and dysfunction of motor neuron circuitry. Alsin is a member of the small GTPases gene family that are involved in cytoskeleton maintenance and vesicle trafficking inside the cell, among other important functions. Mutations in the Alsin gene have been shown to manifest into early onset ALS, in which upper motor neurons are primarily affected. Our study reveals the molecular and genetic mechanisms that are
involved in the very early stages of neuronal dysfunction in the absence of Alsin. We previously generated and characterized UCHL1-eGFP mice, in which CSMN are genetically labelled with eGFP expression that is stable and long lasting. This reporter line distinguishes CSMN from other neurons in the motor cortex and allows their specific and precise investigation. The UCHL1-eGFP mice were crossbred with $Alsin^{KO}$ mice to generate $Alsin^{KO}$-UeGFP mice, allowing purification of CSMN that lack alsin function via FACS-mediated approaches. We performed RNA-Seq analysis on pure populations of CSMN isolated from $Alsin^{KO}$-UeGFP and used CSMN from $Alsin^{WT}$-UeGFP mice as the healthy control. Our ongoing study reveals key cellular events that are affected even at very early stages of the disease. Genes involved in fatty acid metabolism, immune response, and mitochondrial functions were found differentially regulated. We also identified key genes that are alternatively spliced in the absence of Alsin.

Upon completion, this study will uncover important molecular clues about why upper motor neurons degenerate in the absence of alsin function.

**Title:** Defects in a dynamic tubular lysosomal network drive age-related degeneration of neurons and muscle

**Authors: *A. E. JOHNSON**[1], B. O. ORR[1], A. TONG[1], G. W. DAVIS[1,2]
[1]Biochem. and Biophysics, UCSF, San Francisco, CA; [2]Kavli Inst. for Fundamental Neurosci., San Francisco, CA

**Abstract:** Age-related degenerative diseases including Amyotrophic Lateral Sclerosis (ALS), Alzheimer's disease (AD) and Parkinson's disease (PD), are becoming more prevalent as the average life expectancy continues to rise. The current lack of disease-modifying treatments to alter the course of degenerative diseases reflects our lack of knowledge about the molecular basis of the disease pathology. An early hallmark common to most degenerative diseases is an accumulation of protein aggregates and damaged organelles, implying underlying defects in proteostasis. The predominant cellular degradation sites for clearing damaged proteins and organelles are lysosomes and lysosome dysfunction has been linked to a broad spectrum of degenerative diseases. In recent years, it has become apparent that lysosomes are not rigid organelles. Instead, lysosomes have been observed to adopt highly plastic states, altering their shape, size and molecular components to accommodate changing intracellular and extracellular environments. We previously demonstrated that lysosomes can form extended, highly dynamic, tubular networks in diverse cell types including muscles and glia. Additionally, we found that the integrity and maintenance of tubular lysosomes requires the activity of Valosin Containing Protein (VCP/p97), a AAA+ ATPase that when mutated causes muscle, bone and neuronal degenerative diseases (Johnson et al., *eLife* 2015). These data suggest that the integrity of this

unique class of tubular lysosomes may be directly relevant to the cause of VCP-related degenerative diseases. However, VCP has many diverse functions within the cell, so to elucidate the specific function of VCP at the tubular lysosomal network, we developed genetic tools in *Drosophila* to specifically disrupt VCP at tubular lysosomes, without disrupting its other cellular functions. Using these genetic models, we find that loss of VCP function at tubular lysosomes correlates with defects in tubular lysosome fusion, autophagy-dependent clearance of protein aggregates and subsequently leads to progressive muscle and neuronal degeneration. Mechanistically, we have identified a small VCP interacting protein (SVIP) that directly recruits VCP to tubular lysosomes and a specific disease-causing mutation in VCP that impedes VCP-SVIP interaction. Collectively, our data suggest that defects in tubular lysosome function are an underlying molecular cause for age-related degenerative diseases caused by VCP mutations.

**Title:** Calpain-dependent degradation of nucleoporins contributes to motor neuron death in a mouse model of chronic excitotoxicity

**Authors: *K. SUGIYAMA**, T. AIDA, K. TANAKA
Tokyo Med. and Dent. Univ., Bunkyo-Ku, Japan

**Abstract:** Glutamate-mediated excitotoxicity induces neuronal death by altering various intracellular signaling pathways and has been considered as a final common pathway of neuronal death in several neurological disorders, such as Alzheimer's disease, amyotrophic lateral sclerosis (ALS), and multiple sclerosis. Interestingly, nucleocytoplasmic transport defect has been recently reported in several neurological disorders. However, its contribution to excitotoxic cell death and the molecular mechanisms linking excitotoxicity to nucleocytoplasmic transport dysfunction remain still unknown. To investigate the mechanisms of excitotoxic neuronal death *in vivo*, we developed a novel animal model of chronic excitotoxicity by conditionally deleting astroglial glutamate transporters, which play pivotal role in preventing neurons from

excitotoxicity by reuptake of extracellular glutamate, GLT1 and GLAST in the spinal cords of mice (GLAST$^{+/-}$/GLT1-cKO). GLAST$^{+/-}$/GLT1-cKO mice displayed severe hindlimb paralysis and motor neuron death in lumbar ventral horn, and these abnormalities were reversed by AMPA receptor antagonist perampanel, but not NMDA receptor antagonist memantine. GLAST$^{+/-}$/GLT1-cKO mice also exhibited nuclear irregularity and calpain-mediated degradation of NPCs, which is responsible for nucleocytoplasmic transport. The nuclear export inhibitor KPT-350 prevented motor neuron death at an early stage, whereas long-term treatment of the AMPA receptor antagonist perampanel and the calpain inhibitor SNJ-1945 has continued beneficial effects in these abnormalities. Thus, exacerbated nuclear export due to NPC degradation is involved in excitotoxic neuronal death at an early stage, and preventing NPC degradation by calpain inhibitor and/or AMPA receptor antagonist has robust protective effects on motor neurons. Our results suggest the maintenance of NPC function serves as a novel therapeutic strategy in many neurological disorders.

**Abstract:** Tunicates (or sea squirts) are the closest living relatives to vertebrates. Adult sea squirts are simple, sessile, filter-feeding animals, but their free-swimming tadpole larvae are composed of only ~2600 cells, and display a simplified body plan that is chordate in mode of development. The dorsally located larval central nervous system of the sea squirt *Ciona robusta* comprises only 177 neurons distributed rostrocaudally in a brain vesicle, a motor ganglion and a nerve cord. Due to its small size, cellular simplicity, rapid development, and streamlined, compact genome that has not undergone the duplications seen in vertebrates, *Ciona* is particularly amenable to molecular perturbation and imaging, and its connectome is only the second one to be completely mapped after that of the nematode *C. elegans*. We present data here showing that *Ciona* can be a powerful model organism to study RNA-regulatory networks that are critical for neuron biology. NOVA1 and NOVA2 are splicing regulators specifically expressed in neurons and targeted in an autoimmune paraneoplastic motor neuron disorder.

Molecular analysis of NOVA function in vertebrates is complicated by the presence of two NOVA genes. A known NOVA target is a neuron-specific splice form of the ubiquitously expressed secreted proteoglycan AGRIN termed $Z^+$ AGRIN. This neuron-specific splice form of AGRIN is critical for the formation, development, and maintenance of the neuromuscular junction (NMJ), as it promotes clustering of the acetylcholine receptors (AChRs) by interacting with the transmembrane receptor LRP4 in muscle cells. Interestingly, AGRIN mutations lead to congenital myasthenic syndrome, and deterioration of the NMJ is at the center of Amyotrophic Lateral Sclerosis. We cloned the *Ciona* ortholog of NOVA, which is present as a single copy gene in tunicates, and that of AGRIN, and characterized their function and expression pattern during larval development. We discovered that, as in vertebrates, Agrin also undergoes alternative splicing to generate the $Z^+$ isoforms in *Ciona*, indicating that the Nova-Agrin-Lrp pathway for AChR clustering is shared between tunicates and mammals. However, we present evidence for coevolution between Nova proteins and the *cis*-regulatory sequences embedded in Agrin introns that promote Nova-dependent alternative splicing, revealing "developmental system drift" of an otherwise highly conserved RNA regulatory switch.

**Title:** Reduced $Ca^{2+}$ influx through voltage-gated $Ca^{2+}$ channels is associated with hyper-activity of striatal medium spiny neurons in the HIV brain

**Authors: *C. KHODR**, L. CHEN, L. AL-HARTHI, X.-T. HU
Dept. of Immunity and Emerging Pathogens, Rush Univ. Med. Ctr., Chicago, IL

**Abstract:** Up to 50% of $HIV^+$ patients have deficits in attention, working memory and psychomotor behavior, termed HIV-Associated Neurocognitive Disorders (HAND). Cortico-striatal pathways regulate these HIV-affected behaviors. We have reported that HIV increases the excitability of pyramidal neurons in the medial prefrontal cortex (mPFC), using HIV-1 transgenic (Tg) rats. Glutamatergic projections from these mPFC neurons innervate the caudate-putamen (CPu), where GABAergic medium spiny neurons (MSNs) are the prevalent neuronal

population. Here, we examined the impact of HIV on $Ca^{2+}$ influx and functional activity of MSNs in the CPu from 12 month-old HIV-1 Tg rats. The majority of neurons exhibited spike responses at rheobase currents ≤300pA (63.6% in non-Tg and 65.0% in HIV-1 Tg rats). In these neurons, we found increased neuronal firing in HIV-1 Tg rats compared to non-Tg rats. To determine if $Ca^{2+}$ influx through voltage-gated $Ca^{2+}$ channels (VGCCs) is involved in the increased firing in striatal MSNs (as we previously demonstrated in mPFC neurons of adolescent HIV-1 Tg rats), $Na^{+}$ channels, $K^{+}$ channels, and excitatory/inhibitory inputs were blocked in this study. We found that neuronal $Ca^{2+}$ influx was significantly reduced in HIV-1 Tg rats compared to non-Tg rats, which was accompanied by increased protein levels of a less functional, cleaved form of the $Ca_v1.2$ L-type VGCC in the CPu of HIV-1 Tg rats. The levels of full length $Ca_v1.2$ and $Ca_v1.3$ L-type VGCC protein were unaltered. These results indicate that VGCCs are not functionally involved in the increased MSN spiking in the HIV-1 Tg rat. Additionally, protein levels of NMDA receptor (NR2B subunit) and $GABA_AR$ ($\beta_{2,3}$ subunits) in the CPu of HIV-1 Tg rats were unaltered compared to non-Tg rats, suggesting that the number of these receptors in MSNS is unchanged. Together with our unpublished studies that found $K^{+}$ channel activity is not involved in the increased CPu neuronal firing, our findings suggest that aberrant synaptic neurotransmission, rather than independent over-activation or over-expression of intrinsic $Ca^{2+}/K^{+}$ channels, drives HIV-induced MSN hyper-excitability. Further studies are needed to determine whether the increased firing of CPu MSNs in HIV-1 Tg rats is mediated by alterations in functional activity of NMDA receptors and $GABA_A$ receptors, or by changed neurotransmission of glutamate and GABA.

[3]Psychiatry, Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA

**Abstract: Purpose.** Although many studies have documented cortical and subcortical gray matter volume (GMv) changes following HIV infection, GMv is also known to decline with age and drug use. As the HIV infected population is steadily aging, the effects of age and past drug use may confound attempts to identify specific effects of serostatus on regional GMv, or to use neurostructural measures more generally in HIV diagnostic and treatment assessment contexts. In a cross-sectional study, we examined the effects of serostatus, age and past drug use on regional GMv. **Materials & Methods.** Participants included 113 seropositive and 88 seronegative men, ages 23-73, with 118 reporting past drug use. Seropositive participants were all treated with anti-retroviral therapies. Regional GMv was estimated using $1mm^3$ T1-weighted brain images. Mixed effects linear regression models were used to explore effects of serostatus, race, age, field strength, intracranial volume and drug use on regional GMv using both *a priori* regions and voxel-based morphometry. **Results.** Seropositive participants exhibited bilateral decreases in caudate and putamen GMv ($p<0.05$ FWE-corrected). Spatially independent effects of age and past drug use were also seen ($p<0.05$ FWE-corrected), with age broadly affecting numerous frontal and temporal cortical regions (Figure 1). **Conclusions.** Regional GMv is subject to additive effects of serostatus, age and past drug use, with HIV infection having neurostructural effects in the basal ganglia equivalent to 20-30 years of typical aging. Serostatus effects had high regional specificity when age and drug use were controlled, suggesting that basal ganglia GMv measured using computational neuroanatomy methods may be a useful biomarker to follow effects HIV infection and its treatment.

**Title:** HIV-1 mediated increased striatal medium spiny neuronal excitability is associated with enhanced $K^+$ efflux and influx

**Authors: *L. CHEN**, C. E. KHODR, L. AL-HARTHI, X.-T. HU
Dept. of Immunity and Emerging Pathogens, Rush Univ. Med. Ctr., Chicago, IL

**Abstract:** Despite combined antiretroviral therapy (cART), HIV-associated neurocognitive disorders (HAND) occur in >50% of $HIV^+$ patients. The striatum is one of the key brain structures in the basal ganglia that mediates psychomotor activity and is altered by HIV-1. We previously demonstrated an abnormal hyper-excitability of mPFC pyramidal neurons in HIV-1 transgenic (Tg) rats (that express 7 of 9 HIV-1 proteins), which was associated with altered voltage-gated $Ca^{2+}$ channel function and $K^+$ efflux/influx and was independent of NMDAR activation. We assessed here the impact of HIV on GABAergic medium spiny neurons (MSNs), the predominate neurons in the dorsal striatum in 12 month-old (12m) HIV-1 Tg rats using whole-cell patch-clamp recording. We found that the majority of striatal MSNs (~75%) in non-Tg rats responded to moderate excitatory stimuli (e.g., rheobase ≤300pA; though the others showed less responses). Evoked firing was abnormally increased in the majority of MSNs in HIV-1 Tg rats compared to those from age-matched non-Tg rats. To elucidate the mechanism that underlies the hyperactivity of striatal MSNs in HIV-1 Tg rats, we assessed HIV-mediated changes in $K^+$ channel activity in these neurons. To insure that $K^+$ channel activity would not be affected by activity of other ion channels, we blocked $Na^+/Ca^{2+}$ channels, $GABA_A$ receptors and glutamate receptors. We found that voltage-sensitive $K^+$ ($K_v$) efflux was significantly increased in striatal MSNs from 12m HIV-1 Tg rats, indicating enhanced $K_v$ channel activity. Meanwhile, membrane hyperpolarization-induced $K^+$ influx was also significantly increased in MSNs from

HIV-1 Tg rats, suggesting enhanced activity of $K_{ir}$ channels (and $I_h$ channels) that leads to an increased inward rectification. However, an increased $K_v$ channel activity could render neurons less excitable; and an enhanced $K^+$ influx via $K_{ir}$ channels could decrease extracellular $K^+$ levels, which could also reduce neuronal excitability. Therefore, the HIV-induced hyper-excitability of striatal MSNs could not be attributed to these changes in $K^+$ channel activity found in this study. Additionally, we also found that the inward rectification was not altered in MSNs of HIV-1 Tg rats without blockade of GABA/glutamate receptors; and voltage-gated $Ca^{2+}$ channels were not involved in this increased firing of MSNs (unpublished data). Collectively, these findings suggest a potential involvement of GABA/glutamate neurotransmission and synaptic activity that mediates the increased MSN firing.

**Abstract:** The introduction of combined and highly active anti-retroviral therapies (cART) has transitioned HIV from a disease with short-term survival into a chronic disease, and has changed the profile of HIV-associated neurocognitive disorders (HAND). While severe neurocognitive deficits leading to dementia are now rarely found, the prevalence of mild and moderate cognitive and motor deficits has remained constant or increased, even among patients with systemic viral suppression. This phenomenon likely reflects inefficient penetration of current antiretroviral drugs through the blood brain barrier, which allows the central nervous system (CNS) to exhibit low levels of persistent infection. HIV-infected patients commonly show neurocognitive deficits that affect memory, attention/concentration, mood, and fine motor skills. Furthermore, although the percentage of women in the HIV-infected population has increased, sex-related effects on memory/cognition deficits in HIV patients remain unclear. We utilized a transgenic mouse

model of HIV (conditionally expressing HIV-1 $Tat_{1-86}$ protein in CNS) and examined both males and females for changes in cognitive behavior and for expression of biochemical markers related to memory and learning, especially the Arc protein. Arc is an immediate early protein, and its expression can be induced by any environmental experience leading to learning and memory. Dysfunction of Arc-related signaling pathways is involved in disruption of memory after radiation therapy and in disease-related situations. The transient induction of Arc occurring after contemporaneous acoustic/odor stimuli was reduced by HIV-1 Tat exposure in both sexes, although Arc expression remained significantly higher in $Tat^+$ females compared to males. Somewhat parallel results were seen in a test of spatial memory (Barnes maze), since only $Tat^+$ males exhibited significant deficits. Sex-specific differences were also found in other Arc pathway proteins including CREB, Homer1 and Zif268. Our findings suggest that cognitive deficits of $HIV^+$ individuals might be influenced by sex-related differences in Arc signaling.

**Abstract:** Neurocognitive impairments such as motor dysfunction and mood disorders affect approximately 30-50% of HIV patients, despite the use of combined antiretroviral therapy (cART). Additionally, the use of opiates, whether therapeutic or recreational, can exacerbate the behavioral and morphological deficits seen in HIV-infected patients and animal models. Using a transgenic mouse with glial fibrillary acidic protein-driven *tet*-on (doxycycline) inducible CNS

expression of HIV-1 Tat, our laboratory recently showed that dopamine receptor type 2 (D2) containing medium spiny neurons (MSNs) in the striatum are selectively vulnerability to 2 weeks of HIV-1 Tat induction. Specifically, a relatively short duration (2 weeks) of HIV-1 Tat exposure increases dendritic injury and has biphasic effects on disrupting firing patterns in striatal D2 MSNs, which coincides with anxiety-like behaviors, while longer-term Tat exposure (≥ 1 month and especially 3 months) is associated with motor deficits. To investigate possible therapeutic targets to ameliorate these D2 MSN and behavioral deficits, the effects of a D2/D3 selective agonist, pramipexole (PPX), were assessed in HIV-1 Tat mice. Further, animals were given morphine (10 mg/kg, s.c.) to assess interactions of HIV-1 Tat, PPX and/or morphine. Preliminary data showed that following 2 weeks of HIV-1 Tat induction, morphine increased locomotor behavior in the open field task without reducing measures of anxiety-like behaviors, regardless of genotype. Additionally, PPX (0.1 mg/kg, i.p.) was able to block the locomotor stimulating effects of morphine. In the elevated plus maze, PPX was mildly anxiolytic both on its own and in combination with morphine. Ongoing experiments examining locomotor behavior following 4 weeks of HIV-1 Tat induction are being conducted. These data will help separate and clarify potential interactive effects of PPX and morphine on HIV-1 Tat-related alterations in locomotion versus anxiety-like behaviors. These studies will provide insight into how the dopaminergic system may affect behavioral deficits following either HIV-1 Tat and/or morphine exposure.

**Title:** Dopaminergic and serotonergic dysfunction in HIV-1 transgenic rats: Implications for depression in HIV-1 patients

**Authors: *A. DENTON**, S. SAMARANAYAKE, R. ROSCOE, Jr., S. HARROD, H. LI, C. MACTUTUS, P. HASHEMI, R. BOOZE
Univ. of South Carolina, Columbia, SC

**Abstract:** HIV-1 infection is a serious condition affecting approximately 37 million individuals. Between 30% and 60% of seropositive individuals will develop symptoms of clinical depression. These individuals are five times more likely to commit suicide than non-seropositive clinically depressed patients. Dysfunction in serotonergic and dopaminergic transmission has consistently been implicated in the pathogenesis of depression. Specifically, dysfunction in the prefrontal cortex (PFC) and in the nucleus accumbens core (NAcc) region have been shown to be underlying factors in the trajectory of depression. Given these underlying neurological features, we analyzed serotonin release from the PFC and dopamine release from the NAcc using fast scan cyclic voltammetry in HIV-1 transgenic (Tg) rats. Subjects (HIV-1 Tg n=7 males/7 females; F344N n=8 males/8 females) were anesthetized and placed in a stereotaxic apparatus. For serotonin and dopamine, a stimulating electrode was implanted in the medial forebrain bundle, while carbon fiber micro-electrodes were placed in the PFC and NAcc, respectively. Biphasic pulse trains were applied through a linear constant current stimulus isolator to evaluate both serotonin and dopamine release. Both serotonergic and dopaminergic release and reuptake were impaired in HIV-1 Tg animals relative to controls. Additionally, female rodents experienced slower reuptake rates of dopamine. Collectively, these findings illustrate neurochemical factors that may potentially underlie the pathogenesis of clinical depression in HIV-1 seropositive individuals.

**Abstract:** HIV-associated neurocognitive deficits (HAND) occur in up to 50% of infected individuals despite effective antiretroviral therapies. In terms of causality, infection of monocyte-derived cells (MDCs) is thought to be critical in pathogenesis. MDCs represent the predominant cell types that are infected by HIV. In the present study we focus on signaling through protease-activated receptor-1 (PAR-1) for its potential to modulate effectors of enhanced CNS entry of monocyte-derived cells. PAR-1 is a GPCR that is unique in its ability to be activated by a subset of matrix metalloproteinases (MMPs). PAR-1 can be activated by MMP cleavage of the N-terminal domain, which reveals a tethered peptide ligand. Both MMPs and PAR-1 expression are increased in the context of HAND. We observe that treatment of astrocytes with HIV-1 transactivator of transcription (Tat) protein significantly increases expression and release of MMP-13—a particularly potent PAR-1 agonist. We also observe that MMP-13 promotes astrocyte release of monocyte-chemoattractant protein-1 (MCP-1). This effect is observed to be PAR-1-dependent as astrocytes derived from PAR-1-KO mice fail to respond to MMP-13 stimulation. Interestingly, Tat's ability to increase release of MCP-1 is significantly reduced by a broad-spectrum MMP inhibitor (GM6001). Together, these results suggest that targeting the PAR-1/MMP axis may have potential therapeutic implications for HAND. Currently, PAR-1 antagonists and MMP inhibitors are being investigated in clinical trials. These results also support the possibility that in addition to transport across a damaged blood-brain barrier, MMPs may promote recruitment of MDCs through PAR-1-dependent release of MCP-1. Levels of MCP-1 have been previously shown to correlate with disease severity and recruitment of MDCs may therefore reinforce disease progression.

**Title:** *In vivo* manipulation of the CXCL12/CXCR4 signaling axis increases dendritic spine density and enhances cognitive flexibility in wild-type and HIV-Tg rats: Role of the Rac1/PAK pathway and implications for neurocognitive disorders

**Authors: *L. FESTA**[1], Y. TIAN[1], B. PLATT[1], S. B. FLORESCO[2], O. MEUCCI[1]
[1]Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Psychology, Univ. British Columbia, Vancouver, BC, Canada

**Abstract:** HIV-associated neurocognitive disorders (HAND) continue to persist despite the advent of combination antiretroviral therapy (cART). Research focus has shifted from neuronal loss, which predominantly occurred prior to the cART era, to sub-lethal synaptodendritic alterations since it is correlated with neurocognitive impairment and it may be reversible. Research conducted in our laboratory has revealed the role of the chemokine CXCL12 in several critical homeostatic processes in the CNS, including neurotransmission, pro-survival signaling, and neuronal-glial interactions. Recently, we have also demonstrated that the CXCL12/CXCR4 axis can regulate dendritic spine number on cortical neurons; however, the mechanism by which this occurs is currently unknown. Additionally, CXCL12/CXCR4 signaling is disrupted during HAND, suggesting that restoration of this pathway might alleviate cognitive deficits in HIV+ patients. In this study, we sought to determine the molecular mechanisms regulating CXCL12-mediated spine alterations, as well as whether *in vivo* administration of CXCL12 can alter dendritic spines and cognitive function in a small rodent model of HAND (HIV-Tg rat). We have demonstrated that the Rac1/PAK pathway, known to be essential for spine stabilization, is activated by CXCL12 (20 nM) in cultured cortical neurons. Furthermore, this effect is blocked by pre-treatment with the CXCR4 antagonist, AMD 3100, or the specific Rac1 inhibitor NSC23766. Since thin spines are likely targets of spine stabilization due to their transient nature, we also investigated whether particular spine morphologies are preferentially targeted by CXCL12. In cultured cortical neurons treated with CXCL12, there is a specific increase in the percentage of thin spines and a subsequent decrease in stubby ones. *In vivo* treatment of CXCL12 (25ng/5µL once per day) in WT and HIV-Tg rats significantly increased overall dendritic spine density on layer II/III pyramidal neurons in the medial prefrontal cortex (mPFC). As we observed in our *in vitro* cultures, CXCL12 treatment specifically increased thin spine density in WT and Tg rats. Importantly, rodents treated with CXCL12 displayed improvement in cognitive flexibility, as measured by an attentional set-shifting task, and this was positively correlated with dendritic spine number in the mPFC. Taken together, this study suggests that enhancement of the CXCL12/CXCR4 signaling axis may have therapeutic potential in HAND, as well as in other neurocognitive disorders characterized by synaptodendritic alterations, such as Alzheimer's and schizophrenia.

**Abstract:** By including 4 groups of subjects, our studies are able to clearly distinguish specific from general effects of disease burden on the brain. The 4 groups included 230 control subjects, 218 individuals with Alcohol Use Disorders (AUD, E), 54 individuals infected with HIV (H), and 62 subjects comorbid for AUD + HIV (HE). SPoiled Gradient Recalled Echo (SPGR; TR=7ms, TE=2.2ms, TI=300ms, thick=1.25mm, skip=0mm, 124 slices) and dual-echo fast spin echo (FSE; TR=8583ms, TE1/2=13.5/108.3ms, thick=2.5mm, skip=0mm, 62 slices) sequences were collected on a GE 3.0T Signa whole-body system with an 8-channel phased-array head coil. After registration, skull stripping, and reformatting, regions of interest were quantified: cortical surface areas, volumes, and thickness were parcellated using FSL; white matter regions were parcellated using the SRI24 atlas. Two group comparisons showed that gray matter volume was smaller in the 3 patient groups relative to controls in frontal (E: $p=4.3e^{-12}$, H: $p=1.3e^{-09}$, HE: $p=1.9e^{-09}$), temporal (E: $p=10e^{-09}$, H: p=.01, HE: p=.007), and parietal (E: $p=1.3e^{-12}$, H: $p=3.2e^{-05}$, HE: $p=2.5e^{-07}$), but not occipital (E: p=.17, H: p=.71, HE: p=.11) cortical brain regions. The insula was also smaller in the 3 groups (E: $p=9.4e^{-06}$, H: p=.04, HE: p=.005), and all 3 groups showed an elevated number of T1 (white matter) hypointensities (E: $p=1.1e^{-08}$, H: p=.01, HE: $p=8.9e^{-08}$). The volume of the cingulate was only affected in the E and HE groups (E: p=.0001, H: p=.15, HE: p=.004); corpus callosum volume (E: p=.002, H: p=.60, HE: p=.28) was only affected in the E group. In the E and H groups, individuals with hepatitis C sero-positivity had smaller frontal gray matter volumes (t=2.86, p=.0048) and thinner frontal cortices (t=2.75, p=.0066) than sero-negative E and H participants. These data support previous findings suggesting that in these kinds of pathologies, the occipital lobes are relatively spared and indicate that the cingulate may be especially affected by addiction. Further, co-infection with hepatitis C contributes an additional burden to the brain already compromised by AUD or HIV infection.

**Abstract:** About half of HIV positive individuals develop HIV-associated neurocognitive disorder (HAND), which is a broad spectrum of cognitive, motor, and behavioral disturbances of varying severity. Combined antiretroviral therapy (cART) has led to a significant decrease in occurrence of the most severe form of HAND; however, less severe forms of the disorder have been reported to persist in 30-50% of patients. In this post-ART era, white matter pathologies are prevalent, including thinning of the corpus callosum, and reduction in white matter volumes. Moreover, white matter loss is correlated to the duration of ART exposure. Interestingly, a recent transcriptome analysis comparing untreated and ART treated patients with HAND showed downregulation of genes critical for oligodendrocyte differentiation and myelin production in patients treated with ART. These studies demonstrate that ART, as well as HIV, may perturb myelin production and oligodendrocyte growth and maturation. We have begun to study the effects of ART exposure on oligodendrocytes and their precursor cells. We hypothesize that ART compounds alter oligodendrocyte differentiation, function, and survival influencing the persistence of HAND in the post-ART era. In our lab, previous studies have shown that HIV antiretroviral compounds, lopinavir and ritonavir, both of the protease inhibitor (PI) class, inhibited oligodendrocyte precursor differentiation, while zidovudine, a nucleoside reverse transcriptase inhibitor (NRTI), did not. New data now shows another PI, darunavir, has similar effects as ritonavir and lopinavir. Preliminary studies are now examing the newest class of HIV antiretroviral compounds, the integrase inhibitors, raltegravir and elvitegravir. These studies suggest that elvitegravir also decreased differentiation of oligodendrocyte precursors while raltegravir does not. We have also begun to test other new frontline ARTs, Tenofovir alafenamide fumarate (TAF), Preliminary data show that TAF halt oligodendrocyte precursor differentiation through decreased expression of integral myelin proteins. Investigation of the effects of these first line compounds will provide insights into the observed persistent white

matter changes seen in HAND patients with implications for their contribution to cognitive impairment.

**Abstract:** Pur-alpha is a highly conserved sequence specific DNA and RNA binding protein with established roles in DNA replication, RNA transcription and translation, cell cycle regulation, maintenance of neuronal differentiation, and regulation of myelin basic protein gene transcription. Pur-alpha expression levels are developmentally regulated and are essential for survival as knockout of the PURA gene, which encodes Pur-alpha, are homozygous lethal in the mouse model. Mutations in the PURA gene have been identified in individuals with the rare developmental disorder, PURA syndrome, which is associated with severe developmental delays, seizures, dystonia, dyskinesis, skeletal abnormalities, and delayed myelination. We recently reported that mice that are heterozygous (+/-) for Pur-alpha show cognitive deficiencies and neuropathology in the cerebellum and hippocampus, as well as decreased escape to touch responses, decreased limb tone and increased foot drags. From this, we hypothesized that there may also be peripheral nerve neuropathology. Therefore, mice that were heterozygous for Pur-alpha (+/-) were bred by crossing C57/BL6 wild type females (+/+) with heterozygous Pur-alpha (+/-) knockout males. When 9 months of age, 8 wild-type C57/BL6 mice and 5 heterozygous Pur-alpha littermates were tested for cold to hot temperature sensitivity using a temperature place preference assay. Forelimb and forepaw tissues were then collected and examined for inflammatory or myelination changes in the median and ulnar nerves and their branches in the forepaw using immunohistochemical methods. The heterozygous Pur-alpha (+/-) showed hyposensitivity to hot temperatures (41$^{o}$ and 45$^{o}$C), yet normal responses to warm, cool and cold

temperatures, compared wild type littermates. The median and ulnar nerves (examined from the forelimb into the forepaw) showed no increase in CD68-immunopositive macrophages in heterozygous Pur-alpha mice, compared to wild type mice. However, myelin disruption (Hematoxylin and eosin) and increased degraded myelin basic protein were present in the median and ulnar nerves of heterozygous Pur-alpha mice, as were decreased numbers of axon terminals to the forepaw skin. Thus, peripheral nerve neuropathology was present in heterozygous Pur-alpha mice in association with indices of forepaw hyposensitivity, yet an absence of neuroinflammatory processes.

**Abstract:** HIV-Associated Neurocognitive Disorder (HAND) affects 55% of HIV-infected individuals worldwide. While antiretroviral treatments have reduced the severity of HAND, the prevalence has increased due to increased life expectancy. In addition, little progress has been made in developing therapeutics to reduce the prevalence of HAND. While the major pathological manifestation of HAND is synaptodendritic damage, the full, underlying mechanism is unknown partly due to the fact that there is no *in vitro* model to study the direct interactions between HIV- infected macrophages/microglia and neurons. In order to address this problem, we have developed a human-induced pluripotent stem cell (HiPSC) based model; whereby, we separately differentiate HiPSCs into forebrain, glutamatergic-like neurons, astrocytes, and microglia-like cells and create a co-culture of the three cell types with or without HIV-infection. This novel, reductive system allows us to study the direct interactions and mechanisms by which macrophages/microglia cause synaptodendritic damage in HAND progression.

**Abstract:** Macrophages and microglia (M/M) play pivotal roles in the pathogenesis of HIV associated neurocognitive disorders. The ensuing inflammatory M/M activation causes neuronal damage. Studies utilizing exogenous anti-inflammatory and antioxidants to mitigate disease progression have been unsuccessful; however, targeting endogenous antioxidant pathways such as the endogenous antioxidant response (EAR) pathway, which upregulates key antioxidant enzymes, including heme oxygenase 1 (HO-1) may be useful. In this study, we investigated the role of a flaxseed lignin, secoisolariciresinol diglucose (SDG), on oxidative stress in HIV-infected macrophages. To evaluate EAR, human monocyte derived macrophages were infected with HIV and/or SDG for 10, 30 and 60mins and immunoblotted or stained with Nrf2 to evaluate its translocation from the cytoplasm to the nucleus. Treatment of SDG alone increased Nrf2 translocation while HIV resulted in a small increase in Nrf2 translocation. Concurrent treatment with SDG and HIV exacerbated the translocation of Nrf2. Consistent with these findings, macrophages infected with HIV for one day slightly increased HO-1 expression, however, HO-1 was suppressed by peak infection. To determine if SDG can reverse the prolonged HO-1 deficits, macrophages were pretreated with SDG for 1hr prior to infection and replenished every three days. SDG treatment altered HO-1 protein levels throughout infection. Also, pretreatment of SDG partially suppressed viral replication 12 days post infection in human macrophages, assessed by a reverse transcriptase assay. Given these data, SDG increases endogenous antioxidants pathways, thereby, reducing oxidative stress and partially blocking productive infection in macrophages and may be a possible adjunctive therapeutic for HIV associated neurocognitive disorders.

**Title:** ER stress regulator ATF6b contributes to HIV-induced neurotoxicity

**Authors: *C. AKAY ESPINOZA**, P. LIN
Pathology, Univ. of Pennslyvania Sch. of Dent. Med., Philadelphia, PA

**Abstract:** Synaptic injury, neuronal dysfunction, and damage in patients with HIV-associated neurocognitive disorders (HAND) on suppressive antiretroviral therapy are partially driven by immune activation and chronic inflammation in response to soluble factors released by HIV-infected and/or activated macrophages as well as a low level of HIV replication in central nervous system (CNS) reservoirs. The majority of these mediators, as well as many of the comorbid conditions, can induce the ubiquitous unfolded protein response (UPR) in the endoplasmic reticulum (ER). Based on our previous results showing UPR activation in post-mortem tissue from HAND patients *in vivo,* we expanded our investigation to determine the contribution of one of the regulators of UPR in the ER, ATF6b, to HIV-induced neurotoxicity *in vitro.* Following cleavage by site-1 and site-2 proteases (S1P and S2P), ATF6b translocates to the nucleus for transcriptional induction of ER-resident chaperones, apoptotic genes, and secretory pathway regulatory genes. We found that infection of primary human monocyte-derived macrophages (MDMs) with HIV led to the nuclear translocation of the cleaved, thus active, ATF6b (N-ATF6b), which could be blocked by S1P inhibition. We also observed that blocking nuclear accumulation of N-ATF6b in macrophages by S1P inhibition led to the attenuation of death of primary rat cortical neuroglial cultures exposed to supernatants from HIV-infected MDMs (HIVMDMs). Furthermore, siRNA-mediated ATF6b knockdown in primary human MDMs led to an attenuated production of HIV p24 and reverse transcriptase activity over 15 days *in vitro* and attenuated HIVMDM-mediated neurotoxicity. These findings suggest ATF6b as a potential contributor to sustained HIV replication and subsequent release of neurotoxic factors from infected MDMs, which might impact outcomes in several cell types within the CNS of patients with HAND and illustrate ATF6b as a novel endogenous target for modulation during HIV infection.

**Title:** HIV-1 viral proteins and Drd1α expression in medium spiny neurons of the nucleus accumbens

**Authors: *J. M. ILLENBERGER**, H. LI, S. B. HARROD, C. F. MACTUTUS, R. M. BOOZE
Psychology, Univ. of South Carolina, Columbia, SC

**Abstract:** The dopamine (DA) system is a major target of HIV infection and contributes to the progression of HIV-1 associated neurocognitive disorder (HAND) in HIV-1+ individuals. Combination antiretroviral therapies (cART) control HIV viremia. However, HIV-1 viral proteins transactivator of transcription (Tat) and envelope glycoprotein GP120 (gp120) continue to impair DA function through mechanisms that are still unclear. The HIV-1 transgenic (Tg) rat expresses 7 of 9 HIV-1 proteins, with the exception of Gag and Pol. The current experiment classifies DA-related circuitry in HIV-1 Tg and F344/N rats by examining RNA and protein expression, as well as dendritic spine morphology of medium spiny neurons (MSNs) of the nucleus accumbens (NAc) region. Dopamine transporter (DAT), tyrosine hydroxylase (TH), and dopamine D1-alpha receptor (Drd1α) expression in D1-type MSNs of HIV-1 Tg and F344/N rats were compared by combining immunohistochemistry (IHC) and RNAscope procedures. Next, MSNs were diOlistic labeled with Helios Gene Gun (Bio-Rad) to analyze the volume, length, and distribution of dendritic spines of the NAc using Neurolucida 360 software (MBF Bioscience). HIV-1 Tg animals present altered dendritic spine lengths and distribution across branch orders of MSNs of the NAc region. We hypothesized that MSNs from the NAc region of HIV-1 Tg animals relative to controls display reduced Drd1α, DAT, and TH expression in addition to altered dendritic spine morphology due to the presence of HIV-1 viral proteins. Identifying the specific alterations that occur in dopaminergic circuitry with exposure to Tat and gp120 offers valuable insight for effectively treating cognitive decline in HIV-1+ patients.

**Title:** HIV-1 Tat impairs cognitive performance in an exposure-dependent manner

**Authors: *T. J. CIRINO**[1], J. J. PARIS[2], J. P. MCLAUGHLIN[1]
[1]Pharmacodynamics, Univ. of Florida, Gainesville, FL; [2]BioMolecular Sci., Univ. of Mississippi, University, MS

**Abstract:** Although antiretroviral therapy (cART) has decreased the severity of Human Immunodeficiency Virus (HIV)-associated dementia, cognitive impairment and the prevalence of HIV Associated Neurocognitive Disorders (HAND) persists. The means by which HAND persists in the presence of cART in HIV+ patients remains unknown. In animal studies, exposure to the inflammatory HIV-1 regulatory protein transactivator of transcription (Tat) was found to produce cognitive learning and memory deficits. We hypothesized that brain exposure to HIV-1 Tat protein is sufficient to induce oxidative stress and neuroinflammation, ultimately impairing cognitive performance. Using the GT-tg bigenic mouse model, where brain-selective Tat expression is controlled by activation of a doxycycline (Dox) promotor, we tested the effects of Tat protein on two non-hippocampal associated cognitive tasks, the Pre-Pulse Inhibition (PPI) model of sensorimotor gating and the prefrontal cortex (PFC)-dependent Attentional Set Shift task. Western blot analysis confirmed the expression of Tat protein in GT-tg bigenic mouse brain correlated with dose and duration of Dox treatment, and magnitude of exposure to Tat protein was shown to elevate total ROS/RNS levels in whole brain homogenate assessed by a fluorophore probe assay and activate microglia in the PFC measured by Iba1 immunohistochemical labeling. Behaviorally, a 1, 7 or 14 day exposure to HIV-1 Tat protein attenuated pre-pulse inhibition. In contrast, a 7-day exposure to HIV-1 Tat protein improved certain sessions of the Attentional Set Shift associated with rule acquisition and enforcement. However, a longer exposure (14 d) reversed most improvements, and caused significant impairments in performance during intradimensional shift testing and in reversal of established compound discrimination. The role of Tat-induced neuroinflammation was confirmed through prophylactic treatment with the anti-inflammatory, indomethacin (10 mg/kg/d, i.p.). Daily

pretreatment with indomethacin concordant with Dox reversed impairment of PPI after a 1, but not 7, day exposure to Tat protein. Likewise, 14-d prophylactic indomethacin treatment prevented all Tat-induced deficits of performance in the attention set shift assay. Overall, these data suggest that expression of HIV-1 Tat protein in mouse brain was sufficient to impair cognitive performance in an exposure-dependent manner involving neuroinflammatory responses, and suggests a direct biological means by which HIV infection may promote persistent HAND and cognitive impairment in HIV patients.

**Title:** HIV-1 envelope protein gp120 potentiates extrasynaptic GABARs

**Authors: *M. GREEN**[1,2], S. THAYER[3]
[2]Neurosci., [3]Pharmacol., [1]Univ. of Minnesota, Minneapolis, MN

**Abstract:** HIV-associated neurocognitive disorder (HAND) affects nearly half of the 37 million patients with HIV. Symptoms of HAND range from subclinical cognitive impairment to severe dementia. Infected cells in the brain such as microglia release viral proteins and toxins that alter neuronal function. The HIV-1 envelope protein gp120 is one such viral protein which is toxic to neurons. Using patch clamp electrophysiology in hippocampal cultures, here we describe how treatment with gp120 potentiates extrasynaptic GABA receptor (GABAR)-mediated currents. A 4 h treatment with gp120 (600 pM) significantly increased currents through extrasynaptic GABARs and this increase persisted for 24 h. Microglial release of interleukin-1β (IL-1β) likely mediates the gp120-mediated increase in GABAR currents. IL-1β directly applied to hippocampal cultures potentiated extrasynaptic GABAR currents, and inhibition of the IL-1 receptor with IL-1ra blocked gp120's effects. Furthermore, inhibition of CXCR4 on microglia with AMD3100, which is known to be upstream of IL-1β release, prevented the gp120-induced potentiation of extrasynaptic GABARs. Preliminary results show that elimination of microglia with L-Leucine Methyl Ester block gp120's effects. Preliminary results also show that α5-containing GABARs may be responsible for gp120's effects. The enhanced GABA evoked current produced by 4 h treatment with gp120 was sensitive to the α5-containing GABAR inverse agonist basmisanil. Finally, treatment with another viral protein, HIV-1 Tat (50 ng/mL) did not potentiate extrasynaptic GABARs suggesting this may be a gp120-specific effect.

Inhibition of synaptic GABARs lowers seizure threshold and induce anxiety. However, selective inhibition of extrasynaptic GABARs spares synaptic GABAR function and does not affect seizure threshold or induce anxiety. Drugs that inhibit extrasynaptic GABARs have been shown to boost cell excitability and improve cognitive function in animal models of Alzheimer's disease, stroke, and neuroinflammation. Extrasynaptic GABARs may be a promising target for the treatment of HAND.

**Title:** Inhibition of LTP in CA1 pyramidal neurons by the commonly prescribed antiretroviral, efavirenz

**Authors: *E. K. BICHLER**[1,2], P. S. GARCIA[3]
[1]Res. Div., Atlanta VA Med. Ctr., Decatur, GA; [2]Emory Univ., Atlanta, GA; [3]Anesthesiol., Atlanta VA Med. Ctr. / Emory Univ., Decatur, GA

**Abstract:** Over half of patients receiving pharmacotherapy to treat their HIV infection demonstrate some form of cognitive dysfunction. These mild impairments might be in part due to the drugs used to treat HIV infection, as recent data suggests that antiretroviral agents (ARVs) themselves may exert central nervous system (CNS) neurotoxic effects. Efavirenz, a non-nucleoside reverse transcriptase inhibitor, was associated with a decline in cognitive performance where no deficits were previously noted (Ciccarelli, Fabbiani et al. 2011) after initiation of drug treatment. Recently, our laboratory demonstrated that efavirenz conferred a detrimental effect on neuronal viability, morphology, and mitochondrial respiration in cultured rat primary cortical neurons at concentrations (20 - 50 µM) near the target plasma concentration, 6.8 µM (Ciavatta et al. 2015). To explore the potential effects of efavirenz on neurophysiologic mechanisms underlying neurocognitive tasks like learning, acutely dissociated ex vivo brain slices were exposed to study drug for 2-4 hours prior to whole cell patch-clamp recordings from CA1 pyramidal cells in the hippocampus. Theta-burst pairing (TBP) protocol (three trains of EPSPs at 5 Hz; each train consisting of 5 evoked EPSPs paired with 5 concurrent action potentials generated by somatic current injections; Rosenkranz et al. 2009) was implemented to induce

synaptic plasticity. This protocol resulted in long-term potentiation (LTP) of EPSP amplitude (mean±SD: 190±40.8%; n=15) in brain slices exposed to control conditions. Neurons subjected to 100 µM efavirenz demonstrated very little LTP by comparison (123.7±23.3%; n=8). Efavirenz concentrations at 30 µM or less did not affect synaptic potentiation. Our data suggest that although in vitro studies demonstrate detrimental effects on neuronal health at efavirenz concentrations as low as 20 µM, LTP is impaired at concentrations over ten times the target plasma concentration. Taken together, these results suggest that neurocognitive deficits associated with efavirenz treatment are not likely to result from acute network dysfunction specifically related to LTP mechanisms. It remains possible that a cumulative effect involving mitochondrial toxicity underlies the association of efavirenz with cognitive dysfunction. Future studies involving chronic administration of efavirenz to as well as an investigation of blood brain barrier permeability in an in vivo model, will aid in the understanding of the clinical consequences of ARV therapy.

**Title:** Neurocognitive behavioral assessment following isoflurane anesthesia in a rat model of chronic administration of select HIV anti-retroviral drugs

**Authors: *J. FIDLER**[1], S. P. DOYLE[2], P. S. GARCIA[3]
[1]Anesthesiol., Emory Univ. / Atlanta VAMC, Decatur, GA; [2]Pharmacol., Emory Univ., Atlanta, GA; [3]Anesthesiol., Atlanta VA Med. Ctr. / Emory Univ., Decatur, GA

**Abstract:** The antiretroviral (ARV) drugs azidothymidine (AZT) and efavirenz (EFV) are commonly prescribed in treatment regimens for HIV. AZT is a nucleoside analog reverse transcriptase inhibitor (NRTI) that acts by halting viral DNA synthesis via chain termination, while EFV is a non-nucleoside reverse transcriptase inhibitor (nNRTI) that blocks the function of reverse transcriptase by directly binding with the enzyme. Whereas HIV-associated neurocognitive disorder (HAND) is a known effect of microglia and macrophage activation in the brains of HIV patients, some clinical reports have also identified mild cognitive dysfunction as a result of antiretroviral therapy (ART). However, these effects remain poorly described in

scientific literature. We have previously shown that, while AZT did not have any acute effects on neuronal viability in vitro, efavirenz may be neurotoxic through a reduction in mitochondrial respiration. Furthermore, 20 µM EFV reduced excitability of CA1 neurons in an ex vivo slice preparation. We hypothesize that any in vivo effects of ARVs on cognition may be exacerbated in the presence of an anesthetic challenge. As these drugs are often used as preventative or prophylactic agents, here, we administered clinically relevant doses of each drug to healthy, young adult Sprague Dawley rats via TID subcutaneous injection for 14 days prior to, then during, testing. On the first day of testing, rats were administered 2 hours of isoflurane (1.5% - 2.0%) or sham anesthesia (100% oxygen), followed by an emergence paradigm including time to return of righting reflex and ambulation, as well as time to attempt to remove a sticky dot placed on the forepaw. This was immediately followed by 1 hour of recording in an open field arena, then a novel object recognition (NOR) task with 24-hour intra-trial interval. AZT-treated rats given sham anesthesia showed no difference in time to remove a sticky dot, nor in NOR performance, as compared to vehicle-treated animals. However, AZT-treated rats exhibited a trend toward lower activity, including reduced exploration and grooming, in an open field arena. This ongoing research may help guide clinical decisions in those prescribing ART.

**Title:** Low level laser promotes cortical neurogenesis in a photothrombotic stroke model

**Authors: *L. YANG**[1,2], D. TUCKER[2], Y. DONG[2], C. WU[1], Q. ZHANG[2]
[1]South China Normal Univ., Guangdong, China; [2]Augusta Univ., Augusta, GA

**Abstract:** Recent work has indicated that low-level laser irradiation (LLI) may confer beneficial effects in altering the pathological status of several neurological disorders, although the underlying mechanisms are currently unclear. The current study was designed to investigate the beneficial effects of LLI on behavioral deficits and neurogenesis in a photothrombotic (PT) model of ischemic stroke in rats. Rose bengal was injected intraperitoneally (i.p.) and a cold light source was applied to exposed scalp over the right sensorimotor cortex, generating a concise and repeatable ischemic infarct. LLI treatment was performed on days 1 through 7 following PT stroke induction. Rats received i.p. injections of 5-bromodeoxyuridine (Brdu) (a cell proliferative marker) twice daily (50 mg/kg) on days 2 through 8, followed by sample collection on day 14.

Our results demonstrated that LLI significantly attenuated behavioral deficits and infarct volume after PT stroke. Further investigation revealed that LLI significantly enhanced neurogenesis as evidenced by increased expression and colocalization of Brdu, DCX, MAP2, spinophillin and synaptophysin. Mechanistic studies revealed that these beneficial effects were accompanied by a robust suppression of oxidative damage, levels of reactive gliosis, and production of pro-inflammatory cytokines. On the contrary, the release of anti-inflammatory factors, cytochrome c oxidase activity, and ATP production in peri-infarct regions were increased in LLI group animals compared with PT group controls. LLI effectively shifted activated microglia from a pro-inflammatory M1 to an anti-inflammatory M2 phenotype, in accordance with its effect on the release of inflammatory cytokines. Our studies indicated that LLI promotes neurogenesis and improves the neuronal microenvironment by altering a broad spectrum of pathological features in ischemic conditions, including oxidative stress, mitochondrial dysfunction and neuroinflammation. These findings provide further support for the promising therapeutic effect of LLI on ischemic stroke.

**Title:** The combination of DNMT inhibitor and task-specific training contributes to recovery in chronic stroke

**Authors: I.-A. CHOI**[1], *D.-H. CHOI[1], J. LEE[2]
[1]Konkuk Univ. Sch. of Med., Seoul, Korea, Republic of; [2]Rehabil., Konkuk Univ. Med. Ctr., Seoul, Korea, Republic of

**Abstract:** *Background* - Behavior and experience are capable of inducing plastic changes within the normal and injured brain. Especially, specific behavioral experience, such as motor skill training after experimental brain injury, provides functional benefit. There is currently no

specific treatment for improving functional recovery after stroke except for rehabilitation. 5-Aza-2'-deoxycytidine (decitidine) is a DNMT inhibitor. It involved in reducing extent of injury in stroke models but its effects on recovery of function are not known. The beneficial effects of early rehabilitation on neuroplasticity and functional recovery have been modeled in acute stage of experimental stroke. However, the impact of rehabilitation in chronic stage of stroke remains poorly understood. *Objectiv*e - The purpose of the study is to examine the effectiveness of the task specific training (TST) combined with decitabine as a treatment to enhance neural plasticity in the chronic stage after ischemic stroke. *Methods* - Rats underwent a photothrombosis surgery to impair sensorimotor cortex. Eight weeks after stroke, animals were trained staircase test. Before the beginning of a rehabilitation, decitabine was started to infuse in contralesional hemisphere using osmotic pump and lasted for 28 days. During the decitabine delivering, animals were exposed to TST for 4 weeks. Functional recovery was assessed using staircase test, cylinder test, modified neurological severity scores (mNSS) every 2 weeks. Biotinylated dextran amine tracing was injected into the non-lesioned forelimb sensorimotor cortex at the end of behavioral test to determine axonal plasticity in the corticorubral tract (CRT). *Results* - The TST combined with decitabine significantly improved skilled reaching ability in the staircase test at 4 weeks. Only TST group is significantly ameliorated in the mNSS scores and cylinder test at 4 weeks. Tracing the corticorubral tract, the crossing fibers from the contralesional red nucleus were significantly increased in TST and TST with decitabine groups. *Conclusion* - Functional recovery after chronic stroke may involve contralesional CRT plasticity by modulating DNA methylation in contralesional motor cortex. Our results suggest that combined therapy to enhance CRT plasticity based on TST and decitabine would constitute a promising therapy for promoting recovery of function in the chronic stage of stroke.

**Title:** GPR81, a novel metabolic receptor reverses brain injury following a post hypoxic-ischemic stress

**Authors: *P. M. CHAUDHARI**[1], A. MADAAN[2], X. HOU[3], I. CHARFI[3], G. PINEYRO[3], S. CHEMTOB[3]

**Abstract: Purpose**: Premature infants are subjected to a plethora of drastic events, often leading to potential adverse consequences for neurodevelopment in addition to severe neurological insults. Although inadequate hemodynamics is an underlining feature of these encephalopathies, it is accompanied by marked neovascularization in the penumbral regions as a repair mechanism, especially for the preservation of neurons. Notwithstanding the paramount role of VEGF in post-ischemic neovascularization, other factors also partake in this process. Since vascular supply is coupled to tissue energy consumption, a role for metabolic intermediates such as lactate in angiogenesis can be surmised. We propose that lactate via its receptor GPR81 governs post-natal brain angiogenesis and is crucial during post-hypoxic ischemia (HI).
**Methods**: Changes in microvasculature were quantified using lectin staining on brain cryosections. Ex-vivo aortic explants were treated with lactate condition media from primary neuronal culture. Gene expression analysis was performed by real-time PCR. GPR81 expression was determined by immunofluorescence, lactate concentration in HI model was quantified using Lactate Assay Kit (Bio-Vision) and TTC (tetrazolium chloride) staining was used to determine the post-natal hypoxic ischemic insult in KO and WT mice.
**Results:** Intra cerebroventricular injections of lactate increased brain vascular density; no such effect was observed in GPR81 KO. GPR81 was specifically expressed on the neurons and a significant decrease (up to 20%) in vascular density was observed in the GPR81 KO as compared to age matched WT C57/BL mice. Furthermore, GPR81 regulates pro-angiogenic, angiostatic and inflammatory factors like VEGF, ANG-1, ANG-2, TSP, COX-2, TLR-4, CCL-2. Moreover, TTC staining showed an increase in infarct size in GPR81 KO mice as compared to WT mice after post-hypoxic ischemia.
**Conclusion:** The result suggests GPR81 plays a vital role in brain developmental angiogenesis and reverses brain injury in post HI mice model via regulation of various angiogenesis factors. Collectively, our study shows GPR81 is a metabolic sensor of developmental brain angiogenesis and may promote post HI recovery.

**Title:** A role for brain pericytes in cerebrovascular regeneration after stroke

**Authors: *L.-P. BERNIER**[1], J. HEFENDEHL[1], C.-A. LEWIS[2], W. SCOTT[3], L. DISSING-OLESEN[1], F. ROSSI[2], M. UNDERHILL[3], B. MACVICAR[1]

**Abstract:** Brain pericytes are a critical component of the neurovascular unit as they are essential for the developmental maturation of cerebral blood vessels and for the integrity of the blood-brain barrier (BBB). However, their role in repairing and restoring the cerebral microvasculature following CNS trauma remains unclear, partly because their identification has traditionally relied on protein markers that are expressed in a non-specific and cell state-dependent pattern. We generated a novel transgenic mouse with highly specific and heritable expression of tdTomato in pericytes to investigate their roles following stroke *in vivo* and *ex vivo*. The mice were subjected to a photothrombotic focal stroke and the involvement of pericytes in post-stroke recovery was investigated relative to peri-lesion revascularization. We show that following initial cell death, proliferating pericytes migrate into the infarct zone where they accumulate on the ischemic side of the reactive astroglial border. Pericytes in that region drive a progressive angiogenic front that supports a wave of local tissue revascularization into the lesion, as evidenced by immature pericytes extending ramifications along vessels and associating with endothelial cells prior to functional blood flow establishment. Within a few weeks normal vessels with an intact BBB are found perfusing a previously ischemic cortical area. We provide a novel transgenic model for pericyte investigation and show that pericytes have the ability to contribute to the regeneration of cerebral blood vessels in a process that recapitulates their role in developmental vasculogenesis.

**Abstract:** Decreased long term disabilities after stroke are dependent on neuronal survival. Secondary neuronal death in the penumbra is facilitated by the conversion of glial cells to the proinflammatory phenotype that induces neurodegeneration. Therefore, regulation of glial activation is a compelling strategy to reduce brain damage after stroke. This regulation is challenging due to the difficulty of some drugs to access the central nervous system (CNS), and specifically target glial cells. Effective stoke therapy demands a carrier that can cross the blood-brain barrier, and target activated glial cells. Furthermore, activated glial cells (astrocytes and microglia) are a highly heterogenic population, with a broad, context dependent, spectrum of possible activation profiles. Given that different activation phenotypes can drive neuronal fate, it is important to include assorted activating stimuli. In the present work we set up to exploit the tailorable qualities of nanoparticles, and explored the use of a polyamidoamine core-shell tecto-dendrimer (G5G2.5 PAMAM) as a carrier for distinct populations of stroke activated glia. We found that G5G2.5 tecto-dendrimer is actively engulfed by glial cells in a time- and dose-dependent manner showing high cellular selectivity and lysosomal localization. In addition, *in vitro* oxygen-glucose deprivation (OGD) or lipopolysaccharide (LPS) exposure increased astroglial G5G2.5 uptake; but this was not observed in glial scar forming astrocytes. I*n vivo* brain ischemia showed an increased incorporation of the tecto-dendrimer in the lesioned area, with specific preference for immune engaged cells . We conclude that G5G2.5 tecto-dendrimer is a highly suitable carrier for targeted drug delivery to glial cells after brain ischemia.

**Title:** Wnt7a regulation of post-stroke neurogenesis

**Authors: *H. ZHAO**[1], T. B. LENGNING[2], M. MACHNICKI[1], A. BRUMM[1], S. T. CARMICHAEL[1]
[1]Neurol., UCLA, Los Angeles, CA; [2]Univ. Med. Ctr., Hamburg-Eppendorf, Germany

**Abstract:** Stroke is a leading cause of adult disability, but despite its prevalence current treatments do not provide long-term recovery. Stroke itself induces a wide-range of repair mechanisms, including the proliferation and long-distance migration of immature neurons (neuroblasts) from the subventricular zone (SVZ) to peri-infarct tissue, a process termed post-stroke neurogenesis. These neuroblasts localize to and migrate along angiogenic blood vessels, forming a neurovascular niche in the peri-infarct zone. The reciprocal signaling between neuroblasts and endothelial cells has not been clearly characterized. Understanding these endogenous signaling systems may provide novel targets for pharmaceutical intervention to enhance functional recovery.
In genome-wide expression profiling studies, we identified Wnt7a as a candidate signaling gene that is down-regulated in stroke-responsive neuroblasts. Wnt7a stimulates neural stem cell proliferation and is important for neuronal differentiation and maturation in the hippocampus of adult mouse brains (Qu, et. al, 2013). However, its role in post-stroke neural repair is not well understood. In previous studies, Wnt7a has been shown to promote angiogenesis, resulting in increased vessel density, endothelial cell proliferation, and blood brain barrier maturation after stroke. Based on these findings, Wnt7a may play a key role in the neural repair by promoting neural progenitor proliferation and maturation. Here, we identify Wnt7A's role in post-stroke neurogenesis in a set of gain-of-function (GOF) and loss-of-function (LOF) studies in the photothrombotic stroke model using lentiviral vectors for overexpression and microRNA-mediated knockdown of Wnt7a in the peri-infarct cortex.

**Title:** Effects of chronic administration of the selective histamine $H_4$ receptor antagonist JNJ7777120 on cerebral injury in a model of transient brain focal ischemia in the rat

**Authors: I. DETTORI**[1], L. GAVIANO[1], A. MELANI[1], L. LUCARINI[1], *G. PEPEU[2], E. MASINI[1], F. PEDATA[1]
[1]Dept. of Neurosciences, Psychology, Drug Res. and Child Hlth., [2]Univ. of Florence, Florence, Italy

**Abstract:** Cerebral ischemia is a multifactorial pathology characterized by different events evolving in time. The acute injury, characterized by a massive increase of extracellular glutamate levels, is followed by a secondary brain injury that develops from hours to days after ischemia. Histamine is a neurotransmitter/ neuromodulator in the Central Nervous System (CNS). Recently, it was demonstrated in the experimental model of focal cerebral ischemia induced by occlusion of the middle cerebral artery (MCAo) in the rat, the levels of histamine, evaluated by microdialysis, increase in the ischemic areas. The human histamine $H_4$ receptor is the most recently discovered member of the G protein-coupled receptor subfamily of histamine receptors. It is predominantly expressed in several cell types of immune system and in numerous areas of the CNS including cortex and striatum.
The aim of our study was to assess the putative neuroprotective effects of the potent and selective histamine $H_4$ receptor antagonist, JNJ7777120, chronically administered (1 mg/kg, i.p., twice/day for 7 days) on damage parameters in a model of focal ischemia induced in the rat by the transient (1 hour) occlusion of the MCA (tMCAo) by the monofilament technique.
Chronic treatment with the histamine $H_4$ receptor antagonist, JNJ7777120, significantly protected from the neurological deficit 1, 5 and 7 days after tMCAo (score at 7 day: 3.5±0.5, n=10 versus 5.8±0.4, n=13 in vehicle group; $p<0.001$) and significantly reduced the body weight loss at 5 and 7 days after tMCAo with respect to vehicle-treated rats (respectively $p<0.05$; $p<0.01$). Seven days after the ischemic insult, JNJ7777120 reduced the volume of the ischemic cortical damage (16.6±2.18 $mm^3$, n=10 versus 28.7±1.83 $mm^3$, n=10 in vehicle group; $p<0.0005$) and the volume of the ischemic striatal damage (4.2±0.47 $mm^3$, n=10 versus 10.1±1.14 $mm^3$, n=10 in vehicle group; $p<0.0001$). Seven days after ischemia, chronic treatment with JNJ7777120, significantly reduced the number of $IBA1^+$ (specific for microglia) and $GFAP^+$ (specific for astrocytes) cells in the ischemic core and boundary zones of striatum and cortex with respect to vehicle-treated rats. JNJ7777120 also decreased the plasma levels of the proinflammatory cytokines, IL-1β and TNF-α seven days after tMCAo.
Results demonstrate that the selective antagonist of histamine $H_4$ receptor JNJ7777120, systemically and chronically administered after ischemia, reduces the ischemic brain damage and improves the neurological deficit, suggesting that the $H_4$ histamine receptor is a valuable pharmacological target after brain focal ischemia.

**Title:** Axonal remodeling induced by rehabilitative training on the isometric pull task after middle cerebral artery occlusion in the rat

**Authors: *K. S. VALENZUELA**[1], S. LANGNER[2], M. BLAKER[2], S. BREWER[2], T. A. JONES[1], T. SCHALLERT[1]
[1]Psychology, The Univ. of Texas At Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

**Abstract:** Reaching tasks are commonly used to assess various facets of paretic forelimb function and the influence of motor rehabilitative training in rat stroke models. Behavioral manipulations such as reach training can influence patterns of neural connectivity post-stroke. It has yet to be determined how reach training influences patterns of axonal reinnervation in the lesioned hemisphere after strokes that cause subcortical damage. Long Evan rats were trained with their preferred limb to reach outside a chamber, grasp a handle, and pull to receive a food pellet (Isometric Pull task, Vulintus). Transient focal ischemia (60 mins) was induced in the hemisphere contralateral to the preferred limb by an intraluminal middle cerebral artery occlusion suture method. Rats received either six weeks of rehabilitative training (RT) with the paretic limb (n=8) or non-training control procedures (n=6) on the Isometric Pull task. Forelimb strength, as measured in grams, and the number of trials completed during 30 min sessions were probed weekly for seven weeks. At the completion of the behavioral study, all animals received an axon tract tracer (biotinylated dextran amine) via pressure injection in layer V motor cortex in the ipsilesional hemisphere. The tracer was allowed to travel for 21 days and then brains were harvested. Prior to ischemic induction, animals reached with an average of 192.40g and completed an average of 160 trials per 30 minute session. Average forelimb force dropped to 79.02g and average trials per session dropped to 29 at an initial one week post-stroke assessment. Animals were then assigned to either RT or a control group. After 1 week, forelimb force was similar for the RT group (88.46±29.62g) and control group (75.36±24.41g). However, the groups' performance began to steadily separate at the week 2 time point. The RT group (111.28±28.33g) was able to reach with twice as much force as the control group (53.64±24.69g) at week 2. By week 6, the RT group (135.02±22.93g) reached with about two and a half times as much force as the control group (55.94±27.45g). A similar temporal pattern of group differences was found in the measure of trials completed per session. After 1 week, the RT (74.00±21.90) and control (64.00±21.49) groups had similar performance. By week 6, the RT group

(100±16.23) completed nearly 4 times as many trials per session as the control group (28.00±14.14). Thus, rehabilitative training on the Isometric Pull task resulted in major improvements in paretic forelimb strength and performance. Work to examine the influence of rehabilitative training on axonal reinnervation of regions denervated by the MCAo damage is ongoing. All data are mean±SEM.

**Title:** Intranasally delivered recombinant MANF protein reduces infarction volume and promotes recovery in a rat cortical stroke model

**Authors: *J. E. ANTTILA**[1], K. MÄTLIK[1], O. S. MATTILA[2], P. LINDHOLM[1], P. J. LINDSBERG[2], M. AIRAVAARA[1]
[1]Inst. of Biotech., [2]Res. Program for Mol. Neurol., Univ. of Helsinki, Helsinki, Finland

**Abstract:** Introduction: Mesencephalic astrocyte-derived neurotrophic factor (MANF) is an 18 kDa endoplasmic reticulum (ER) resident protein that is upregulated and secreted upon ER stress, and has neurotrophic properties. Intracranial delivery of MANF provides neuroprotection in rat models of ischemic stroke. Our aim was to test if non-invasive intranasal delivery of MANF is neuroprotective and determine the pharmacokinetic profile of MANF after intranasal administration.
Methods: Unilateral cortical infarction was induced in adult male Sprague Dawley rats by transiently ligating the distal branch of the right middle cerebral artery with a 10-0 suture and occluding both common carotid arteries for 60 minutes. Recombinant human MANF (rhMANF) or vehicle was administered intranasally before the induction of ischemia and immediately after reperfusion in all experiments. Effects on infarct volume were measured 48h post-stroke (n=10-17). In separate experiments, behavioral recovery was monitored for 14 days (Bederson's score,

body asymmetry test and measurement of locomotor activity [n=14-15]). The distribution of rhMANF after intranasal delivery was investigated using $I^{125}$-rhMANF and an enzyme-linked immunosorbent assay (n=6), and the effect of rhMANF on ischemic and post-ischemic cerebral blood flow (CBF) was evaluated with Laser Doppler Flowmetry (n=9-10).
Results: Intranasally administered rhMANF decreased infarction volume by 30% ($p<0.05$) and reduced neurological deficits measured on days 7 ($p<0.05$) and 14 ($p<0.0001$) post-stroke. No significant differences were found between the treatment groups in CBF during occlusion or reperfusion. One hour after intranasal delivery 0.4% of the total dose of $I^{125}$-rhMANF reached systemic circulation and only 0.003% was detected in the brain.
Conclusions: Our results show that rhMANF is neuroprotective also when administered intranasally, providing reduced infarct volumes and improved functional recovery. Further investigation is warranted to determine the individual contribution of circulating and intracerebral rhMANF in these effects.

**Title:** Extended therapy time window in rat model of ischemic stroke by salvianolic acid a

**Authors: *N. J. LI**, C. JIAO, L. XU
Kunming Inst. of Zoology, Yunnan, China

**Abstract:** Acute ischemic stroke (AIS) is a leading cause of death and disability in middle and aged population. Major challenge is to extend the time window (< 3-4.5 hours) of using tissue plasminogen activator (tPA) and to preserve the penumbra for functional recovery after AIS. We here report that treatment of salvianolic acid a (SAA) at the time up to 8 hours after AIS-like brain injury is markedly beneficial, and that with higher doses or longer delay (12 hours) is intriguingly harmless. A novel mechanism of SAA is attributable because co-treatment with tPA leads to synergic efficacy in aged rats, and because SAA enhances transdifferentiation of reactive astrocytes into neurons in the penumbra and promotes recovery from long-lasting impairment of spatial memory and glucose metabolism. Our data suggest a novel mechanism of SAA

underlying neuroprotection and compatibility with tPA, relevant to the development of a novel-generation of agents for treating AIS.

**Title:** Sensorimotor & fine motor skill deficits were chronically sustained in mild ischemic stroke rats

**Authors: *A. N. SATO**, Z. WARRAICH, E. MORADI, D. BATES, Y. ANDREWS-ZWILLING
Res. and Develop., SanBio, Inc., Mountain View, CA

**Abstract:** In rodent models of ischemic stroke, loss of function can be variable over prolonged periods of time and mild impairments can be difficult to detect depending on the extent of the stroke. In this study, we investigated several behavioral outcome measures for a mild stroke model in rats, which showed sustained deficits in sensorimotor and fine motor skilled tasks up to 1.5 months. The present study assessed behavioral deficits of rats 7, 21, 28, 35, 42 and 49 days following 120 minutes of transient Middle Cerebral Artery occlusion (MCAo) using a 0.33 mm filament in the left hemisphere. Deficits were assessed by sensorimotor and locomotor behavioral tests: Rotarod test, Paw Whisker test, Akinesia (Stepping) test, and Isometric Pull test. The Isometric Pull test, an updated method of the reach-to grasp task, is automated and incorporates accurate quantitative force generation, pull attempts, and success rate to assess forelimb function in rats (Hays et al., 2012). Rats were highly proficient in all the behavioral assays prior to stroke. There were no significant differences between non-stroke and stroke rats in the Stepping and Rotarod tests, which assessed gross motor skills. However, a sustained trend of sensorimotor deficit in the impaired forelimb (right whisker stimulation, right paw placement) and in the cross-midline (left whisker stimulation, right paw placement) in the Paw Whisker test was observed in mild stroke but not observed in non-stroked rats. In addition, rats with mild stroke showed sustained deficits in mean peak force and % successful hits in the Isometric pull test and maintained fine motor deficits compared to the non-stroked group. The force generated

from the impaired right paw in the mean peak force was substantially decreased in all rats after stroke. The frequency of reaching the minimal reward threshold of 120 g ratio to number of attempts were decreased in all stroke rats post-operatively. Deficits for both Paw Whisker and Isometric Pull Test were sustained 49 days following lesion. Fine functional and sensorimotor behavioral assays, such as the Isometric Pull and Paw Whisker test, were able to detect sustained long-term functional impairments compared to gross locomotor behavioral assays in mild stroke rats.

**Title:** The effects of increasing activation of cholinergic neurons in the nucleus basalis on stroke recovery

**Authors: *A. BECKER**[1], D. BETZ[2], M. P. GOLDBERG[3]
[1]UT Southwestern, Dept. of Neurol. and Neurotherapeutics, Dallas, TX; [2]Dept. of Neurol. and Neurotherapeutics, [3]Neurol., UT Southwestern Med. Ctr., Dallas, TX

**Abstract:** Cholinergic long-range projections from the nucleus basalis (NB) are important for learning and cortical plasticity. In rats, electrical stimulation of the NB timed with sensory or motor activity increases the size of task-relevant cortical maps and increases performance after training. We tested the hypothesis that increasing the firing of cholinergic NB neurons during rehabilitative motions can increase the extent or speed of recovery after stroke. Using a mouse line that expresses cre in cholinergic cells under control of the choline acetyltransferase promoter, we injected a cre-dependent Gq DREADD (Designer Receptors Activated by Designer Drugs) or control GFP virus bilaterally into the nucleus basalis of C57/BL6 mice. Stroke-related behavioral deficits were measured using the automated reach task (Becker et al, J Neurosci Meth, 2016) before and up to 1 week after stroke. The DREADD-activing drug clozapine-N-oxide was injected before rehabilitative sessions from weeks 2-6 and final performance evaluated on week

7. Preliminary results show a trend toward greater improvement at week 7 after stroke in the DREADD-injected mice; results and methods for increasing effect size will be discussed.

**Abstract:** Osteopontin (OPN), an acidic phosphoglycoprotein, is upregulated in the brain after cerebral ischemia. We previously reported OPN to support migration, survival, and proliferation of neural stem cells (NSC) in primary cell culture, as well as their differentiation into neurons. We here analyzed the effects OPN on neuroblasts *in vivo* in the context of cerebral ischemia. Transgenic mice expressing luciferase (luc) under the control of the neuroblast-specific doublecortin- (DCX-)promotor, allowing visualization of neuroblasts *in vivo* using bioluminescence imaging (BLI), were injected with OPN intracerebroventricularly (n=8), control mice were injected with vehicle-buffer (n=8). To assess the effects of OPN after stroke, additional mice were subjected to photothrombosis, and injected with either OPN (n=14) or vehicle (n=13). OPN enhanced the migration of neuroblasts both in the healthy brain as well as after stroke, as quantified by BLI *in vivo*. Moreover, the number of neural progenitors was increased following OPN-treatment, with maximum effects on 2 days after OPN-injection into the healthy brain, and 14 days after OPN-injection following stroke. After stroke, OPN quantitatively promoted the endogenous, ischemia-induced neuroblast expansion, additionally recruiting progenitors from the contralateral hemisphere. Data suggest OPN as a promising substance for the targeted activation of neurogenesis in future preclinical stroke studies.

**Title:** Effects of 3K3A APC on subcortical white matter stroke in mice

**Authors: *Y. WANG**, Z. ZHAO, A. MONTAGNE, B. V. ZLOKOVIC
Zilkha Neurogenetic Inst., Keck Sch. of Medicine, USC, Los Angeles, CA

**Abstract:** Subcortical white matter stroke constitutes up to 30% of all stroke subtypes, occurs initially as silent infarcts in the white matter (WM), and contributes significantly to the development of vascular dementia. Activated protein C (APC) is a plasma serine protease that is capable of antithrombotic, anti-inflammatory, anti-apoptotic, and cell-signaling activities. 3K3A-APC, a recombinant variant of APC with reduced anticoagulant activity, engineered to reduce APC-associated bleeding risk while retaining normal cell-signaling activity, have shown benefits in preclinical models of ischemic stroke with big infarct involved common large artery and gray matter. In this study, subcortical WM stroke model was induced by vasoconstrictor N5 (1 iminoethyl) L nornithine, dihydrochloride (L Nio). L Nio (Calbiochem) was injected into subcortical WM of the anterior cingulum (AC) of the corticolimbic circuit or the subcortical white matter ventral to the mouse forelimb motor cortex using the Neurostar motorized ultra precise small animal stereotaxic instrument (Model 963SD). Mice received 0.2 mg/kg intravenously of recombinant murine 3K3A APC or saline at 4, 24, 48 and 72 h after stroke. The results showed that 3K3A APC significantly reduced the lesion volume and protected blood brain barrier damage 3 days after stroke, and improved remote memory function 4 weeks after stroke, compared to vehicle. These results demonstrated that 3K3A APC might be an effective treatment for white matter stroke.

**Title:** Casein kinase 2 inhibition promotes white matter recovery after ischemia

**Authors: *S. BRUNET**, C. BASTIAN, D. AQUILA, S. BALTAN
Cleveland Clin. Fndn., Cleveland, OH

**Abstract:** Ischemic stroke is the third leading cause of death globally and axonal injury and dysfunction are responsible for much of the disability observed following a stroke. Human brain comprises equal proportions of gray matter and white matter. White matter is injured in most strokes and contributes to the behavioral deficits following a stroke. Casein kinase 2 (CK2) is expressed in brain, including white matter, and is regulated by ischemia. We therefore hypothesized that transient CK2 inhibition would protect white matter (WM) from ischemic injury. To assess the impact of CK2 inhibition on axonal electrical activity following oxygen glucose deprivation (OGD), mouse optic nerves (MONs), a pure white matter track, from C57BL/6J were subjected to OGD (1h) while eliciting compound action potentials (CAPs) when exposed to either CX-4945, a selective CK2 inhibitor, or control artificial cerebrospinal fluid (ACSF). We observed that CX-4945 preserved CAPs when applied either before or after OGD. Then to determine the impact of CK2 inhibition on glial cell survival following OGD, MONs exposed to OGD treated with either CX-4945 or control ACSF were processed for immunohistochemistry. We observed that CX-4945 treatment protected oligodendrocytes from OGD. To determine if CK2 inhibition protected mitochondrial from OGD, MONs from Thy-1 mito-CFP mice were similarly subjected to OGD in the presence of CX-4945 or control ACSF. We observed that CX-4945 maintained Thy-1 mito-CFP fluorescence following OGD. Lastly, to determine which signaling pathway CK2 employed to protect axonal function against OGD we tested the role of AKT and CDK5 signaling. We observed that MK-2206 and roscovitine, selective AKT and CDK5 inhibitors respectively, protected WM function only when applied before OGD. Overall, we demonstrated that CK2 inhibition preserves axonal function by preserving oligodendrocytes and mitochondrial function following ischemic injury. Also, we showed that AKT and CDK5 signaling likely contribute to the protective mechanism conferred by CK2 inhibition on WM functional recovery from ischemia. We suggest that CK2 inhibitors, which are currently in phase I-II clinical trials for cancer therapy could be repurposed and provide a novel therapeutic target for ischemic stroke patients.

**Title:** Lamina I spinoparabrachial neurons: Sensitization to noxious stimuli in rats with chronic constriction injury of the sciatic nerve and poor response to pregabalin

**Authors: *J. ALLARD**[1], C. LE CUDENNEC[2], V. CASTAGNÉ[2]
[1]E-Phys, Clermont-Ferrand, France; [2]Porsolt S.A.S., Le Genest-Saint-Isle, France

**Abstract:** Chronic constriction injury (CCI) induced by loose ligation of the sciatic nerve results in robust behavioural mechanical and thermal hypersensitivity in rats. The aim of the present work was to assess 1) whether electrophysiological recordings of spinoparabrachial neurons could evidence this hypersensitivity and 2) the impact of acute pregabalin treatment on the responses of these neurons in CCI and SHAM rats. Spinoparabrachial neurons receiving C fibre input and innervating the glabrous skin of the hind paw were recorded under isoflurane anaesthesia. Spontaneous activity and evoked responses to mechanical (von Frey probe (VF), calibrated pinch) and thermal (water jet (WJ)) stimuli were measured on the side ipsilateral to the surgery in 20 CCI rats and SHAM rats (1 neuron per rat). After this initial characterisation, responses to pinch and water jet at 50 °C were assessed before and after the i.v. delivery of 30 mg/kg pregabalin or the corresponding vehicle, for 60 min post-injection. Behavioural testing confirmed the existence of a significant hypersensitivity to mechanical and thermal stimulations in the CCI rats compared with SHAM rats in advance of their use for electrophysiology. The search of neurons was based exclusively on antidromic stimulation from the parabrachial area. Seventeen and 20 neurons responding to inclusion criteria were initially characterised in SHAM and CCI rats respectively (median conduction velocity, 13 m/s, range, 4.7-22.2 m/s, n=37). Twenty five out of the 29 recovered recording sites were located in lamina I. Spontaneous activity was virtually inexistent. Thermal responses were significantly increased in CCI rats compared with SHAM rats (p=0.007, 0.041, 0.051 and 0.040 for WJ at 0, 42, 46 and 50 °C, Mann-Whitney test, respectively). Responses to pinch (p=0.013, Mann-Whitney test) but not to VF 400, 600 and 800 mN were also significantly increased in CCI rats compared to SHAM rats. The effect of pregabalin or the corresponding vehicle on responses to pinch and WJ 50 °C was completed in 7 SHAM and 8 CCI rats. In the present conditions, there was no evidence of any inhibitory activity of pregabalin 30 mg/kg at 20, 40 or 60 min post-injections. Thus, evoked responses confirmed the sensitization of lamina I spinoparabrachial neuron to noxious stimuli in rats with CCI, in agreement with previous reports. In the present experimental conditions, pregabalin 30 mg/kg failed to decrease responses of lamina I spinoparabrachial neuron to noxious stimuli.

**Title:** The molecular mechanism of acid sensitive ion channel mediated pain in promoting the proliferation of breast cancer cells

**Authors:** ***C. YANG**[1], G. DING[2]
[1]Xinhua Hosp. Chongming Br., Shanghai City, China; [2]Shanghai Intl. Med. Ctr., Shanghai, China

**Abstract:** Abstract:
Background: Cancer pain seriously affects the life quality of patients with tumor. Our previous research indicated that relieve of pain availably prolong the survival period of patients with advanced cancer. However, the mechanism about how pain impact cancer is still unclear. A novel kind of ion channels - acid sensing ion channels (ASICs), are widely participate into the initiation and development of pain. Earlier studies have shown that the acid sensitive ion channels also are high expression in a variety of tumor cells. These results show acid sensitive ion channels are likely to involve with both tumor and pain. ASICs might be important role which contribute to the impact of pain to cancer.
Result: In this research, Based on our cancer biobank and pain biobank, there are 30 tumor tissues of breast cancer patients were chosen and grouped according to the patient's pain rating, a rat cancer pain model was established by sciatic nerve ligation of a rat with tumor. Through a combination of cell and molecular biology, immunochemistry, electrophysiology, animal behavior testing, system illustrate the following three results: 1) The alteration of distribution and property of ASIC1a underlying cancer pain, the expression of ASIC1a increases as the patient's pain level increases; 2)The influence of cell factor in microenvironment to ASIC1a, the result of high - throughput cytokine microarray detection show that the expression of cytokines in patients with severe pain was higher than that in painless patients, After receiving analgesic treatment, the expression of tumor cytokines decreased in patients with severe pain; 3) The mechanism of

ASIC1a mediating breast tumor development induced by pain. Inhibition of or interfering with the expression of ASIC1a in pain tumor rats compared with painless tumor rats can significantly inhibit tumor growth.
Conclusion: The up-regulation of tumor cytokines in tumor microenvironment increase the up-regulation of ASIC1a expression in patients with cancer pain, and the increase of ASIC1a expression promotes the proliferation of tumor cells.
Significance: It is expected to enrich the hypothesis “Pain – Microenvironment - Cancer”, and explore the potential of ASIC1a as a key therapeutic target for cancer and pain.

**Title:** Encoding of acute nociception by specific population of lamina I projection neurons

**Authors: K. AGASHKOV**[1], V. KROTOV[2], M. KRASNIAKOVA[1], B. V. SAFRONOV[4], *N. V. VOITENKO[3], P. BELAN[2]
[1]Sensory Signalling, [2]Mol. Biophysics, [3]Bogomoletz Inst. of Physiol., Kiev, Ukraine; [4]Neuronal Networks, IBMC, Porto, Portugal

**Abstract:** Spinal lamina I projection neurons (PNs) are key elements of the pain processing system, which relay peripheral input to supraspinal structures generating sensation of pain. The population of PNs is small (~5% of lamina I neurons) but very heterogeneous according to their intrinsic and synaptic properties. For this reason, we know little about how the nociceptive peripheral input integrated by the spinal neuron network is finally encoded by PNs in a form of modality-specific discharge patterns. Here, whole-cell recordings were done in an intact spinal cord preparation with attached dorsal roots to examine the input-output characteristics of lamina I PNs retrogradely-labeled from the lateral PB area. We identified a specific group of PNs (16%)

having high action potential (AP) output to the supraspinal structures in a response to nociceptive dorsal root stimulation. In these high output PNs (HO-PNs), a stimulation of nociceptive afferents evoked gradual strength-dependent amplification of synaptic input expressed as an increase in the number of generated APs. Upon a root stimulation at C-fiber-intensity, the HO-PN group generated more than 80% of APs of the entire population of lamina I PNs, thus, being the major group of PNs codifying acute pain sensation. We have also identified several mechanisms of this nociceptive input amplification. First, HO-PNs are strongly and selectively innervated by the high-threshold Adelta- and C-afferents providing robust and reliable spike generation. Second, the nociceptive input was amplified by intrinsic bursting capabilities of HO PNs. Third, the afferent input was prolonged (to 0.-1.5 s) and potentiated (to -45 mV to -20 mV) by the NMDAR-dependent synaptic component forming intrinsic plateau potentials generated by HO-PNs. The afferent stimulation increased, for several seconds, spontaneous excitatory drive to HO-PNs that became suprathreshold during the plateau potential and evoked an additional series of network-driven APs. In conclusion, we have described a new type of lamina I PNs efficiently transmitting the main part of primary nociceptive input to supraspinal structures playing an important role in acute pain generation. A complex interplay between synaptic, intrinsic and network activities underlies unique nociceptive encoding features of this group of PNs.

**Abstract:** Although the administration of dexmedetomidine (DEX), an alpha-2 adrenoceptor agonist, significantly attenuates nociception and hyperalgesia in several pain models, the clinical trial of DEX is limited by several side effects including drowsiness, hypotension and sedation. The present study aims to determine whether intraperitoneal injection of DEX suppresses the nociceptive responses in a mouse orofacial inflammatory pain model, and whether it affects

motor coordination and blood pressure. Moreover, we examined whether co-administration of lidocaine with ineffective dose of DEX produced an anti-nociceptive effect without side effects. The 5% formalin (10$\mu l$) was subcutaneously injected into the right upper lip, and the rubbing responses were counted for 45 minutes. DEX (3, 10, 30 or 100$\mu$g/kg) were treated 30 min before formalin injection. DEX (10$\mu$g/kg) reduced inflammatory nociceptive responses in the second phase. However, higher dose (30, 100$\mu$g/kg) of DEX totally blocked the formalin induced nociceptive responses in both the first and the second phases, which was likely to be associated with a sedative effect of DEX. The high dose of DEX (30$\mu$g/kg) significantly reduced the motor performance in the rotarod test. In addition, both blood pressure and heart rate also decreased in the high dose of DEX-treated mice. On the other hand, when the lidocaine (0.5%) alone was subcutaneously injected, the nociceptive responses in the first phase, but not in the second phase were reduced. Interestingly, although lower dose of DEX (3$\mu$g/kg) did not reduce nociceptive responses, the co-administration with lidocaine potently suppressed the nociceptive responses in both the first and the second phases without a significant side effect. These results suggest that co-administration of DEX with lidocaine can be a safe therapeutic strategy for orofacial inflammatory pain management.

**Title:** Electrophysiological characteristics of SP-mediated antinociception in muscle nociceptors

**Authors: *C.-T. CHANG**[1,2], C.-H. LEE[2], C.-C. CHEN[1,2]
[1]Dept. of Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [2]Inst. of BioMedical Sciences, Academia Sinica, Taipei, Taiwan

**Abstract:** Fibromyalgia is a disease that causes chronic widespread muscle pain without apparent tissue damage or nerve injury. Animal models of that mimic the chronic muscle pain syndromes of fibromyalgia can be induced by intermittent cold stress (ICS) or dual intramuscular acid injection. Previous data have shown intramuscular acid injection activates acid-sensing ion channel 3 (ASIC3) to depolarize muscle nociceptors and results in the development of chronic muscle pain. Interestingly, intramuscular acid signaling also induces SP release and mediates an antinociceptive effect in muscle nociceptors, by which SP specifically enhances M-type potassium current and attenuates ASIC3-induced inward current on most gastrocnemius muscle (GM) afferent dorsal root ganglion (DRG) neurons. However, the role of ASIC3 in SP-mediated antinociception, especially in chronic pain context, is still unknown. Due to the fact that ICS-

treated ASIC3 knockout mice develop chronic widespread pain, we can explore the role of ASIC3 in SP-mediated anti-nociceptive signaling. We hypothesize ASIC3 could contribute to SP-mediated anti-nociception in ICS model. Here, we conducted whole-cell patch clamp recordings of medium-size (30-40μm) GM afferent DRG neurons. We applied [Sar9,Met(O2)11]-Substance P (SM-SP), a synthetic peptide analog of SP, to stimulate the patched neurons and characterized 3 different SM-SP-induced (outward current, inward current and no response). The result showed that SM-SP-induced outward current ($I_{SP\text{-}O}$) in about 35% of GM afferent DRGs. Also, we found 85.71% GM afferent DRGs with $I_{SP\text{-}O}$ showed salicylic acid-sensitive acid(pH6.8)-induced inward current indicating the expression of ASIC3. We further evaluated the expression of $I_{SP\text{-}O}$ in muscle afferent DRG neurons of ICS- and non-ICS-treated WT mice and found the population of neurons with $I_{SP\text{-}O}$ was decreased in ICS-treated mice as compared with that of WT mice. However, ASIC3 KO did not change the neuron population that express $I_{SP\text{-}O}$ in ICS and non-ICS treated mice. The result suggests that ICS-treated mice may partially cause the deficit of SP-signaling, whereas the SP-signaling is independent of ASIC3.

**Title:** Effects of neonatal vincristine administration on spinal nociceptive processing in the developing rat

**Authors: *K. A. SCHAPPACHER**[1], M. L. BACCEI[2]
[1]Univ. of Cincinnati Dept. of Anesthesiol, Cincinnati, OH; [2]Univ. of Cincinnati Dept. of Anesthesiol., Cincinnati, OH

**Abstract:** Vincristine (VNC) is commonly used to treat pediatric cancers, including the most prevalent childhood malignancy, Acute Lymphoblastic Leukemia. While clinical evidence suggests that VNC causes peripheral neuropathy in children, the degree to which pediatric chemotherapeutic regimens influence nociceptive signaling throughout life remains unclear, in part due to the lack of an established animal model of chemotherapy-induced neuropathic pain during early life. Therefore, the present study investigated the effects of neonatal VNC exposure on pain sensitivity in the developing rat. In addition, given that noxious sensory experience during the neonatal period can evoke persistent changes in synaptic function within spinal nociceptive circuits, we investigated the degree to which early life VNC modulates synaptic

transmission in the superficial dorsal horn (SDH).
Male and female Sprague Dawley rats received a total of five i.p. injections of 60 µg/kg VNC, or equivalent volumes of saline, over a ten day period starting on postnatal day (P)11. VNC-treated rats of both sexes demonstrated significantly lower mechanical withdrawal thresholds compared to control groups beginning at P26 which persisted throughout the first eight weeks of life. To determine if the onset of VNC-induced mechanical hypersensitivity is accompanied by an imbalance of excitatory and inhibitory synaptic transmission within the SDH, we used whole-cell patch clamp techniques to record miniature excitatory and inhibitory postsynaptic currents (mEPSCs and mIPSCs) from lamina I projection neurons in rat spinal cord slices at P26-P30. VNC treatment did not significantly influence the functional properties of excitatory or inhibitory synaptic signaling onto the key output neurons of the spinal nociceptive network. Overall, the present results demonstrate that VNC evokes a mechanical hypersensitivity in rats that is slow to emerge during adolescence and may not depend on a dramatic reorganization of the synaptic circuits within the developing spinal SDH.

**Title:** Measuring anxiety- and depression-like behaviors in a mouse model of neuropathic pain is critically dependent on the testing environment

**Authors: *H. H. AHN**, S. MARTINEZ GONZALEZ, S. HONG, T. WILSON, Y. CARRASQUILLO
Natl. Ctr. for Complementary and Integrative Hlth., NIH, Bethesda, MD

**Abstract:** Chronic pain is associated with mood disorders such as anxiety and depression. The effects of pain on affective behaviors in current mouse models of persistent pain, however, have been controversial due to inconsistency and limited reproducibility between laboratories. Several groups have reported increases in anxiety-like and depression-like behaviors using the elevated zero maze, the open field test and the forced swim test following placement of a cuff around the sciatic nerve. However, using the same behavioral tests and pain models, our initial experiments were unable to detect changes in affective behaviors between sham and nerve cuffed mice 5-13 weeks following surgery, in spite of the clear presence of tactile hypersensitivity, measured using von-Frey filaments. Our inability to measure changes in affective behaviors was not due to the specific time-point tested or the specific mouse strain selected. Experiments performed at several time-points following the sham or cuff surgery and in several mouse strains and C57 substrains

also failed to detect differences in affective behaviors between sham and cuff groups. Given the convincing positive published data, we undertook a systematic evaluation of the testing conditions and found that the presence of robust pain-induced changes in affective behaviors in the nerve cuff model is highly dependent on the precise environmental testing conditions. The testing conditions that we found were critical to measure pain-related changes in affective behaviors were: specific testing apparatus, room lighting, color of the walls surrounding the testing apparatus, and water temperature during the forced swim test. Importantly, the optimal testing conditions worked when the test was performed by both male and female experimenters. In addition, the results from our experiments further revealed that different mouse strains require different environmental testing conditions to detect affective behavioral changes, likely reflecting strain-dependent differences in baseline levels of anxiety- and depression-like behaviors. Altogether, our results validate the use of the nerve cuff neuropathic pain model to measure pain-related changes in affective behaviors in mice and further demonstrate that these behaviors are highly dependent on the environmental testing conditions used. Ongoing experiments in the laboratory aim at identifying the brain mechanisms underlying the onset and expression of pain-related affective behaviors at the circuit and cellular level using molecular genetics, chemogenetic and optogenetic approaches.

**Title:** Role of macrophage derived exosomes in inflammatory pain

**Authors: *R. JEAN-TOUSSAINT**, S. RAMANATHAN, Y. TIAN, H. HU, S. AJIT
Drexel Univ. Col. of Med., Philadelphia, PA

**Abstract:** Chronic inflammatory pain ensues when the normal process of inflammation does not resolve, resulting in excess proinflammatory cytokines and chemoattractants that can eventually lead to central sensitization. Neuroimmune signaling links peripheral neuronal injury or inflammation with the activation of central nervous system neuroglial cells, resulting in sustained neuronal hyperexcitability. Exosome-mediated transfer of biomolecules to acceptor cells constitutes a novel mechanism of cell-to-cell communication. Exosomes are 30-100 nm membrane vesicles that carry mRNAs, miRNAs and proteins to recipient cells via circulation. Exosome uptake results in modulation of gene expression in recipient cells. Exosomes derived from antigen-presenting cells such as dendritic cells and macrophages are capable of inducing

therapeutically relevant adaptive immune responses, but the mechanistic basis of this protection is not well understood. In a previous study, we have shown that exosomes secreted by RAW 264.7 macrophages after lipopolysaccharide (LPS) stimulation can upregulate three miRNAs known to have immunomodulatory effects. Moreover, a single intraplanar injection of exosomes derived from LPS stimulated RAW 264.7 cells attenuated thermal hyperalgesia in the complete Freund's adjuvant (CFA) mouse model of inflammatory pain. Here, we sought to determine the mechanistic basis of anti-inflammatory effects of macrophage-derived exosomes using primary mouse neurons and microglia in vitro. Our preliminary data shows efficient uptake of exosomes by both neurons and microglia. However, gene expression changes in microglia was more robust following exosome uptake when compared to neurons. Additionally, an intrathecal injection of exosomes into CFA model mice reversed mechanical but not thermal sensitivity. These data indicate that gene expression changes induced by exosomal uptake differ between neurons and microglia, and the route of administration of exosomes can influence inflammatory pain-induced nociceptive behavior in mice.

**Title:** Sexually motivated hedonic behavior is related to persistent pain-induced stress in male rats

**Authors: *M. H. PITCHER**[1,2], F. TARUM[2], M. LEHMANN[3], M. C. BUSHNELL[2]
[1]NIH, Bethesda, MD; [2]Pain and Integrative Neurosci. Laboratory, Natl. Ctr. for Complementary and Integrative Health, Natl. Inst. of Hlth., Bethesda, MD; [3]Natl. Inst. of Mental Health, Section on Functional Neuroanatomy, Lab. of Cell. and Mol. Regulation, Natl. Inst. of Hlth., Bethesda, MD

**Abstract:** Anhedonia, or the loss of interest in previously rewarding or pleasurable activities such as sexual activity, is a diagnostic criterion for major depressive disorder. In male rodents, scent marking of urine from pro-estrous females is a hedonic behavior that is sensitive to stressors such as social defeat. Considering that depression is often comorbid with chronic pain in humans and depressive-like behavior may also be seen in rodent models of persistent pain, we tested (i) how urine scent marking behavior in rodents is altered in persistent inflammatory pain

states, and (ii) if scent marking behavior relates to post-injury outcomes such as pain and stress. We compared urine scent marking behavior in rats (n=12/group) at baseline and one, two and three weeks after unilateral sham injection or intra-articular injection of Complete Freund's Adjuvant (CFA), known to elicit profound deficits in weight bearing on the ipsilateral paw for at least three weeks. Male rats were allowed to scent mark in a large arena with an absorbent paper floor containing a spot of urine harvested from pro-estrous female rats. Marking preference for the female urine zone was calculated in relation to the amount of marking in the remaining arena, where a preference score >1 represents a preference for the female urine zone and a preference <1 represents a preference for the remaining arena.
At baseline, all rats exhibited robust marking preference for the female urine zone, where marking preference for the CFA and sham groups were not significantly different (2.83±0.29 and 2.57±0.25, respectively). Marking preference was unchanged one and two weeks after CFA. However, by three weeks the CFA group exhibited a significantly reduced marking preference (1.56±0.26, *p=0.015*) as well as increased plasma corticosterone (1362.0±156.2pg/ml vs 676.7±88.7pg/ml in shams; *p=0.002*). While post-injury marking preference was not associated with pain, stress or pre-injury (basal) marking preference, a significant positive correlation between basal marking preference and post-injury corticosterone levels was found (R=-0.58, p=0.03), suggesting that higher basal hedonic behavior may be protective against persistent pain-induced stress.
Together, our findings indicate (i) that urine scent marking behavior may represent an ethologically relevant assay supporting translational research of persistent pain-induced depression, and (ii) that post-injury stress responsiveness may be related to pre-injury bio-psycho-social factors.

**Title:** Physiological contribution of genetically-distinct cells of the central amygdala in the modulation of tactile hypersensitivity in a mouse model of neuropathic pain

**Authors: *T. WILSON**, H. AHN, S. VALDIVIA, A. KHAN, S. MARTINEZ GONZALEZ, Y. CARRASQUILLO
Natl. Ctr. for Complementary and Integrative Hlth., NIH, Bethesda, MD

**Abstract:** Increasing evidence over the last 15 years supports the critical contribution of the central nucleus of the amygdala (CeA) to the modulation of pathological pain and its related affective comorbidities. Previous studies have demonstrated that neurons in the CeA are genetically diverse. More importantly, recent advancement in our ability to selectively manipulate the activity of genetically-defined neurons has revealed differential contributions of distinct CeA neuronal subtypes to emotional behaviors. However, the genetic identity of the CeA neurons that are recruited during pain and contribute to the modulation of pain-related behaviors, remains unknown. The experiments here began to address these questions by using a combination of molecular genetic, chemogenetic, electrophysiological, behavioral and histological approaches. To induce persistent tactile hypersensitivity, we used the sciatic nerve cuff and the Complete Freund's Adjuvant (CFA) rodent paradigms, as models of neuropathic and inflammatory pain respectively. The combined results from our experiments specifically demonstrate that there are at least three functionally distinct populations of nociceptive neurons in the CeA: 1) a population of "pain ON" cells that becomes hyperexcitable in the context of persistent pain; 2) a second population of "pain ON" cells that undergoes pain-induced plasticity; and 3) a population of "pain OFF" cells that becomes hypoexcitable in the context of pain. *In vivo* selective chemogenetic inhibition of either of the "pain ON" cell populations decreased tactile hypersensitivity in models of persistent pain, demonstrating that activation of these cells is necessary for pathological tactile hypersensitivity. In contrast, *in vivo* selective inactivation of the "OFF cells" in naïve animals induced tactile hypersensitivity in the absence of injury, demonstrating that inactivation of these cells is sufficient to induce tactile hypersensitivity. Altogether, the results from our experiments provide the first causal evidence for the existence of "pain ON" and "pain OFF" cells in the CeA that are genetically-distinct and have opposing contributions to the modulation of peripheral tactile hypersensitivity in models of persistent pain.

**Abstract:** Invasive painful procedures are often performed in infants admitted to intensive care units. The acute and long-term effects of these stimuli can be investigated in animal models, such as in newborn rats. Previous studies have shown that animals undergoing nociceptive stimulation in the neonatal period do not display adequate physiological manifestations when facing stressful events in adulthood. This indicates that stressful experiences at critical periods of development may mitigate the mechanisms of stress resilience. Based on this, the aim of this study is to investigate the sleep (macro and microarchitecture) parameters in the baseline, post-challenge and sleep deprivation (homeostatic response) conditions in adult rats that underwent neonatal nociceptive stimulation (induced on the first or eighth postnatal day, with CFA - complete Freund's adjuvant intraplantar injection). The animals were submitted to two days of sleep recording (2 × 24 h), classified as basal. After that, the animals were challenged with a stressor agent to evaluate the sleep homeostatic response to stress. The movement restriction was performed for two hours so that the sleep of these animals was evaluated for another 24 h. After one week, the animals went through a baseline (2 × 24h) and were submitted to total sleep deprivation using the gentle handling method for 6 h, in order to verify the expression of the sleep homeostatic response to deprivation. Briefly, the data obtained with the sleep record were: total sleep time, total REM (Rapid Eye Movement) sleep time, total low-amplitude sleep time in NREM (no REM) sleep, total high-amplitude wave sleep time in NREM sleep, total number of episodes in REM sleep, total duration time of REM sleep episodes, total wake time, total active waking time, total quiet waking time. All data are being analysed in male and female rats. To date, in the light phase, the females P8 group presented higher sleep time of high amplitude waves when compared to the control group, both at baseline and post-restriction ($P<0.05$). In addition, P8 female group had lower REM sleep time when compared to P1 and control female groups in the post-restriction light phase ($P <0.05$).

**Title:** Effects of chronic exposure to tumor necrosis factor on pain-related behavior and sodium channel gene expression in dorsal root ganglion neurons

**Authors: M. E. O'LEARY**, A. BOTTARO, I. KUZIN, C. HO, *B. D. FISCHER
Cooper Med. Sch. of Rowan Univ., Camden, NJ

**Abstract:** The goal of these studies was to investigate the links between chronic exposure to the pro-inflammatory cytokine tumor necrosis factor (TNF), hyperalgesia and the excitability of dorsal root ganglion (DRG) sensory neurons. We employed transgenic mice that constitutively express TNF (TNFtg mice), a well-established model of chronic systemic inflammation. At 6 months of age, TNFtg mice demonstrated increased sensitivity to both mechanical and thermal heat stimulation relative to aged-matched wild-type controls. These increases in stimulus-evoked behaviors are consistent with nociceptor sensitization to normal physiological stimulation. The mechanisms underlying nociceptor sensitization were investigated using single-cell analysis to quantitatively compare gene expression in small-diameter (<30 μm) DRG neurons. This analysis revealed the upregulation of mRNA encoding for tetrodotoxin-resistant (TTX-R) sodium ($Na^+$) channels (Nav1.8, Nav1.9), $Na^+$ channel β subunits ($\beta_1$ - $\beta_3$), TNF receptor 1 (TNFR1) and p38α mitogen-activated protein kinase in neurons of TNFtg mice. Whole-cell electrophysiology demonstrated a corresponding increase in TTX-R $Na^+$ current density, hyperpolarizing shifts in activation and steady-state inactivation, and slower recovery from inactivation in the TNFtg neurons. Increased overlap of activation and inactivation in the TNFtg neurons produces inward $Na^+$ currents at voltages near the resting membrane potential of sensory neurons (i.e. window currents). The combination of increased $Na^+$ current amplitude, hyperpolarized shifts in $Na^+$ channel activation and increased window current predicts a reduction in the action potential threshold and increased firing of small-diameter DRG neurons. Together, these data suggest that increases in the expression of Nav1.8 channels, regulatory $\beta_1$ subunits and TNFR1 contribute to increased nociceptor excitability and hyperalgesia in the TNFtg mice.

**Title:** The experimental and clinical study: Persistent pain could be a potential stimulus on tumor

**Authors: *F. JIANG**[1], *F. JIANG[1], J. LI[2], G. DING[3]
[1]Xinhua Hosp. Chongming Br., Shanghai, China; [2]Xinhua Hosp., Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China; [3]Shanghai Intl. Med. Ctr., Shanghai, China

**Abstract:** With the progress in diagnosis and treatment techniques, the survival of patients with tumor has been much prolonged. However, for the Lack of health knowledge, many penitents are still suffering from various persistent pain. Recent studies revealed that persistent pain does not only affect the quality of life or bring great mental pressure to the patients, but also may promote tumor recurrence and metastasis. Our study established two pain models to explore the potential impact of pain on the tumor. In the first model, we mimicked neuropathic pain by sciatic nerve ligation on rats with tumor. The mechanical pain response threshold was lower in the trial group than in the control group ($p<0.05$). Seven days later, we found that the rats weight of the trial group were significantly lower than those in the control group ($p<0.001$). Besides, the tumor weight of the trial group was higher than that of the control group ($p<0.05$). The tumor volume of trial group was also larger compared with control group ($p<0.05$). In another animal model, we mimicked tumor cell bone metastasis induced pain on rat. We found that the tumor volume and weight of trial group at day 7, 10 and 14 was significantly higher than those of the control group ($p<0.05$). Clinical observations showed more valuable results. We counted the clinical data of 57 patients with advanced hepatocellular carcinoma and found that the median survival period of patients who received effective pain relief is 5.0 months (95% CI, 1.210 to 5.234), which is much longer than painful patients (3.0 months, 95% CI , 0.1911 to 0.8261). Therefore, both animal and patient research suggested that persistent pain is not symptom only. Long term pain might be a deathful threat for cancer patients.

**Title:** Chronic pain state mediates development of renal inflammatory response

**Authors: *V. DURIC**[1], B. DUONG[1], M. CARDER[1], G. CROSBY[1], V. BABICH[1,2], F. DI SOLE[1]
[1]Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA; [2]Mercy Col. of Hlth. Sci., Des Moines, IA

**Abstract:** Chronic pain state and related stress can correlate to the development of mood disorders and disease of peripheral organs, such as kidney disease, via chronic systemic inflammation and elevation of proinflammatory cytokines. Chronic pain is one the most distressing symptoms among patients with chronic kidney disease (CKD). The prevalence of chronic pain in CKD patients has been associated with development of depressive symptoms, while major depression episodes have been linked with a substantially increased risk of death. This clinical evidence suggests that an effective treatment of chronic pain-related stress and depression may reduce mortality in people with CKD. This study aims to determine whether an immune reaction is the mechanism that links depressive behavior induced by chronic pain and anomalies of kidney function. The neutrophil gelatinase-associated lipocalin (NGAL) and IL-18 are early diagnostic inflammatory biomarkers. They accumulate in the kidney in response to inflammation, kidney injury and decreased kidney function. Protein levels of NGAL and IL18 were analyzed by immunocytochemistry in animals exposed to chronic pain that have developed depressive-like behavioral phenotype. NGAL and IL18 protein levels were significantly increased in rat models of neuropathic (spared nerve injury) and inflammatory (injections of complete Freund's adjuvant) pain when compared with their controls; a prevalent increase in NGAL and IL18 protein levels was measured in the inflammatory pain model (~40% increase in both glomeruli and tubules, quantified using novel MATLAB algorithm). These observations suggest that chronic pain and related stress effects induce renal inflammation and possibly a reduction in kidney function. Ongoing studies aim to determine whether chronic stress *per se* mediates a similar inflammatory response in the kidney. In summary, this study might support a mechanistic understanding of a bidirectional pathway between chronic pain related-stress and kidney dysfunction.

**Authors: *T. ANDOH**, T. MAKI, S. LI, D. UTA
Univ. Toyama, Toyama, Japan

**Abstract:** Uremic pruritus is an unpleasant symptom in patients undergoing hemodialysis, and the underlying mechanisms remain unclear. In patients undergoing hemodialysis, the concentration of plasma β2-microglobulin (β2-MG), which is well-known as an MHC class I molecule, is increased. In this study, we investigated whether β2-MG was a pruritogen. Intradermal injections of β2-MG into the mouse rostral back elicited hind paw scratching in the injected site and the surroundings. In addition, intradermal injection of β2-MG into the cheek also elicited scratching, but not wiping. β2-MG-induced scratching was inhibited by the μ-opioid receptor antagonist naltrexone hydrochloride. These findings suggest that β2-MG-induced scratching is an itch-related response. β2-MG-induced scratching was not inhibited by antagonists of itch-related receptors (e.g., H1 histamine receptor, TP thromboxane receptor, BLT1 leukotriene $B_4$ receptor, and proteinase-activated receptor 2) activated the factors released from keratinocytes or mast cells. However, β2-MG-induced scratching was attenuated in mice desensitized by repeated application of capsaicin. In addition, β2-MG induced phosphorylation of extracellular signal-regulated kinase (a marker of activated neurons) in primary culture of dorsal root ganglion neurons that expressed transient receptor potential vanilloid 1 (TRPV1). These results suggest that β2-MG is a pruritogen and elicits itch-related responses, at least in part, through TRPV1-expressing primary sensory neurons.

**Title:** No evidence for social contagion of itch in mice observing histamine-injected demonstrators

**Authors: *J. LILJENCRANTZ**[1,2], M. H. PITCHER[2], L. A. LOW[2], L. BAUER[2], M. C. BUSHNELL[2]
[1]NCCIH, Natl. Inst. of Hlth., Bethesda, MD; [2]Pain and Integrative Neurosci. Laboratory, Natl. Ctr. for Complementary and Integrative Health, Natl. Inst. of Hlth., Bethesda, MD

**Abstract:** It is recognized in humans and other primates that the sensation of itch does not require the presence of a pruritogen; contagious itch can be induced simply by observing others engaged in scratching behavior. Here, we investigate the existence of itch contagion in mice using histamine injected (sub-cutaneous, nape of neck, 500µg histamine) demonstrator mice exhibiting scratching behavior. Adult male C57BL6 mice (n=44) were used in the experimental conditions (i) Un-injected observer (n=12) adjacent to a histamine-injected demonstrator (n=12), (ii) Two un-injected mice adjacent to each other (n=12), (iii) Un-injected control mice tested alone (n=8). Test chambers were separated by a transparent wall allowing for visual contact (auditory/olfactory transmission possible through mesh floor).
Our data analysis included three behavioral quantification methods to assess contagious itch in un-injected observers but failed to provide supportive evidence for the existence of this phenomenon in mice. (1) *Total scratching*: total scratching bouts in 30 min. Scratching bouts of un-injected observers next to histamine-injected demonstrators (2.0±0.6) was indistinguishable from that of un-injected observers next to un-injected demonstrators (3.3±0.6) or mice tested alone (1.5±0.6; H(3)=4.372, *p=0.112*). There was no association between total scratching bouts of un-injected observer with that of histamine-injected demonstrators (r=0.02, p=0.96). (2) *Temporally contiguous scratching:* scratching bouts within 30 secs following demonstrator scratching, regardless of if the observer was facing the demonstrator or not. We found no difference in temporally contiguous scratches in un-injected mice observing histamine-injected mice (0.5±0.2) compared to those observing un-injected mice (0.5±0.3; $X^2$=0.75,1(24), *p=0.387*).
Finally, in light of the recent publication by Yu et al. (2017. Science. 355:1072-1076) presenting support for contagious itch in mice, behavioral quantification was also scored according to their method (3) *Imitative scratching*: observer scratching bouts within 5 secs of pausing (~1 sec) and looking at the demonstrator mouse scratching. However, none of our 12 un-injected observers paired with histamine injected demonstrators exhibited this scratching behavior and only 1 of 12 un-injected observer mice paired with an un-injected demonstrator scratched (between groups not significant: X2=1.04,1(24), p=0.307).
Taken together, we find no evidence supporting the occurrence of itch contagion in mice. Our inability to replicate the findings of Yu et al. may depend on differences in the itch model used for the demonstrator mice.

**Title:** Role of $Na_V1.6$ and $Na_V\beta4$ sodium channel subunits in the rat back pain model induced by chronic compression of the lumbar dorsal root ganglia

**Authors: *J. A. STRONG**, W. XIE, J. ZHANG, J.-M. ZHANG
Dept Anesthesiol, Univ. of Cincinnati Col. of Med., Cincinnati, OH

**Abstract:** Hyperexcitability of sensory neurons plays a key role in initiating pain behaviors in several different rodent chronic pain models. Previously, we have shown that the sodium channel subunit $Na_V1.6$ and its modulatory subunit $Na_V\beta4$ play important roles in the pain behaviors and sensory neuron hyperexcitability (especially repetitive firing) induced by local inflammation of the dorsal root ganglion (DRG) with the immune stimulator zymosan. In this study we examined the role of these subunits in another, commonly used model of low back pain in which the L4 and L5 DRG are chronically compressed by small metal rods (CCD model). This results in sensory neuron hyperexcitability and marked mechanical and cold hypersensitivity. The L4 and L5 DRG were injected with previously validated siRNA constructs directed against either $Na_V1.6$ or $Na_V\beta4$ just prior to DRG compression in rats of both sexes. Control rats were injected with a non-targeting siRNA. Knockdown of either $Na_V1.6$ or $Na_V\beta4$ reduced CCD-induced static mechanical allodynia (von Frey test), dynamic mechanical allodynia (withdrawal to stroking of the paw with a fine cotton wisp), cold allodynia (withdrawal to acetone stimuli) and guarding behavior of the ipsilateral paws. Reduced mechanical pain behaviors were observed for the entire time course of the experiment (4 weeks), likely outlasting the duration of protein knockdown by the single siRNA injection. Overall the two siRNA constructs gave similar results, and results were similar to those obtained in the DRG inflammation model although the reduction in mechanical pain behaviors was not quite as complete in the CCD model and reduction in cold pain behaviors was more robust in the CCD model. Upregulation of the $Na_V1.6$ in the compressed DRG (70% increase on postoperative day 3) was observed with immunohistochemical methods, as previously reported for the DRG inflammation model. An additional similarity between the CCD and DRG inflammation models was that in both models pain behaviors were remarkably reduced by prior “microsympathectomy”, i.e., by cutting the grey rami bringing sympathetic postganglionic fibers to the L4 and L5 DRG and spinal nerves. Previously, we have observed that both the CCD and the DRG inflammation model cause increased pro-inflammatory cytokines and decreased anti-inflammatory cytokines as measured by protein multiplexing in the DRG. It will be of interest to examine the cytokine profiles in these models after knockdown of $Na_V1.6$ or $Na_V\beta4$, in order to determine which cytokines are directly regulated by the local inflammatory signals, and which also depend on changes in neuronal excitability.

**Abstract:** The Centers for Disease Control and Prevention recommend non-opioid therapy for chronic pain. Here, we investigated the possible antinociceptive effects of several light emitting diodes (LED), in the visible spectrum, on naïve and neuropathic pain rats. Green LED (wavelength 525 nanometers) exposure for eight hours for five days increased withdrawal latency to a noxious thermal stimulus, which persisted for four days following termination of last exposure. The antinociception was mediated via actions on central mu-opioid receptor pathways unrelated to stress. No apparent side-effects were noted and motor performance was not impaired. Blocking pain-modulatory pathways by inactivation of the rostral ventromedial medulla prevented expression of light-induced antinociception. Antinociception was mediated through the visual system. Additionally, green-LED exposure reversed thermal and mechanical hyperalgesia in rats with spinal nerve ligation or injection of envelope glycoprotein 120 of HIV-1. Further work revealed that Green-LED acts additively to produce antinociception when combined with morphine. This suggests that green-LED may be opioid sparing. Given the safety profile of Green-LED, we conducted a pilot clinical trial for the management of migraine and fibromyalgia. Eight patients were divided into two groups. The first group received white-LED as a control and the second group received green-LED. The patients were blinded to the effect of Green-LED. Patients were asked to self-administer themselves green- or white-LED for 1-2 hours every night for 10 weeks. We used the Numerical Pain Scale (NPS) from 0-10 as the primary outcome measurement. Of the four patients enrolled in the control white LED, two patients quit the study for lack of any perceived benefit. The other two patients completed the study and reported 0% pain change. Patients enrolled in the Green-LED group reported on average 44.5% improvement of their fibromyalgia and migraines. This pilot study sets the stage

for an appropriately powered larger clinical trial for green light therapy as a possible adjunct for chronic pain conditions.

**Title:** Development and characterization of an injury-free rodent model of hyperalgesia relevant to fibromyalgia syndrome

**Authors: *R. KHANNA**, A. PATWARDHAN, K. GILBRAITH, J. HANSON, A. MOUTAL, W. LI, L. CHEW, S. S. BELLAMPALLI, A. DORAME, X. YANG, P. MALAN, T. VANDERAH, F. PORRECA, M. IBRAHIM
Pharmacol., Univ. of Arizona, Tucson, AZ

**Abstract:** Fibromyalgia syndrome is a common and chronic disorder characterized by widespread pain, diffuse tenderness, and a number of other symptoms including fatigue, sleep disturbances, as well as depression and anxiety. Fibromyalgia affects 5 million Americans age 18 or older. Between 80 to 90 percent of those diagnosed with fibromyalgia are women; however, men and children also can be affected. Thus, an animal model of fibromyalgia syndrome ideally should include widespread pain and associated symptoms. Here, we present a novel rat model for generalized allodynia following exposure to red light emitting diodes (LEDs). Rats exposed to red LEDs (620-630 nanometer) exhibited time- and dose-dependent diffuse thermal and mechanical hypersensitivity. The nociceptive effects of red LED were mediated through the visual system, with female rats being more sensitive to the effects of red LED. Red LED-induced generalized allodynia was reversed with some current medications used for managing fibromyalgia including gabapentin, tricyclic antidepressants, serotonin/norepinephrine reuptake inhibitors, and NSAIDs. Acetaminophen failed to reverse the red LED induced hypersensitivity. The hyperalgesic effects of the red LED were blocked when bicuculline, a GABA-A receptor antagonist, was administered into the ventromedial medulla suggesting a role for increased descending facilitation in the pain pathway. Using the elevated plus maze assay, rats exposed to red LED also exhibited increased levels of anxiety. Pharmacological and proteomic profiling of dorsal root ganglion and trigeminal root ganglion neurons from red-LED exposed rats identified significant increases in activity of voltage-gated calcium channels, with no changes in potassium

or sodium currents. Thus, we propose red LED induced hyperalgesia as an injury-free model that may allow mechanistic exploration of fibromyalgia syndrome.

**Abstract:** BACKGROUND: “Winding of connective tissue” induced by needle grasp force has been suggested as involving in therapeutic effectiveness of twirling-manipulated acupuncture. We sought to investigate how the frictional force on twirling needle surface affects the winding of connective tissue and acupuncture’s analgesic effect in rats with peripheral nociceptive stimulus. METHODS: To make different level of scratch on the needle surface, the needles were longitudinally rubbed with silicon carbide sandpapers of different grit numbers. The roughness of surface and rotating torque were then measured by atomic force microscope and Acusensor®, respectively. The morphological changes of connective tissue induced by twirling manipulation of acupuncture with various roughness were analyzed using hematoxylin and eosin (H-E) staining. Finally, the effects of coarse surface on anti-nociception were tested in rat tail-flick latency (TFL) and formalin test. RESULTS: The rougher surface induced the stronger needle grasp force and the thicker winding of subcutaneous connective tissue while acupuncture was twirling-manipulated. TFL was increased as the rougher surface needle was applied into the acupuncture point ST36 on rat’s tibialis muscle. In the formalin test, the rougher needle also

showed the larger analgesic effect during both early and late phases compared to non-rubbed normal needle. CONCLUSION: The rougher surface of the acupuncture needle significantly enhances anti-nociceptive effect in rats, which partially supports the mechanical signaling theory through wound connective tissue induced by twirling-manipulated acupuncture.

**Abstract:** Docetaxel, a chemotherapeutic agent used to treat breast cancer, produces a robust painful neuropathy signs that are aggravated by mechanical and thermal stimuli. The aims of this study were to investigate the analgesic effects of low frequency stimulator on docetaxel-induced neuropathic pain in mouse and to identify a role of median nerve. Peripheral neuropathy was induced with intraperitoneally injected docetaxel (5mg/kg) on 5 consecutive days in male ICR mouse. Low frequency stimulation (Care band, 30 Hz) was administered on top of the median nerve of the bilateral wrist. The pain behavior signs were evaluated by von Frey filaments and thermal stimulator on the hind paw, respectively. Also, we measured “50 kHz” and “22 kHz” ultrasonic vocalizations using ultrasound microphones (frequency range: 10-200 kHz, Avisoft Bioacoustics) before and after low frequency stimulation. After the mouse developed neuropathic pain behavior, a single administration of low frequency stimulator significantly attenuated docetaxel-induced mechanical allodynia and thermal hyperalgesia. In addition, treatment with docetaxel for five consecutive days selectively increased the 22 kHz ultrasonic vocalization while administration with low frequency stimulator showed a meaningful decrease. Interestingly, the amputation of bilateral median nerve completely reversed analgesic effect of

low frequency stimulator. We showed that low frequency stimulator significantly alleviated docetaxel-induced mechanical allodynia and thermal hyperalgesia in neuropathic mouse via a bilateral median nerve. Collectively, results of this study suggest that median nerve stimulation using low frequency can be a potential strategy for the management of chemotherapy induced neuropathy. Although this study might be performed in the animal model by well-designed manner, clinical study will be needed to confirm the analgesic effect of low frequency stimulator.

**Title:** Chemogenetic Gq-linked sensitization of nociceptive pathways in freely moving rodents

**Authors: *H. ALKHANI**, A. ASE, P. A. SEGUELA
Montreal Neurolog. Institute, Dept of Neurol. and Neurosurgery, McGill Univ., Montreal, QC, Canada

**Abstract:** Pain is an unpleasant acute or chronic sensation experienced following peripheral injury, inflammation or ischemia. Current models used to investigate pain behaviors in rodents are plagued with pitfalls ranging from lack of spatiotemporal specificity to mandatory invasiveness. Here, we report a novel transgenic mouse model based on hM3D (Gq-coupled DREADD)-mediated sensitization of peripheral nociceptive pathways in virally-transduced Nav1.8(+) nociceptors, without administration of any external noxious stimuli or injury. Systemic activation of hM3D induced by intraperitoneal clozapine N-oxide (CNO) injections evoked strong nocifensive behavior with reduced locomotion, squinting of the eyes and ruffled fur. Intradermal paw injections of CNO resulted in robust acute thermal and mechanical sensitization as measured in Hargreaves and Von Frey tests. Moreover, CNO induced edema and redness in the injected paws, indicating the activation of neurogenic inflammatory mechanisms

similarly observed in sensitization protocols with capsaicin. The observed nocifensive behaviors appear to be specifically due to the contribution of small and medium diameter Nav1.8(+) DRG neurons, as indicated by our histology data, with fiber projections limited to the lamina I and II layers of the dorsal horn of spinal cord. These findings demonstrate for the first time the chemogenetic control of peripheral sensitization in behaving mammals and enables selective activation of the same class of afferents in vivo. Our results provide a proof-of-concept demonstration that chemogenetic interrogation of the contribution of specific classes of genetically-identified primary afferents to peripheral sensitization is possible. Non-invasive chemogenetic rodent pain models combining effective spatial penetrance with neuronal specificity have the potential to facilitate drug development and target validation for migraine or chronic pain relief.

**Title:** Dopaminergic modulation of the medial prefrontal cortex: A role in chronic pain?

**Authors: *K. LANCON**, M. ZAMFIR, P. A. SEGUELA
Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada

**Abstract:** The anterior cingulate cortex (ACC) in the medial prefrontal cortex (mPFC) has long been associated with the affective components of pain perception. Pyramidal neurons in layer 2/3 of the ACC display hyperexcitable characteristics in chronic pain. Optical silencing of these same neurons has proven to reverse neuropathy-induced hyperalgesia. Hyperpolarization-activated HCN channels, highly expressed in the mPFC, have been reported to modulate neuronal excitability. The inward currents of these cAMP-gated cation channels (Ih) control the input resistance of cells and therefore play a major role in the function of normal and pathological cortical circuits. Gs-coupled D1 dopamine receptors (D1R), localized close to HCN channels, are responsible for up regulating intracellular cAMP. Our whole cell patch clamp results indicate that D1R activation is inhibitory in layer 2/3 pyramidal cells in the ACC, hinting at a dopaminergic control on prefrontal activity in chronic pain conditions. We are in the process

of establishing the role of HCN channels as well as the molecular target in dopamine-mediated prefrontal inhibition. Furthermore, we will investigate potential analgesic effects of increasing dopamine release in the ACC in vivo in acute and chronic pain conditions. Selective optogenetically-evoked release of dopamine in the ACC has the potential to cause a D1R-mediated inhibition of layer 2/3 ACC pyramidal neurons. We plan on stimulating optically ascending ChR2+ dopaminergic projections from the ventral tegmental area (VTA) to the ACC, in hopes of producing an analgesic effect or a loss of neuropathy-induced hyperalgesia and allodynia in freely-moving mice.

**Title:** Dynorphin- and nNOS-containing neurons in the mouse spinal dorsal horn play different roles in itch and pain mechanisms

**Authors: *E. POLGAR**[1], H. WILDNER[2], H. U. ZEILHOFER[2], A. J. TODD[1]
[1]Univ. Glasgow, Glasgow, United Kingdom; [2]Inst. of Pharmacol. and Toxicology, Univ. of Zürich, Zürich, Switzerland

**Abstract:** Chronic itch and pain are often difficult to treat and represent major unmet clinical needs. Although there has been extensive study of the neuronal circuits that process nociceptive information, interest in itch mechanisms emerged only more recently and we know less about the neuronal circuitry responsible for transmitting and modulating pruriceptive input. To understand how different types of sensory information are processed in the spinal dorsal horn we need to unravel the complex synaptic circuits involving interneurons, which form the vast majority of neurons in the superficial laminae.
Recently we identified four largely non-overlapping classes of inhibitory interneurons in laminae I-III defined by expression of specific neurochemical markers: 1) dynorphin/galanin, 2) neuronal nitric oxide synthesise (nNOS), 3) neuropeptide Y and 4) parvalbumin. We subsequently reported that the dynorphin/galanin and nNOS populations were specifically lost in mice lacking the transcription factor Bhlhb5, a model of chronic itch. This suggested a role for one or both of these populations in suppressing itch. However, a recent study reported that ablation of cells that

expressed Cre recombinase in a preprodynorphin-Cre ($Pdyn^{Cre}$) knock-in mouse prevented mechanical pain, but had no effect on itch.
In the present study we tested whether activating the dynorphin- and/or nNOS-containing neurons by DREADD technology would suppress itch and/or pain. AAV2.flex.hM3Dq-mCherry was injected into the L3-5 segments of the spinal dorsal horn in $Pdyn^{Cre}$ and $nNOS^{CreERT2}$ mouse lines. After appropriate survival times mice were randomly assigned to clozapine-N-oxide (CNO) or vehicle groups to study itch and pain behaviour. In the CNO-treated $nNOS^{CreERT2}$ mice we found an increase in mechanical and thermal pain thresholds but no significant effect on chloroquine (CQ)-evoked itch. In contrast, CNO-treated $Pdyn^{Cre}$ mice showed a significant reduction of CQ-evoked itch, but also developed mechanical allodynia.
These results suggest that among the inhibitory interneurons that are lost in the Bhlhb5 knock-out mice those that express dynorphin, but not those that express nNOS, are involved in suppressing itch. We also demonstrate that nNOS-containing neurons have an anti-nociceptive effect. The pro-nociceptive effect of CNO seen in the $Pdyn^{Cre}$ mice presumably results from activation of excitatory dynorphin-expressing cells (which were not ablated in the above-mentioned study).

**Title:** Effects of burn size on post-burn itch in mice

**Authors: *T. AKIYAMA**, K. SAKAI, K. SANDERS, G. YOSIPOVITCH
Dermatol., Univ. of Miami, Miami, FL

**Abstract:** The majority of the post-burn patients suffer from chronic itch, which is often resistant to antihistamine treatment. Patients with larger burn surface areas exhibit more severe itch. Post-burn itch involves sensitization of itch-signaling pathways, leading to ongoing itch and alloknesis (touch-evoked itch), but the underlying mechanisms behind post-burn itch are largely unknown. We presently investigated if different sizes of scald burn affect the time course of post-burn itch in mice. We further tested whether a histamine H1R antagonist inhibits post-burn itch in mice. Moreover, we investigated if the density of intraepidermal fibers is altered in the scald burn model. A scald burn injury (7 mm or 10 mm diameter) was produced in adult C57BL/6 mice by exposing the shaved back skin to boiling water. To assess spontaneous

scratching, mice were videotaped on Days 0, 1, 3, 5, 7, 10, 14, 21, and 28 after the scald burn treatment. The 7 mm scald burn caused a transient increase in spontaneous scratch bouts that declined within 14 days. The 10 mm scald burn caused two phases of post-burn itch. Counts of spontaneous scratch bouts increased transiently on Days 1, 3, and Day 5 compared to Day 0, returned to the basal level by Day 10, and reincreased significantly on Days 14, 21, and 28. To test for alloknesis, a weak von Frey filament (VF; 0.7 mN) was repeatedly applied to post-burn skin on Days 0, 1, 3, 5, 7, 14, 21, and 28 after the scald burn treatment, and the presence or absence of evoked hindlimb scratch bouts was noted (VF stimulation does not elicit any response in naïve C57BL/6 mice). VF-evoked scratching increased significantly on Days 1 and 3, and Days 21 and 28 in the 7 mm and 10 mm scald burn model, respectively. The histamine H1 receptor antagonist chlorpheniramine was tested on Day 22 but did not inhibit spontaneous scratching or alloknesis, suggesting that non-histaminergic itch pathways are involved in post-burn itch. To investigate the density of intraepidermal fibers, the skin sections were immunostained with Protein Gene Product 9.5 antibody. Reduction of epidermal nerve fiber density was observed in the 10 mm scald burn model on Day 28. The reduction of epidermal nerve fiber density may contribute to post-burn itch through disinhibition of itch (reduction of pain signals). This new animal model appears to be useful for investigations of post-burn itch and sensitization of itch-signaling pathways.

**Title:** Visualize nociceptor changes in neuropathic mice with chronic constriction injury

**Authors: Y.-W. WU**, *C.-T. YEN
Natl. Taiwan Univ., Taipei, Taiwan

**Abstract:** Neuropathic pain is caused by injury of the somatosensory nervous system. In this study we aim to use in vivo and ex vivo microscopic methods to examine the change in nociceptors under the paw skin after chronic constriction injury (CCI) of the sciatic nerve, a commonly used animal model for neuropathic pain research. Our basic hypothesis is that direct microscopic observation of free nerve endings of the nociceptors in situ and en bloc will reveal the life history of the development and maintenance of the neuropathic pain. We used genetically modified mice that intrinsically express the fluorophore tdTomato tagged to a small fiber marker,

the Nav1.8 molecule. A battery of behavior tests including von Frey hair stimulation, hot/cold plate test, acetone drop test were applied to the hind paws of the mice to test their sensitivity to mechanical, heat and cold stimuli, respectively. Ex vivo confocal microscopic and in vivo longitudinal two-photon fluorescent microscopic observation of dynamic changes of nerve plexus and free nerve endings in the hind paw were performed first before and then 2 to 21 days after CCI of the sciatic nerve. Using behavioral tests we validated mechanical and thermal hyperalgesia of the CCI mice. Combining ex vivo and in vivo microscopic observations we found the density of the Nav1.8-tdTomato nerve ending in the hind paw can be a useful biomarker for the severity of the neuropathy.

**Title:** Effects of early noxious stimulation and early systemic infection on response to painful stimuli in Long-Evans hooded rats

**Authors: *C. GOMES**[1], G. A. BARR[2]
[1]Neonatology, The Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Anesthesiol. and CCM, Children's Hosp. of Philadelphia, Philadelphia, PA

**Abstract:** Painful procedural interventions are necessary in neonatal intensive care, but our knowledge of the long-term effects of these interventions is limited. Establishing a causal relationship between early painful experiences and altered responses to pain long-term remains difficult because human infants experience many confounding medical complications throughout their NICU course. Early systemic infections, for example, are commonly encountered in preterm infants but their effects on the pain response in both infancy and adulthood are unknown. The main goals of our research are to understand how painful experiences occurring early in life influence future responses to pain and how early systemic infection alters these responses. Rat pups were injected subcutaneously with either PBS or $0.1x10^6$ CFU of E-coli (ATCC 15746) suspended in PBS on post-natal day 2 (PNd2). On PNd3, pups had their left hind paw injected with 0.25% carrageenan. A separate group of pups were similarly handled but received no injection. Behavioral testing occurred at one of three specified time points: PNd8, PNd15 or after

PNd65 (corresponding with humans at full term, mid-infancy, and young adulthood, respectively). Standard pain assessments performed included plantar heat latency testing to measure basal pain levels, formalin testing to measure the acute inflammatory pain response following reinjury, and condition place aversion testing (CPA) to determine if rats develop a learned aversion to the testing chamber where they were conditioned with a painful stimulus. After behavioral testing, animals were sacrificed and brain tissue was harvested for assessment of c-fos expression as a marker of neural activation. There were no significant differences in thermal pain thresholds in carrageenan exposed pups vs. controls at any age. Early infection with E-coli did not alter this. Upon reinjury with formalin, there were no significant differences in pain response in the carrageenan vs. control group at any age. However, infection significantly increased pain scores following reinjury on both PNd8 and PNd15, but not in adults. Early systemic infection with E-coli did increase learned aversions to painful stimulation in late-infancy that persisted into adulthood, where there was a trend for infant carrageenan treatment augmenting the learned aversion. Thus, early systemic infection augments both pain and pain affect both pre-weaning and in adults.

**Title:** Using iPSC-derived noiceptor neurons from familial dysautonomia patients to study pain physiology

**Authors: *Y. SAPIR**, J. KOH, B. WAINGER
Massachusetts Gen. Hosp., Boston, MA

**Abstract:** Familial Dysautonomia (FD) is an autosomal recessive disease characterized by broad symptoms of sensory and autonomic dysfunction. FD is caused by a single mutation in intron 20 in the *IKBKAP* gene, leading to a tissue-specific splicing defect and decreased level of wild-type IKAP protein. The disease affects the development and survival of sensory, sympathetic and some parasympathetic neurons. The main sensory manifestations in FD patients are impaired temperature and pain perceptions which involve primarily nociceptive functions, in addition to the characteristic profound dysautonomia. The ability to use nociceptors derived from FD patient induced pluripotent stem cells (iPSCs) has already served as a powerful tool to model the deficiency in FD *in vitro* and validate candidate treatments. Here, we derive nociceptor neurons from FD patient iPSCs and investigate nociceptor function on the physiological level using calcium imaging and whole-cell patch clamp. We assess the response to typical nociceptor

activators, including an assortment of transient receptor potential (Trp) channel ligands, as well the basic excitability profile of the neurons, including rheobase and action potential firing properties. The results suggest a picture of distinct physiological dysfunction as part of the FD disease process.

**Title:** Generation of patient-derived sensory neurons using iPSCs & smNPCs obtained from patients with Fabry disease

**Authors: T. KLEIN**[1], K. GÜNTHER[2], C. L. SOMMER[1], F. EDENHOFER[2], *N. ÜÇEYLER[1]
[1]Dept. of Neurol., [2]Inst. of Anat., Univ. of Würzburg, Würzburg, Germany

**Abstract: Background & Objective:** Fabry disease (FD) is an X-linked lysosomal storage disorder that particularly affects heart, kidneys, & the nervous system. Due to deficiency of the alpha-galactosidase A (GLA), the glycolipid globotriaosylceramide 3 accumulates in cells, including human dermal fibroblasts (HDFs). The major neurological symptom in FD is acral burning pain, which manifests as episodic pain like attacks & crises, or as permanent pain. The pathophysiology of FD pain is unknown & research is hindered by the lack of suitable biomaterial. Using patient-derived HDFs, our aim was to generate induced pluripotent stem cells (iPSCs), followed by the derivation of small molecules neural precursor cells (smNPCs) & subsequently differentiate these into nociceptors. Such a disease model would help to elucidate underlying mechanisms of pain pathophysiology in FD.
**Methods:** A six-mm skin punch biopsy was taken from the lateral lower leg of two female FD patients with a mutation of the *GLA* gene (patient 1: 25 years, missense mutation; patient 2: 50 years, nonsense mutation). HDFs were isolated & reprogrammed to iPSCs using a transgene-free synthetic mRNA approach. smNPCs were then derived from iPSCs, by means of dual-SMAD inhibition in suspension culture & use of chemically defined medium. smNPCs were differentiated to nociceptors using a combination of three inhibitors to promote sensory lineage commitment. Expression of pluripotency & NPC marker proteins were analyzed using immunocytochemistry (ICC). iPSC clones were characterized using fluorescence activated cell sorting & differentiation into all three germ layers.
**Results:** We generated two iPSC lines from patient 1 & three lines from patient 2. All lines displayed strong immunoreaction against established pluripotency markers. Furthermore, >98% of the cells from all three lines from patient 2 expressed TRA-1-60, & SSEA4. Embryoid body

formation was performed for one clone from patient 2 with subsequent ICC proving the presence of all three germ layers. smNPCs were generated from one clone of each patient & all showed expression of the NPC marker proteins SOX1, SOX2, Nestin, & PAX6. Differentiations showed neuronal outgrowth, with cells being positive for the neuronal marker TUJ1 & the peripheral marker peripherin.
**Conclusions:** We successfully generated iPSCs & smNPCs of FD patients using synthetic mRNA & were able to differentiate these to neurons. Upon completion of histological, molecular, & electrophysiological characterization, we will provide functional neurons as the basis of a novel *in vitro* model for mechanism-based research on FD pain pathophysiology.

**Abstract:** Psoriasis is one of the most prevalent chronic skin diseases associated with intense itching although the cellular and molecular mechanism of pruritus in psoriasis remains unclear. Many cytokines are selectively up-regulated in psoriasis and become candidate molecules for psoriatic itch. Human beta-defensin 2 (hBD2) is the most up-regulated member of cytokines in

the epidermis and considered as a biomarker of disease activity. However, the role of hBD2 in the genesis of itching is not understood. Here we show that hBD2 elicited a dose-dependent scratching behavior in mice. Interestingly, the hBD2-elicited scratching response was severely reduced by genetic ablation of TRPV1 function although hBD2 did not directly activate TRPV1, suggesting hBD2 activates upstream targets to release TRPV1-sensitive endogenous pruritogens to initiate itch sensation in mice. Although the putative hBD2 receptors C-C chemokine receptor type 2 (CCR2) and 6 (CCR6) are abundantly expressed by skin-resident cells, the hBD2-elicited itching was not affected by genetic ablation of either CCR2 or CCR6 function. Surprisingly, the hBD2-elicited scratching response was substantially reduced in global knockouts or myeloid cell-specific knockouts of the Toll-like receptor (TLR4) that is primarily expressed by $CD11b^{+}/CD11c^{-}$ dermal macrophages. Our findings suggest that hBD2 could act as a potent endogenous pruritogen acting on cutaneous innate immune cells through TLR4 signaling to promote TRPV1-dependent itch sensation, which expands the roles of the antimicrobial beta-defensin family and may also provide new therapeutic targets against psoriatic itch.

**Title:** Gait analysis in mouse mouse models of chronic widespread pain

**Authors: *C.-H. LEE**[1], S.-Y. HSIEH[2], T.-H. HSIEH[3], C.-C. CHEN[4]
[1]Inst. of Biomed. Sci. Academia Sinica, Taipei, Taiwan; [2]Dept. of Biochem. Sci. and Technol., Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Physical Therapy and Grad. Inst. of Rehabil. Sci., Chang Gung Univ., Taoyuan, Taiwan; [4]Academia Sinica, Taipei, Taiwan

**Abstract:** Chronic widespread pain is quite unbearable and affecting quality of life in patients but is often difficult to treat. In preclinical studies, many drugs with high efficacy on evoke-pain monitoring platforms (e.g., von Frey and/or hot plate tests) were often failed in clinical trial. Thus, besides evoked pain assessment, methods to evaluate non-evoked pain (e.g., spontaneous pain) responses are urged in preclinical studies. Previous reports have demonstrated gait analysis is a useful method to evaluate spontaneous pain in mouse models of acute pain. However, whether it is still not known whether gait analysis has good sensitivity to chronic pain assessment, especially for chronic widespread pain in mouse. We analyzed mouse gait after treatment of intermittent cold stress (ICS), an animal model of fibromyalgia, which causes

mouse wide spread pain. After ICS treatment, mice developed chronic mechanical hypersensitivity at both hind paws and gastrocnemius muscle. We analyzed temporal and special parameters of mouse gait including Stance time (ST), Swing phase time (SWP), Double support time (DS), Walking speed (WS), Step length (StepL), Stride length (StrideL), Base of support (StepW), Print length (PL), Foot angle (FtAng), Intermediary toe spread (ITS) and Toe spread (TS). As compared with naïve mice, ICS-treated mice significantly decreased scores in ST, DS, PL and increased scores in StepW. Interestingly, the StepW parameters of ICS mice could be corrected after intraperitoneally injection of pregabalin, a well-known analgesic drug for fibromyalgia. Taken together, gait analysis might be useful for detecting chronic widespread pain behavior in mice.

**Abstract:** Numerous studies have reported that women have a higher prevalence of chronic pain disorders than men. We have previously shown that estrogen attenuates opioid receptor like -1 (ORL1) receptor mediated thermal antinociception in females [Claiborne et al. J Neurosci. 26:13048-53, 2006]; and down-regulates the ORL1 gene expression [Flores et al. Neurosci. 118:769-78, 2003]. Recently, we have demonstrated that activation of membrane estrogen receptors (GPR30, Gq-mer, ER α, but not ER β) rapidly abolishes ORL1-mediated acute thermal antinociception via an ERK2-dependent non-genomic mechanism [Small et al. Neurosci. 255:177-190, 2013]. However, the effect of membrane estrogen receptors (mERs) on ORL1-mediated attenuation of neuropathic pain and the underlying mechanisms remain unknown. Thus, the present study investigated whether selective activation of mERs attenuates ORL1-

mediated suppression of nerve injury-induced tactile hypersensitivity. The spared nerve injury (SNI) model as previously described by Decosterd and Woolf [Pain. 87:149-58, 2000] was employed to induce mechanical hypersensitivity in male and OVX female Sprague Dawley rats. After a 7-day recovery period, sham and SNI rats were intrathecally administered a selective mER agonist immediately followed by OFQ, the endogenous ligand for the ORL1 receptor, into the lumbosacral spinal cord of rats through an implanted PE-10 cannula. Paw withdrawal thresholds (PWTs) were recorded using an automated dynamic plantar aesthesiometer. A thallium flux assay [Weaver et al. J Biomol. Screen. 9(8);2004] was also utilized in HEK cells transfected with GIRK I,II channels, ORL1 and mERs to determine the rapid effect of mER activation on ORL1-mediated thallium flux. SNI significantly reduced PWTs in both males and OVX females. Intrathecal administration of OFQ significantly increased PWTs in both males and OVX females while selective mER activation rapidly abolished (within two minutes) OFQ-induced increase in PWTs. Further, preliminary data suggest an increase in thallium flux following OFQ application, which seems to be reduced by pretreatment with mER agonist. Thus, we conclude that activation of mERs rapidly attenuates ORL1-mediated suppression of nerve injury-induced tactile hypersensitivity possibly via decreasing the GIRK channel function. This work provides evidence of a biological mechanism that may underlie female vulnerability to the development of chronic pain disorders.

**Title:** Chemogenetic interrogation of anxiety- and depression-like behaviors in a mouse model of fibromyalgia

**Authors: *W.-Y. WONG**[1], C.-C. LIEN[1,2]
[1]Inst. of Neuroscience, Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Brain Res. Center, Natl. Yang-Ming Univ., Taipei, Taiwan

**Abstract:** Fibromyalgia (FM) is a chronic pain disorder, which is considered to be a chronic "centralized" pain state underpinned by aberrant neurotransmissions and brain excitability. Clinical studies show that patients of FM often suffer from psychiatric disorders such as anxiety and depression. However, little is known about circuit mechanisms underlying comorbid pain and emotional disorders. Our preliminary study found that the phosphorylated ERK (pERK) level increased in the lateral subdivision of central amygdala (CeL) in a FM-like mouse model, so called acid-induced muscle pain model. The amygdala is not only a key structure for emotions but also serves a major receiver of purely nociceptive signals. In this study, we assumed that modulation of CeL activity could ameliorate comorbid pain and emotional disorders. The CeL consists of two types of neurons: somatostatin-expressing ($SOM^+$) and non-somatostatin-expressing ($SOM^-$) neurons. We found that silencing of $SOM^+$ neurons in the FM-like mouse model using inhibitory designer receptors exclusively activated by designer drugs (DREADDs) resulted in a significant decrease in mechanical hypersensitivity in both hindpaws of the FM-like mouse model after intraperitoneal injection of clozapine-N-oxide, a ligand for DREADD receptors. Furthermore, anxiety- and depression-like behaviors in the FM-like mouse model were significantly reversed after silencing $SOM^+$ neurons. Our findings suggest that the CeL might be a therapeutic target for chronic pain and associated mood disorders.

**Title:** Meal pattern differences between mid- and late-pregnant rats after CFA-induced temporomandibular joint (TMJ) nociception

**Authors: *M. UMORIN**, P. KRAMER, L. BELLINGER
Biomed. Sci., Texas A&M Univ. Col. of Dent., Dallas, TX

**Abstract:** Women often report having fewer TMJ symptoms during pregnancy.
Thus, our study aimed at answering the question: does TMJ nociception, as measured by a behavioral assay differ during pregnancy, potentially due to the effect of sex steroids? We have shown that meal pattern analysis including rate, duration, and frequency can be used to measure orofacial nociception. In rats, the estradiol concentrations commonly observed during pregnancy vary from 10 pg/mL (mid pregnancy) to 60 pg/mL (late pregnancy).
In these experiments, 32 Sprague-Dawley rats were randomly allocated to either mid (E11)- or

late (E18) pregnancy groups. The animals within each group were further allocated to a saline or CFA treatment. At E11 or E18, the animals were injected bilaterally into TMJ with either saline (10 µL) or 1 µg/µL CFA (10 µL). Nociception was measured with a feeding assay (pellet recording) and analyzed by comparing intra-meal rates using a distance-based permutation method.
While aggregate statistics showed very little differences between groups, the intra-meal rate analysis revealed differences between the saline and CFA groups for both mid-and late-stage pregnant rats. Furthermore, comparison of intra-meal rates indicated that CFA-injected rats in the mid-pregnant group would start meals at half the rate of the control group and would continue eating a meal for almost twice as long suggesting a greater nociceptive response in this mid-pregnancy group. CFA-injected rats in late-pregnant group would start at the same rate as the control group but would continue eating for longer periods compared to the corresponding controls. The observed differences may be due to different plasma concentrations of estradiol that were observed in the mid-and late-pregnant rats.
This is the first time the intra-meal patterns were used to study TMJ nociception in pregnant rats. Thus, we conclude that one potential reason women report fewer TMJ symptoms during pregnancy is the higher level of circulating sex hormones.

**Title:** The role of astrocyte elevated gene-1 in mouse models of inflammatory and neuropathic pain

**Authors: *D. BAGDAS**[1,2], M. CARPER[1], D. SARKAR[1], M. DAMAJ[1]
[1]Virginia Commonwealth Univ., Richmond, VA; [2]Uludag Univ., Bursa, Turkey

**Abstract:** Astrocyte elevated gene-1 (AEG-1), also known as metadherin or LYRIC, is a novel human immunodeficiency virus-1 and tumor necrosis factor-α inducible oncogene. AEG-1 mRNA is ubiquitously expressed in all normal tissues. However, the physiological function of AEG-1 is not well known. It has been shown that enhanced angiogenesis and inflammation upregulates AEG-1. In addition, AEG1 is one of the modulators of HIV-1-associated neuroinflammation. AEG-1 activates NF-κB and NF-κB is a key regulator of pro-inflammatory cytokines, which suggest a potential role of AEG-1 in the inflammatory processes.
We aimed to determine whether AEG-1 influences the development of inflammatory and neuropathic pain behavior in mouse models of complete Freund's adjuvant (CFA)-induced

inflammatory pain and chronic constriction nerve injury (CCI)-induced neuropathic pain in the presence (WT mice) and absence (KO mice) of AEG-1. Our hypothesis was that AEG1 inhibition will reverse the initiation and maintenance of inflammation and pain.
The results showed that hyperalgesic and allodynic response to CFA injections were reduced in male and female AEG-1 KO mice. However, both hyperalgesia and allodynia observed in the CCI model were similar in AEG-1 WT and KO mice. Interestingly, the antiallodynic properties of gabapentin and morphine in CCI model were enhanced in AEG-1 KO mice compared with WT mice.
In summary, our results highlight the involvement of the AEG-1 in development inflammatory pain but not neuropathic pain. Morphine and gabapentin have higher potency in AEG-1 KO mice. Our results indicate an important modulatory role of AEG-1 in chronic inflammatory pain.

**Title:** Effects of oxaliplatin on the development of neuropathy and cognitive impairment in the mouse

**Authors: *L.-H. CHEN**[1], Y.-F. CHEN[1], H.-C. HAN[2], M.-R. SHEN[1]
[1]Dept. of Pharmacol., Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Biomed. Platform and Incubation Services Div., Instrument Technol. Res. Ctr., Zhubei, Taiwan

**Abstract:** Oxaliplatin treatment, a platinum-based chemotherapy used to treat colorectal cancer, is afflicted by prominent dose-limiting neurotoxicity. About 20% patients receiving oxaliplatin with a cumulative dose of 850 mg/m$^2$ have been reported with severe, partially irreversible sensory or motor neuropathy. In the clinical practice, patients receiving oxaliplatin also often experience changes in mood and cognitive function. Consequently, the present study was designed to develop a mouse model of oxaliplatin-induced cognitive deficit and affective symptoms to identify treatment strategies and their underlying mechanisms of action. Intraperitoneal injections of oxaliplatin (3 mg/kg, 5 consecutive days for 2 cycles) resulted in the development and maintenance of mechanical and cold allodynia. Oxaliplatin-treated mice displayed cognitive impairment as measured by novel object recognition, Y-maze alteration and

Y-maze recognition test. In addition, oxaliplatin also induced depression-like behavior, as assessed in the forced swim test, tail suspension and sucrose preference test. Taken together, oxaliplatin showed significant impacts on nociception, cognition, affective states in C57BL/6J mice. The characterization of this murine model of chemotherapy-induced neuropathic pain and cognitive impairment provides the basis for determining the mechanisms underlying severe adverse effects elicited by oxaliplatin.

**Title:** Hypersensitivity to acute pain in a mouse model of early blindness

**Authors: *S. TOUJ**[1], S. ALAIN[2], G. BRONCHTI[3], M. PICHE[4]
[1]Anat., UQTR, Trois-Rivieres, QC, Canada; [2]Anat., UQTR, Trois-rivieres, QC, Canada; [3]Anat., Univ. Quebec Trois-Rivieres, Trois-Rivieres, QC, Canada; [4]Dept. de Chiropratique, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada

**Abstract:** Early blindness results in anatomical, functional and behavioral changes in human and animals. Recently, the nociceptive system of congenital blind individuals was investigated and it was reported that they have lower heat pain thresholds. The aim of the present study was twofold. Firstly, we aimed at developing a mouse strain from which half of individuals are born sighted with normal eyes (heterozygous) and half are born anophthalmic (homozygous). The so-called ZRDBA mouse was obtained through genetically controlled crossing between ZRDCT eyeless mice and DBA eyed mice. This unique strain allows studying the impacts of early blindness on sensory functions without the potential confound of strain differences. Secondly, we aimed at investigating the behavioral response to acute pain in this model of blindness. A total of 40 mice were used, including 20 anophthalmic and 20 sighted mice, with each group comprising 10 males and 10 females. All experimental procedures were approved by the animal care committee of “Université du Québec à Trois-Rivières”, in accordance with the guidelines of the Canadian Council on Animal Care and the guidelines of the Committee for Research and Ethical Issues of the International Association for the Study of Pain (IASP).To assess the response to acute pain, the formaline test was performed by injecting 20 $\mu l$ of a formaline solution (2.5% v/v in saline) subcutaneously, into the right dorsal hindpaw. Mice were observed for a total of 45 minutes and the number of hindpaw licking events was calculated for every 5-minute interval. Formalin injection induces pain with an early acute phase lasting around 10 minutes and an inflammatory phase beginning 20 minutes after the injection and lasting around 10 minutes. Pain

sensitivity was different between phases and was affected by blindness (PHASE x GROUP interaction: $F_{1,36} = 7.4$, $p = 0.01$; $\eta p = 0.17$) and marginally by sex (PHASE x SEX interaction: $F_{1,36} = 3.7$, $p = 0.06$; $\eta_p = 0.09$). Planned contrasts revealed that during the acute phase, blind mice were more sensitive to pain compared with controls for both sexes combined ($p = 0.006$), although the effect was significant in females ($p = 0.03$) but not in males ($p = 0.07$). In the inflammatory phase, no difference was observed between groups, either in females or males or for both sexes combined (all p's > 0.3). Consistent with human studies, these results indicate that blindness is associated with pain hypersensitivity. Future anatomical and functional studies are needed to determine the underlying mechanisms of this pain hypersensitivity.

**Title:** Involvement of HMGB1 in postoperative pain

**Authors: *Y. KAWABATA**[1], M. TSUBOTA[1], R. TSUJITA[1,2], M. NISHIBORI[3], A. KAWABATA[1]
[1]Fac. Pharm, Kindai Univ., Higashi-Osaka, Japan; [2]Asahi Kasei Pharma, Tokyo, Japan; [3]Dept. Pharmacol., Okayama Univ., Okayama, Japan

**Abstract:** Severe pain accompanying histological damage and inflammation after surgical invasion may continue for several days. Since the relief of postoperative pain is extremely important to avoid complications and improve QOL, it is necessary to develop more effective therapeutic drugs on the basis of the molecular mechanisms for postoperative pain. High mobility group box 1 (HMGB1), a nuclear protein, is passively released from necrotic cells and actively secreted by certain cells including activated macrophages (Mφ). Given our evidence for the involvement of HMGB1 in inflammatory hyperalgesia, chemotherapy-induced neuropathic pain and visceral pain following cystitis or pancreatitis, we examined whether HMGB1 contributes to the development or maintenance of postoperative pain induced by hindpaw plantar incision in mice. The surgery caused significant decrease in nociceptive threshold within 2 h, as assessed by von Frey test, and the mechanical allodynia lasted for 48 h. The anti-HMGB1-neutralizing antibody (Ab) or recombinant human soluble thrombomodulin (TMα), capable of inactivating HMGB1, when administered i.p. 1 or 24 h after the surgery, transiently restored the postoperative allodynia. Pretreatment with Ab or TMα slightly delayed the development of the postoperative allodynia. Any of antagonists of receptor for advanced glycation end-products (RAGE), Toll-like receptor 4 (TLR4) and CXC chemokine receptor 4 (CXCR4), known as

pronociceptive targets for HMGB1, reversed the postoperative decrease in nociceptive threshold. Preadministration of ethyl pyruvate, known to inhibit the release of HMGB1 from Mφ, or minocycline, a Mφ/microglia inhibitor, did not affect the postoperative allodynia. Plasma HMGB1 levels did not change after the surgery. On the other hand, the protein levels of HMGB1, but not RAGE, TLR4 and CXCR4, decreased in the dorsal root ganglion and increased in the sciatic nerves 1 day after the surgery. Together, HMGB1 derived from the cells other than Mφ is considered to participate in postoperative pain by activating RAGE, TLR4 and CXCR4.

**Title:** Evaluation of cannabinoid, opioid and serotoninergic receptors on the antinociceptive effect of peripheral administration of docosahexaenoic acid (DHA)

**Authors: *A. G. ARROYO LIRA**, A. E. CHÁVEZ-PIÑA
Escuela Nacional de Medicina y Homeopatía. Lab. de Farmacología, Inst. Politécnico Nacional, Mexico, Mexico

**Abstract: Introduction:** Pain is the oldest medical problem and has been a challenge for physicians since the origin of humanity and remains as a global public health issue. Pain relief can be achieved by a diversity of methods, with drug use being the basis of analgesic treatment but the adverse effects caused by analgesics limit their use. As part of endogenous pain perception and modulation has been involved cannabinoid, opioid and serotoninergic agonist and their receptors. Docosahexaenoic acid (DHA) is an omega-3 fatty acid. Even though its antinociceptive effect has been demonstrated, the mechanisms still not well-defined. Based on the above consideration the aim of his work was to evaluate the participation of cannabinoid, opioid and serotoninergic receptors on the antinociceptive effect of peripheral administration of docosahexaenoic acid (DHA). **Methods:** Female Wistar rats were administered with DHA (562

µg/paw) 75 min before the formalin (1%) injection and percentage of antinociception was calculated. In the same way, the antinociceptive mechanisms of DHA was evaluated using specific antagonist for cannabinoid (rimonabant; 30-100 µg/paw), opioid (naloxone; 50-100 µg/paw) and serotoninergic (methiothepin; 100-177.82 µg/paw) receptors. **Results:** Administration of DHA induced an antinociceptive effect (46.41 ± 3.92 %). Rimonabant administration reduces DHA´s antinociceptive effect in a dose dependent fashion, abolishing the antinociceptive effect of DHA when 100 µg/paw was administered. Naloxone administration attenuated DHA-induced antinociception. Finally, methiothepin administration did not modify the antinociceptive effect of DHA. **Conclusions:** Our results suggest that DHA produces antinociception *via* cannabinoid and opioid receptors located at peripheral sites in the rat formalin test. **Acknowledgments:** The authors acknowledge the support provided by the National Council for Science and Technology (Project CONACyT 178027) and SIP 20171838. **Title:** The SAD weekend: A perilous north american tradition

**Authors: *S. K. TOTSCH**, *S. K. TOTSCH, S. A. LOPEZ, T. L. QUINN, R. Y. MEIR, R. E. SORGE
Psychology, Univ. of Alabama At Birmingham, Birmingham, AL

**Abstract:** Obesity and chronic pain often co-occur. It is known that poor quality diet and/or obesity contribute to a chronic inflammatory state that may lead to susceptibility to chronic pain. Previously, we developed a Standard American Diet (SAD) and an Anti-inflammatory Diet (AID) to investigate the effects of diet on pain. The SAD is high in refined sugar, carbohydrates, trans and saturated fatty acids. The AID includes omega-3 fatty acids, green tea extract, sulforaphane, resveratrol, curcumin, and ginseng; all known to have anti-inflammatory properties. In the current study, we were interested in the impact of unhealthy weekend binges on pain and recovery from inflammatory injury. Male and female mice were fed a SAD, AID or regular (REG) chow diet for 14 weeks Monday to Friday. On Saturday and Sunday, subsets of animals from the AID or REG groups were switched to the SAD diet, to model weekend eating habits. Mechanical sensitivity and body weight were assessed weekly whereas glucose tolerance

was assessed at weeks 8 and 16. Microbiome analysis was performed at week 14. At this time after 14 weeks of diet consumption, chronic pain was induced through intraplantar injection of complete Freund's adjuvant (CFA). Following CFA injection, the SAD-fed mice showed prolonged recovery while the AID-fed mice had shortened recovery time. Interestingly, animals that were switched to the SAD on weekends had further protracted recovery, comparable to animals who solely consumed the SAD. Of clinical interest, animals that solely consumed the SAD had a greater proportion of proteobacteria and less bacteroidetes, while animals that solely consumed the AID had greater proportion of actinobacteria and less proteobacteria. Animals that switched between diets had a mixture of the two. These data suggest that short-term, repeated consumption of the SAD has similar detrimental effects to sole SAD consumption. However, consuming AID during the week remains beneficial in terms of gut microbiota. Work is currently underway using flow cytometry to determine the impact of the diets on T cell infiltration into the spinal cord.

**Title:** The impact of inflammatory pain on decision-making

**Authors: *C. A. SALCIDO**, M. K. GELTMEIER, P. N. FUCHS
Univ. of Texas At Arlington, Arlington, TX

**Abstract:** Clinical assessments using the Iowa Gambling Task reveal that pain negatively affects decision-making processes and leads to risky decisions. Despite the gains made in elucidating the cognitive component of pain, the neurobiological factors of how pain alters decision-making is not clear. Therefore, we examined the impact of inflammatory pain and morphine on decision-making processing. Sprague Dawley rats were trained using a rodent version of the Iowa Gambling Task (RGT). Animals were administered a s.c. injection of Complete Freund's Adjuvant (CFA) or saline to induce an inflammatory condition. Thirty minutes after, animals were administered morphine (3 mg/kg) or saline. Thirty minutes later, animals were tested using the RGT. Percent of best choice and percent omissions in the RGT were used to assess cognitive performance. After the RGT, animals were subjected to the Place Escape/Avoidance Paradigm (PEAP) to measure the affective response to CFA. On day ten, animals were given the same drug injection as test day and then thirty minutes later, were tested using RGT and PEAP paradigms. RGT data revealed no differences in best choice regardless of pain, drug, or time conditions.

However, morphine treatment significantly increased percent of omissions versus saline. PEAP results revealed a significant increase in avoidance behavior for CFA animals on days one and ten of testing. The escape/avoidance response was reduced in morphine treated animals. In conclusion, specific patterns of decreased cognitive performance in decision-making were not apparent for the CFA inflammatory condition. There was significant escape/avoidance indicating robust pain affect. The findings of significant pain affect, but lack of impaired cognitive functioning highlights a possible separation of pain affect/motivation from evaluative/cognitive component. Future studies will further assess the multidimensionality of pain and cognition in order to obtain a comprehensive understanding of pain behaviors. Such approaches can provide critical information that will ultimately translate to clinical populations, leading to enhanced understanding of pain and improvement of human health.

**Title:** Perturbation of central amygdala neuron excitability reduces pain- & anxiety-like behaviors

**Authors: *Y.-L. LIN**, C.-C. LIEN
Natl. Yang Ming Univ. Inst. Of Neurosci, Taipei, Taiwan

**Abstract: Abstract**
Chronic pain disorder is associated with anxiety- and depression-like behavior. Although the amygdala is thought as a key node of the neural circuits mediating emotions, it also serves a major receiver of purely nociceptive signals. However, the circuit mechanisms by which the amygdala contributes to the pain-related anxiety has remained unclear. Here, we investigated circuit mechanisms underlying comorbid symptoms in chronic pain mouse models, including acid-induced muscle pain and spinal nerve ligation-induced neuropathic pain. We first found that the phosphorylated ERK (pERK) level increased in the lateral subdivision of central amygdala (CeL) after chronic pain development. To address the role of the CeL in chronic pain, we attempted to manipulate CeL neurons using chemo- and opto-genetic approaches. We hypothesized that silencing of somatostatin-positive ($SOM^+$) neurons in the CeL, which may

activate CeL output neurons (i.e., $SOM^-$ neuron) and thereby suppresses the CeM projecting neurons, which reduces mechanical sensitivity and chronic pain-related behavior. In chemogenetic part, selective expression of designer receptors exclusively activated by designer drugs (DREADDs) was achieved by injecting a virus encoding Cre-dependent inhibitory DREADDs (i.e., hM4Di receptor) into a SOM-Cre driver, a mouse line specifically expressing Cre recombinase in a major population of the CeL. In optogenetic part, we expressed inhibitory halorhodopsin (eNpHR) in $SOM^+$ cells in the CeL. Consistent with this hypothesis, we found that both chemo- and opto-genetic silencing of $SOM^+$ neurons in the CeL reduced mechanical sensitivity and comorbid anxiety-like behavior.

**Title:** $H_1$-antihistamines promote electroacupuncture analgesia

**Authors: *Y.-H. CHEN**[1,2], I. MACDONALD[2], H.-Y. CHUNG[2]
[2]Grad. Inst. of Acupuncture Sci., [1]China Med. Univ., Taichung, Taiwan

**Abstract:** Acupuncture has been used to treat disease for over 2,500 years. Acupuncture has become a popular treatment modality in Western countries. This study investigated the influence of the histamine $H_1$ receptor antagonists, chlorpheniramine and pyrilamine, on the analgesic effects of acupuncture in mice. Nociceptive response was evaluated by the acetic acid-induced abdominal writhe test. Electroacupuncture (EA) at bilateral ST36 reduced the manifestations of acetic acid-induced abdominal writhing, whereas needle insertion without electrostimulation had no such effect. The analgesic effect of EA was reversed by naloxone pretreatment. While administration of chlorpheniramine (0.6 mg/kg; p.o.) or pyrilamine (2.5 mg/kg; i.p.) as monotherapy did not affect acetic acid-induced abdominal writhing, the combination of each agent with EA reduced the manifestations of abdominal writhing by a greater extent compared with EA alone. The effects of chlorpheniramine on acupuncture analgesia were not completely reversed by pretreatment with naloxone. Acetic acid also induced increases of phospho-p38 expression in spinal cord by Western blot analysis. These effects were reversed by EA-ST36 or

low doses of histamine $H_1$ receptor antagonists. Clearly, histamine $H_1$ receptor antagonists at relatively low doses facilitate EA analgesia via non-opioid receptors. These results suggest a useful strategy for increasing the efficacy of EA analgesia in the clinical situation.

**Abstract:** In order to study the pathophysiology and pharmacology of orofacial neuropathic pain in a multidimensional way, we use surgical and behavioral procedures to study trigeminal neuropathic pain in rats. The mental nerve is subjected to a chronic constriction injury (mNC) by loosely ligating the nerve. In the sensorial
evaluation of chronic pain in this model, rats exhibit changes in spontaneous behavior and in response to von Frey stimulation that are indicative of persistent pain and mechanical allodynia; in the same way the rats show thermic hyperalgesia. The spontaneous activity functions as pain indicator; 15 days post
mNC, rats decrease facial grooming activity, and both allodynia and hyperalgesia decrease as well. After this time, we evaluate the hedonic and cognitive dimension in this model. Using a progressive ratio schedule, we determine an important decrease in motivation for sucrose solution and cognitive alterations in learning,
persistence, familiar memory and adaptation process no regarding with pain, but regarding with chronic changes in circuits at central nervous system induced by orofacial pain.

**Title:** Aggravation of inflammatory pain after sound stress exposure

**Authors: *C. HUNG**
Neurol., Kaohsiung Med. Univ. Hosp., Kaohsiung city, Taiwan

**Abstract:** Stress is a well-known trigger of several pain syndromes, including fibromyalgia and painful inflammatory diseases. To simulate these clinical conditions, sound stress models use unavoided sound stimulus to aggravate algesics-mediating pain responses (e.g. cytokines and prostaglandins). So far, comprehensive behavioral studies have not been investigated, and information of co-morbid symptoms and therapeutic responses remain lack. In addition, mechanisms of peripheral nociceptive activation have been seldom studied. Our study indicated not only mechanical but also thermal hyperalgesia developed in the stressed mice. Sound stimulus alone didn't change nociceptive threshold but enhance pain response. Our study also suggested stressed mice developed behaviors of anxiety, fatigue, and visceral hyperalgesia evidently. Regarding therapeutic responses, sound stress mice had similar pharmacotherapeutic responsiveness to clinical pharmacological agents. With addition of algesic substances, nociceptive activation was absent in peripheral sensory neurons in immunostaining study. No evidence of nerve injury was observed. These results helped to elucidate the validity of the current model, and also helped to better understand the potential peripheral mechanism.

**Abstract:** Over 100 million Americans suffer from chronic pain and many of them are inadequately treated. Although opioids work well against many types of chronic pain, significant side effects deter patients and physicians from using them for these conditions. We have developed a mu-opioid receptor selective endomorphin (EM) analog (ZH853) that does not cause the side effects of currently used opioids including: abuse liability, respiratory depression, motor impairment, tolerance, and glial activation (1). In the current study, we evaluated acute and chronic dosing of ZH853 and morphine in chronic pain states. Both intravenous and intrathecal administration of ZH853 produced a long lasting reversal of hypersensitivity compared to morphine acutely, providing up to two additional hours of pain relief. We are also evaluating the use of chronic, moderate doses of ZH853 and whether it prolongs chronic pain as has been shown with morphine (2). We used classical pain tests (e.g. von Frey) to determine pain sensitivity, while assessing functional recovery with a multitude of gait parameters from the CatWalk XT system. Using these tests, we will determine whether functional and pain recovery correlate, and whether ZH853 or morphine alters the trajectory of recovery.

**Title:** A painful neuroma model in rats is objectively assessed using the automated neurobehavioral monitoring system - smartcage™

**Authors: *X. S. XIE**, C. PASCUAL, B. ZOU, W. S. CAO, K. XIAO, O. V. HORST
Afasci Res. Laboratories, Afasci, Inc., Redwood City, CA

**Abstract:** Traumatic nerve injury or postoperation-induced neuroma formation occur in approximately 30% of cases and are one of the main causes of neuropathic pain. Painful neuroma is particularly difficult to treat since it usually responds poorly to all existing therapies including local injection of lidocaine and systemic medication of gabapentin or other analgesics such as opioids. To develop a more effective, non-opioid analgesic, translational animal models and face-validity tests must be established. The tibial neuroma transposition (TNT) in rats is a model of painful neuroma that has been reported.
After establishing the TNT model in rats, we used AfaSci's noninvasive rodent neurobehavior monitoring system SmartCage™ to assess neuroma pain effects on rodent homecage activity. In parallel, we conducted conventional mechanical pain measurements with von Frey monofilaments and used current therapies to validate the objective and automated assessment. After measuring baseline of the pain threshold and homecage activity of individual rats, the posterior tibial nerve was exposed and the calcaneal branch was dissected free from the main trunk of the tibial nerve under anesthesia. The surgical rats were then returned to their homecages. A neuroma gradually formed in around 70% of rats operated which was confirmed histopathologically. Persistent pain associated with neuroma developed over a 2-3 week period indicated by an increase in mechanical hypersensitivity assessed using a peri-neuromal mechanical allodynia test on the skin overlying the neuroma, and in the ipsilateral hindpaw in respect with the contralateral side of the same subject, or compared to sham animals. The SmartCage recorded for 1 - 3 days and showed decreases in active time, travel distance, speed, and especially rearing in neuroma rats compared to sham control.
Intradermal injections of 1.5% lidocaine (50µl x 2) around the neuroma or oral administration of gabapentin (50-100mg/kg) restored the four behavioral parameters to the sham level and significantly decreased allodynia compared to control. The TNT model and the combined assessment of mechanical pain thresholds and homecage activity are now being employed in-house to evaluate new compounds that modulate key targets that play critical roles in the pain signaling pathway.

**Abstract:** By adapting the human action coding system, researchers have recently discovered that facial expressions are conserved across a variety of mammalian species. The Mouse Grimace Scale (MGS) is one such adaptation that allows researchers to quantify mouse pain faces and assess spontaneous pain (Langford et al., 2010). Despite advances to automate image collection, the MGS still relies on trained laboratory personnel to asses the presence of pain faces, preventing the widespread use of this behavioral assessment. Here we adapt and train a convolutional neural network (Google TensorFlow) on over 2000 mouse face images to quickly and accurately assess the presence of grimacing in novel images. Coupled with the previously published Rodent Face Finder (c) we outline a viable pipeline that will allow untrained personnel to take recorded footage of mice and quickly determine the presence of pain from a large number of samples. We also show a degree of granularity in mouse grimacing that was not possible with human coding.

**Title:** Pain in Autism: SHANK3 deficiency in sensory neurons impairs mGluR5-induced signaling via peripheral and presynaptic modulation

**Authors: *L. ZHANG**[1], Q. HAN[2], H. LUO[2], Y. KIM[2], X. WANG[2], Y.-H. JIANG[2], R.-R. JI[2]
[1]Anesthesiology, Duke Univ., Durham, NC; [2]Duke Univ., Durham, NC

**Abstract:** Self-injurious behaviors are considered a devastating trait in autism spectrum disorder (ASD). Although pain-related sensory abnormalities may be a pivotal determinant in this process, the mechanisms have yet to be understood. SHANK3, a postsynaptic scaffold protein, is strongly implicated in the pathogenesis of ASD-related phenotypes. SHANK3 deletion results in dysfunction of metabotropic glutamate receptor 5 (mGluR5), suggesting a link between SHANK3 and mGluR5 in ASD. Recently, we found that SHANK3 is expressed by DRG primary sensory neurons and regulates TRPV1 function and heat hyperalgesia (Han et al., Neuron, 2016, PMID:27916453). Given an important role of mGluR5 in pathological pain, we tested the hypothesis that mGluR5 is also a target of SHANK3 in primary sensory neurons, using *Shank3* conditional knock-out (CKO) mice with specific loss of SHANK3 in Nav1.8-expressing sensory neurons. We tested mGluR5-mediated spontaneous pain and mechanical pain following both central (intrathecal) and peripheral (intraplantar) administration of mGluR5 agonist DHPG. CKO mice exhibited a marked reduction in DHPG-induced spontaneous pain after intrathecal injection. CKO mice also showed a reduction in DHPG-induced mechanical allodynia after intraplantar injection. Furthermore, mGluR5 expression in DRG and spinal dorsal horn tissue is downregulated in CKO mice. We are currently investigating the mGluR5-mediated synaptic transmission in the spinal cord of CKO mice. Our findings suggest that peripheral and presynaptic regulation of mGluR5 expression by SHANK3 may be an important mechanism of SHANK3-related pain deficits in ASD.

**Title:** Antinociceptive effects of NSAIDs on acid-stimulated stretching and acid-depressed feeding in rats

**Authors: *A. ALTARIFI**[1], B. YOUNIS[2], M. ALSALEM[3], K. NUSEIR[2]
[1]Jordan Univ. of Sci. and Technol., Zarqa, Jordan; [2]Jordan Univ. of Sci. and Technol., Irbid, Jordan; [3]The Univ. of Jordan, Amman, Jordan

**Abstract:** Pain is a major problem that burden the health and economy of societies worldwide. The main pharmacological treatments of pain include nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids. Because of their side effects, new analgesics are needed to improve pain management clinically. The main aim of our study was to establish new animal models to enable investigators to assess antinociceptive effects of candidate analgesics in comparison to currently used analgesics. Thus, we studied the antinociceptive effects of different NSAIDs in inflammatory pain conditions in rats. Noxious stimuli can produce pain-stimulated behaviors and pain-depressed behaviors. Effective analgesics are determined by blocking both behaviors. Here, we used intraperitoneal lactic acid as noxious stimulus to produce acid-stimulated stretching and acid-depressed feeding. Next, we assessed the efficacy of ibuprofen, diclofenac, naproxen, and acetaminophen on acid-stimulated stretching and acid-depressed feeding behaviors in adult male Fischer rats. We hypothesized that NSAIDs will block acid-stimulated stretching and acid-depressed feeding. In stretching studies, lactic acid produced dose-dependent increase in stretching, that was significant after 1.8%, which was used in subsequent studies. In feeding studies, rats were allowed to eat regular chow for 1 hour after different durations of food restriction. 24 hours of food restriction was selected for subsequent feeding studies. Afterward, lactic acid produced dose-dependent decrease in food consumption, that was significant after 3.2% lactic acid which was used in subsequent studies. ibuprofen reduced lactic acid-stimulated stretching and acid-depressed feeding behaviors after 10 and 32 mg/kg, respectively. 10 mg/kg Diclofenac and 100 mg/kg acetamoniphen reduced both acid-stimulated stretching and acid-depressed feeding behaviors. Also, 3.2 mg/kg of naproxen reduced lactic acid-stimulated stretching behavior only. These data showed that feeding behavior provides good preclinical animal model to assess nociception pain and antinociceptive effects of drugs, especially if combined with pain-stimulated behaviors. Finally, there was comparable efficacy between tested NSAIDs in both acid-stimulated stretching and acid-depressed feeding.

**Title:** Differential patterns of glial expression in the hippocampus of rats with behavioural changes following nerve injury

**Authors: *N. T. FIORE**, P. J. AUSTIN
Anat. and Histology, Univ. of Sydney, Sydney, Australia

**Abstract: Aims**: Chronic constriction injury (CCI) evokes sensory 'pain' in all rats, and evokes affective-motivational disturbances in a sub-population. We examined whether foraging behaviour and spatial memory on the radial maze task as well as glial expression in the hippocampus were altered after CCI. **Methods**: Outbred male Sprague-Dawley rats underwent daily radial maze testing for 14 days after CCI (n=32) or sham injury (n=10). Rats were habituated to the radial maze prior to testing. During each test 4 arms were baited with sucrose pellets and rats were given 5 minutes to complete the task. Foraging behaviour was assessed with the 'time in the central atrium per entry' (an index of risk-assessment) recorded. Working memory errors (an index of spatial memory) were also recorded. Rats also underwent von Frey and rota-rod testing. Immunofluorescent labelling of GFAP (n=6 sham and n=18 CCI) and IBA-1 (n=4 sham and n=12 CCI), with a detailed anterior/posterior-dorsal/ventral analysis conducted to quantify % immunoreactivity (-IR) of astrocytes and microglia respectively within sub-fields of the hippocampus (cornu ammonis, dentate gyrus and subiculum). **Results**: CCI reduced withdrawal thresholds and motor activity in all rats and no differences in spatial memory were observed, whilst foraging behaviour was altered in some but not all rats. One group (n=12), termed '*No effect*', had no behavioural changes compared to sham injured rats. Another group (n=8), termed '*Acute effect'*, had a temporary 3-standard deviation (SD) increase in their risk-assessment on the initial 7 days post-injury. In a third group (n=12), termed '*Lasting effect*', rats displayed a sustained 3SD increase in their risk-assessment for the entire post-injury period. There was no change in astrocyte or microglia-IR between CCI and sham rats. *Lasting effect* rats displayed reduced astrocyte-IR in the contralateral posterior dentate gyrus ($p<0.05$ n=6 from each group) and reduced microglia-IR in the contralateral ventral cornu ammonis ($p<0.05$ n=4 from each group) relative to *No effect* rats. **Conclusions**: These data highlight that nerve injury drives three differing phenotypes of foraging behaviour on the radial maze task. Considering the degree of sensory 'pain' does not predict development of behavioural changes clinically, the decoupling of allodynia from the changes in foraging behaviour triggered by nerve injury are indicative of the clinical relevance of this model. Further, differential patterns of glial expression

in the contralateral ventral hippocampus across nerve-injured rats may predispose the *Lasting effect* group to the development of affective-motivational disturbances after CCI.

**Title:** Pain tolerance measured with the Operant Plantar Thermal Assay is altered in inflammatory and neuropathic pain models

**Authors: *A. N. REKER**[1], S. CHEN[2], S. DAVIDSON[1]
[1]Anesthesiol., [2]Univ. of Cincinnati, Cincinnati, OH

**Abstract:** We developed a novel apparatus: the Operant Plantar Thermal Assay (OPTA). The OPTA has dual chambers, each having independently thermally adjustable floors and a reward zone, requiring an animal to engage in decision-making and evaluation of pain tolerance to cross the investigator-set thermal stimulus to obtain a reward. The time and count spent traversing the noxious floor and entering the reward zone are indices of the level of pain an animal is willing to accommodate to receive a reward and thus a gauge of pain tolerance. Results show that baseline reward access was highest when the floor was set to 40°C, and dropped significantly when set below 10°C and above 45°C, indicating that floor temperatures in the noxious range were less tolerated. We further validated the OPTA using models of inflammatory (complete Freund's adjuvant, CFA) and neuropathic (chronic constriction injury, CCI) pain. CFA injected to the mouse hind paw resulted in reduced time in the 45°C zone compared to the 30°C zone, as well as less time in the reward zone. When administered to mice pre-treated with CFA, the nonsteroidal anti-inflammatory Meloxicam resulted in significantly increased time spent in the reward zone suggesting increased pain tolerance. CCI resulted in reduced overall time in the uncomfortable zone, but an increase in time spent in the reward zone. Parallel studies in our lab show that anterior cingulate cortex (ACC) mGluR2$^+$ neurons exhibit hyperexcitability in a model of persistent inflammatory pain and that this is effectively reversed, *in vitro*, via administration of an mGluR2$^+$ agonist. We hypothesized that mGluR2+ ACC neurons are involved in regulating higher order pain processing, such as establishing pain tolerance level, which requires limbic and cognitive processing. Therefore, we examined whether *in vivo* pain-related behaviors are influenced by direct infusion of the mGluR2$^+$ agonist, (2R-4R)-4-aminopyrrolidine-2-4-

dicarboxylate (APDC) to the ACC as well as optogenetic manipulation of *GRM2+* ACC neurons in *GRM2*x*ChR2*-EYFP mice that we generated.

**Title:** Behavioral characteristics of capsaicin mediated cutaneous, myogenic, and arthrogenic orofacial nociception in rats

**Authors: E. L. ROHRS**[1], J. K. NEUBERT[1], K. D. ALLEN[2], *R. M. CAUDLE[3]
[1]Orthodontics, [2]Biomed. Engin., Univ. of Florida, Gainesville, FL; [3]Dept Oral Surg, UFCD, Gainesville, FL

**Abstract: Objective**: To assess changes in orofacial mechanical sensitivity and gnawing in rat models of capsaicin mediated cutaneous, myogenic, and arthrogenic nociception. **Design**: To assess cutaneous sensitization, eleven female CD-Hairless rats were tested with bilateral capsaicin cream application to the cheek or with isoflurane anesthesia alone. After recovery from anesthesia, orofacial mechanical sensitivity and gnawing were assessed using operant testing methods. Following a few weeks of recovery, animals received either 10 µL unilateral masseter injections of capsaicin solution (1%), vehicle, or PBS. Again, after recovery from anesthesia, orofacial mechanical sensitivity and gnawing were assessed. Finally, animals received either 10 µL unilateral TMJ injections of capsaicin solution (1%) or vehicle, with mechanical sensitivity and gnawing assessed after recovery from anesthesia. **Results**: Capsaicin cream to the skin significantly affected gnawing (increased puncture time by 338.5 seconds) and orofacial mechanical sensitivity (decreased tolerated bottle distance by 0.227 inches). Similarly, capsaicin injection to the masseter significantly affected gnawing (increased puncture time by 424.7 seconds) and orofacial mechanical sensitivity (decreased tolerated bottle distance by 0.360 inches). However, intra-articular capsaicin in the TMJ only affected gnawing (increased puncture time by 207.9 seconds), with no changes found in orofacial mechanical sensitivity. **Conclusion**: Capsaicin masseter injections and cutaneous application of capsaicin cream had similar behavioral effects; however, intra-articular injections to the TMJ only affected gnawing. These

data indicate that the behavioral changes in a rodent models of myogenic and cutaneous pain may be markedly different than models of arthrogenic pain originating from the TMJ.

**Authors: *S. M. JAFFAL**[1], M. A. ABBAS[2]
[1]Pharmaceut. Sci., [2]Al-Ahliyya Amman Univ., Amman, Jordan

**Abstract:** *Ajuga chamaepitys* is a small herbaceous perennial plant belonging to Lamiaceae family. It is one of the medicinal plants that grow in the Middle East and has several therapeutic effects in the treatment of rheumatism, sclerosis, jaundice and gout. In this study, we examined the antinociceptive effect of the methanol extract of *Ajuga Chamaepytis* collected from Jordan. The antinociceptive effect of the extract was studied using chemical (acetic acid writhing test and formalin induced nociception test) and thermal (hot plate) pain models in BALB/c mice. Our data showed that the intraperitoneal (i.p) injection of 300 mg/kg of *A. chamaepitys* extract (for 30 min) decreased the number of writhes that were induced in mice by the acetic acid injection (i.p), significantly, compared to negative control group. In addition, the treated animals showed a remarkable decrease in the time of paw licking in the second, but not the first, phase of formalin induced paw licking test suggesting the involvement of the central sensitization as a possible mechanism of action for the methanol extract of *A. chamaepitys*. Furthermore, the treatment with *A. chamaepitys* extract increased *the latency of paw licking and the jumping responses by 3 folds compared to non-treated animals* in hot plate test indicating the analgesic effect of the extract in this thermal test. In summary, our results suggest that the methanol extract of *A. chamaepitys* has pronounced antinociceptive effects and can have promising therapeutic applications in pain. The mechanism of action is being currently investigated in our lab.

**Abstract:** Chronic pain is a condition in which pain no longer functions as a defense mechanism, but as a neuroplastic alteration in the structures that integrate pain and other vital functions, in addition to reducing the quality of life of those who suffer from it. Various investigations have revealed a possible overlap between brain regions involved in pain modulation and susceptibility to developing alcoholism, including structures of the limbic system. On the other hand, periodontal disease is a common, inflammatory, infectious and painless pathology that affects dental support tissues. It has been associated with diabetes mellitus, cardiovascular disease, rheumatoid arthritis, psoriasis, stress, oral cancer, and mental illness. The present study aimed to validate the increase in binge-type ethanol consumption induced by chronic neuropathic pain caused by constriction of the mental nerve and periodontal lesion. Forty five male Wistar rats, with an initial weight of 300 to 400g, were divided into 4 groups: 2 experimental groups; 1 of surgery with mental constriction [CCNM] and 1 group with periodontal lesion [LP], and 2 groups with sham surgery. For alcohol consumption, the drinking-in-the-dark model was used, starting on the postoperative day 48 for the LP group and 52 for the CCNM group. Immediately after the baseline days, a 10% ethanol concentration was used; afterwards, it was increased to 20 and 40% by carrying out the same protocol. The results showed that the constriction of the mental nerve and periodontal disease were factors that considerably increased the binge eating of ethanol without correlating with the degree of spontaneous pain. The present work shows evidence for the first time, that chronic inflammatory and neuropathic orofacial pain may

generate alterations in neuronal circuits of the central nervous system that induce alcoholism.

**Abstract:** Persistent pain associated with burn injury is a major clinical challenge primarily due to the lack of efficacious analgesics. Although opioids are the gold standard for pain control, their efficacy in burn injury is insufficient and dosage increases are limited by their fatal side effect of respiratory depression. Thus, exploring mechanisms underlying burn injury-related pain is essential for developing more effective treatments with fewer side effects. Previously, we developed a mouse model of burn injury that recapitulates the persistent thermal and mechanical hypersensitivities reported clinically. In this study, we investigated the contribution of ANO1 in our burn model at a time-point corresponding to peak hypersensitivity post-burn. We determined that an intraplantar injection of a selective ANO1 antagonist, dose-dependently attenuated burn injury-evoked thermal and mechanical hypersensitivity. Preliminary analysis of mRNA transcript levels indicates that ANO1 expression is reduced in skin biopsies from the ipsilateral hindpaw 4 days following induction of burn injury. ANO1 transcript levels were unchanged in lumbar DRG or spinal cord. To provide a neurophysiological correlate to burn injury-induced hypersensitivity observed behaviorally, we investigated spontaneous and stimulus-evoked response properties of sensory nerve fibers innervating burn-injured glabrous skin at peak hypersensitivity. Pain-transducing sensory nerve fibers were activated at lower mechanical forces and displayed increased spontaneous firing in burn-injured glabrous skin relative to sham controls. Furthermore, in congruence with clinical reports, we detected a decrease in C-fiber conduction

velocity from burn-injured skin preparations. The complementary behavioral and electrophysiological approaches provide a means to correlate changes in the transmission of nociceptive signals with the existence of ongoing burn injury-associated pain. Ongoing experiments will further characterize the stimulus-evoked and spontaneous discharge phenotype of sensory neurons at their peripheral terminals and how ANO1 may contribute to burn injury-evoked alterations. Pharmacological modulation of this channel may serve as an effective treatment strategy for ongoing debilitating burn pain in patients.

**Abstract:** In lumbar radiculopathy rat models of constriction in proximity to the dorsal root ganglion (DRG), the animals response differs dramatically dependent on whether the constriction sites distal or proximal to DRG. Although the evidences showed constriction distal to DRG caused more severe radiculopathy than constriction proximal to DRG, the mechanism is largely unknown. The purpose of this study was to compare the severity of radiculopathy following constriction proximal or distal to the DRG by using pain behaviors, the extent of hypoxia, and the ratios of DRG neuron subpopulation. The three pain behaviors tests, 50% paw withdraw threshold, incapacitence test, and acetone test, demonstrated that animals with distal spinal nerve injury had more persistent pain behaviors than those with proximal spinal nerve injury. The optical density of hypoxia-probe 1 as well as the ratios of ATF3-positive DRG neurons were significant higher in distal spinal injury group than those in proximal spinal injury group. The ratio of CGRP+ DRG neurons after distal spinal nerve injury was higher than those after

proximal spinal nerve injury, but the difference did not reach the statistical significance. The ratios of IB4+ or N52+ DRG neuron were not different among three groups. This study demonstrated animals with distal spinal nerve injury presented more persistent pain behaviors and the mechanism may be the more hypoxia and more nerve injury in the DRGs after distal spinal nerve injury.

**Title:** Pronociceptive effect of calcium-activated chloride channel Bestrophin-1

**Authors: *G. GARCÍA**, R. NORIEGA-NAVARRO, P. A. MUÑOZ-CASTILLO, J. MURBARTIÁN
Cinvestav Sede Sur, Mexico DF, Mexico

**Abstract:** The calcium-activated chloride channels (CaCC) are transmembrane proteins activated by intracellular $Ca^{2+}$ concentration. CaCC are involved in several physiological processes including transepithelial secretion, neuronal excitation, neuronal regeneration and sensory transduction. Bestrophin-1 (Best-1) belongs to the family of CaCC and it was the first channel to settle within this family. Although Best-1 is expressed in dorsal root ganglion (DRG) neurons and participate in regeneration processing, the function in DRGs of this channel is not complete known. It has been reported that CaCC currents increase after sciatic nerve axotomy. Previously, we determine that Best-1 protein expression strongly increase after L5 spinal nerve axotomy than L5/L6 spinal nerve ligation. Thus, Best-1 may contribute to maintain nociceptive behaviors in neuropathic pain induced by lesion of spinal nerves.
The aim of this study was to determine the nociceptive effect of up-regulation of Best-1 expression in naïve rats. *E. coli* bacteria were transformed with a plasmid that contain a Best-1 DNA sequence (pCMV6-Best1). The plasmid was isolated and identified by PCR and restriction enzyme digestion. After that, we realized intrathecal injection (i.t., into the subarachnoid space, between L4 and L5 disc) of pCMV6-Best1 10µg during 3 days and determined mechanical tactile allodynia in naïve rats. Besides, we determined protein expression of Best-1, neuronal injury marker ATF-3, apoptosis marker caspase-3 and neuronal regeneration marker GAP-43, in L4 and L5 DRG neurons by western blotting. I.t. injection of Best-1 plasmid increased the protein expression of this channel in L4 and L5 DRGs. Moreover, up-regulation of Best-1

developed nociceptive behaviors. Our results suggest that Best-1 channels have a pronociceptive role.

**Abstract:** Nuclear import factors from the importins family are involved in dendritic, axonal and nuclear transport mechanisms in neurons, but their physiological importance is still not clearly understood. We have found sensory deficits in an importin alpha KO mice, most prominently a significantly reduced responsiveness to noxious heat, together with changes in axonal growth and morphology in the sciatic nerve. In order to understand the underlying molecular mechanisms we performed RNA seq analyses on wild type versus embryo dorsal root ganglia (DRG) followed by bioinformatics analyses. The results show changes in c-FOS dependent transcription in KO DRG, with a corresponding mislocalization of c-FOS out of the nucleus in KO neurons. Since c-FOS has been implicated in pain signaling via unknown mechanisms, these findings raise the possibility that the reduced heat sensitivity in an importin alpha KO mice are actually due to a c-FOS nuclear import deficit in these animals.

**Abstract:** Extensive alternative splicing of the mu opioid receptor (OPRM1) gene creates an array of splice variants that are conserved from rodent to human. Of these splice variants, the carboxyl (C-) terminal 7 transmembrane (TM) variants share an identical receptor structure, but have a different intracellular C-terminal tail. Although several C-terminal 7-TM variants have been characterized in vitro for agonist-induced G protein coupling, phosphorylation, internalization and post-endocytic sorting, their in vivo functions remain largely unknown. The present study generates three mutant mouse models truncating either all C-terminal tails or only C-terminal tails encoded by exon 4 or exon 7 in two different inbred strains, C57BL/6J (B6) and 129/SvEv. Characterizing these mice reveals divergent roles of individual C-terminal tails in various morphine actions, such as tolerance, physical dependence, locomotor activity and reward, highlighting the importance of individual intracellular C-terminal tails in mediating

complex morphine actions. For example, truncating exon 7 (E7)-associated C-terminal tails in B6 mice (mE7M-B6) attenuated morphine tolerance and reward with no change in morphine dependence, whereas truncating exon 4 (E4)-associated C-terminal tails in B6 mice (mE4M-B6) facilitated morphine tolerance and reduced morphine dependence without affecting morphine reward. Truncating E7-associated C-terminal tails in B6 mice resulted in loss of morphine-induced receptor desensitization in the hypothalamus and brainstem, consistent with exon 7 involvement in morphine tolerance. Down-regulating E7-associated C-terminal variants with an antisense vivo-morpholino oligo mimicked the attenuation of morphine tolerance seen in mE7M-B6 mice, providing potential clinical utility for altering mu opioid action through modulating OPRM1 alternative splicing. Furthermore, the similarity in several morphine-induced behaviors and receptor desensitization between mE7M-B6 homozygous and β-arrestin 2 KO mice suggests a physical and functional association of exon 7-associated C-terminal tails with β-arrestin 2, a hypothesis further supported by our in vitro data showing that several mu agonists displayed greater β-arrestin bias against exon 7-associated variants than against the exon 4-associated mMOR-1. Together, the differential effects of C-terminal truncation illustrate the pharmacological importance of OPRM1 alternative splicing.

**Title:** Dysgranular area in somatosensory cortex of mice represents nociceptive information

**Authors: *H. OSAKI**, Y. UETA, M. MIYATA
Dept. Physiology, Tokyo Women's Med. Univ., Tokyo, Japan

**Abstract:** It has been extensively studied that cortical representation of tactile information in the granular area of the primary somatosensory cortex (S1). However, cortical representation of nociceptive information is still poorly understood. In this study, to identify the area that receives nociceptive information in S1, we mapped the activated S1 region in neuropathic pain model mice by intrinsic signal optical imaging. To induce neuropathic pain, the infra-orbital nerve that transfers whisker sensory information was ligated. After ligation, we detected the signal in the dysgranular area (Dys) evoked by mechanical whisker stimulation, while the signal in the granular S1 largely reduced. Dys was also activated by a 50°C thermal stimulation. To confirm noxious stimulation activates Dys, we injected capsaicin into the whisker pad and counted the number of neurons expressing c-Fos, a marker of neural activity. Capsaicin injection significantly increased the number of c-Fos positive neurons in Dys, compared to vehicle injection into the whisker pad. These data suggested that Dys represents nociceptive information. It is already known that nociceptive information is processed in the posterior nucleus (Po) in the thalamus and sent to layer 5a in the granular S1. Therefore we anatomically investigated the thalamic input into Dys using anterograde and retrograde labelling. The thalamocortical neurons retrogradely labeled from Dys were found locally in Po, and axonal projections anterogradely labeled from Po were found in layer 4 of Dys. From these observations, we conclude that Dys is a part of the paralemniscal pathway that processes nociceptive information. Because cytoarchitectonic features in mouse Dys are similar to those in human area 3a, which receives nociceptive and proprioceptive information from somatosensory thalamus, our results may be of help to understand the cortical representation of the neuropathic pain in human.

**Title:** Alteration of thalamic submedius activity following lumbar spinal thrust

**Authors: *W. R. REED**[1], J. T. CRANSTON[2], S. M. ONIFER[2], J. W. LITTLE[3], R. S. SOZIO[2]
[1]Sch. of Hlth. Professions, Univ. of Alabama Birmingham, Birmingham, AL; [2]Palmer Col. of Chiropractic, Davenport, IA; [3]Surgery, St. Louis Univ., Saint Louis, MO

**Abstract:** Thalamic submedius (Sm) neurons typically have large (bilateral) receptive fields and respond predominately to noxious convergent sensory input from spatially separated cutaneous, muscle, joint, and visceral tissues which suggests a non-discriminatory role in nociception. These characteristics make Sm nociceptive-specific neurons good candidates for investigating supraspinal changes related to manual therapy interventions. The purpose of this study was to determine if lumbar (L5) vertebra high velocity low amplitude thrusts alter spontaneous and/or noxious evoked Sm activity. Extracellular recordings were obtained from 94 Sm neurons in 54 urethane-anesthetized adult male Wistar rats. Spontaneous activity was recorded 5min before and after an L5 control (no thrust) and thrust (85% rat body weight; 100ms) procedure. In a subset of responsive nociceptive-specific neurons, mean changes in noxious evoked response (10s pinch with clip; 795g) at 3 sites (tail, contra- and ipsilateral hindpaw) were determined following an L5 thrust. Mean changes in Sm spontaneous activity (60s bins) and evoked response were compared using repeated measures ANOVA and paired t-tests, respectively. Compared to control, spontaneous Sm activity decreased 180-240s following lumbar thrust ($p<0.005$†). lnhibitory evoked responses were attenuated in the contralateral hindpaw following an L5 thrust compared to control ($p<0.05$*). A delayed, but prolonged suppression of spontaneous Sm activity along with changes in noxious evoked responses in the contralateral hindpaw following lumbar vertebra thrust suggest that thalamic submedius neurons may play a role in central pain modulation related to manual therapy intervention.

**Title:** Excitatory input from the Anterior Cingulate Cortex to the dorsal Periaqueductal Gray facilitates the affective dimension of pain

**Authors: *J. DICKINSON**, G. F. CORDER, A. FRANCOIS, G. SCHERRER
Stanford Univ., Palo Alto, CA

**Abstract:** Pain is a conscious perceptual experience characterized in large part by its aversive qualities and consequent motivation for relief. Several decades of research have identified the Anterior Cingulate Cortex (ACC), a non-sensory cortical structure, as a critical region for the emotional dimension of pain. In both humans and rodents, acute and chronic pain excites the ACC while lesions and reduced ACC excitability decrease reports of pain being unpleasant. However, the ACC receives diverse inputs from a multitude of brain regions, and responds to a variety of stimuli and circumstances. It thus remains unclear what circuit mechanisms in the

ACC contribute to shaping pain experience. Recent work showed that in prelimbic cortex, a neighboring structure with similarities to the ACC, segregated populations of neurons respond to positively and negatively valenced stimuli. Other studies indicated that the dorsal Periaqueductal Gray (dPAG) is a critical structure for the expression of defensive behaviors and the acquisition of learned responses to aversive stimuli. The ACC projects to the dPAG, but the contribution of this pathway to pain experience has not been resolved. Here, we tested the hypothesis that excitatory input from the ACC to the dPAG during pain facilitates the affective-motivational dimension of pain. First, whole-cell patch-clamp electrophysiology confirmed excitatory transmission between ACC terminals and dPAG Vglut2+, but not Vgat+ neurons. Next, we genetically targeted the ACC neurons projecting to the dPAG with viral vectors to express the hM4Di inhibitory DREADD, and exposed the animals to an assortment of pain tests. We found that inhibition of the ACC-dPAG pathway reduced place avoidance to a noxious heat stimulus as measured by overall increased time spent exploring the noxious zone, increased frequency of zone entries, and increased duration of zone visits. When the noxious stimulus was inescapable, ACC-dPAG inhibition decreased attending-motivational behaviors (such as licking, grabbing, and prolonged lifting), with minimal changes in sensory-reflexive behaviors. In response to mechanical stimuli, ACC-dPAG inhibition reduced attending-motivational nocifensive behaviors and locomotive escape responses. In a neutral environment, inhibition did not change gross motor behaviors, suggesting our pain test results are not merely a reflection of altered motor capacity. Collectively, these results establish the necessity of the ACC-dPAG pathway for the expression of the aversive quality of pain.

**Title:** Group II mGluR+ neurons in anterior cingulate cortex are sensitized in mouse models of pain and are positioned to contribute to pain threshold and tolerance behaviors

**Authors: *S. CHEN**[1], S. DAVIDSON[2]
[2]Anesthesiol., [1]Univ. of Cincinnati, Cincinnati, OH

**Abstract:** Anterior cingulate cortex (ACC) is a limbic region associated with emotional processing of pain. Excitatory responses in ACC are predominantly mediated by glutamate receptors. In this study, we focused exclusively on a group of neurons in mouse ACC expressing

Group II metabotropic glutamate receptors subtype 2 (mGluR2), canonically coupled to a Gi/o second messenger pathway. We hypothesized that mGluR2+ neurons in the ACC undergo plastic changes in response to pain. Immunohistochemical studies showed that *GRM2+* neurons, identified by tdTomato expression, were pyramidal type neurons localized to layer 2/3 in the ACC and did not co-express somatostatin or parvalbumin suggesting they are unlikely to be inhibitory interneurons. To study the intrinsic membrane properties of *GRM2+* neurons, we performed whole-cell patch clamp electrophysiology on brain slices containing ACC obtained from adult male and female mice. To explore the characteristics of these cells under persistent peripheral inflammation, we injected the hind-paw with Complete Freund's adjuvant (CFA) and examined *GRM2+* neurons in contralateral ACC 24 hours later. After inflammation, *GRM2+* neurons exhibited significantly higher action potential discharge and sensitized membrane physiology compared to the naïve group. This hyperexcitability was reversed by bath applied (2R,4R)-4-aminopyrrolidine-2,4-dicarboxylate (APDC, 1 μm), an agonist for mGluR2. Similar results were obtained after the chronic constriction injury neuropathic pain model. In order to determine how ACC affects pain perception, hM4Di-mCherry virus was injected bilaterally into ACC in wildtype mice. Mice subsequently injected with clozapine-n-oxide (CNO, 1mg/kg, i.p.) to activate Gi DREADD showed significantly prolonged paw withdraw latency in a heat plantar test and increased pain tolerance in the Operant Plantar Thermal Assay, compared to a vehicle injected group. Following behavior testing, in vitro slice electrophysiology study was performed to verify injection sites and Gi DREADD activation. hM4Di-mCherry neurons in ACC exhibited decreased membrane potential as well as firing rates after bath application of CNO (5μm). With the goal of specifically modulating mGluR2+ neural activity acutely in the ACC in vivo, we generated GRM2xChR2-EYFP mice and examined light-induced activation of these neurons using whole-cell patch clamp in vitro to determine the optimal parameters for light intensity and pulse frequency for modulation of neural activity. Future studies will test *in vivo* modulation of ChR2 expressing mice to specifically activate GRM2+ neurons in ACC during tests of pain tolerance and threshold.

**Title:** Objective evaluation method for the sudden type of pain

**Authors: *A. NAKAE**, T. SOSHI, Y. TSUGITA
Osaka Univ. Grad. Sch. of Frontier Biosc, Suita-Shi, Japan

**Abstract:** [Background & goal of the study] International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience which leads to the concept that pain is subjective. Everyone must agree that doctors have to treat patients' pain if they say that they feel severe pain. However, for example, doctors sometimes encounter problems due to lack of objective evaluation methods of pain. For example, even after the doctor has administered full strength of the medicine for the specific patient for the pain he/she is experiencing, the patients at times still remain satisfied. This is because patients are not always able to tell that the medicine has already taken effect. To evaluate patients' pain correctly, objective evaluation methods should be developed. The goal of the study is to develop the way to evaluate the sudden type of experimental pain objectively using EEG. [Methods] After signing the written informed consent, 20 healthy volunteers attended the study. Five different electrical stimuli (20, 40, 60, 80,100 microA) were applied randomly using Pain Vision (Nipro Co Ltd., Japan). Participants' subjective evaluation of pain was done using Visual Analog Scale (VAS). Moreover, participants were randomly subjected to 20 pairs of the above mentioned stimulus. The relative rating scale of subjective pain for each electrical stimulus was used as subjective evaluation. Rating were based on the subjective declaration of ("-3: The former is very painful" "0: Neither can you say" "+3: the latter is very painful"), the pairing comparison method of Chefe Method) used for scale. [Results] In the electrical stimulation, median correlation coefficient was 0.91. Discrimination rates between maximum stimulation and middle stimulation was 90%, middle stimulation and minimum stimulation also 90%, whereas maximum and minimum stimulation was 100% based on subjective evaluation and fluctuation of amplitude data.
[Discussion] A close relationship between the stimulation intensity of pain and EEG data is clarified. Objective discrimination of pain can be developed using EEG, and in particular, it must be useful for the patients who cannot describe the amount of pain they are experiencing properly.

**Title:** Assessing the functional specialization of prefrontal cortical neurons in acute pain versus non-pain-related processes

**Authors: *O. A. RETANA**, M. J. OSWALD, R. KUNER
Pharmakologisches Inst., Universitätsklinikum Heidelberg, Heidelberg, Germany

**Abstract:** Structures in the brain involved in nociception are also attributed various functions that are unrelated to pain. The medial prefrontal cortex (mPFC), for example, is not only engaged by painful stimuli, but is also active during memory tasks, decision making, and the processing of emotions like fear, among other contexts. In order to examine the structural correlate that brings about these distinct functions within the same brain region, we address the detailed nature of circuits involving the mPFC in pain and pain-unrelated functions. Our project employs methods with single cell resolution to analyze neuronal activity in different contexts. We use adeno-associated viral vectors expressing marker proteins in an activity-dependent manner to visualize neurons stimulated during acute pain and non-painful conditions. Furthermore, we perform electrophysiological recordings to study the properties of neurons with added temporal precision. We also seek to evaluate the functional contribution of these neural populations to live animal behavior in acute pain and associative learning models. Our experiments promise insights into the cortical circuitry underlying distinct cognitive processes on a cellular level. In addition, this understanding of the microscopic representation of acute nociceptive signaling will enable the investigation of the changes that take place during chronic and pathological pain conditions.

**Title:** Behavioural and cortical pain responses in human infants are dissociable by their relationship to physiological stress

**Authors: *L. JONES**[1], M. LAUDIANO-DRAY[1], K. WHITEHEAD[1], L. FABRIZI[1], J. MEEK[4], M. VERRIOTIS[2], M. FITZGERALD[3]

**Abstract:** Introduction: In adults, noxious stimulation evokes a cortical pain response and subjective pain report that are modulated by the level of physiological stress. The relationship between pain and stress is proposed to be a significant factor in individual variability of pain perception[1]. In newborn infants noxious stimulation evokes well-described pain behaviour, which is commonly used in place of pain report[2] and nociceptive specific cortical activity (nociceptive Event Related Potential, nERP) as measured with EEG[3]. However, the effect of physiological stress levels upon infant cortical and behavioural pain measures is not known. Here, we investigate this by simultaneously measuring salivary cortisol, heart rate variability (HRV), nERP, and pain behaviour in neonates following a heel lance.
Method: 56 healthy neonates (mean GA 38.8 weeks; mean PNA 3.6 days) were studied during a clinically required heel lance. Ethical approval was given by the UK NRES and UCL/UCLH Joint Research Office.
Cortical activity, time locked to the heel lance, was recorded using EEG[3]. Salivary cortisol and ECG data for HRV calculation were collected before and after the procedure. Pain behaviour was scored using the Premature Infant Pain Profile (PIPP)[2].
Results: The nERP amplitude was positively correlated with the PIPP following a heel lance ($r$=.36, $p$=.033). In addition, higher cortisol concentration and lower HRV, indicative of higher levels of physiological stress, were associated with larger nERP amplitude ($r$=.41, $p$=.029; $r$=-.42, $p$=.027). In contrast, PIPP was unrelated to the level of stress. Interestingly, the direct relationship between the nERP and PIPP was disrupted in babies that had a higher level of physiological stress ($r$=.27, n.s.).
Conclusion: The findings suggest that the cortical nociceptive response provides a more comprehensive measure of the pain experience of infants compared to pain behaviour as it also reflects their level of stress. Moreover, when infants are in a higher state of stress their behaviour in response to a lance is no longer an accurate reflection of the cortical pain processing.

**Abstract:** Neuropathic pain (NP) is a complex pain difficult to treat mediated by different mechanisms, including central and peripheral neuroinflammation. Motor cortex stimulation (MCS) is an effective treatment to refractory NP patients, reducing pain in approximately 50% of patients. Our group has shown that MCS reverses the NP in rats by the activation of analgesic descendent pathway, with consequent inhibition of hyperalgesic cytokines release by spinal glial cells, but its mechanisms of action still unclear. In this study, we evaluate the relationship between the MCS-induced analgesia and peripheral cytokine expression in neuropathic animals. Male Wistar rats (45 days) with unilateral chronic constriction injury of the sciatic nerve (CCI) were evaluated in nociceptive tests, submitted to MCS (one session of 15 minutes) and reevaluated in the tests. False-operated (FOP) and CCI unstimulated were used as control. The expression of TNF-α, interleukins-1β, 4, 6, 10 and 17, interferon-γ (IFNγ) and fractalkine (CX3CL1) were analyzed in dorsal root ganglion of the spinal cord (DRG) and in sciatic nerve by multiplex assay. CCI enhanced the expression of IL-1β (57%), IFNγ (23%) and CX3CL1 (29%) in DRG and of CX3CL1 (35%) in sciatic nerve, and conversely inhibited IL-4 (82 %) and IL-10 (37%) in sciatic nerve when compared with FOP. Regardless the therapeutic effect, MCS inhibited TNF-α (20%) and IL-17 (18%) and reversed the increase of IL-1β, IFNγ e CX3CL1 in the DRG while enhanced TNF-α (105%), IL-1β (122%) and IL-6 (411%), inhibited IL-17 (50%) and restored the IL-10 levels in the sciatic nerve. Refractory animals showed a marked increase of IL-1β (28%) and CX3CL1 (26%) in the local of the lesion. The cortical stimulation *per se* modulates the peripheral neuroinflammation, restoring anti-inflammatory IL-10 cytokine level in the local of the lesion and the refractoriness may be correlated with the inflammation status of the injured nerve. Understanding the mechanisms of action of MCS in NP is important to overcome their therapeutic limitations

**Title:** Multivariate mediation analysis separates functional networks of pain processing

**Authors: *S. GEUTER**[1,2], T. D. WAGER[3], M. A. LINDQUIST[1]
[1]Dept. of Biostatistics, Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [3]Psychology and Neurosci., Univ. of Colorado Boulder Dept. of Psychology and Neurosci., Boulder, CO

**Abstract:** The brain produces a complex, multi-dimensional experience of pain from nociceptive stimulation, including sensory, emotional, and motivational components. This complexity is reflected by a broad diversity of active brain regions during pain. However, the exact functions and interactions of those brain regions that produce the complex pain experience are not understood.

Here, we aim to identify different functional networks involved in pain perception using a novel multivariate mediation analysis on a large fMRI data set (N=209). The multivariate mediation analysis successively estimates linear combinations of voxels (directions of mediation [DM]) that act as mediators between stimulus intensity and pain report.

Using this novel method, the first DM identified somatosensory areas (including, thalamus, insula, S1, and S2) as well as the PAG, midcingulate cortex (MCC), superior parietal lobe (SPL) and cerebellum as positive mediators of pain (Fig.1). Interestingly, the medial prefrontal cortex and a region encompassing contralateral S1 and M1 contributed negatively, i.e., activity in those regions was negatively related to stimulation intensity and pain reports. These negative mediators were not identified by a standard mediation analysis on the same data. Clustering of the regional responses showed that somatosensory regions and MCC were functionally related to the SPL, a region controlling top-down attention.

The second DM included positive contributions from frontal operculum and lateral prefrontal cortex. Parietal and medial orbitofrontal cortices were negative mediators. The third DM revealed contributions from S1, M1, and parietal regions. Interestingly, contralateral M1 was negatively related to pain, whereas ipsilateral M1 was positively related to pain.

In summary, the novel multivariate mediation analyses identified brain regions contributing to pain beyond the classic somatosensory brain regions and groups them into functional networks that may serve different functional aspects of pain processing.

**Abstract:** The experience of pain and itch is a multidimensional phenomenon and can be monitored with fMRI. With a 3 T MRT subcortical areas like thalamus and brain stem as distributing centers of incoming signals as well as areas involved in the modulation can be explored. Itch evokes the desire to scratch to produce relief. But scratch without itch in the background can turn nasty. In this study we included a paradigm to compare central processing of scratch to itching and non-itching skin.
20 healthy subjects (10 f/10 m, mean 27,1 ± 11,3y) participated on 2 separated sessions; first psychophysical pre- and second fMRI-examination each with 2 runs: a) scratch of the untreated skin (SC-I), b) scratch after inducing itch (SC+I). Itch was applied by iontophoresis (30 sec, 1mA) of histamine to the left volar forearm. Recording started when itch intensity passes 30% of the VAS (0: no itch; 30: desire to scratch; 100: maximal conceivable itch). The left volar forearm was scratched by the experimenter using an L-shaped cupper device. Rating was continuously performed with the right hand (VAS). After each fMRI-sequences one rating was given (mean perceived itch).

MRI was done on a Siemens 3.0 T Scyra. Anatomical data: MPRAGE (1x1x1mm³) and T2-weighted brainstem set with the same orientation as EPI (36 slices). Data evaluation was done by creating a transformation matrix by manual alignment of T2-brainstem images to one selected MPRAGE. The matrix was used to align the fMRI data to the MPRAGE and to create a GLM-multi-study with predefined VOI's in BrainVoyager. Brainstem activations were identified by comparison to Duvernoy's Atlas. For the SC+I analysis periods of high itch were defined as the periods 15 seconds immediately before a scratching period (HI). In a GLM contrast were calculated between high itch period and scratching periods (CIP).
During SC-I significant activations ($p<0,05$) were found in right pontine nuclei, medial nucl. parabrachiales on bilateral and right post. hypothalamus. During SC-I activation in left locus ceruleus decreased. During HI BOLD increase were found in left pontine nuclei and decrease in PAG. During SC+I activation of the PAG significantly increased leading to a significant contrast of CIP analysis. A similar behavior was found for the right post. hypothalamus. The left nucl. ruber was activated by SC+I but not by SC-I. Significant cortical activations for itch were found in left S1, bilateral insula, S2 and BA's 40, 43 and 44.
These finding support the role of the PAG and other brainstem nuclei as key regions in modulating the pruritic input. In particular for the PAG these results show some similarities to the findings of fMRI studies on the processing of pain.

**Abstract:** Introduction: Fibromyalgia (FM) is a chronic centralized pain disorder in which patients experience hypersensitivity to multiple sensory stimuli. FM show increased sensitivity and brain activity in the insula, a pain processing region, during aversive visual stimulation. It is unknown whether altered network connectivity in FM also occurs during a visual task. Using graph theoretical measures, we examined changes in functional network architecture in FM during a visual stimulation task and at rest.
Methods: 40 FM patients and 19 age- and sex-matched healthy controls (HC) received visual stimulation (flashing checkboard) during fMRI. Task-specific (checkerboard and rest) correlation matrices were created for each subject, using the Conn toolbox in SPM8. Regions of interest were used based on the 264 brain regions shown to reliably produce functional network topologies at rest and during task (Powers et al, 2011). With the fully connected and weighted correlation matrices, changes in global modularity were calculated using Louvain modularity Q score for each subject for both conditions with 1000 repetitions. A consensus clustering technique was then used to define subject-level community structure for each condition. We tested whether community assignments were conserved within groups and across conditions using normalized mutual information (NMI) to quantify pairwise similarity of community structure. Higher NMI values suggest greater similarity in community structure. Independent sample t-tests were used to compare groups in each condition separately while a repeated measures General Linear Model was used to compare group by condition interactions. Statistical analyses were significant at $p < 0.05$ and determined using IBM SPSS 24.
Results: We observed no change in global modularity during visual stimulation for both FM and HC. However, NMI was significantly lower among FM patients as compared to HC during both rest and visual stimulation (both, $p < 10^{-6}$). Furthermore, there was a significant interaction between group and conditions ($p < 10^{-4}$) such that changes from rest to visual stimulation decreased NMI in HC and increased NMI in FM.
Conclusion: Despite no differences in brain network modularity, FM have more variable community structure than HC, suggesting subgroups of patient pathologies. Dynamic changes in network architecture during the visual task and rest also differed across groups suggesting that patients differ in both static and dynamic network architecture from pain free healthy controls. It remains unknown whether these differences in network architecture are consistent with other sensory stimuli either alone or in combination.

**Title:** Robot guided neuronavigated rTMS in central neuropathic pain - Clinical experience and long term follow up

**Authors: *R. PEYRON**, C. QUESADA, B. POMMIER, C. CRÉAC'H, F. VASSAL
Hosp. Nord, Saint-Etienne Cedex 2, France

**Abstract:** Background: The non-invasive brain stimulation by Repetitive Trans-cranial Magnetic Stimulation (rTMS) is increasingly used in clinical practice as a possible treatment of chronic neuropathic pain. Here we report our clinical experience on more than 1000 rTMS sessions. Eighty patients entered in an open but prospective evaluation of rTMS. All of them presented clinical symptoms typical of a unilateral central pain that was drug-resistant and lasted for at least 1 year with a moderate to severe intensity (Numerical pain scale >4/10). Methods: We used a neuronavigated rTMS to stimulate the primary motor cortex contralateral to pain with high frequencies (20Hz). A minimum of 4 sessions was proposed, each separated by 3-4 weeks. Pain was assessed by % of pain relief, Duration of Pain Relief (DPR), Neuropathic Pain Symptom Inventory (NPSI), Numerical pain Rating Score (NRS) and the Pain Relief Scale (PRS). Results: No adverse-effect was reported in the 71 patients who completed the first four sessions: pain relief was 28% in average with a mean duration of 11 days. Fifty-four patients (76%) were responders if we consider a permissive threshold of ≥10% pain-relief. With more stringent thresholds of ≥ 30% and ≥50% pain relief, the proportion of "responders" dropped to 61% (43 patients) and 45% (32 patients), respectively. Patient considered as responders kept on having rTMS sessions for 380 days on average [maximum 6 years]. After a mean number of 15 sessions per patient, cumulative effects were found on the pain relief (48%), its duration (20 days) and the prevailing NPSI sub-score (-28%). This effect was reached after 4 sessions and maintained over at least one year (15 sessions). Conclusion: These results confirm the interest and the safety of rTMS for central pain with a cumulative effect over the first 4 sessions and a stable effect after 15 sessions. The ongoing randomized controlled study will allow to precise this effect with regard to a placebo effect.

**Authors: *L. SUN**[1], C. CHEN[2], W. GAN[2], G. YANG[1]
[1]Dept. of Anesthesiology, Perioperative Care, and Pain Med., [2]Dept. of Physiol. and Neurosci., New York Univ., New York, NY

**Abstract:** Inflammatory pain is precipitated by an insult to the integrity of tissues, which sensitize peripheral nociceptor terminals and produce pain hypersensitivity. Intraplantar formalin injection is a model of tonic inflammatory pain, which causes a stereotypic two-phase pattern of behavioral responses, with a quiescent phase in between and a termination of the noxious stimuli responses after 45-60 minutes. Here, we developed an *in vivo* two-photon imaging technique which allows repeated imaging of dorsal root ganglion (DRG) cells in awake mice over intervals ranging from seconds to weeks. Using this technique, we found that intraplantar formalin injection substantially increases calcium activity in mouse L4 DRG sensory neurons within 1 hour, which is phase-locked with formalin-induced tonic pain behavior. This elevation of DRG neuronal activity persists for $\geq$ 6 days and gradually recovered to baseline level after 28 days. In parallel to the increased spontaneous activity of sensory neurons, formalin-injected mice

displayed non-evoked ongoing pain for at least a week in the absence of noxious stimuli. Together, our results revealed sensory neuron changes that arise during the onset and development of inflammatory pain in awake mice.

**Abstract:** Physiologically relevant human models of chronic pain are essential to developing new therapeutics and overcome poor translation between animal studies and the clinical setting. We therefore developed a humanized screening assay with sensory neurons derived from human induced pluripotent stem cells (hiPSCs). The resulting assay can be applied in screening to identify compounds that change a disease phenotype, such as neuronal excitability, rather than the activity of specific targets. Human iPSCs were obtained from the European bank of induced stem cells (EBiSC) and a working bank of hiPSCs was produced. We differentiated the hiPSCs by dual SMAD inhibition followed by further neural commitment and patterning. Neural crest cells were cryopreserved and quality control performed to determine quality and yield of neuronal cultures. Neural crest cells were subsequently matured into functioning neurons using growth factors to induce sensory neuronal development. To determine the optimal cell density and time in culture for the assay, sensory neuronal progenitors were plated at four different densities and electric field stimulation (EFS) experiments were run after 2, 3 and 5 weeks in culture. On the day of the experiment the cells were incubated with a calcium probe and an electrode array was used to electrically excite the neurons and simultaneously an integrated imaging-based microplate reader was used to monitor the calcium response of the neurons. At the gene and protein level expression, markers for of neural crest, peripheral and sensory neurons were used (e.g. SOX10, BRN3A, *NEUROG1, OTX2*) as well as markers for pain-relevant neuronal targets such as *SCN9A*, *SCN10A*, *NTRK1*, and *TRPV1*. Using optimal settings identified during assay development, the EFS assay performance was stable and the protocols used selectively and specifically stimulated voltage-gated sodium channels. To determine whether the assay could be used for single concentration screening, it was validated by testing a LOPAC library (Sigma-Aldrich) in neurons from different batches. There was a good agreement between the replicates demonstrating assay robustness and capability to support primary screening. In

conclusion, we have identified an in vitro, human assay approach utilizing human iPSC-derived sensory neurons and a physiological stimulus that yields highly reproducible and sensitive responses in a high capacity format. This enables true phenotypic screening of compound libraries using a highly relevant stimulus (current) in human sensory neurons.

Ctr., Memphis, TN; [4]Liverpool John Moores Univ., Liverpool, United Kingdom; [5]Sir Peter Mansfield Imaging Ctr., Univ. of Nottingham, Nottingham, United Kingdom

**Abstract:** In the mid-20th century, surgical ablations of the primary somatosensory cortex (SI), called postcentral topectomy, were used as a therapeutic means of treating patients suffering from intractable chronic pains. The outcomes varied from permanent relief of pain (approx. 60%) to temporary relief of pain (25%), and to complete ineffectiveness (15%). SI contains nociresponsive neurons in two regions: one in area 1, with properties resembling sharp, discriminative, first pain; and the second region in the anterior part of area 3a, with properties resembling burning, affective, second, slow pain. We hypothesized that permanent pain loss in postcentral topectomy was achieved when the nociresponsive part of area 3a was removed, whereas when an ablation of the postcentral gyrus failed to extend deep enough into the central sulcus to remove area 3a, the loss of pain at most was transient until area 3a recovered from indirectly induced trauma.
We tested this hypothesis by performing local SI ablations in 3 squirrel monkeys. The monkeys

were trained to obtain food reward by pulling a noxiously heated metal rod. Pull duration shows high sensitivity to rod temperature and was used as a measure of each subject's pain sensibility. In support of the hypothesis, even small ablations targeting the hand region of nociresponsive area 3a in 2 subjects significantly elevated pull durations for at least 5 months (i.e., until the subjects were euthanized), thereby indicating permanently reduced pain sensibility. In contrast, ablation of SI posterior to nociresponsive area 3a in the 3rd subject significantly reduced pull durations for at least 7 months, indicating permanently elevated pain sensibility.
Although the precise location of area 3a in the central sulcus varies extensively among humans, its nociresponsive regions can be accurately localized in any given subject by using high-resolution fMRI to image the responses evoked in the depth of the central sulcus by thermonoxious stimulation associated with chronic pain.
Once localized, the area 3a nociresponsive region can be targeted for reversible or permanent inactivation. Such precisely targeted inactivation might greatly improve the success rate of the postcentral topectomy in amelioration of pathological pain, making it a highly attractive means of treating otherwise intractable chronic pain.

**Title:** Anti-NGF reverses pain behaviors and anterior cingulate cortex activation in a rat model of neuropathic pain

**Authors: *J. T. SILVA**[1], B. EVANGELISTA[1], R. VENEGA[1], D. A. SEMINOWICZ[2], M. CHACUR[1]
[1]Anat., Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Dept of Neural & Pain Sci., Univ. of Maryland, Baltimore, Baltimore, MD

**Abstract:** Introduction: Nerve growth factor (NGF) has been widely studied by the scientific community for its pro-nociceptive role in chronic pain conditions, and it is characterized as a chemical mediator responsible for the induction and maintenance of these pathologies. Chronic neuropathic pain is characterized by spontaneous burning pain accompanied by allodynia and hyperalgesia. Anti-NGF drugs have been used to reduce these symptoms in cancer pain, irritable bowel pain and osteoarthritis in both animal models and humans. However, in chronic

neuropathic pain its multiple actions are not fully understood. Methods: Male Wistar rats (200-220g, 2 months old) underwent induction of neuropathic pain by chronic constriction injury of the sciatic nerve (CCI). Sham-operated animals (Sham), which underwent the same incision, but without nerve ligation were used as control. We performed mechanical, thermal hyperalgesia and cold allodynia behavioral tests. After 14 days, we made intraplantar injections of Anti-NGF (1 and 3ug) or saline into the right hindpaw and a dose-response curve was observed. Analysis of Western blot to detect NGF and Substance P in the sensory ganglia (DRG) and spinal cord were made. In addition, neuronal activation was measured using Immunohistochemistry for Fos protein in Anterior Cingulate Cortex (ACC) and Periaqueductal gray (PAG). Results: CCI + saline demonstrated increased mechanical, thermal hyperalgesia and cold allodynia compared to Sham. After pharmacological treatment with Anti-NGF (CCI + 3ug Anti-NGF) we observed a total reversal of hyperalgesia and allodynia behaviors. Anti-NGF decreased the NGF in DRG and spinal cord after CCI, however, Substance P was decreased only in DRG. This treatment induced a reduction of neuronal activation in ACC, while it did not interfere with PAG activity. Conclusions: Our results suggest that NGF is an important factor in the induction and maintenance of neuropathic pain, since increased NGF and Substance P levels were observed in the DRG and spinal cord after injury. We also demonstrated the relevance of NGF as a therapeutic target, since Anti-NGF was able to reverse the symptoms and physiological responses in this pathology. The ACC could mediate those improvements, since it is related to emotional/motivational aspects of pain.

**Abstract:** The anterior cingulate cortex (ACC) is a well-known brain area recognized for its association with pain perception. According to previous studies, the ACC has been more

specifically identified for its roles in processing pain related emotional factors. Long-term potentiation (LTP) induced by abnormal sensory signaling after peripheral nerve injury is one of the main features of chronic pain in the central nervous system. Novel treatment methods for chronic pain include the termination, attenuation, or prevention of the LTP-induced excitatory transmission. Therefore, it is necessary to identify new therapeutic targets for controlling chronic pain through studies on induction and expression mechanisms of pain-related LTP. Mechanistic target of rapamycin (mammalian target of rapamycin, mTOR) is a serine-threonine protein kinase that has an important role in cell proliferation and differentiation in the nervous system. Activation of mTOR regulates protein synthesis by phosphorylating downstream factors such as eukaryotic initiation factor 4E binding protein 1 (4EBP1) and p70 ribosomal S6 protein kinase (p70S6K). Based on these studies, it can be seen that the signal transduction process associated with mTOR plays an important role in the neuroplastic changes that occur in various pain processes such as chronic pain development. In this study, we investigated the association and interactions between neuropathic pain and mTOR signaling pathway in the ACC. Under pentobarbital anesthesia, male Sprague-Dawley rats were subjected to nerve injury. The experimental animals were microinjected with rapamycin into the ACC on postoperative days (PODs) 7. Behavioral test for assessing mechanical allodynia was performed after neuropathic surgery. Inhibition of mTOR with rapamycin reduced mechanical allodynia, down-regulated the expression of phosphorylated mTOR (p-mTOR), and changed the expressions of downstream effectors, such as p70S6K and 4EBP1. These findings suggest that mTOR and its downstream pathway in the ACC may contribute in the modulation of neuropathic pain. **Abstract:** We previously reported that neocortical theta rhythms are correlated positively with pain, and negatively with analgesia, in awake unrestrained animals [Leblanc et al. PAIN 2014, 2016a,b]. Recently, we elucidated a thalamocortical circuitry that plays a modulatory role in controlling theta and sensory perception using optogenetic tools [Leblanc et al. Sci Rep 2017]. Here, we investigate the analgesic effects of a clinically-relevant neuromodulatory method for pain management: epidural spinal cord stimulation (SCS). Whereas SCS is widely used, its mechanisms are poorly understood, especially at a cortical level. Moreover, there is urgent need for enhancing the efficacy of non-opioid based therapies such as SCS while reducing side effects. Here, we hypothesize that conventional SCS attenuates theta recorded via EEG in Sprague Dawley rats following chronic constriction injury of the sciatic nerve. Our results show that SCS (50 Hz, 200 microsec pulse width, current amplitude below perception threshold) reverses theta with a modest effect on thermal hyperalgesia. Taken into consideration our recently reported human data [Levitt et al. Brain Res Bul 2017], we conclude that cortical theta is a valid and reliable method for the assessment of pain, analgesia and for the optimization of neuromodulation therapies including SCS

**Abstract:** We previously reported that neocortical theta rhythms correlate positively with pain, and negatively with analgesia in animals [Leblanc et al. PAIN 2014, 2016a,b]. Here, we record EEG to further compare the sensitivity of theta versus behavioral measures in detecting sub-therapeutic doses of pregabalin (PGB), and potential side effects at high doses in awake, unrestrained Sprague Dawley rats following chronic constriction injury of the sciatic nerve. Our

results show that PGB reverses thermal hyperalgesia, invariably, at sub-therapeutic, therapeutic and extra-therapeutic doses, whereas theta predicts a therapeutic dose in accordance with clinical data. Moreover, extra-therapeutic doses of PGB induces a paradoxical increase in theta and theta/gamma ratio, suggesting possible detection of side effects such as drowsiness. Taken into consideration our recently reported data in humans [Levitt et al. Brain Res Bul 2017], we conclude that EEG rhythms in the theta and gamma bands are valid correlates of pain, analgesia and side effects of high-dose analgesia.

**Abstract:** Sensory experience can cause long-lasting alterations to the activity and circuitry of the neocortex, but the cell-type and pathway-specific sequence of events underlying these changes is unknown. This is especially true for plasticity driven by naturalistic stimuli which may not follow the principles of cortical rewiring established for coarse manipulations like sensory deprivation. Here we define the characteristic sequence of cell-type and pathway-specific changes that occur across the cortical column during sensory association training in the mouse barrel cortex. Using an automated, home-cage training chamber that couples whisker deflection to a water reward, we characterized neural responses following activation of VPM and POm, the two main thalamic inputs to the cortex, during different phases of learning. Optogenetic stimulation of thalamic afferents revealed pathway- and cell-type specific changes in evoked spike output, assessed by patch-clamp recordings in acute brain slices. After just 24 hours of sensory training, POm afferent stimulation drove significantly increased evoked firing in layer 2 and layer 5 pyramidal neurons. Elevated spiking activity was present both during the stimulation window and during the recurrent intracortical network activity that persisted for

seconds after stimulus cessation. In contrast, spiking activity evoked by stimulation of VPM afferents was unchanged by sensory association training. These data indicate that sensory association training drives rapid and specific enhancements in the POm-recipient circuitry of the somatosensory cortex. The sequence of these changes across different layers and cell types reveals principles for the reorganization of neocortical circuits associated with learning and also suggests a possible role for second-order thalamic nuclei in facilitating cortical plasticity.

**Abstract:** Lasting modifications of sensory input induce structural and functional changes that have been extensively studied in higher levels of the central nervous system. The participation in these plastic phenomena of structures involved in the early stages of sensory processing has been largely ignored. In our group we have demonstrated that sustained alterations of sensory input in the vibrissal system in adult rats induce morphometric changes in the dendritic arbors of second order neurons in the principal (Pr5) and the caudal (Sp5c) trigeminal nuclei. More recently, we also showed that the trigeminal ganglion, where primary sensory neurons reside, displays marked expression changes in genes and proteins involved in glutamatergic neurotransmission following sensory input manipulation. Here, we examined whether the same manipulations are capable to structurally modify central terminal arbors of primary sensory neurons. We have performed injections in a single deep vibrissal nerve (DVN) of a mixture of cholera-toxin B (CTB) and isolectin B4 (IB4), tracers for myelinated and unmyelinated fibers respectively, in three groups

of young adult male rats: controls, rats chronically deprived of haptic touch by repeated unilateral whisker trimming, and rats exposed to environmental enrichment for the same period of time. The central terminations of these axons in the trigeminal complex were studied by immunostaining and stereology. The regional and laminar pattern of terminal arborizations in the trigeminal nuclei of the brainstem did not show gross changes after sensory input modification. However, there were significant and widespread increases in the number and size of CTB-labeled varicosities in the enriched condition, and more modest increases in the whisker trimming condition, save for a prominent expansion in both parameters in laminae III-IV of Sp5c. No obvious changes were detected in IB4-labeled terminals in laminae I-II. These results show that a prolonged exposure to changes in sensory input without any neural damage is capable of inducing structural changes in terminals of primary afferents in mature animals, and highlight the importance of peripheral structures as the presumed earliest players in sensory experience-dependent plasticity.

**Title:** The effect of sensory deprivation on vasculature organization in the mouse barrel cortex

**Authors: *E. YAKUBOVA**[1], F. A. ISKHAKOVA[2], J. C. BRUMBERG[3]
[1]1996, Rego Park, NY; [2]Neurosci., Queens College, CUNY, Flushing, NY; [3]Dept Psychology, Queens Col., Flushing, NY

**Abstract:** Whisker trimming is a commonly studied form of sensory deprivation in mice, whose prominent facial whiskers are represented in a one-to-one fashion in the layer four barrel cortex. Following one month of whisker trimming induced deprivation neural morphology is altered; how deprivation impacts the associated vasculature is unknown. Whisker trimming was performed from birth to post-natal day 30, by clipping the mystacial whiskers every other day, followed by transcardial perfusion and fixation. Brains were then sliced in the coronal plane and their neural vasculature was revealed using Lycopersicon esculentum lectin conjugated to Texas Red. Image stacks were obtained using a confocal microscope; NeuroLucida software was used to reconstruct a three-dimensional representation of the neural vasculature that was then quantified. Results showed that trimming affected vasculature distribution on several scales of

measurement. Trimmed animals exhibited significantly decreased overall vascular length, surface area, and volume and less torturous vessels with fewer terminal endings. Similar to neural structures the neural vasculature is influenced by afferent sensory inputs via the animals' whiskers.

**Title:** Unilateral loss of whisker sensation leads to synaptic remodeling across the corpus callosum

**Authors: *E. R. PETRUS**, A. P. KORETSKY
NINDS, NIH, Bethesda, MD

**Abstract:** The corpus callosum (CC) is a major fiber bundle which links the two brain hemispheres, and is critical for bilateral integration of senses and coordination of motor output (Berlucchi et al. 1995). The CC plays a complex role when coordinating homotopic contralateral cortical areas, with a balance of inhibitory and excitatory inputs enabling this integration to occur (Bloom and Hynd 2005). For bilateral senses such as the somatosensory whisker system in rodents, the loss of one whisker set via infraorbital nerve transection (ION) produces changes in the spared thalamo-cortical pathway, but also inappropriate response of the deprived somatosensory barrel cortex (S1BC) to ipsilateral intact whisker stimulation (Yu et al. 2012). In addition, unilateral ablation of the spared S1BC produces profound cortical reorganization in the deprived S1BC and neighboring nose and forepaw areas (Yu et al. 2014). This indicates that the CC may mediate circuit reorganization in the deprived S1BC in adult rodents.
Our work seeks to identify the synaptic targets of the CC from the spared to deprived S1BC which drives this cortical rewiring. We used channel rhodopsin to activate the spared S1BC and recorded responses in principal cells in deprived S1BC in 3 month old mice. We have identified layer 5 neurons as the major remodeled targets of the CC, which experience a doubling of AMPA receptor mediated response size in ION vs. controls. This potentiation is associated with occlusion of LTP which normally occurs along this pathway. These results support the hypothesis that even fully mature circuits can undergo synaptic plasticity. Further characterization of the cells and the synaptic basis for these changes in adults will be helpful for

understanding how the brain rewires after injury due to stroke, traumatic brain injury or loss of peripheral sensation due to the loss of limbs or nerve damage. Future work will study how the potentiation of these inputs leads to effects on cortical map plasticity.

**Abstract:** Lesions of the spinal cord dorsal columns produce a permanent loss of primary afferents to the brainstem cuneate nucleus, depriving cortex of activating inputs. Months after unilateral lesions to the cervical dorsal columns, primary somatosensory cortex (area 3b) reactivates and hand use improves. These recoveries are incomplete; therefore, we investigated a treatment with chondroitinase ABC (ChABC) using an affinity release hydrogel (Pakulska et al. 2015). ChABC digests extracellular chondroitin sulfate proteoglycans to reduce barriers that prevent axons from growing to their targets. Here we focus on how the ChABC hydrogel delivered at and around the spinal cord lesion affected responsiveness to touch on the ipsilateral hand. Neurons in the area 3b hand representation do not appear to respond to ipsilateral stimulation, but stimulating both hands tends to suppress activity in 3b. We hypothesized that reorganization after unilateral dorsal column lesion (DCL) allows some inputs from the ipsilateral hand to activate deprived cortex. We further hypothesized that ChABC hydrogel treatment would promote normal cortical reactivation and possibly eliminate ipsilateral responses. Subjects were New World owl monkeys (*Aotus*) and squirrel monkeys (*Saimiri*). We

recorded responses to tactile stimulation using implanted multi-electrode arrays in the 3b hand representation of intact monkeys (N = 5) and monkeys 5-12 weeks after unilateral DCL, with (N = 4) or without ChABC treatment (N = 4). ChABC did not reactivate all neurons in area 3b, but those that reactivated responded to touch on the contralateral hand with properties that did not differ from those of intact monkeys. Responses to the ipsilateral hand were detected in 3 out of 4 ChABC cases (15 responses). In DCL cases without ChABC, 17 responses to the ipsilateral hand were detected. Peak response magnitudes were similar in all three groups to ipsilateral and contralateral stimulation, but contralateral response latencies in the ChABC group were faster than those in the DCL group. In the ChABC group, ipsilateral response latencies were slower (~30ms) than contralateral response latencies (~18ms). In the DCL group, ipsilateral and contralateral latencies were similar (~29ms, ~33ms, respectively). Overall, within the 12-week period, the ChABC treatment did not eliminate ipsilateral responsiveness, despite contralateral response properties within normal ranges. The sources of ipsilateral hand responses in area 3b are uncertain, but they seem to be more prevalent in monkeys after DCL, with and without the ChABC treatment.

**Title:** Intracortical connections of area 3b after cortical treatment with chondroitinase ABC in squirrel monkeys with a dorsal column lesion

**Authors: *C.-C. LIAO**, J. L. REED, H.-X. QI, M. P. SARAF, J. H. KAAS
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

**Abstract:** After injuries of the tactile dorsal column afferents in cervical spinal cord, the primary somatosensory hand cortex in the contralateral hemisphere is inactivated, and dexterous hand use is impaired. Over weeks to months, the deafferented neurons become responsive to touch on the hand, and hand use recovers. Previous studies have revealed that chondroitinase ABC (chABC) treatment at subcortical levels could increase the reactivation of cortex after spinal cord injuries.

Here we test whether chABC treatment in cortex promotes the cortical reactivation by increasing the growth of intracortical connections. A unilateral dorsal column lesion (DCL) was made at the C5 level in one squirrel monkey (*Saimiri boliviensis*). The lesion interrupted the inputs from digits 3 to 5 and part of the digit 2, but spared the inputs from the digit 1. Immediately after the DCL, chABC was locally injected at the rostral and caudal borders of area 3b, where hand cortex adjoins the forelimb region medially and the face region laterally (4 sites). After 2 months, biotinylated dextran amine (BDA) and fluoro-ruby (FR) were injected into the electrophysiologically identified forelimb and digit 1 representations in area 3b, respectively. We mapped the hand region in area 3b by microelectrode multiunit recordings to evaluate the postlesion cortical reactivation. The results were compared to the data from one control squirrel monkey (*Saimiri boliviensis*). We found that neurons in the most medial region of the hand cortex remained unresponsive after DCL, but neurons in the lateral region responded to touch on digits 1 and 2, occasionally to digit 4, multiple digits, or larger areas involving the hand and forelimb. Nevertheless, the organization of intracortical connections after the DCL resembled the normal pattern. BDA-labeled neurons and terminals were primarily distributed in the forelimb region in area 3b, slightly spreading medially into the hand region. Yet, their distribution did not overlap the newly-formed forelimb representations in the deafferented hand cortex. Populations of BDA-labeled neurons and terminals were also present in the expected locations of forelimb regions in areas 3a, 1, and 2, and primary motor cortex. We also found scattered BDA-labeled neurons and terminals in the supplementary somatosensory cortex, parietal ventral, secondary somatosensory cortex, ventral somatosensory area, and the retroinsular area. Taken together, our preliminary data suggest that with the acute chABC treatment in the cortex, most of the expected intracortical connections of area 3b neurons remain intact in the monkey after the DCL, and the treatment did not greatly alter the connections.

**Title:** Rapid remapping of hand-to-face representation in primary somatosensory SI cortex in rat following brachial plexus nerve cut and brachial plexus anesthesia

**Authors: *A. L. CURRY**[1], V. PELLICER MORATA[2], J. W. TSAO[2], O. V. FAVOROV[3], R. S. WATERS[4]

[1]Univ. of Memphis, Memphis, TN; [2]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [3]Biomed. Engin., Univ. North Carolina, Chapel Hill, NC; [4]Dept. of Anat. and Neurobio., Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN

**Abstract:** Introduction: In some patients, brachial plexus (BP) injury can result in phantom limb pain (PLP) and phantom limb sensation (PLS) in the deafferented limb immediately after the injury. BP injury may also result in remapping the deafferented forelimb onto the face, examined 6 months after injury, but whether remapping also occurs in temporal register with PLP and PLS is unknown. Here, we examined this temporal question using an animal model employing forepaw and lower jaw (LJ) representations in the rat barrel field in primary somatosensory (SI) cortex.
Methods: In adult Sprague-Dawley rats, anesthetized with Ketamine/Xylazine (100-mg/kg), the BP nerve was cut (BPnc) or anesthetized (BPA) using lidocaine. Extracellular recordings and mechanical and electrical stimulation were used to map forepaw and LJ [chin, lip, lower jaw] representations and the boundary between the representations in SI cortex immediately before and within 1 hour after BPA and BPnc.
Results: Neurons in forepaw and LJ representations received input only from their respective peripheral locations. Following BPnc and BPA, neurons in the deafferented forepaw SI cortex immediately adjacent to the LJ representation became responsive within 1 hr to new input from the lower jaw. In contrast, neurons in non-adjacent forepaw sites remained unresponsive. Ablation of the LJ SI cortex immediately adjacent to the forepaw SI cortex abolished the new LJ responses in forepaw cortex. BPnc produced more robust remapping than did BPA.
Conclusion: Rapid forepaw-to-face remapping in the border region of rat forepaw SI cortex occurs following BPA and BPnc. We propose that new LJ input is very likely relayed from adjacent LJ barrel field. Our finding may assist in identifying cortical and subcortical mechanisms relevant to remapping human cortex subsequent to limb deafferentation.

**Abstract:** How do sensory and motor networks change after damage to somatosensory cortex? Although cortical plasticity after somatosensory damage has been studied extensively in animal models, little research has been done in humans examining the behavioral and neural correlates of primary somatosensory cortex (S1) damage in humans. We tested an individual who, due to a stroke, suffered a unique lesion with extensive damage to left S1 and posterior parietal cortex, while leaving left primary motor cortex (M1) and subcortical structures intact. First, a sensorimotor behavioral battery revealed the expected sensory deficits on the contralesional limb, including impaired tactile localization, finger identification, and proprioception. Although his tactile perception was diminished, he could still feel tactile stimuli of moderate intensity. Given the extensive damage to the traditional hand area of S1, we then used functional neuroimaging to examine what brain regions represented touch after stroke. To do this, we presented either hand with tactile stimulation (brush strokes) using a blocked fMRI design. As expected, we found activation in right S1 when stimulating the ipsilesional (left) hand. However, when stimulating the contralesional (right) hand, we found activation in left M1, providing evidence for somatosensory reorganization into intact cortex neighboring the lesion site. Given this reorganization into motor cortex, we then examined what brain regions were active for hand movement (opening and closing the hand without seeing the hand) versus rest in a second imaging session. Movement of either the left or right hand resulted in significant activation in two areas - bilateral putamen and right area MT. Interestingly, there was a relatively limited amount of cortical activation in sensorimotor cortex for hand movement versus rest. These findings provide evidence for reorganization of somatosensory processing into neighboring motor cortex. Furthermore, with limited sensory feedback, individuals may strongly rely on areas outside of sensorimotor cortex for movement control and execution.

**Title:** Neurofeedback-induced modulation of somatosensory alpha power controls subsequent tactile learning

**Authors: *M. BRICKWEDDE**[1,2], H. R. DINSE[1,2]
[1]Inst. for Neuroinformatics, Ruhr-University, Bochum, Germany; [2]Dept. of Neurology, BG-University Clin. Bergmannsheil, Ruhr-University, Bochum, Germany

**Abstract:** Oscillatory alpha power is believed to occupy an inhibitory function which gates neuronal resources (Klimesch et al., 1999, Cogn Brain Res). To obtain information about processes controlling learning variability, we have previously shown that baseline power of somatosensory alpha recorded before tactile learning predicted 36 % of the learning variance (Freyer et al. 2013, J Neurosci). Here we took advantage of these findings by aiming at purposefully altering somatosensory alpha power to systematically manipulate subsequent learning success in human participants.
A total of 74 participants were randomly assigned to three groups. The first group (alpha up) trained to increase somatosensory alpha power for 20 min using a Thera Prax® Mobile neurofeedback system. The second group (alpha down) trained to decrease somatosensory alpha power under otherwise identical conditions. The control group performed no neurofeedback training. We induced perceptual learning with high frequency LTP-like repetitive sensory stimulation (RSS) applied to the right fingertip. Before and after RSS, we assessed the tactile spatial discrimination ability as marker of plastic changes. RSS was applied for 20 min on the second day immediately after a second session of 15 min of neurofeedback training. We could show that the alpha up group strongly increased their somatosensory alpha power, while the alpha down group showed a slight decrease. As a result of neurofeedback training, the alpha up group showed significantly higher tactile learning gains than controls. In contrast, in the alpha down group tactile learning was suppressed. Individually, the amount of somatosensory alpha power gain correlated with the subsequent learning success in the tactile spatial discrimination task.
Our results suggest that high levels of alpha power create an optimal state for subsequent stimulation based perceptual learning. We currently investigate whether altered alpha power affects the efficacy of sensory processing, or the learning processes itself, or both. Since RSS is a promising intervention in the rehabilitation of stroke patients, a combination with neurofeedback training could be utilized to further enhance the rehabilitation process.

**Title:** Responses to outgrowing / young and old whiskers in layer 4 barrels of rat somatosensory cortex

**Authors: *E. MAIER**, M. BRECHT
Biol., BCCN Berlin / Humboldt-University, Berlin, Germany

**Abstract:** Rodents touch objects with their whiskers in order to make sense of the external world. Similar to other hair, whiskers adhere to a cycle that is characterized by different phases whereby a young whisker grows out of the same follicle and the old whisker falls out when the young one reaches a certain length (Ibrahim et al. 1975). Responses of single neurons in the barrel cortex to external stimulation of the whiskers have been studied extensively during the past decades both in anesthetized and awake animals. To our knowledge, however, no study has focused on stimuli applied separately to the young and the old whisker respectively. Moreover, although anatomical examinations of the follicle during whisker regrowth have been described (Kim et al. 2010), the topographic relationship between the young and old whisker has not been addressed. In this study we report a robust and stereotypic topographic relationship between young and old whiskers, with the base of the young whisker mostly being located rostro-ventrally of the old one. In order to assess how young and old whiskers are represented by the activity of neurons at different locations within the barrel, we recorded and identified layer 4 neurons in the barrel cortex of anesthetized rats with juxtacellular electrophysiological experiments. The young and old principle whiskers were deflected in different angular directions. We find that for the majority of layer 4 neurons (12/15) the total spike count response appears to be larger for deflections of the old whisker. The few neurons (3/15) with higher total spike count after young whisker stimulation were located at the caudal proportion of the barrels. Neurons that responded to both whiskers showed similar angular tuning. Our findings suggest a dominance of the old whisker in sensory responses and a matching of angular properties of old and young whisker responses.

**Abstract:** As in other primary sensory cortices, both layer 4 (L4) and layer 5 (L5) of the primary auditory cortex (A1) receive substantial thalamic inputs. Temporal processing in L4 of both developing and adult A1 has been extensively studied. However, conclusions about temporal response properties in L5 compared to L4 are still controversial. Furthermore, the maturational process of temporal processing in L5 remains unknown. Using loose-patch recordings in-vivo, we found that the temporal response resolution of L5 neurons in the adult rat A1 is not significantly different from that of L4 neurons. However, very interestingly, L5 neurons exhibit superior stimulus-following ability immediately after hearing onset, in contrast to the poor temporal responses of L4 neurons. In fact, no significance difference in temporal processing was observed between L5 neurons in the developing and adult A1. In-vivo whole-cell voltage-clamp recordings showed that L4 and L5 neurons in the developing A1 are not significantly different from each other in terms of both resting membrane potential and the adaptation of both excitatory and inhibitory inputs, although L5 neurons are more depolarized and the adaptation of inhibition is stronger in the adult A1. However, the duration of inhibitory input to L5 neurons is remarkably shorter than that to L4 neurons in the developing A1, while they are similarly short in adults. Moreover, the difference in inhibitory duration between L5 of developing and adult A1 is only a fraction of that between L4 of the two age groups. Repetitive stimulation does not evoke summation of inhibition in L5, keeping the classical temporal sequence between excitation and inhibition. These results have several implications. First, they further confirmed that the duration of inhibition plays a critical role in setting the pace for the maturation of cortical temporal processing. Second, they suggest that the inhibitory circuits in L4 and L5 are distinct, at least partly underlying the difference in the developmental trajectory of functional properties. Last but not least, they support the notion that although both L4 and L5 are thalamocortical recipient layers, they may represent two separate systems subserving distinct functions.

**Title:** Behavioral assessment of sound intensity discrimination in rats exposed to noise as juveniles

**Authors: *D. SUTA**[1], N. RYBALKO[2], T.-W. CHIU[3], J. SYKA[2]
[1]Dept. of Cognitive Systems and Neurosciences, CIIRC Czech Tech. Univ., Prague, Czech Republic; [2]Dept. of Auditory Neurosci., Inst. of Exptl. Medicine, Czech Acad. of Sci., Prague, Czech Republic; [3]Dept of Biol. Sci. and Technology, NCTU, Hsinchu, Taiwan

**Abstract:** Several studies demonstrated that brief noise exposure in rat pups can result in altered behavioral responses to sounds in adulthood even in individuals with normal hearing thresholds. Rybalko et al. (Physiol Behav 102: 453, 2011) reported anomalies in intensity coding and loudness perception in adult rats exposed as juveniles. In this study we tested sound intensity discrimination in rats exposed to noise as juveniles and compared them with control animals. Behavioral testing was performed by a modified method of the prepulse inhibition of the acoustic startle response. Measurement of prepulse inhibition of the acoustic startle response is a behavioral method that has been frequently used for efficient and accurate assessment of both simple and complex acoustic discrimination in rodents. During each session, a background tone of a constant frequency and intensity was continuously presented to the animal. Intensity of the background tone was either increased or decreased for a short period preceding presentation of the startle stimulus; this change in sound intensity served as the prepulse stimulus. Presentation of the prepulse (i.e. a modulation of the sound intensity) systematically reduced startle response - the magnitude of startle response was generally smaller (inhibited) than that without intensity modulation. The inhibition of startle response was observed for prepulses with a positive as well as negative difference in sound intensity. In summary, our results illustrate that measurement of the startle response can be successfully applied for evaluation of intensity discrimination at moderate sound intensities in control as well as noise-exposed animals.

**Abstract:** Faithful representation of sound envelopes in primary auditory cortex (A1) is vital for temporal processing and perception of natural sounds. However, the emergence of cortical temporal processing mechanisms during development remains poorly understood. Although cortical inhibition has been proposed to play an important role in this process, direct *in vivo* evidence has been lacking. Using loose-patch recordings in rat A1 immediately after hearing onset, we found that stimulus-following ability in fast-spiking (FS) neurons was significantly better than in regular-spiking (RS) neurons. *In vivo* whole-cell recordings of RS neurons revealed that inhibition in the developing A1 demonstrated much weaker adaptation to repetitive stimuli than in adult A1. Furthermore, inhibitory synaptic inputs were of longer duration than observed *in vitro* and in adults. Early in development, overlap of the prolonged inhibition evoked by two closely following stimuli disrupted the classical temporal sequence between excitation and inhibition, resulting in slower following capacity. During maturation, inhibitory duration gradually shortened accompanied by an improving temporal following ability of RS neurons. Both inhibitory duration and stimulus-following ability demonstrated exposure-based plasticity. These results demonstrate the role of inhibition in setting the pace for experience-dependent maturation of temporal processing in the auditory cortex.

**Abstract:** Growing evidence in experimental and computational neuroscience suggests that higher order brain function emerges from causal interaction and collective cooperation of functionally inter-connected networks of neurons. These functional networks are highly dynamic and comprise sparse patterns of connectivity, which enable the brain to robustly adapt to rapid changes in the environment. Existing methods for inferring causal interactions in a network of neurons often provide static measures of causality. Moreover, most of these methods are restricted to models with linear Gaussian statistics, and do not take into account the sparsity of the underlying functional network structure. They are therefore not well-suited to neuronal spiking data with rapid task-dependent dynamics, binary statistics, and sparse functional dependencies. To address these challenges, we develop a novel inference framework through integrating Granger causality analysis, adaptive filtering, compressed sensing, point process modeling and high-dimensional statistics. We propose an adaptive Granger causality (AGC) measure, with embedded sparsity and dynamic features, specifically tailored for neuronal spiking observations. We derive efficient estimation algorithms and precise statistical inference procedures for the AGC measure, which allow us to detect and assess the statistical significance of the functional network dynamics in a neuronal ensemble. Application of our method to two-photon recordings from the mouse auditory cortex reveals the highly sparse and dynamic structure of functional network interactions underlying spontaneous activity at unprecedented spatiotemporal resolution. Our analysis of simultaneous electrophysiology recordings from the ferret primary auditory (A1) and prefrontal cortices (PFC) under auditory task conditions suggests evidence for the role of rapid task-relevant changes in the functional network dynamics within and across these two cortical regions in robust attentive behavior at the neuronal scale.

**Title:** Effect of focal attention on the cortical entrainment of the speech envelope

**Authors: *D. LESENFANTS**, J. VANTHORNHOUT, E. VERSCHUEREN, L. DECRUY, B. SOMERS, T. FRANCART
ExpORL, Dept. of Neurosciences, KU Leuven, Leuven, Belgium

**Abstract:** Recent progress in decoding brain responses to a speech stimulus has allowed developing novel measures for speech intelligibility based solely on electroencephalography (EEG). However, the cortical entrainment to speech varies over time independently of the intelligibility, reducing its applicability as an objective measure of speech intelligibility. We here hypothesized that periods with low-attention to the speech signal are associated with a lower cortical entrainment to speech, while higher levels of attention produces higher cortical entrainment. To evaluate this hypothesis, we presented running speech from a narrated story binaurally to fifteen normal hearing subjects. The reconstructed speech envelope was decoded from low-frequency EEG signals (0.5-4Hz; 64 electrodes) using a linear regression model (integration window: 0-250 ms) and the cortical entrainment was then computed as the correlation between presented and reconstructed speech envelope. In parallel, brain markers of focal attention were also extracted for each recording electrode using normalized spectral entropy. Finally, Spearman's correlation between each channel's spectral entropy and cortical entrainment over time was computed in the frontal area. Average cortical entrainment was 0.21 ± 0.08. Interestingly two participants presented lower cortical entrainment (respectively, 0.15 ± 0.06 and 0.14 ± 0.09) than the others (range: 0.20-0.27). These participants presented the highest correlation (respectively, 0.28 and 0.30) between the frontal entropy and the cortical entrainment (average: 0.03 ± 0.17) over time, suggesting a modulation of cortical entrainment with attention. Selection of periods with highest entropy (threshold was set as the 75th percentile) allowed to increase cortical entrainment to 0.18 (increase: 0.03) and 0.20 (increase: 0.06) respectively. Other individuals showed no difference in average in the cortical entrainment using only high frontal entropy periods. This study suggests that an increase in focal attention could induce an increase in the cortical entrainment to speech independently of the level of speech intelligibility. We here proposed to track and correct the effect of attention using spectral entropy-based markers in the frontal area. This could provide objective measures of speech intelligibility in clinical routine and open doors to automatic cochlear implant parameter adaptation without the intervention of a clinical expert.

**Abstract: Background**: Sensorineural hearing loss is primarily associated with cochlear hair cell loss followed by cochlear nerve degeneration. Recent studies have revealed that "synaptopathic" noise exposure can result in primary auditory neurodegeneration and "hidden hearing loss." This phenomenon results in dramatically diminished auditory brainstem response (ABR) wave 1 amplitude in animals subjected to noise trauma that only created a temporary threshold shift. This phenomenon may also contribute to tinnitus, hyperacusis, difficulty hearing in noisy environments, and other auditory processing anomalies. In addition to noise exposure, closed head injury (CHI) is known to be associated with tinnitus, often despite unchanged hearing thresholds. The mechanism by which TBI affects the auditory system is poorly understood. We aim to investigate the impact of repeated mild CHI (rmCHI) on the auditory system.
**Methods**: Baseline ABR thresholds were obtained in seven 10-week old litter-mate male wild-type C57/Bl6 mice. Wave I-V amplitudes and latencies were measured at 8, 16, 24, and 32 kHz. Stimuli were presented at 40, 50, 60, 70, and 80 dB SPL. A single standardized head injury (speed: 5 m/s, depth: 1 mm, dwell time: 500 ms) was delivered to each anesthetized mouse daily for 5 days with a TBI-0310 Impactor, and ABRs were re-measured.
**Results**: Pre- and post-concussion ABR thresholds were within 5 dB at lower frequencies, while there was a 10 dB threshold shift at 32 kHz. While there were no significant changes in suprathreshold amplitudes at the lower frequencies measured, a 60% decrease in amplitude (SE: 0.15) and .28 ms latency shift (SE: 0.11) in wave 1 at 32 kHz was observed.
**Conclusion**: Our results show that rmCHI resulted in reduced ABR wave I amplitude and increased latency at the frequency exhibiting a greater threshold shift and may be suggestive of auditory synaptopathy. Ongoing investigation will be directed at establishing rmCHI levels that

result in temporary and permanent threshold shifts and determining their short- and long-term impact on auditory neurophysiology.

**Title:** Data-driven segmentation of mouse auditory cortical fields based on mesoscale optical Ca2+ imaging

**Authors:** ***S. A. ROMERO PINTO**[1], D. B. POLLEY[2], A. HIGHT[1], J. RESNIK[2]
[1]Eaton-Peabody Labs., Massachusetts Eye and Ear Infirmary, Boston, MA; [2]Dept. of Otolaryngology, Harvard Med. Sch., Boston, MA

**Abstract:** Microelectrode mapping studies have identified two tonotopically organized fields in the mouse auditory cortex (ACtx), the primary ACtx (A1) and the anterior auditory field (AAF),

surrounded by a secondary auditory field (A2), a dorsoposterior field (DP) and the insular auditory field (IAF). Interest in cortical organization at “mesoscale” resolution (i.e., roughly 50 microns) has been revived thanks to optical imaging of genetically encoded calcium indicators (GECIs) that offer a higher signal-to-noise ratio than intrinsic signals, flavoproteins or bulk-loaded calcium indicators. Widefield epifluorescence imaging of GECIs in mouse ACtx has confirmed the basic organization published in earlier microelectrode mapping studies, with two unexplained discrepancies: First, a “dead” zone between A1 and AAF that does not respond to tones (but may instead respond to more complex sounds such as FM sweeps). Second, high-frequency regions lateral to the principal tonotopic vectors that link A1 and AAF. These two differences, in combination, have inspired a variety of new naming conventions and field demarcations for the mouse ACtx. The principal motivation for this study was to perform mesoscale optical imaging of GECIs in the mouse ACtx and develop objective, data-driven approaches to parcel the various fields. Widefield GCaMP6s imaging through chronically implanted cranial windows in awake mice confirmed the basic spatial layout of A1, AAF, A2, DP and IAF. We also observed the existence of high-frequency regions lateral to A1 and AAF as well as a region at the center of the ACtx that was weakly activated by pure tones. A closer examination revealed that this central region was tone-responsive, albeit with higher thresholds and lower response amplitudes. A pixel-based thresholding approach confirmed that best frequencies in this region formed a single tonotopic reversal between A1 and AAF. With this analytic adjustment in place, it was evident that tonotopic gradients within A1 and AAF did not bifurcate into two parallel lateral and medial fields, but instead formed a continuous tonotopically organized field. We developed an objective analysis approach to establish boundaries between fields based on points of tonotopic reversal or abrupt drops in signal amplitude. This analysis approach reveals strong tonotopic organization in A1 and AAF that “fans” out from low-frequency regions and collides at a single medial-lateral boundary, consistent with other species. Repeated imaging in the same mouse suggested that organization was reliable, with only minimal day-to-day variations, at least at this relatively coarse spatial scale.

**Title:** Acoustical enrichment during early postnatal period improves responses of AI cortical neurons in adult rats

**Authors: *J. M. SYKA**, K. PYSANENKO, J. LINDOVSKÝ, Z. BUREŠ
Inst. Exptl. Med. ASCR, Prague, Czech Republic

**Abstract:** It is well known that auditory experience during early development shapes response properties of auditory cortex (AC) neurons, affecting, e.g., tonotopical arrangement, response thresholds and strength, or frequency selectivity. Here we show that rearing rat pups in a complex acoustically enriched environment (AEE) leads to an improved representation of sounds in the AC when recorded later in adulthood, influencing spectral and temporal characteristics and also the reliability of neuronal responses. The acoustic enrichment comprised a continuous wide-band amplitude-modulated rippled noise with varying periodic spectral envelope complemented with several types of randomly occurring acoustic target signals, one of which triggered a reward release. The AEE was presented at 55 dB SPL (target stimuli at 60 dB SPL) 12 hours a day between postnatal days 14 and 28. Consistently with the results of our previous experiments on inferior colliculus (Bureš Z. et al., Acoustical enrichment during early postnatal development changes response properties of inferior colliculus neurons in rats. Eur. J. Neurosci. 40, pp. 3674–3683, 2014), the application of the AEE resulted in lower excitatory thresholds and better frequency selectivity of AC neurons. These changes were nonspecific and present at the whole range of neuronal characteristic frequencies. Importantly, the acoustic enrichment resulted in increased reliability of neuronal representation of the stimulus based both on the rate and the temporal codes. For a repetitive stimulus, the neurons in the AEE-exposed rats exhibited a lower spike count variance, indicating a more stable rate coding. The reduced variance was present both during the strong onset reaction and during the sustained part of the neuronal response. Also at the level of timing of individual spikes, the discharge patterns showed a higher degree of similarity across stimulus repetitions: the computed van Rossum distances of different spike trains evoked by the same stimulus were significantly smaller in the enriched animals. Furthermore, the neurons followed more precisely the temporal course of the stimulus, as manifested by better phase-locking (higher vector strength values) to frequency- and ampliude-modulated sounds. The results document that besides basic alterations of the receptive fields, the acoustic environment during the critical period of postnatal development permanently affects also the stochasticity, reproducibility, and fine structure of neuronal spiking patterns.

**Title:** Temporal sound processing in the auditory cortex is influenced by changes in myelin integrity

**Authors: *S. Y. MOORE CORONA**[1,2], W. MÖBIUS[1,3], T. RUHWEDEL[1], M.-T. WEIL[1,3], K.-A. NAVE[1], L. DE HOZ[1]
[1]Dept. of Neurogenetics, Max Planck Inst. For Exptl. Med., Goettingen, Germany; [2]Intl. Max Planck Res. Sch. for Neurosciences, Göttingen Grad. Sch. of Neurosciences and Mol. Biosci., Goettingen, Germany; [3]Ctr. for Nanoscale Microscopy and Mol. Physiol. of the Brain, Goettingen, Germany

**Abstract:** The textbook view of myelin as a passive insulator has changed with the increasing understanding of the roles that oligodendrocytes (OLs) play in information processing in the brain. Even tough myelin plays a crucial role in action potential propagation, OLs have been shown to have important metabolic support roles, which might be essential during periods of high frequency firing. Since the auditory system is optimized for a fast and accurate timing along different stations, we aim to dissect to which extent myelin and OLs help maintain reliable firing in this sensory system. Specifically, we aim to understand how different degrees of dysmyelination affect auditory cortex responses to diverse physical sound properties. We recorded multiunit activity in the auditory cortex of anesthetized mice, using sounds protocols to test spectral and temporal processing. To test temporal acuity, we used a gap-in-noise detection protocol. This was paralleled by comparable behavioral tests, in order to understand the relationship between the neuronal responses and perception. Temporal reliability was tested through the continuous presentation of clicks at different stimulation rates. We used three mouse models with either **1)** complete (shiverer$^{-/-}$), **2)** partial (MPB-hypomorph$^{-/-}$), or **3)** cortical-specific (Emx1-cre::MBP$^{fl/fl}$) dysmyelination. As expected, we found that dysmyelination caused a major increase in response latencies, whose magnitude was correlated with the extent of dysmyelination. In addition, complete dysmyelination caused hyperexcitable responses, possibly due to the mislocalization of nodal channels. Complete dysmyelination also caused temporal acuity deficits, reflected in the neurons' inability to detect short silent gaps in a noise, and reliability deficits, observed in fatigue when responding to click sequences. Neither can be explained simply by a delay in conduction velocity. Strikingly, spectral processing appeared normal. Likewise, partial dysmyelination caused a reduction of behavioral temporal acuity, in the absence of a frequency discrimination deficit. In summary, we found that complete dysmyelination generated deficits only in auditory temporal processing. Partial dysmyelination generated similar effects at the behavioral level. This suggests that specifically temporal-detection mechanisms require axons that are not only fast and reliable, but also metabolically stable. These characteristics might be given by the structure of myelin and probably the OLs metabolic capacities, respectively.

**Title:** Distinct sensory and extra-sensory processing differences in two types of deep layer auditory cortex projection neuron

**Authors: *R. S. WILLIAMSON**[1,2], D. B. POLLEY[1,2]
[1]Eaton Peabody Labs., Massachusetts Eye and Ear Infirmary, Boston, MA; [2]Otolaryngology, Harvard Med. Sch., Boston, MA

**Abstract:** Neurons in layers (L) 5 and 6 of the auditory cortex (ACtx) give rise to a massive subcortical projection that innervates all levels of the central auditory pathway as well as non-auditory areas including the amygdala and striatum. L5 and L6 neurons feature distinct morphology, connection patterns, intrinsic membrane and synaptic properties, yet little is known about how these differences relate to sensory selectivity *in vivo*. Here, we performed cell-type-specific single-unit recordings and wide-field calcium imaging from two classes of ACtx L5 and L6 projection neurons; L5 corticocollicular neurons (L5CC), and L6 corticothalamic neurons (L6CT).
We first used an antidromic optogenetic “phototagging” approach to isolate individual L5CC and L6CT units on high-density multichannel probes in awake, head-fixed mice. We constructed a bank of complex stimuli by endowing noise tokens with randomly chosen acoustic parameters, and then quantified each neuron’s lifetime sparseness. We found that L5CC neurons had a lower lifetime sparseness index, indicative of reduced stimulus selectivity and a broader response distribution than L6CT neurons. Linear spectrotemporal receptive field fits were also able to explain a higher percentage of response variance in L6CT neurons, indicating a higher degree of linearity in their responses when compared to L5CC neurons. Recent studies have shown that an animal’s “internal state”, as indexed through locomotion or pupil diameter, exerts a powerful influence over ACtx excitability. We expressed GCaMP6s in L5CC and L6CT neurons and noted that bouts of locomotion were associated with opposite effects on the wide-field calcium signal: a decrease in L5CC neurons but a surprising increase in L6CT neurons. Collectively, these studies show that each class of deep-layer projection neuron performs distinct operations on internal and external signals, which likely impart distinct effects on their subcortical targets.

**Abstract:** All animal and human auditory communications are limited in capacity by the listener's auditory functionalities for processing spectrotemporal features of sounds. Poor discrimination in frequency or time, for example, compromises the amount of receivable information per unit time. It is thus prudent to consider the possibility that the evolution of human auditory communication, hallmarked by language and music, was supported by some enhancement in auditory functions for processing spectrotemporal features of sounds.
This hypothesis was addressed by investigating whether humans and macaque monkeys differ in their ability to detect spectral changes over time, an ability fundamental to auditory information processing. Scalp event-related potentials (ERPs) were recorded while subjects listened to five-chord sequences played with two distinct articulations: staccato or legato. Chords (600 ms duration) were presented without gaps in the legato condition, while, in the staccato condition, a silent gap (300 ms) was inserted after each chord (300 ms). The final chord of the chord sequence was either identical to or different from the preceding four chords, which were always simple repetitions of a randomly chosen major chord.
In humans, the chord change in the final position evoked distinct brain responses around N1-P2-N2 latency in both legato and staccato conditions, as expected. Also in the monkeys, the chord change in the legato condition modulated the ERP around the N1-P2-N2 latency. However, the macaque ERP did not show any specific responses to the chord change in the staccato condition, suggesting that the chord change was undetected in the monkey.
The result echoes previous findings that discrimination of upward vs. downward frequency change in macaque monkeys is hindered by inserting a short gap (e.g., 200 ms) immediately before the frequency transition. Such disability can be explained by postulating that monkeys can detect frequency changes only when they occur within a short time window. Stated the other way

around, the human brain has evolved to have an extended time window for representing spectral changes, a capacity that would be beneficial for processing complex sound features that characterize music and language.

**Title:** Modulation of neural activity during locomotion in the mouse auditory midbrain

**Authors: Y. YANG**, J. YANG, *G. KIM
CNIR-IBS, Sungkyunkwan Univ., Suwon, Gyeonggi-Do, Korea, Republic of

**Abstract:** Behavioral states can powerfully modulate sensory processing. This is highlighted by the recent evidence that neural activity is altered during locomotion, as has been demonstrated in visual and auditory cortices. Locomotion related suppression of neural activity has also been observed in the auditory thalamus, suggesting subcortical auditory stations are also impacted by behavioral states. However, the extent of this subcortical modulation and its relationships with cortical modulation remain unclear.
We recorded spontaneous and sound evoked neural activity in the inferior colliculus (IC) of awake head-fixed mice. During recording sessions, mice were free to run on a disc-shaped treadmill. Sound-evoked responses were probed by playing out 5 different pure tones (4, 8, 16, 32, 64 kHz, 100 msec duration) at 70 dB sound pressure level. A unit's response strength (RS) was quantified as the mean firing rate during the initial 25 msec of tone presentation with the baseline firing rate preceding the tone subtracted.
We analyzed neural activity of 39 single units recorded from the inferior colliculus. When mice were not walking, mean spontaneous firing rates ranged 0.1 to 79 Hz with the mean of 21±4 Hz. In 28 of the 39 units (72%), spontaneous firing rate was significantly modulated during locomotion. The modulation of spontaneous activity was bidirectional in that the rate increased by 319±82% in 22 units during locomotion, while the rate decreased by 54±11% in 6 units.
To determine whether sound-evoked activity of the IC neurons is also modulated during locomotion, we compared RS that measures the tone-evoked firing rate relative to the spontaneous rate between the non-walking and walking periods. Of the 27 units that showed excitatory response at the onset of a tone stimulus, 22 units showed significant modulation in RS.

During locomotion, RS decreased by 190±99% from the initial positive value in most units (n=21). In one unit, RS increased by 171% (n=1). In addition to the reduction in RS to tone stimuli, the units tended to show excitatory response at fewer frequencies during locomotion, indicating that the suppression leads to a narrower tuning (1.8±0.3 vs 1.1±0.2 tone frequencies; n=27).
By recording the neural activity of IC neurons in awake behaving mice, our results demonstrate that both spontaneous and sound-evoked activity of midbrain auditory neurons can be modulated during locomotion. Our results suggest that auditory midbrain neurons integrate internal behavioral states with external sound stimuli.

**Title:** Neural correlates of pitch encoding in the auditory cortex of awake mice

**Authors:** ***S. SYLVESTER**[1], N. A. FRANCIS[1], K. SHILLING-SCRIVO[2], P. O. KANOLD[1]
[1]Dept. of Biol., Univ. of Maryland, College Park, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

**Abstract:** Discrimination between auditory objects in music and speech is due, in part, to an object's perceived pitch. Key spectral and temporal predictors of pitch are the frequency and periodicity of the auditory object's fundamental frequency. Despite being heavily examined in both human and animal models, the neural correlates underlying pitch perception are not fully known. Past research has pointed to low frequency areas of the primary auditory cortex (A1) as the location of pitch perception in primates. However, non-primary regions have also demonstrated pitch-selectivity in non-primate animal models. In addition to the ambiguity of pitch encoding regions across animal models, the functional characteristics of pitch-selective neurons have not been examined extensively at the single cell level. In this study, we used a combination of wide-field and two-photon (2P) calcium imaging to acquire coarse and single cell resolution of neuronal activity across the auditory cortex of unanesthetized transgenic mice that express GCaMP6s, a calcium sensor, throughout the brain. Since different areas of the auditory

cortex may be implicated in pitch perception, we initially monitored calcium transients across primary and non-primary areas of the auditory cortex using wide-field imaging, and used two-photon microscopy for careful dissection of low frequency areas. To identify areas that respond to stimuli that evoke the percept of pitch, and to distinguish between frequency and temporal properties of sound, we presented dynamic iterated rippled noise (IRN) and pure-tones. Across trials, we detect consistent activation of small populations of neurons positioned within low and high frequency regions of the auditory cortex. 2P population averages of fluorescent responses during stimulus presentation showed variation in the velocity (ramping) of responses at different frequencies with steeper ramping occurring at frequencies below 1600Hz. By using IRN and different calcium imaging techniques, we are able to record the activity of hundreds of neurons simultaneously at single cell resolution and are able to image primary and non-primary regions of the auditory cortex at the same time. Together, our preliminary results suggests organization of pitch-selectivity in both low and high frequency regions of the mouse auditory cortex and dynamic responses to IRN.

**Title:** The organ of Corti extracts and processes the envelope pattern of a tonal complex

**Authors: *A. L. NUTTALL**[1], G. W. S. BURWOOD[2], A. FRIDBERGER[3]
[1]Oregon Hearing Res. Ctr., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Dept. of Clin. and Exptl. Med., Linköping Univ., Linköping, Sweden

**Abstract:** Speech, music and animal communication calls contain many different frequencies that change rapidly over time. Yet, studies have shown that a limited amount of information about the slowly varying envelope of the stimulus is sufficient for accurate speech recognition, at least in quiet conditions. Direct evidence for this comes from cochlear implant users, most of whom get very good speech recognition when only a few frequency bands of envelope

information are presented through the implanted electrodes. Frequency components corresponding to the envelope are not found in the sound-evoked vibrations of the basilar membrane, but they are clearly present in the discharges of the auditory nerve. How can the auditory nerve encode information absent from the basilar membrane, which provides the stimulus that drives the nerve?
Using experiments in guinea pigs, we demonstrate that envelope extraction is possible because mechanically sensitive ion channels introduce distortion. This distortion tracks the envelope, excites the auditory nerve, and ensures that information about the envelope is transmitted to the brain. The hearing organ can therefore be viewed as a non-linear real-time extractor of the magnitude of the Hilbert transform of the acoustic stimulus.

**Title:** Differential encoding of auditory information by subgroups of neuronal spikes associated with coordinated neuronal ensembles

**Authors:** ***J. SEE**, C. ATENCIO, V. SOHAL, C. SCHREINER
UCSF, San Francisco, CA

**Abstract:** There is mounting evidence suggesting that sensory stimuli are processed by interconnected populations of neurons. However, most studies of information processing in the primary auditory cortex (AI) involve either single-unit spectrotemporal receptive field (STRF) estimation or paired neuronal correlation analyses, and assume that AI neurons filter auditory information either as individual entities or as pairs. Determining how AI encodes information will require an integrated approach that combines receptive field and multi-neuronal ensemble analyses.
To assess multi-neuronal information processing in AI, we performed dense extracellular recordings in rat AI while presenting dynamic, broadband stimuli. We used dimensionality reduction techniques to identify distinct groups of AI neurons (coordinated neuronal ensembles, or cNEs) that have reliable synchronous activity. We identified cNE events and used them to

assess spectrotemporal information processing. Neuronal spikes associated with cNE activity conveyed greater information than spikes that were not associated with cNE activity. For neurons that participated in multiple cNEs, spikes associated with one cNE had receptive field properties that were significantly different from that of spikes associated with other cNEs.
These findings challenge the classical idea that AI neurons produce a homogeneous set of spikes that may be equally weighted to estimate a single STRF. Instead, AI neurons can have multiple receptive fields based on associations with different cNEs, with each cNE representing the convergence of thalamocortical, intracortical and top-down inputs into AI. For each AI neuron, equally weighting all neuronal spikes to form a single STRF ignores this enhanced coding capacity. Therefore, by taking into account the stimulus preferences associated with each cNE, we may gain a more complete evaluation of information processing in AI.

**Title:** Activation and deactivation of somatostatin-expressing GABA neurons disrupts temporal coding of sound frequency in the auditory cortex

**Authors:** *A. T. LANDAU[1], ***A. T. LANDAU**[1], *A. T. LANDAU[2], W. GUO[3], D. B. POLLEY[4,2]
[1]Harvard Univ., Boston, MA; [2]Eaton-Peabody Labs., Massachusetts Eye and Ear Infirmary, Boston, MA; [3]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [4]Otolaryngology, Harvard Med. Sch., Boston, MA

**Abstract:** The dynamic interplay between excitation and inhibition sculpts the neural representation of sound features at every stage of central auditory processing. At the level of the auditory cortex, where all inhibition is local, fast-spiking GABA cells balance the tuning of excitatory cells, but other populations of cortical GABA cells may play a crucial role in shaping cortical responses to sound. Here, we use an optogenetic strategy to manipulate and record from dendrite-targeting somatostatin-expressing (SST) GABA neurons in the primary auditory cortex (A1) of awake, head-fixed mice. We made extracellular recordings of single units from all layers of A1 using linear, multi-channel probes. A transgenic strategy was used to express

channelrhodopsin 2 selectively in SST interneurons. Sounds were presented when SST neurons were either activated via laser or immediately following laser offset (i.e., deactivation). We characterized the effects of SST neuron activation and deactivation on regular- and fast-spiking A1 units through a linear classifier that allowed us to determine how reliably sound frequency was encoded over time. Optogenetic activation of SST neurons bi-directionally modulated cortical excitability, strongly suppressing activity during laser stimulation but producing rebound excitation upon deactivation. Neurons typically exhibited a short-latency, prolonged response to their best frequency (BF); however, spectrotemporal encoding of preferred stimuli was disrupted during both activation and deactivation of SST neurons. Deactivation of SST neurons unmasked subthreshold input that destabilized frequency tuning preference over time. Together, these changes degraded cortical decoding of sound frequency, particularly when the stimulus decoder was trained with longer integration windows. Finally, a sliding window decoder revealed that frequency processing during modulation of SST neurons diverges from normal such that the decoder fell to chance just 25 milliseconds after tone onset. These results suggest that cortical SST neurons are necessary to shape the temporal dynamics of cortical encoding of sound. SST neurons synapse onto dendrites and control both dendritic integration and active dendritic mechanisms. Disrupting their activity may occlude their ability to shape the intraneuronal processing required to generate a robust, time-insensitive representation of elementary sound properties.

**Title:** Transforming continuous temporal cues to a categorical spatial code in human speech cortex

**Authors: *N. P. FOX**[1], M. J. SJERPS[2], M. K. LEONARD[3], E. F. CHANG[4]
[1]Dept. of Neurolog. Surgery, Univ. of California San Francisco, San Francisco, CA; [2]Linguistics, UC Berkeley, Albany, CA; [3]Neurolog. Surgery, [4]Neurosurg., UCSF, San Francisco, CA

**Abstract:** During speech perception, listeners extract acoustic cues from a continuous sensory signal to map it onto behaviorally relevant phonetic categories. Many such cues are encoded within the fine temporal structure of speech. For example, voice-onset time (VOT), the interval between a stop consonant’s release and the onset of voicing, distinguishes voiced (e.g., /b/, short

VOT) from voiceless (e.g., /p/, long VOT) stops in English. Despite the ubiquity of time-dependent cues like VOT in the world's languages, the neurophysiological mechanisms that allow listeners to distinguish sounds that differ along temporal dimensions remain unclear. To investigate this question, we recorded neural activity directly from the cortex of nine human subjects while they listened to and categorized syllables along a VOT continuum from /ba/ (0ms VOT) to /pa/ (50ms VOT). We found that spatially distinct neural populations respond preferentially to one category (either /b/ or /p/). In both populations, responses are sensitive to VOT differences within the preferred, but not the non-preferred, category. This graded VOT encoding rapidly evolves to reflect the ultimate (categorical) behavioral response function, showing that categorical perception of VOT emerges across time in auditory cortex. Additionally, /b/-selective responses are lagged depending on VOT, while /p/-selective responses are time-locked to the burst, suggesting differential sensitivity to spectral cues indicative of burst vs. voicing. To probe what computations might give rise to these response properties, we implemented a neural network model that simulates neuronal populations as leaky integrators tuned to detect either coincident or temporally-lagged burst and voicing cues. The same temporal dynamics and encoding patterns observed in real neural data emerged in the computational model, suggesting that local tuning for distinct spectral cues at precise lags may underlie temporal cue integration in auditory cortex. Finally, we also recorded neural responses to naturally-produced sentences containing multiple speech sounds differing in VOT (e.g., /d/ vs. /t/, /g/ vs. /k/). Results demonstrated that neuronal tuning for this temporal cue generalized across speech sounds containing different spectral cues. Our results provide direct evidence that continuous temporal information is transformed into a categorical spatial code by discrete, phonetically-tuned neural populations in human auditory cortex.

**Title:** Unique roles for delta and theta frequency bands in the cortical analysis of temporal speech structure

**Authors: *J. C. LEE**, A. J. FALCONI, T. OVERATH
Duke Univ., Durham, NC

**Abstract:** Speech perception entails the mapping of the acoustic waveform to its linguistic representation. For this mapping to succeed, the speech signal needs to be tracked across a large temporal range at high temporal precision in order to decode linguistic units (phonemes,

syllables, words). Here we test how cortical processing of such temporal speech structure is modulated by higher-order linguistic analysis. To control the temporal scale of analysis, we used a novel sound-quilting algorithm that controls acoustic structure at different temporal scales (Overath et al., 2015). To control the linguistic content, we constructed speech quilts from both familiar and foreign languages. This ensures that any changes at the signal-acoustics level affect both languages identically, while manipulating the linguistic percept differently. Thus, neural responses that vary as a function of segment length, but are shared or similar across the two languages, suggest analysis at the signal-acoustics level, whereas neural responses that differ based on language familiarity imply the presence of linguistic processing. We recorded EEG while subjects listened to 6 s long English or Korean speech, quilted with 30 ms or 960 ms segment lengths. Neural entrainment to the speech quilt envelope, assessed via inter-trial correlation (ITC), in the theta band increased with segment length in both languages; however, ITC in the delta band increased with segment length only in English. This dissociation indicates that neural entrainment in the theta and delta frequency bands serves different functions: acoustic and linguist analysis of temporal speech structure, respectively. In particular, linguistic analysis tracks syllabic and word content that is preserved with increasing segment lengths. The results advance our understanding of the neural mechanisms underlying the acousto-linguistic mapping of temporal speech structure.

**Title:** Impact of articulator velocity-controlled rhythm in perceiving speech

**Authors:** ***S. HIROYA**[1], N. LAVAN[2], S. H. CHEN[3], S. MEEKINGS[4], S. K. SCOTT[5]
[1]NTT Corp., Kanagawa, Japan; [2]Dept. of Psychology, Royal Holloway, Egham, United Kingdom; [3]Inst. of Cognitive Neurosci., London, United Kingdom; [4]UCL, London, United Kingdom; [5]Univ. Col. London, London, United Kingdom

**Abstract:** Speech sound is composed of temporal and frequency information. In perceiving speech, the role of frequency (segmental) information has been widely examined, but few studies have investigated that of temporal (supra-segmental) information. In linguistics, languages can be categorized into three different rhythms: stress-timed rhythm (e.g., English and German), syllable-timed rhythm (e.g., French and Spanish) and mora-timed rhythm (e.g., Japanese). It is known that acquisition of the foreign language is strongly affected by the learner's native language. For instance, native Japanese speakers tend to speak English to fit into mora-timed

rhythm of Japanese: The rhythm of English spoken by native Japanese speakers is less natural. We have proposed a method that can convert the speech rhythm of an English sentence spoken by a native Japanese speaker into stress-timed rhythm by a native English speaker. We have performed fMRI scans for native English speakers during passive listening and found that supplementary motor area (SMA) was more activated by Japanese (less natural) rhythm more than by English (natural) rhythm. This indicates that SMA involves in processing of language-dependent naturalness of rhythm. By the way, movements of articulators such as the lips and tongue, which reflect bell-shaped velocity profiles, generate speech. However, few studies have investigated the role of SMA in perceiving speech with non-biological velocity profiles. In this study, we developed a method that can convert temporal patterns of speech based on articulator velocity. The velocity was calculated from articulatory data, which were collected using the electromagnetic articulography (EMA) system. Forty English sentences were used. The bell-shaped velocity profile of natural speech was converted to emphasized, uniform and reversed velocity profile, without altering sentence duration. Sixteen native British English speakers participated in the experiment. They were asked to listen to the stimuli and repeat them. The result of speech intelligibility (percent keywords correct) showed natural = emphasized > uniform > reversed. Also, they were asked to rate the naturalness of speech rhythm. Results showed natural > emphasized > uniform > reversed. These indicate that speech intelligibility is affected by the non-biological articulator velocity profile, such as uniform and reversed, but naturalness of speech rhythm is affected by any manipulation of velocity profiles. By multivariate pattern analysis of fMRI data using these stimuli, we will be able to investigate the involvement of SMA related to the speech intelligibility and the naturalness of speech rhythm.

**Title:** Encoding of irregular amplitude modulations in gerbil auditory cortex

**Authors: *K. PENIKIS**, M. N. SEMPLE, D. H. SANES
Ctr. for Neural Sci., NYU, New York, NY

**Abstract:** The encoding of sound envelope by the auditory system is typically studied with periodic amplitude modulated (AM) stimuli. However, the relatively slow modulations found in the sound envelopes of species-specific vocalizations, including speech, are irregular. If neural responses to AM depend only on moment-to-moment changes in amplitude, then responses to periodic stimuli should predict the response to individual AM periods of corresponding duration when they occur within an irregularly fluctuating stimulus. We tested this assumption by measuring the responses of auditory cortex (ACx) neurons to stimuli with envelopes that were modulated with or without a fixed periodicity. The periodic stimulus was 4 Hz AM noise and irregular stimuli contained a range of periods between 1 and 16 Hz, centered at 4 Hz. Preliminary results indicate that, for most ACx units, the response to a standard 250 ms period (i.e., 4 Hz) presented in the middle of each trial was similar, regardless of whether the AM stimulus was periodic or irregular. This observation implies that ACx neurons may not depend on periodicity for encoding envelope. To explore this idea, we designed a second stimulus in which a continuous, dynamic stream of noise transitioned between periodic (AM rates of 2 to 64 Hz) and irregular (periods of 2 to 64 Hz interleaved randomly) sequences. With this stimulus, we can compare the full AM rate tuning functions constructed from periodic and from irregular trials. Taken together, these studies address the relationship between periodicity coding and the representation of the irregular envelopes found in natural stimuli.

**Title:** Developmental hearing loss impairs fast temporal processing

**Authors: *J. YAO**[1], D. SANES[2]
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

**Abstract:** Fluctuations in sound level support speech comprehension, and perceptions of rhythm, prosody, and pitch, depending on the rate of amplitude modulation (AM). However, AM sensitivity may be vulnerable to hearing loss (HL) during its prolonged period of maturation. In fact, the processing of rapid (>100 Hz) modulation rates may be particularly impaired (e.g., Park

et al., 2015). Here, we sought to determine whether behavioral and neural AM detection thresholds display a similar sensitivity to developmental HL. Normal hearing (NH) adult gerbils, and those reared with conductive HL, were trained and tested on an appetitive Go-Nogo AM detection task (Go stimuli were broadband noise modulated at 64-512 Hz across a range of depths; Nogo stimulus was unmodulated noise). HL animals displayed poorer behavioral thresholds than NH animals at all AM rates, but performance was much worse at very fast rates, 256 and 512 Hz. To determine whether these perceptual deficits were attributable to degraded encoding mechanisms within the auditory brainstem, we recorded envelope following responses (EFRs) across a range of AM rates and depths from NH and HL animals that had been trained previously on the AM detection task. NH animals displayed similar EFR and behavioral thresholds, whereas HL animals displayed EFR thresholds that were better than those obtained behaviorally. This suggests that a neural deficit associated with behavioral impairment may be found downstream of the auditory brainstem. To test this idea, we are recording extracellular responses from ACx neurons while gerbils perform the AM detection task.

**Title:** The representation of spatial location and temporal modulation in marmoset parabelt auditory cortex

**Authors: *D. GAMBLE**[1], X. WANG[2]
[1]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

**Abstract:** The current working model of primate auditory cortex comprises the hierarchical arrangement of a series of functionally distinct information processing stages: a primary 'core' region, a secondary 'belt' region, and a tertiary 'parabelt' region. The ‘auditory dual stream hypothesis’ suggests that caudal belt and parabelt regions form a ‘where’ pathway that selectively processes auditory location, whereas the rostral cortical fields form a ‘what’ pathway responsible for auditory identification. (Rauschecker 1997, Kaas & Hackett 2000, Romanski et al. 1999) Crucially, data testing this hypothesis have come only from studies in core and belt auditory cortex, and not parabelt. We analyzed single unit receptive field data from extracellular physiology studies in rostral and caudal parabelt in the the awake, behaving marmoset.

Unexpectedly, single units throughout parabelt, in both rostral and caudal regions, exhibited sharp tuning for spatial location similar to that found in earlier levels. Neurons in both fields also represented stimulus frequency and temporal modulation with sharp tuning and high fidelity. Thus both identity and location are represented faithfully in both auditory cortical pathways.

**Abstract:** Pitch and timbre are two primary dimensions of auditory perception that are generally considered to be independent. However, under some circumstances they have been shown to interact with one another. For example, an increase in the fundamental frequency of a sound, the nearest physical correlate of pitch, can be confused for an increase in spectral centroid, a physical correlate of brightness (i.e., an attribute of timbre), and vice versa. An earlier passive fMRI study indicated that pitch and brightness are processed in largely overlapping regions of the auditory cortex, but their patterns of activation are separable via multi-voxel pattern analysis (MVPA). The aim of the current fMRI study was to determine whether allocating attention to one dimension or the other would make their cortical representations more spatially distinct. We collected BOLD data at 3T while participants listened to pairs of tones varying in either pitch, timbre, or both, and judged which tone had higher pitch or brighter timbre. While task performance was high in all conditions, subjects were significantly worse at performing the task when both dimensions were varying, confirming previous behavioral findings. Consistent with our previous results, we found that pitch and timbre engaged a common set of auditory regions with no clear distinctions at a univariate level. Furthermore, we found that increased attentional demands in the conditions in which both sound dimensions varied led to increased engagement of frontal regions, including the inferior and middle frontal gyri, compared to conditions in which just one dimension varied. However, heightened attentional demands did not appear to

improve the separability of the neural representations of pitch and timbre at either univariate, or multivariate levels. These results suggest that the computations underlying pitch and timbre perception are subserved by overlapping populations, likely on a scale that is difficult to disentangle without higher resolution and/or more sophisticated computational encoding models.

**Title:** Cortical mechanisms underlying responses to temporal gaps

**Authors: *B. H. AWWAD**, I. NELKEN
neurobiology, Hebrew Univ. of Jerusalem, Jerusalem, Israel

**Abstract:** High temporal acuity of auditory processing is crucial for speech understanding. A Gap-detection test is used clinically to measure auditory temporal acuity. Abnormal gap detection thresholds are believed to reflect central hearing difficulties even in the presence of normal hearing sensitivity. In spite of their clinical relevance, cortical mechanisms for gap processing are poorly understood.
Using an oddball paradigm, we studied the coding of gaps in the rat auditory cortex. Gaps are composed of two noise markers separated by the gap duration. The sensory response to a gap consists of two components (called here P1 and P2), representing the responses evoked by the two markers. In cortex, these are usually mostly tonic responses. Because of forward masking, the P2 response is smaller than the P1 response, so that the P2/P1 ratio is typically smaller than 1.
We recorded responses to sequences consisting of either gap stimuli or continuous noise stimuli, and manipulated the probability of gap stimuli in the sequences. When the gap stimuli were rare (gap deviants), the P2/P1 ratio was greater than when the gap stimuli were common (gap standards). Moreover, in many neurons, when the gap was long (20ms), the P2/P1 was greater than 1, reversing the ubiquitous effect of forward masking. Thus, neurons in rat auditory cortex show strong Stimulus Specific Adaptation (SSA) to gaps, even at detection threshold (~ gap duration of 2ms).

Using intracellular recordings, we observed that in the P2 the excitation-inhibition (E/I) balance of the sensory response changes, with excitation becoming more prominent, accounting for the larger response of P2 when the gap is deviant. We hypothesize the existence of a class of neurons that are activated only by the second marker of the gap, and who are responsible on the large P2 excitatory response; such responses may arise from the action of disinhibitory circuits that are known to be present in cortex.

**Title:** Missing fundamental pitch perception with semitone precision in marmosets

**Authors: *X. SONG**[1], M. S. OSMANSKI[2], X. WANG[3]
[1]Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD; [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

**Abstract:** The perception of the missing fundamental, in which one perceives the fundamental frequency (F0) of a harmonic complex tone even when the F0 is removed, is one of the most important properties of pitch perception in humans. Some non-human species have also been shown to be sensitive to the pitch of missing fundamental sounds, although these previous animal studies have not demonstrated that this sensitivity to pitch has a precision comparable to that of humans. For humans to perceive Western musical melodies, a precision of at least one semitone is necessary. Marmosets (*Callithrix jacchus*), a highly vocal New World monkey species, have been shown to be able to discriminate a pitch difference of one semitone for harmonic complex tones with a periodicity of 440Hz (the standard A or A4 in ISO16). We hypothesized that marmosets also possess missing fundamental pitch perception with one semitone precision for the periodicity at 440Hz (A4). In the current study, marmosets were trained to discriminate harmonic complex sounds that differed in both periodicity (F0) and the presence of an F0 component. The animals exhibited a high hit rate when a probe sound differed from a reference sound only in periodicity. In contrast, the animal's hit rate was indistinguishable from the false alarm rate when a probe sound differed from the reference sound only in its F0 presence. These results show that marmosets discriminated these harmonic complex sounds based on their periodicity but not the presence of an F0 component, which suggest that they can

perceive the missing fundamental pitch. For a periodicity of 440Hz (A4), marmosets could perform this task even when the pitch change was as small as one semitone. Whereas for a periodicity of 220Hz (A3), the pitch change had to be increased to two semitones. Such an increase is also consistent with their perceptual sensitivity to temporal envelope cue changes on A3, but not A4. This difference in sensitivity suggests that the mechanisms for missing fundamental pitch perception change between A3 and A4. Together, our findings demonstrate that marmosets have the capacity to process missing fundamental pitch similar to humans with a precision of at least one semitone for the periodicity above A4. This is the first time that a non-human species has been shown to have the ability to discriminate the missing fundamental pitch at this precision, which suggests that marmosets may potentially be able to discriminate musical melodies.

**Title:** Excitatory ON and OFF receptive field arrangement confers direction selectivity to slow frequency modulation in mouse auditory cortex

**Authors: *G. A. CHAPUIS**[1], J. SOLLINI[2], C. CLOPATH[1], P. CHADDERTON[1]
[1]Bioengineering, Imperial Col. London, London, United Kingdom; [2]UCL, London, United Kingdom

**Abstract:** Frequency-modulation (FM) is an important feature in human and animal communication. In the auditory cortex, the relative tuning of excitatory and inhibitory synaptic input accounts for direction selectivity at high modulation rates[1]. However, the mechanisms underlying direction selectivity at lower modulation rates relevant to vocalisation encoding have

not been established. We used multi-electrode arrays to record the activity of mouse auditory cortex neurons to pure tones and ascending and descending logarithmic FM sweeps (range: 2.2 - 140 octave/sec). Single units in the auditory cortex of fentanyl-anaesthetised animals exhibited the strongest directional selectivity at low modulation rates (< 8 octaves/second). Surprisingly, we found that the relative tuning of excitatory ON and OFF responses to pure tones was an excellent predictor of the units' direction selectivity (correlation coefficient $r = 0.61$, $p < 0.01$, $n = 30$ cells with V-shaped tuning curves to onset and offset). These results suggest that cortically generated synaptic inhibition may not be required for direction selectivity at low modulation rates. To test this proposal, we have selectively expressed the inhibitory DREADD in parvalbumin-positive (PV+) interneurons to manipulate fast spiking interneurons within the auditory cortex (AAV1/2-hSyn-DIO-hM4Gi-mCherry injected into the auditory cortex of PV-Cre mice; n = 6). Following IP injection of the agonist, clozapine-N-oxide, we demonstrate a strong increase in local field potential response to sound, consistent with a local reduction in cortical inhibition. We are currently analysing the directional selectivity of single units and measuring behavioural discrimination to ascending and descending sweeps in mice trained to perform a Go/No-Go task under conditions of reduced excitability of fast spiking interneurons. These experiments will establish the relative roles of ON and OFF-mediated synaptic excitation and cortical inhibition in the representation of slow modulations in sound frequency.

**Abstract:** Resection of pathology is often necessary in patients with intractable epilepsy or brain tumors. Minimizing functional deficits resulting from that resection requires mapping of eloquent cortex, i.e., cortical locations involved in language, motor, or memory functions. Different methods have been developed for functional mapping including electrocortical stimulation (ECS), which is currently considered the gold standard. However, its application requires active participation of patients, and thus cannot be applied in patients who are not woken up from general anesthesia during surgery. Recent studies demonstrated that passive recordings of electrocorticographic (ECoG) activity can be used to rapidly produce functional maps of receptive language function that are concordant to those acquired using ECS mapping, but did also require active participation of the patient. In our study, we hypothesized that it is possible to derive such functional maps in people under general anesthesia.
In our study, we presented auditory speech stimuli to eighteen patients under anesthesia. Our analyses demonstrated that these speech stimuli did not result in detectable ECoG changes during deep stages of anesthesia. At the same time, during induction of, or emergence from anesthesia, they did elicit ECoG broadband gamma responses in localized cortical regions typically associated with receptive language function. Additional analysis in the subset of patients who underwent chronic implantation of ECoG grids—patients with intractable epilepsy who were awake for periods of several days—demonstrated that the locations identified for receptive language function during anesthesia were usually on or close to the locations identified during the awake state.
The preliminary results demonstrated the possibility of mapping of receptive language function during general anesthesia. With further verification and additional protocol optimizations, our protocol could greatly expand the range of patients that can benefit from mapping of receptive function.

**Title:** Diverse configuration of synaptic tonal receptive fields in the auditory midbrain

**Authors: J. LEE**, J. LIN, *G. K. WU
The George Washington Univ., Washington, DC

**Abstract:** The inferior colliculus (IC) is a major integrative hub of auditory processing, as multiple ascending projections from lower auditory nuclei converge towards the central nucleus of the IC. The interactions of converging excitation and inhibition produce a variety of response properties that either modulate or create new responses. Recently, imbalanced excitation and inhibition has been observed among a subset of neurons in the IC and the primary auditory cortex. However, the detailed structure function of these neurons' excitatory and inhibitory receptive fields were still obscure, especially their relationship with characteristic frequency and complex sound such as frequency-modulated (FM) sweeps. Here we applied in vivo whole cell voltage-clamp recordings to the central nucleus of the IC of mice and systematically examined the receptive field properties of neurons within a single isofrequency laminae. In contrast to the systematic change of the imbalance between excitatory and inhibitory receptive fields along the tonotopic axis in the auditory cortex and the IC of rats, diverse configurations of balance of synaptic receptive fields have been observed with similar characteristic frequency. Moreover, these neurons with the same characteristic frequency but different balance of excitation and inhibition demonstrated selectivity to FM sweeps. It suggests that mouse IC neurons could selectively respond to much narrower range of FM, which could be a neural substrate for their responses to more complex sounds, such as vocal signals.

**Title:** Reduced acoustic startle response and peripheral hearing loss in the 5xFAD mouse model of Alzheimer's disease

**Authors: *R. E. BROWN**[1,2], T. P. O'LEARY[4], J. WANG[3]
[1]Psychology & Neurosci., Dept. of Psychology and Neurosci., Halifax, NS, Canada; [3]Sch. of Human Communication Disorders, [2]Dalhousie Univ., Halifax, NS, Canada; [4]Univ. of British Columbia, Vancouver, BC, Canada

**Abstract:** Hearing dysfunction has been associated with Alzheimer's disease in humans, but there is little data on the auditory function of mouse models of Alzheimer's disease. Furthermore, characterization of hearing ability in mouse models is needed to ensure that tests of cognition that use auditory stimuli are not confounded by hearing dysfunction. Therefore we assessed acoustic startle response and pre-pulse inhibition in the double transgenic 5xFAD mouse model of Alzheimer's disease from 3-4 to 16 months of age. The 5xFAD mice demonstrated an age-related decline in acoustic startle as early as 3-4 months of age. We subsequently tested Auditory Brainstem Response (ABR) thresholds at 4 and 13-14 months of age using tone-bursts at frequencies of 2- 32 kHz. The 5xFAD mice showed increased ABR thresholds for tone-bursts between 8 and 32Khz at 13-14 months of age. Finally, cochleae were extracted and basilar membranes were dissected to count hair cell loss across the cochlea. The 5xFAD mice showed significantly greater loss of both inner and outer hair cells at the apical and basal ends of the basilar membrane than wildtype mice at 15-16 months of age. These results indicate that the 5xFAD mouse model of Alzheimer's disease shows age-related decreases in acoustic startle responses, which are at least partially due to age-related peripheral hearing loss. Therefore, we caution against the use of cognitive tests that rely on audition in 5xFAD mice over 3- 4 months of age, without first confirming that performance is not confounded by hearing dysfunction.

**Title:** Pharmacological inhibition of substantia nigra pars reticulata and sensorimotor gating function: Implications for differential organization of nigral outflow between rodents and monkeys

**Authors: *B. L. AGUILAR**[1,2], L. MALKOVA[2], P. A. FORCELLI[2]
[2]Dept Pharmacol & Physiol and the Interdisciplinary Program in Neurosci., [1]Georgetown Univ., Washington, DC

**Abstract:** Sensorimotor gating is a fundamental process through which the central nervous system filters motor responses to stimuli; this process can be assessed operationally through measurement of prepulse inhibition (PPI) of the acoustic startle response (ASR). ASR is attenuated by presentation of a low-intensity prepulse prior to the startle-inducing stimulus; this phenomenon is well-conserved across species.
Previous studies in rodents have reported (Koch et al., 2000) that lesions of substantia nigra pars reticulata (SNpr) impair PPI. Prior work from our group has shown that the macaque SNpr displays a discrete behavioral topography that is not seen in rodents (Dybdal et al.). Here, we sought to directly compare the effects of reversible pharmacological inhibition of the SNpr across these species.
For the rodent studies, 12 Long Evans rats were surgically implanted with bilateral cannulae inserted into the SNpr. After recovery, either muscimol (2nmol) or saline was intracerebrally microinfused into the SNpr. Rats were tested following either unilateral or bilateral drug administration. We found that muscimol infusion significantly impaired PPI in rats ($P<0.05$, Repeated measures ANOVA). These data are consistent with the prior lesion studies.
For the non-human primate studies, 5 rhesus macaques were surgically implanted with a microinfusion platform. After recovery, a structural MRI scan was run to determine infusion coordinates in the SNpr. Prior to PPI testing, muscimol (9nmol) was intracerebrally microinfused unilaterally. Contrary to our findings in the rat, muscimol infusion into the macaque SNpr **potentiated** prepulse inhibition.
Studies are currently underway examining the role of specific nigral output targets using optogenetic silencing in rats. We propose that a differing architecture of nigral outflow mediates this species difference.

**Title:** Stochastic resonance as a putative cause of tinnitus

**Authors: *P. KRAUSS**, K. TZIRIDIS, C. METZNER, A. SCHILLING, U. HOPPE, H. SCHULZE
Univ. of Erlangen-Nurnberg, Erlangen, Germany

**Abstract:** Subjective tinnitus is generally assumed to be a consequence of hearing loss. In animal studies it has been demonstrated that acoustic trauma induced cochlear damage can lead to behavioral signs of tinnitus. In addition it was shown that noise trauma may lead to

deafferentation of cochlear inner hair cells even in the absence of elevated hearing thresholds, and it seems conceivable that such hidden hearing loss may be sufficient to cause tinnitus. Numerous studies have indicated that tinnitus is correlated with pathologically increased spontaneous firing rates and hyperactivity of neurons along the auditory pathway. It has been proposed that this hyperactivity is the consequence of a mechanism aiming to compensate for reduced input to the auditory system by increasing central neuronal gain, a mechanism referred to as homeostatic plasticity (HP), thereby maintaining mean firing rates over longer timescales for stabilization of neuronal processing. Here we propose an alternative, new interpretation of tinnitus-related development of neuronal hyperactivity in terms of information theory. In particular, we suggest that stochastic resonance (SR) plays a key role in both short- and long-term plasticity within the auditory system and that SR is the primary cause of neuronal hyperactivity and tinnitus. We argue that following hearing loss, SR serves to lift signals above the increased neuronal thresholds, thereby partly compensating for the hearing loss. In our model, the increased amount of internal noise - which is crucial for SR to work - corresponds to neuronal hyperactivity which subsequently causes neuronal plasticity along the auditory pathway and finally may lead to the development of a phantom percept, i.e. subjective tinnitus. We demonstrate the plausibility of our hypothesis using a computational model and provide exemplary findings in human patients that are consistent with that model. Finally we discuss the observed asymmetry in human tinnitus pitch distribution as a consequence of asymmetry of the distribution of auditory nerve type I fibers along the cochlea in the context of our model.

**Title:** Psychophysics of auditory streaming based on spectral and spatial cues in rhesus monkeys

**Authors:** ***J. LEE**[1], T. BANNO[1], Y. I. FISHMAN[2], Y. E. COHEN[1,3,4]
[1]Otorhinolaryngology - Head and Neck Surgery, Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA; [2]Neurol., Albert Einstein Col. of Med., Bronx, NY; [3]Neurosci., [4]Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** A fundamental aspect of hearing is parsing auditory stimuli into discrete perceptual representations of sounds in the environment. The auditory system accomplishes this parsing, in

part, by grouping acoustic stimuli with similar spatial or and spectral features into one perceptual stream and separating those with different features into different streams. However, the degree to which spectral and spatial cues contribute to sound-stream segregation has not been fully elucidated, especially in non-human primates.
Here, we tested how the degree to which spectral and spatial cues affected the ability of rhesus monkeys to effectively group or segregate acoustic stimuli into separate auditory sound streams by conducting a series of psychophysical experiments. Specifically, we presented two sequences of alternating interleaved tone bursts that varied in frequency, sound level, and spatial separation from a free-field speaker array. Monkeys were trained to report hearing a deviantly loud tone burst. This report served as a proxy for stream segregation: by design, this deviant could only be detected if the two sequences of tone bursts were perceived as separate streams[1,2].
As expected, we found that monkeys' ability to detect the deviant tone greatly improved as the frequency difference between the two tone-burst sequences increased. Likewise, as the spatial separation between the two sequences increased, the ability to detect the deviant tone was also substantially enhanced. Interestingly, spatial separation, in this paradigm, was a more potent segregation cue than spectral separation.Interestingly, spatial cues, in this paradigm, served aswere a more potent segregation cue than spectral cues. Furthermore, spatial and spectral cues interacted synergistically to facilitate deviant detection and hence stream segregation. Psychophysical findings are consistent with human performance on a comparable task. This study provides the first demonstration of the combined effect of spectral and spatial cues on auditory streaming in non-human primates.

**Title:** Neural processing of delayed auditory feedback of involuntary self-body movement

**Authors: *T. MOMOKAWA**[1], K. UENO[2], S. SHIMADA[1]
[1]Electronics and Bioinformatics, [2]Architecture, Meiji Univ., Kawasaki-shi, Kanagawa, Japan

**Abstract:** Predicting the timing and occurrence of auditory stimulus is an important feature of auditory processing. Our previous study showed that a delayed auditory feedback of self-action elicits the event-related potential (ERP) component named enhanced-P2 (EP2) (Toida et al., 2016). To further investigate the characteristics of the ERP component, we examined whether EP2 is also elicited by delayed auditory feedback of the involuntary self-body movement as that of the voluntary movement. Fifteen healthy students (7 female, 8 male; aged 21.7 ± 1.6 years) participated in the experiment. We employed an oddball paradigm with a non-delayed 1000-Hz pure tone as the standard stimulus and a delayed 1000-Hz pure tone as the deviant stimulus. Auditory stimulus was presented in association with mouse-click that was caused every 1-2 second involuntarily. In the experiment, the deviant stimulus was temporally delayed from their mouse-click. We introduced four delay conditions (100, 200, 300, and 400 ms) and the control condition (non-delayed). Participants were told to silently count the number of trials in which they could detect the delayed auditory stimulus. The EEG (g.USBamp, g.tec, Austria) signals were recorded at 30 channels of the 10% system with a digital 0.5-30 Hz band-pass hardware filter. The sampling frequency was 512 Hz. The region of interest (ROI) was determined as Pz in order to compare the results with that of our previous study (Toida et al., 2016). The EP2 was also observed in the current experiment. However, while it was observed only in the 100 and 200 ms delay conditions in the previous study (Toida et al., 2016), the current result showed that the EP2 was not observed in the 100 ms delay, appeared only in the 200 and 300 ms delay, and diminished in the 400 ms delay condition. We have argued that EP2 reflects a 200-300 ms temporal window for integrating self-body information (Toida et al., 2016). The present result suggests that the internal generation of the auditory feedback prediction in the involuntary movement is slower for about 100 ms than in the voluntary movement because efference copy is not available in the involuntary movement.

**Abstract:** The auditory brainstem responses (ABR) are consisted of short-latency waves that collectively contain the neural evoked potential. The ABR are used for comparative indicators of

hearing sensitivities. We measured the hearing sensitivity in *Miniopterus fuliginosus* for comparison with properties of acoustic signals and neuronal frequency tuning. The ABR was recorded from inferior colliculus of three awake bats. The 20 types of frequencies of tone pips between 4 and 94 kHz were presented to the subjects. We decreased systematically intensities of tone pips to obtain a threshold of ABR at different frequencies of tone pips. Auditory stimuli were presented for 100 times, and the ABR to each frequency were averaged at each intensity level. As results, the audiogram has a U-shape over the frequency range from 16 to 94 kHz. In addition, the most sensitive frequency region of 44-56 kHz occurs at the terminal portion of echolocation pulses that are down-sweeping sounds. Latencies of ABR were extended along decreasing intensities of stimuli by 7.5 to 11.2 μs/dB at frequency range between 44-56 kHz. These results will be compared with other species of bats.

**Title:** Listening to the mind's iPod: Are there two kinds of auditory imagery?

**Authors: L. RAJAN**[1], *S. A. LACEY[1], K. SATHIAN[1,2]
[1]Emory Univ., Atlanta, GA; [2]R&D Ctr. for Visual and Neurocognitive Rehabil., Atlanta VAMC, GA

**Abstract:** Individual differences in both visual and haptic imagery can be organized along a continuum of preferences for object and spatial imagery subtypes. Object imagers tend to integrate surface properties, such as color and texture, with structural information about shape. By contrast, spatial imagers tend to ignore surface properties and instead focus on structural information and spatial transformations. Here, we tested whether there are corresponding subtypes of auditory imagery and whether musical expertise is a factor. Participants (n=28: m 10, f 18; musicians = 15, non-musicians = 13) listened through earphones to 12-tone sequences in which each tone (of constant pitch and duration) varied in loudness and whether it was played in the right or left channel. The task was to discriminate the spatial pattern (a structural property) across changes in the loudness pattern (a surface property) and vice versa. Poor discrimination of

the spatial pattern across loudness changes would indicate integration of structural and surface properties and reflect the auditory equivalent of object imagery. Poor discrimination of the loudness pattern across changes in the spatial pattern would indicate that surface properties were not attended and reflect the auditory equivalent of spatial imagery. Participants' imagery preferences were classified by their scores on the Object-Spatial Imagery and Verbal Questionnaire, a measure of visual imagery preferences (object imagers = 20, spatial imagers = 8). Participants also completed the Montreal Battery of Evaluation of Amusia (MBEA: Peretz et al., 2003, Ann NY Acad Sci 999:58-75). Consistent with our visual and haptic studies (Lacey et al., 2011, Exp Brain Res 213:267-273), we found that differences in auditory performance tracked participants' visual imagery preference: object imagers could not discriminate the structural property over a change in the surface property while spatial imagers could not discriminate the surface property if the structural property changed. There were no significant differences between musicians and non-musicians and no interactions with musicianship status, nor were MBEA scores correlated with performance. There were no gender differences or interactions. We conclude that there are two kinds of auditory imagery corresponding to object and spatial subtypes, and that the propensity to integrate surface properties into an image (object imagery) or to favor structural properties (spatial imagery) is a multisensory organizing principle of mental imagery across the three modalities of vision, haptics, and audition.

**Title:** Hippocampal reactivity relaying from medial septum only to noise in awake forebodes the sensibility of auditory fear conditioning independent of the sound characteristics

**Authors: *C. XIAO**, Y. LIU, Z. XIAO
Dept. of Physiol., Southern Med. Univ., Guangzhou, China

**Abstract:** Hippocampus integrates various sensory information including visual, tactile, olfactory and auditory, and plays a critical role in many higher-order brain functions especially for learning and memory. It is thought to receive projection from auditory cortex indirectly and process sound information, such as the conditioning stimulus in auditory fear conditioning. However, it is systematically unexplored whether or not the neurons in hippocampus can respond to sound and distribute tonotopically. Using in vivo loose patch recording we found that neurons in hippocampus (CA3, CA1 and entorhinal cortex) respond to noise stimuli only in awake and almost not to pure tone (2-64 kHz) unlike in auditory cortex. What intriguing was that the response latencies (13 ms) of neurons in hippocampus responding to noise stimuli were much shorter than those (18 ms) in auditory cortex. It hints that the auditory pathway of hippocampus may be from other nuclei rather than auditory cortex. Hippocampus receives a strong projection from medial septum. Thus we explored the neuronal responses to noise and pure tone in medial septum. The response characteristic was same as that in hippocampus, but the shortest response latencies (10ms) to noise were shorter than those in hippocampus. Furthermore, silenced the medial septum with lidocaine or muscimol the neuronal discharges in CA3, CA1 and entorhinal cortex decreased significantly even disappeared. Whereas silenced auditory cortex, the responses almost unchanged. It is interpreted that the auditory pathway of hippocampus uploads from medial septum rather than auditory cortex. Hippocampus is involved in auditory fear conditioning and sensitive only to noise, so we hoped that silencing medial septum with lidocaine or muscimol during training would abolish auditory fear conditioning with noise as conditioning stimulus rather than pure tone. Interestingly, not only was the noise induced fear behavior blocked but also 2.5 kHz induced fear behavior when silenced medial septum. It seems that auditory fear conditioning behavior is independent of the characteristics of sound. Then, we trained mice with noise, 2.5, 5, 10, 15, or 30 kHz as conditioning stimulus respectively, and tested the conditioned behavior with noise, 2.5, 5, 10, 15, and 30 kHz after 24h. The freezing behaviors were not significantly different. Our findings suggest that the hippocampus relaying from medial septum responses only to noise stimuli in awake, and that the excitability of hippocampal neurons to noise forebodes the sensibility of auditory fear conditioning, which is independent of the characteristics of conditioning sound.

**Title:** Spiking activity in auditory cortex to identity-preserving changes in sounds

**Authors: *F. A. RODRIGUEZ CAMPOS**[1], J. MCDERMOTT[2], Y. E. COHEN[3]
[1]Univ. of Pennsylvania, Antiguo Cuscatlan, El Salvador; [2]Brain and Cognitive Sci., MIT, Cambridge, MA; [3]Dept. Otorhinolaryngology-Head Neck Surgery, Univ. of Pennsylvania Dept. of Otorhinolaryngology, Philadelphia, PA

**Abstract:** The auditory system transforms acoustic stimuli into representations that subserve perception, recognition, and behavior. One major challenge faced by the auditory system is the creation of sound representations that are invariant to identity-preserving transformations. Indeed, sound recognition by human listeners is invariant to changes in the stimulus due to variation in the pitch of speakers' voices, the location of the sound source, the amount of background noise, etc. The brain areas, neural mechanisms and computations that provide the basis for a listener's tolerance to identity preserving changes are unknown.To address the neural basis of invariant recognition, we conducted large-scale recordings from the auditory cortex of rhesus monkeys while they listened to natural sound exemplars (animal vocalizations and natural background noises) and identity-preserving transformations of these exemplars. These transformations included sound-source location and room reverberation. Additionally, as controls, we presented scrambled versions of these sounds. These scrambled versions were statistically matched to these natural exemplars but could not be identified as originating from the same source as the original sounds. We recorded with MicroProbes' 96-electrode Microwire Brush Array simultaneously from 3 areas of auditory cortex: anterolateral belt (AL), middle-lateral belt (ML), and primary auditory cortex (A1). We report how identity-preserving transformations of sounds are represented in the spiking activity of neurons in these three brain regions. In particular, we describe the degree to which neural populations codes support perceptual representations of invariance.

**Title:** Primate behavioral and functional-imaging model for auditory figure-ground segregation

**Authors: *F. SCHNEIDER**, P. DHEERENDRA, F. BALEZEAU, A. THIELE, T. D. GRIFFITHS
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

**Abstract:** Segregating sounds in a noisy environment is a fundamental aspect of scene analysis. Inability to detect figures from noisy background is a ubiquitous problem in both cochlear hearing loss and in disorders of central sound processing. In normal human listeners, emerging evidence suggests that auditory objects are detected with remarkable sensitivity and robustness based on a mechanism that detects temporal coherence in different frequency bands (Teki et al. 2013). Human imaging studies demonstrate a system including auditory cortex in the superior temporal sulcus (STS) in non-core homologues and in the intraparietal sulcus (IPS) during preattentive, stimulus-driven figure-ground decomposition of stimuli (Teki et al. 2016; Teki et al. 2011). We have developed a primate model in a species in which the system organisation can be compared to humans more easily than in other mammals (Baumann et al. 2013). The eventual aim is to achieve an understanding of figure-ground analysis at the neuronal level based on systematic recordings that are not possible in humans. We present data from behavioural experiments to measure the ability of rhesus macaques (n = 3) to detect target sounds in a noisy background using stimuli and parameters determined by the previous human work (Teki et al. 2013). A Go/No-Go task with bar release measured the detection of figures based on keeping 10 frequencies constant in a random chord sequence where each chord had duration of 50ms. Parallel functional imaging using fMRI on 3 subjects demonstrated the network for detection of similar 10-component figures presented over 40 chords with a duration of 50ms. As in previous human fMRI (Teki et al. 2011) an irrelevant task was carried out with the aim of demonstrating preattentive, stimulus-driven figure-ground detection. Sparse imaging was used. A contrast between scans after presentation of figure plus ground and control trials after figure only demonstrated activity in parabelt homologues in anterior superior temporal gyrus (STG). In one subject we demonstrated significant activity in posterior STS.

**Title:** Evaluation of acoustic information related to discriminability in avian higher-order auditory cortex

**Authors: *M. INDA**, R. TABATA, K. HOTTA, K. OKA
Keio-Univ. Biophysics and Neuroinformatics Lab., Yokohama/Kanagawa, Japan

**Abstract:** Some animals use specific sounds as a communication tool, and they discriminates these sound by extracting precise acoustic information in noisy natural environment. Zebra Finch (*Taeniopygia guttata*) also uses their songs as the communication tool between males and females. Male songs consist of motifs that have stereotyped sequences of syllable with various acoustic information (e.g. Fundamental Frequency, FM, AM, etc.), and females choose their mating partners by distinguishing songs of males. In avian brain, caudal medial mesopallium (CMM) is known as a higher-order auditory region that has a function of sound discriminability. According to previous research, CMM neurons indicated discriminable activities between conspecific and heterospecific songs, but not between unfamiliar and familiar song (Woolley and Doupe, 2008). These studies are, however, based on results from difference in neural responses to different sound stimuli. It is only evaluated whether it can discriminate or not, thus little is known about what the essential information for sound discriminability..In this study, we clarify this problem by designing synthetic stimulus for focusing on acoustic information of male songs. To investigate detailed mechanism of sound discriminability, we obtained neural activities from CMM neurons when we presented conspecific songs and several synthetic stimulus sounds to anesthetized female zebra finches. To quantify sound discriminability of these neural activities, we calculated receiver operating characteristic (ROC) values from the firing rate. We found that there is a tendency that sound discriminability depends on syllable types. Furthermore, to investigate differences of acoustic information between discriminable and indiscriminable syllables, we estimated relationship between ROC values and some acoustic parameters of syllables by making acoustic information surface. From these analysis, we could observe sound discriminability changes depending on combination of particular 2 acoustic information. Then, we found a boundary between discriminable and indiscriminable syllables on Mean Frequency and Entropy acoustic information surface. Furthermore, we set ROC values as the 3rd on this surface to evaluate more detail of relationship between discriminability and these 2 acoustic information. When we saw this 3D space from particular direction, we found a positive correlation. These results suggested that the factor of song discriminability depends on relationship between Mean Frequency and Entropy.

**Abstract:** **Background**:
It is still unclear how, despite diverse molecular and cellular mechanisms, a wide range of anesthetics all bring about loss of consciousness (LOC) and how responses to sensory stimuli differ between wakefulness and anesthesia. Specifically, it remains undecided whether “just hypnotic” anesthesia primarily disrupts feedforward activity up to primary sensory regions via “thalamic gating” or alternatively whether it mainly affects intercortical signaling.
**Methods**:

We recorded ECoG, intracerebral EEG (iEEG), microwire LFPs, and neuronal spiking activity across multiple brain regions of seven epilepsy patients as they were sedated for routine deplantation of intracranial depth/ECoG electrodes serving for clinical monitoring.
Propofol infusion rate was increased gradually over 20-40 minutes (5 to 400 mcg/kg/min) while auditory stimuli (40Hz click-trains, dynamic random chords and words) were presented during wakefulness, deepening sedation, and after achieving unresponsiveness. Patients were instructed to respond to a target word stimulus via a push-button.

**Results**:

During wakefulness, significant iEEG responses to 40Hz click-trains (n=328 depth electrodes) were observed across widespread cortical areas, whereas during anesthesia responses were strongly attenuated and restricted to regions around auditory cortex. This attenuation occurred suddenly around LOC.
In the auditory cortex (Heschel's Gyrus and Superior Temporal Gyrus), the effects of anesthesia on 40Hz responses were more moderate and variable. In response to words during wakefulness, auditory LFPs showed an increase in broadband high-frequency gamma (40-110Hz) power and concurrent decrease in alpha/beta (10-20Hz) power ('desynchronization'). During anesthesia, gamma effects (likely reflecting feedforward processing) were largely preserved, whereas alpha/beta effects (likely reflecting top-down processing) were strongly attenuated.
Preliminary results from spiking responses of auditory neurons showed complex and variable effects of anesthesia on auditory response properties. We are currently investigating to what extent this variability can be explained by factors such as the precise auditory field, early vs. late response components, and stimulus complexity.

**Conclusion**:

Anesthesia preferentially disrupts intercortical aspects of auditory responses such as the spread of activity from A1 to high-order cortical nodes and top-down response signatures, while relatively sparing early bottom-up signaling up to A1.

**Title:** Neural correlates of sine wave speech intelligibility in human frontal and temporal cortex

**Authors: *M. K. LEONARD**[1], S. KHOSHKHOO[2], N. MESGARANI[3], E. F. CHANG[1]
[1]Neurolog. Surgery, UCSF, San Francisco, CA; [2]Partners Neurol. Program, Harvard Med. Sch., Cambridge, MA; [3]Columbia Univ., New York, NY

**Abstract:** Auditory speech comprehension is the result of neural computations that occur in a broad network that includes the temporal lobe auditory cortex and the left inferior frontal cortex. It remains unclear how representations in this network differentially contribute to speech comprehension. Here, we recorded high-density direct cortical activity during a sine wave speech (SWS) listening task to examine detailed neural speech representations when the exact same acoustic input is comprehended versus not comprehended. Listeners heard SWS sentences (pre-exposure), followed by clear versions of the same sentences, which revealed the content of the sounds (exposure), and then the same SWS sentences again (post-exposure). Across all three task phases, high-gamma neural activity in the auditory cortex superior temporal gyrus was the same, distinguishing different words based on bottom-up acoustic features. In contrast, frontal regions were active only when the input was comprehended, which corresponded with stronger representational separability among spatiotemporal activity patterns evoked by different words. We observed this effect only in participants who were not able to comprehend the stimuli during the pre-exposure phase, indicating a direct relationship between frontal high-gamma activity and speech understanding. Together, these results demonstrate that both frontal and temporal cortical networks are involved in spoken language understanding, and that under certain listening conditions, frontal regions are involved in discriminating speech sounds.

**Title:** Characteristics of phase resetting in low-frequency oscillatory activity during a reaction time task

**Authors: *L. MOHEIMANIAN**[1,2], W. COON[3], P. BRUNNER[1,4], G. SCHALK[1,2,4]
[1]Natl. Ctr. For Adaptive Neurotechnologies, Wadsworth Ctr.,, New York State Dept. of Hlth., Albany, NY; [2]Dept. of Biomed. Sci., State Univ. of New York at Albany, Albany, NY; [3]Dept. of Psychiatry, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [4]Dept. of Neurol., Albany Med. Col., Albany, NY

**Abstract:** Understanding the mechanisms that underlie behavioral performance (e.g., reaction time) could lead to improvements in diagnosis and treatment for people affected by disorders of the central nervous system. Oscillatory brain activity affects perceptual and behavioral performance, and represents rhythmic changes in the excitability of neuronal populations in the cortex. Previous studies have suggested that oscillatory phase may be aligned to facilitate quick reaction to external stimuli. This sudden change in oscillatory phase (termed as phase reset) is associated with enhanced cortical excitability and improved behavioral performance. However, the relationship of phase reset with population level activity and its spatio-temporal dynamics have not been studied, making it difficult to infer whether this is a localized or widespread mechanism. In this study, we were interested in determining the spatio-temporal relationship between phase reset and population level activity (i.e., broadband gamma activation). Specifically, we investigated the temporal relationship between phase reset, stimulus onset and broadband gamma activation across wide cortical areas.
To accomplish this, we recorded electrocorticographic (ECoG) activity from frontal, parietal and temporal cortices in eight human subjects while they performed a reaction time task. In this task, subjects were asked to press a push button as quick as possible in response to a salient auditory stimulus. In our single-trial analysis, we determined the timing of phase reset from the band-pass filtered ECoG activity (3-8 Hz) and the timing of the broadband gamma power onset (70-170 Hz). Our results show that phase reset occurs approximately 45 ms after stimulus onset and prior to broadband gamma activation. Interestingly, the delay between phase reset and broadband gamma activation is constant in hand motor cortex, but not in other cortical areas. Finally, our results show that phase reset is a widespread cortical mechanism. These results contribute to a more comprehensive understanding of the neural basis of behavioral performance.

**Title:** Selective auditory attention to a single sound stream suppresses responses to temporally non-coherent sounds in ferret auditory cortex

**Authors: *K. LU**, W. LIU, J. B. FRITZ, S. A. SHIHAB
Inst. for Systems Res., Univ. of Maryland, College Park, MD

**Abstract:** Human listeners can focus attention on speech of a single speaker in a noisy auditory scene. This ability requires segregating the relevant sound stream and ignoring irrelevant sound sources. Our previous studies proposed that temporal coherence plays an important role in segregating sounds. When ferrets were trained to globally attend to two tone-sequences without any behavioral requirement to differentiate or segregate them, we found that coherent activation of cortical neurons tuned to the two tones (when the sequences were synchronous) induced excitatory interactions (or binding) between them; by contrast, asynchronous tones induced incoherent activation and suppressive interactions the two different frequency channels. The current studies tested the effects of *selective* attention when ferrets were trained to focus attention on one of the sequences while ignoring the other sounds. We hypothesized that the attended channel would bind all channels that are coherent with it, while suppressing actively those incoherent with it. Two ferrets were trained to listen attentively to detect a small intensity change in a sequence of narrow bandpass noise bursts. This foreground target stream occurred against a background of sequences of two alternating tones: one tone sequence was synchronized with the target noise sounds, while the other tone sequence was out of phase with the target stream (temporally alternated with the target sequence). Using standard neurophysiological techniques, we recorded auditory responses of single units (N=84) in the primary auditory cortex (A1) of behaving animals. Responses from A1 neurons tuned to the tone streams that alternated with targets were significantly suppressed, while responses from neurons tuned to tones that were synchronized with the targets remain intact, providing further support for the temporal coherence hypothesis as the neural mechanism underlying the ability to filter out irrelevant sounds in complex auditory scenes.

**Title:** Sex differences in lifespan prolongation effect in mice induced by acoustic environmental enrichment

**Authors: *Y. YAMASHITA**[1], N. KAWAI[2], O. UENO[1], Y. MATSUMOTO[1], T. OOHASHI[2], H. MANABU[1]
[1]Natl. Inst. of Neuroscience, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [2]Fndn. for Advancement of Intl. Sci., Tsukuba, Japan

**Abstract:** Environmental enrichment (EE) has been reported to have positive effects on experimental animals including prevention of frailty signs, and accelerations of developments and functions of the brain. A typical experimental setting of EE consists of the interaction of complex factors including larger cages with variety of objects enhancing animal's physical activity and larger groups of animals with the opportunity for more social interaction. In the current study, we simplified the experimental condition and focused on the effect of enrichment of acoustic sensory stimuli through the observations of lifespan and voluntary movements in mice.
Ninety-six 8-week old C57Bl/6J mice were assigned to three groups (16-male and 16-female per group and 4 animals per cage) with different acoustic environmental conditions throughout the experiment: (1) acoustically enriched environmental condition with full range (~100kHz) sounds (FRS condition), (2) acoustically enriched environmental condition with high-cut (~20kHz) sounds (HCS condition), and (3) standard environmental condition with only background noise (control: CNT condition). In FRS and HCS conditions, tropical rain forest sounds were presented through two speakers fixed at the top of each cage. Other properties of environment including cage size were standard rearing condition of experimental animals. Voluntary movements were continuously monitored with a computerized system throughout lifespan.
The mice of HCS condition showed significantly longer lifespan (nearly 17%) and significantly

increased voluntary movements than those of CNT condition. FRS condition also showed a similar tendency although the statistical significance did not reach the predetermined threshold. There was no significant correlation between the voluntary movements and lifespan, suggesting that the increase of voluntary movements was not a primary cause of prolongation of lifespan. In addition, there was sex difference in the effects of acoustic EE. Namely, the prolongation of lifespan was more prominent in male mice, and only in male, the minimal lifespan of each cage was significantly prolonged in FRS and HCS conditions than that of CNT condition. In addition, the variance of lifespan of mice within each cage was significantly smaller in FRS and HCS conditions than that of CNT condition, suggesting that the prolongation of lifespan induced by acoustic EE may result from the changes in the relationship of individuals, i.e. social dominance, which is predominantly observed in male mice.

**Title:** Phase entrainment of neural oscillations is causally relevant for neural responses to intelligible speech

**Authors: *B. ZOEFEL**, A. ARCHER-BOYD, M. H. DAVIS
MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom

**Abstract:** Alignment between neural oscillations and speech rhythm, “entrainment”, is often enhanced during speech comprehension. Nevertheless, the relation between entrainment and comprehension might merely be correlational, introduced by stimulus manipulations that simultaneously reduce speech intelligibility and remove entraining cues for neural oscillations. Only if we manipulate entrainment as a dependent variable and observe consequences for speech comprehension, can we can conclude that there is a causal relation between the two. This is possible using transcranial alternating current stimulation (tACS): tACS has been shown to impose a rhythm on neural oscillations and can thus be used to manipulate entrainment in an experimental setting. However, based on behavioural measures alone, it is difficult to distinguish a specific modulation of speech processing and changes to low-level auditory processes that

would affect processing of non-speech or unintelligible stimuli.
We therefore combined tACS at 3.125 Hz over lateral temporal regions with concurrent fMRI to measure BOLD responses to intelligible (16-channel vocoded) and unintelligible (1-channel vocoded) rhythmic speech stimuli. We manipulated entrainment by systematically varying the phase relation between tACS and speech rhythm, and measured the consequences for neural activity (reflected in the BOLD response) in speech-specific and auditory brain regions.
We found that, for intelligible speech, the relation between tACS phase and speech rhythm significantly modulates the magnitude of the BOLD response in the Superior Temporal Gyrus (compared to a surrogate distribution). Importantly, this modulation was specific to tACS stimulation during intelligible speech; a significant interaction showed that the effect was reduced and absent for unintelligible speech and during sham stimulation. Our results therefore suggest that entrainment has a specific, causal influence on neural responses to intelligible speech. We anticipate that tACS can have a specific effect on enhancing speech perception and comprehension which we will explore in follow-up behavioural studies.

**Abstract:** Predictive coding models of sensory processing emphasize the integration of feedforward and feedback information streams across the sensory cortical hierarchy. Studies employing local/global deviant (LGD) stimulus paradigms (e.g. Bekinschtein et al., 2009, PNAS 106: 1672-7) offer promise for elucidating the neural basis of sensory awareness. Non-invasive studies show that responses to local (within-trial) deviance are robust to changes in the level of consciousness, whereas responses to global (across-trial) deviance are not. Non-invasive recordings offer limited opportunity to investigate the contributions of specific cortical regions to these processes. This study used electrocorticography (ECoG) to refine the localization of LGD responses and test their sensitivity to loss of consciousness (LOC) under general anesthesia. Subjects were neurosurgical patients undergoing removal of intracranial electrodes placed to identify epileptic foci. Stimuli were four repetitions of a vowel, followed by the same or different 5th vowel (local deviant). Global deviance was manipulated by varying the percentage of "same" and "different" patterns. The stimuli were presented during an awake baseline period and during induction of general anesthesia with stepwise increases in propofol dose. The subjects were instructed to respond to global deviants with a button press. ECoG recordings were simultaneously made with depth electrodes implanted in the superior temporal plane and subdural grid electrodes implanted over the hemispheric convexity. Analysis of cortical activity focused on event-related potentials (ERPs) and high gamma (70-150 Hz) power. Local deviance effect - increased ERP amplitude and high gamma power - was localized to auditory cortex on the superior temporal plane and lateral superior temporal gyrus. Increases in high gamma power were more spatially restricted compared to ERP effects. Global deviance effect extended to auditory-related areas, had longer latencies and reflected the subjects' task performance. Induction of general anesthesia led to an early abolishment of global deviant effect, followed by abolishment of local deviant effect in non-primary auditory cortex. Local deviant effect in core auditory cortex was resistant to general anesthesia. Data demonstrate differential effects of general anesthesia on preattentive (local deviance) and higher-level predictive coding (global deviance) mechanisms of novelty detection in the human auditory cortex. LOC is associated with early suppression of higher-level predictive coding processes, followed by attenuation of preattentive components of auditory novelty detection.

**Title:** Effects of propofol anesthesia on connectivity within the human auditory cortical hierarchy: An intracranial electrophysiological study

**Authors: *M. I. BANKS**[1], K. V. NOURSKI[2], H. KAWASAKI[3], M. A. HOWARD, III[4]
[1]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI; [2]Neurosurg., The Univ. of Iowa, Iowa City, IA; [3]Dept Neurosurg., Univ. Iowa Hosp Clin., Iowa City, IA; [4]Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA

**Abstract:** While anesthetic action on subcortical sites likely contributes to loss of consciousness (LOC), there is an emerging consensus on the importance of disrupted cortical network connectivity, a model with extensive, but indirect, experimental support. Previously, we showed in murine core auditory cortex that feedback cortical pathways are differentially sensitive to suppression by general anesthetics compared to thalamocortical feedforward pathways. Whether this applies to the human cortical hierarchy is unclear. We addressed this issue using electrocorticographic (ECoG) recordings in neurosurgical patients during induction of propofol anesthesia.

Subjects were undergoing removal of intracranial electrodes placed to identify epileptic foci. ECoG recordings were made simultaneously with depth electrodes implanted in superior temporal plane and subdural grid electrodes implanted over the hemispheric convexity. We focused on analysis of resting-state data recorded in 5 minute blocks interleaved with responses to a local global deviant (LGD) paradigm .Data were collected during an awake baseline period and during induction of general anesthesia with incrementally titrated propofol infusion. We focused on nodes in the auditory cortical hierarchy that were responsive during the LGD paradigm: posteromedial and anterolateral Heschl's gyrus (PMHG, ALHG), planum temporale (PT), superior and middle temporal gyrus (STG, MTG), supramarginal gyrus (SMG), inferior and middle frontal gyrus (IFG, MFG). Spectral analysis was performed using multitaper methods. Functional connectivity (FC) was measured as weighted phase lag index (WPLI) in conventional frequency bands (delta to gamma), and changes in connectivity were related to with Euclidean distance between electrodes.

In SMG, IFG and MFG, propofol anesthesia was associated with large, wideband increases in spectral power, with the largest increases in the alpha band, but modest or no changes in spectral power elsewhere. Under waking conditions, gamma FC was high locally within auditory cortex (PMHG, ALHG, PT), but was lower elsewhere. Alpha FC was lower in magnitude but more far ranging. Gamma FC was largely resistant to anesthesia, whereas alpha FC, especially between distant nodes, was enhanced under anesthesia.

Data demonstrate frequency band- and region-specific effects of general anesthesia on network connectivity along the human auditory cortical hierarchy. Modest effects on gamma-band WPLI

are consistent with sparing of feedforward cortical connectivity. Enhanced connectivity in the alpha band may contribute to the loss of consciousness during induction of general anesthesia.

**Title:** EEG measurement of cognitive systems during effortful listening

**Authors: *D. RYAN**[1], S. SMITH[1], E. SELLERS[2], M. A. ECKERT[3], K. SCHAIRER[1]
[1]James H. Qullien VAMC, Johnson City, TN; [2]Psychology, East Tennessee State Univ., Johnson City, TN; [3]Otolaryngology, Med. Univ. South Carolina, Charleston, SC

**Abstract:** Adults with hearing loss who report difficulty understanding speech with and without hearing aids often also report increased mental or listening effort. Although speech recognition measures are well known and have been in use for decades, measures of listening effort are relatively new and include objective measures such as working memory tasks, pupillometry, heart rate, skin conductance, and brain imaging. The purpose of this study is to evaluate an electroencephalogram (EEG)-based method to assess cognitive states associated with high-frequency alpha (10-13 Hz), low-frequency alpha (8-10 Hz), and theta (4-8 Hz) during effortful listening. Changes in high frequency alpha have been associated with semantic memory and cognitive demands. Low-frequency alpha has been associated with working memory. In addition, changes in theta have been associated with encoding information and increased listening effort. Correlations between EEG frequency recordings, self-report, and behavioral measures in speech recognition and auditory working memory tasks will be described. Results will be presented demonstrating the extent to which high frequency alpha predicts word recognition in noise performance and self-reported listening effort.

**Title:** An anesthetic dose of ketamine disrupts mismatch activity in common marmosets

**Authors: *M. KOMATSU**[1], N. ICHINOHE[1,2]
[1]RIKEN Brain Sci. Inst., Saitama, Japan; [2]Natl. Inst. of Neurosci., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

**Abstract:** Mismatch negativity (MMN) is a component of event-related potentials evoked by violations of the regularity in sensory stimulus-sequences in human. MMN has been receiving attentions as a clinical and translatable biomarker of psychiatric disorders such as schizophrenia. In agreement with the glutamatergic hypothesis of schizophrenia, N-methyl-D-aspartate (NMDA) receptor antagonists, such as ketamine, elicit many symptoms of schizophrenia when administered to normal human subjects or macaque monkeys, including reductions in the MMN. In this study we sought to effects of NMDA-receptor blockade using anesthetic administration of ketamine on MMN in common marmosets. We recorded the electrocorticograms (ECoGs) from two common marmosets with epidurally implanted electrodes covering a wide range of cortical regions. The 28-32 channel ECoG array was epidurally implanted on the left hemisphere of each marmoset. ECoG recordings were conducted 15 min after ketamine administration (30 mg/Kg i.m.). We used a roving oddball paradigm, in which repetitive tone-sequences with 20 types of frequency (250-6727 Hz with an interval of 1/4 octaves) were randomly presented. We considered the last tones of sequences as standards, and the first tones of sequences as deviants. First, we calculated ERPs for standards and deviant stimulus, respectively. Then, difference wave is obtained by subtracting the deviant stimulus ERP from the standard stimulus ERP. In the case of awake marmosets, we have previously reported MMN-like activity in the temporal area and mismatch related activity in the frontal and parietal areas. In the case of ketamine anesthetized marmosets, we found temporal MMN disappeared or diminished and the frontal and parietal mismatch related activity disappeared. These results suggest that MMN in marmosets' temporal area is formed through the interactions with frontal and parietal areas, and ketamine disturbs the interactions.

**Title:** Distinct timescales of population coding in auditory and parietal cortices

**Authors: *C. A. RUNYAN**[1], E. PIASINI[3], S. PANZERI[4], C. D. HARVEY[2]
[1]Dept. of Neurobio., [2]Harvard Med. Sch., Boston, MA; [3]Neural Computation Lab., Inst. Italiano di Tecnologia, Rovereto, Italy; [4]ISTITUTO ITALIANO DI TECNOLOGIA, Rovereto, Italy

**Abstract:** The canonical organization of cortical circuits has led to the hypothesis that similar basic computations are performed across the cortex. However, the nature of information represented across the cortical hierarchy differs qualitatively, suggesting the possibility that the structure of population codes may differ across cortex. For example, auditory cortex (AC) represents sound stimuli that can fluctuate over tens of milliseconds, while in posterior parietal cortex (PPC), decision tasks can require the maintenance of information for several seconds. We hypothesized that population activity dynamics could differ between sensory and association cortex in order to represent information at different timescales. We imaged the activity of populations of ~50 neurons in AC and PPC, using the calcium indicator GCaMP6f, while mice performed a navigation-based sound localization task in a visual virtual reality environment. We developed a generalized linear model (GLM) to predict the activity of individual neurons using the measured behavioral variables. A Bayesian decoder based on the GLM predictions revealed sound stimulus information in AC but not PPC, and information about the mouse's choice in both regions. We characterized the functional "coupling" among neurons in AC and PPC by measuring the GLM prediction improvement when including activity of other simultaneously imaged neurons as additional predictors. The AC population was only weakly coupled: activity

of other neurons provided little prediction improvement. In contrast, the PPC population was highly coupled: activity of other neurons greatly improved the model's performance beyond what could be explained by task and behavioral features. The coupling in PPC extended across long time lags, including up to 1 second. Reasoning that time-lagged coupling could affect the timescale of the population code, we quantified the population coding timescale as the temporal consistency of the population decoder output. This timescale was twice as long in PPC as in AC. Disrupting coupling with trial shuffling shortened this timescale in PPC, but not AC. Finally, coupling and consistency were higher in PPC in trials in which the mouse performed the task correctly than in error trials. We conclude that AC and PPC populations operate in different modes. AC neurons respond independently of one another across time, resulting in a population code with a short timescale that can respond to moment-to-moment fluctuations in sensory stimuli. In contrast, responses of PPC neurons are highly interdependent across time, allowing for a population code with a long timescale that can accumulate and maintain information.

**Title:** Parallel processing of attended and unattended pattern violations in complex listening environments

**Authors: *R. M. SYMONDS**[1], E. S. SUSSMAN[2]
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Dept of Neurosci., Albert Einstein Col. of Med., Bronx, NY

**Abstract:** To successfully process the complex mixture that enters the ears, listeners must distinguish sounds of interest from unattended background sources. Attention can facilitate this processing by enhancing the representation of attended sounds in working memory; however, the degree of processing of unattended sounds is debated. Work in our laboratory, using pure tones, indicates that unattended sound streams are structured in working memory but there is a limitation on the processing of sound events within the streams. We hypothesized that increasing the distinctiveness of sound streams would strengthen automatic stream segregation and thereby decrease the overall processing load. We predicted that increasing the number of acoustic features that define each stream would allow for a greater degree of within-stream processing of unattended sounds. Event-related brain potentials (ERPs) were used as a covert measure of sound

processing. Normal-hearing adult participants performed a selective listening task in one condition and watched a movie while passively listening to the sounds in another condition. ERPs evoked by pattern violations in the unattended sound streams served as an index of within-stream processing. A similar pattern of ERP responses to unattended pattern violations were obtained between passive and active listening conditions. Our results show that in contrast to previous studies that used pure tones, when the distinctiveness of each auditory stream was high, it facilitated automatic stream segregation. Natural sound sources are defined by multiple acoustic features; thus these results indicate that non-selective processing occurs in parallel during selective listening in noisy environments.

**Title:** Acoustic startle response for tinnitus screening: Concepts, statistics and limitations

**Authors: *A. SCHILLING**, P. KRAUSS, K. TZIRIDIS, H. SCHULZE
Exptl. Otolaryngology, Erlangen Univ. Hosp., Erlangen, Germany

**Abstract:** A standard behavioral paradigm for objectively measuring a possible tinnitus percept in rodents is the paradigm proposed by Turner and coworkers in 2006 based on prepulse inhibition (PPI) modulation of the acoustic startle response (ASR) measurements obtained before and after an acoustic trauma. The major advantage of this method compared to other behavioral paradigms for tinnitus screening in animals is the absence of pre-training and therefore the lack of induction of additional cortical plasticity. However, to date no good statistical method exists to clearly determine if an animal has developed a tinnitus precept or not. Many approaches are based on simple averaging of the obtained PPI values and population comparisons without the possibility to perform valid statistics on the level of the single animal.
We here present a new statistical approach to overcome these limitations. In a first step we show that startle response amplitudes are not normal distributed. We estimate the distribution of the calculated PPIs by the full combinatorial power of all measured amplitudes and show by qq-plotting that the PPI values are approximately lognormal distributed, allowing parametrical testing of the logarithmized values. For comparison of pre and post trauma PPI distributions it has to be taken into account that the obtained values by full combinatorial power are not independent anymore. We present a statistical approach coping with this problem and finally allowing valid statistical statements about changes of PPI and about possible tinnitus percepts in animals.

**Abstract:** Forkhead box proteins (FoxPs) are implicated in vocal communication in humans. Different speech and language phenotypes have been associated with specific mutations in the respective genes encoding these transcription factors which are highly homologous across the animal kingdom. Interestingly, parallels have been discovered in phenotypes associated with dysfunctions of neuronally expressed FoxPs in different species. Experimentally manipulated versions of FoxPs, for instance, lead to altered vocalisations in vocal learning and non-learning animals.
In brains of juvenile and adult songbirds such as the zebra finch (*Taeniopygia guttata*), FoxPs are also found to be expressed. Expression of FoxPs has been observed not only in nuclei involved in song learning and production such as Area X, but also in brain regions associated with song perception that are present in female birds. However, only male zebra finches sing a song, which they learn from a tutor, whereas females do not sing. Thus, expression patterns of FoxPs across sexes and vocalisation types suggest broader roles for these transcription factors in other aspects of vocal communication, beyond their well-studied contributions to vocal production, such as auditory perception.
In order to test the role of FoxPs in adult female zebra finches, we induced a bilateral lentivirally-mediated FoxP1 knockdown in the song nucleus HVC, investigating local contributions of the gene to auditory perception. The knockdown animals were screened for behavioural differences during tasks that rely on auditory perception, using preference tests and Go/NoGo tests. Subsequently, the virally targeted brain areas were dissected and used for RNA sequencing, to investigate changes in transcriptional activity that might be linked to altered behavioural responses.
While knockdown individuals maintained their natural preference for their father's song, their internal motivation to listen to stimulus songs appeared greatly decreased as determined by lower

pecking activity to trigger playback. During tests for song preference, discrimination and categorization of altered stimuli, the knockdown and control birds performed equally well. RNA sequencing results supported the conclusion that FoxP1 plays a role in the intrinsic motivation to listen to a specific song without affecting a bird's ability to identify different sounds.
These preliminary results regarding the functions of FoxP1 in song perception and listening behaviour might shed light on the engagement of FoxPs in auditory feedback and perception which are, next to vocal motor control, critical processes underlying human speech and language learning.

**Title:** Modulation of auditory cortex responses to pure tones by optogenetic stimulation of excitatory neurons in the posterior parietal cortex, using behavior and electrophysiology methods

**Authors: *M. KYWERIGA**, N. AFRASHTEH, C. I. CHADWICK, N. PATEL, J. STEIN, M. H. MOHAJERANI
Inst. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

**Abstract:** The posterior parietal cortex (PPC) is a multi-modal sensory association area involved in auditory, visual and somatosensory perception. The auditory cortex (AC) and PPC have modest reciprocal connections and the PPC shows robust responses following sound presentation. We have replicated these findings in our own hands and hypothesized that the PPC serves in a modulatory role over the auditory cortex.
To test this hypothesis, we first performed pilot electrophysiology experiments in a small cohort

of wild-type mice to search for local field potential and multi-unit responses to pure tone pips in the PPC. We found a “hot-spot” of activity corresponding to previously reported location of PPC in layer V, which we then targeted for fiber optic implantation for further electrophysiological and behavioral characterization in transgenic mice. We used two cohorts of mice expressing Channelrhodopsin-2 in either excitatory neurons or parvalbumin (PV) interneurons using Thy1-ChR2 and PV-Ai32 strain mice respectively.
One month prior to electrophysiology experiments mice (N = 8) were implanted with a single ferrule over the left PPC. Under isoflurane anesthesia, we performed a craniotomy and durotomy over the left auditory cortex and inserted a multi-shank silicone probe into layer V. During tone presentation, we stimulated the PPC with 473 nm blue light that was continuously active for 320 ms, beginning 10 ms before sound onset until 10 ms after sound offset. We found that laser stimulation of excitatory PPC neurons caused a significant reduction of the peak LFP onset responses to pure tones. On the other hand, laser stimulation of inhibitory PPC neurons had no effect on the LFP onset responses.
We next trained water-deprived mice (N = 14), implanted with fiber optics over bilateral PPC, in the two-tone forced-choice operant conditioning paradigm. To initiate a trial the mouse poked its nose into a central port causing a single 300 ms tone to be played. To receive a small water reward, the mouse had to select the left port for low tones (8 - 11.3 kHz) or the right port for high tones (11.3 - 16 kHz). Once trained, we randomly delivered laser stimulation in half of the trials using the same parameters as above. We found that laser stimulation of excitatory PPC neurons caused strong behavioral deficits. However, laser stimulation of PPC PV interneurons had no effect on behavior.
These behavioral and electrophysiological results suggest that the PPC is responsible for suppression of onset responses to pure tones in the anesthetized mouse. Additionally, the PPC appears to be necessary for performance on the tone discrimination task.

Inst. of Sensory Organs, Natl. Inst. of Sensory Natl. Hosp. Organization Tokyo Med. Ctr., Tokyo, Japan; [5]Neurosci., Brown Univ., Providence, RI

**Abstract:** Bats have evolved unique methods of perception to navigate and catch prey using ultrasonic sounds. It has been observed that the greater horseshoe bat (*Rhinolophus ferrumequinum*) rapidly move their pinna and noseleaf structures in coordination with pulse emission and echo reception during echolocation, with everything occurring on a 100ms time scale. Sensorimotor integration is not uncommon in neural systems but bats provide a unique case for auditory processing coinciding motion in the periphery. We have developed biomimetic robotic models to replicate the dynamic emission and reception elements of bat echolocation; current data have shown these dynamics introduce time-variant effects which encode information to inform object identification and location. We have planned experiments to understand how motor and auditory systems are integrated, which will be done by recording midbrain responses interacting with stimuli. These recordings will consist of field potential measurements taken from the inferior and superior colliculi; we hope this work will provide physiological events associated with sensorimotor integration for echolocation.

**Title:** Auditory attention detection in a non-stationary multi-speaker environment

**Authors: *E. TEOH**[1], E. C. LALOR[2]
[1]Trinity Col. Dublin, Dublin, Ireland; [2]Univ. of Rochester, Rochester, NY

**Abstract:** Recently, it has been shown that attentional selection in a naturalistic multi-speaker environment can be robustly decoded from electroencephalography (EEG) (O'Sullivan et al., 2014). In particular, this is done by relating the acoustic envelope of a speech stimulus to the concurrently recorded EEG. Studies so far have nonetheless only considered this problem in the context of stationary speakers. In real life situations, this is usually not the case - speakers are typically more dynamic.
Here, we employ a paradigm in which the listener has to regularly alter their attended direction during the course of a trial. Specifically, participants are asked to attend to one of two speakers (located on their right and left) presenting continuous natural speech whilst EEG is recorded from their scalp. The speakers' perceived locations in space are swapped around at short intervals such that participants have to repeatedly vary their locus of attention to track their target speaker.
We show that decoding of the attended speaker is robust to the frequent changes in their location - the overall accuracy is comparable to previous studies. Additionally, we also investigate oscillatory measures of attention and suppression. In previous studies, it has been shown that EEG alpha band activity is lateralised according to the direction of attention. Consistent with these findings, computation of the alpha Attention Modulation Index (AMI; Wöstmann et al., 2016) by averaging of alpha (8 - 14Hz) power following each switch across all trials shows lateralisation over the occipital scalp area. Moreover, preliminary attempts for decoding attention using the AMI on a trial-by-trial basis lead to accuracies above the chance level.

**Abstract:** When interpreting hemodynamics-based measurements as in fMRI, the HRF is assumed to reflect neurovascular coupling to local neural responses (here, spiking). This coupling is believed to remain locally consistent although its strength can change between drowsy and alert states (Schölvinck et al. 2010). Here we tested if the HRF remained consistent even when switching between states of drowsiness and alert engagement in a task.
We recorded multi-unit spiking activity (MUA) simultaneously with intrinsic-signal optical images (specifically, blood volume) from macaque primary visual cortex (V1). The animal's task, which consisted of periodically holding fixation for a juice reward, elicits a powerful task-related hemodynamic response that entrains to task timing independent of visual stimulation (Sirotin and Das, 2009). We recorded extended sessions in total darkness other than the small (~2 arc min) fixation cue. The recordings thus included segments when the animal was actively engaged in the task, interspersed with segments when he shut his eye and appeared to drift asleep.
During the alert segments the measured hemodynamics was dominated by the task-related response, while the ongoing MUA showed a weak task-entrained modulation in response strength. During drowsy segments the hemodynamics showed large phasic increases in local blood volume while the MUA showed large, multi-second bursts. We used deconvolution to obtain the HRF linking the hemodynamics to the MUA over a moving window (typically 150 sec) sampling alert and drowsy segments. The 'drowsy' HRF resembled a standard causal HRF kernel predicting an increase in local blood volume following the spiking, with the typical times to peak and peak width. The 'alert' HRF was distinctly different, with an acausal temporal profile reflecting the periodic task timing, and a reversed sign predicting local decrease of blood volume following spiking. (This reversed sign is consistent with slight increase of spiking seen following the increased blood volume). Cross validation between the two epochs was poor: the mean of the 'drowsy' HRF kernels gave consistently good predictions (quantified by Pearson's r) over the drowsy segments, but gave incorrect phase-reversed predictions in the alert segments. Neurovascular control thus likely involves very different neural mechanisms in drowsy vs. alert engaged states. These results should have considerable bearing on our understanding of the HRF, and the interpretation of fMRI in terms of local neural activation.

**Title:** Stimulus vignetting and coarse-scale biases for orientation in human visual cortex

**Authors: Z. N. ROTH**[1], D. J. HEEGER[2], *E. P. MERRIAM[1]
[1]Lab. of Brain and Cognition, NIMH, Bethesda, MD; [2]Dept Psychol & Ctr. Neural Sci., New York Univ., New York, NY

**Abstract: Purpose:** Multivariate analyses are widely employed in human fMRI studies. But there is considerable controversy over what decoding analyses reveal about underlying neural architecture. We previously demonstrated that a coarse-scale bias for radial orientations in human primary visual cortex (V1) is both necessary and sufficient for orientation decoding (Freeman et al., 2011). It has been hypothesized that the radial bias is related to the edge of the stimulus aperture, rather than a neural preference for radial orientations (Carlson, 2014, Wang et al., 2014). We tested this possibility by measuring cortical activity with fMRI to oriented gratings modulated by two different apertures.
**Method:** Stimuli consisted of a carrier grating multiplied by a modulator. The carrier was a Cartesian sinusoidal grating that filled an annulus extending from 0.5 to 10 deg. The orientation of the stimulus changed every 1.5 s, cycling through sixteen evenly-spaced angles (0-180 deg) in 24 s. The modulator was a second sinusoidal grating that was constant throughout each fMRI run (i.e., it did not change orientation or phase). On half the runs, the modulator had an angular orientation, producing a series of ‘spokes’ centered on the fixation cross. On the other half of runs, the modulator had a radial orientation, producing a series of ‘rings’ emanating from the fixation cross. The fMRI data analysis characterized the preferred orientation for each voxel to the carrier grating. Five volunteers were scanned with a 3T Siemens Allegra at NYU (8-ch phased-array surface coil, 24 slices, voxel size 2×2×2 mm). Seven volunteers were scanned with a 7T Siemens Magnetom at NIH (32-ch coil, 54 slices, voxel size 1.2×1.2×1.2 mm).
**Results:** The majority of voxels in V1 exhibited robust and reliable orientation preferences to the carrier grating, confirming that fMRI responses in human V1 are selective for orientation. However, the orientation preference of most voxels were determined by the orientation of the modulator grating. For the radial modulator, voxels exhibited a radial bias. For the angular

modulator, voxels exhibited a tangential bias (i.e., rotated 90 deg from radial). We observed no evidence for orientation tuning that was unaffected by the orientation of the modulator grating. **Conclusions:** Ostensible orientation tuning in fMRI activity arises from interactions with the edge of the stimulus aperture.

**Title:** Viewing cortical processing in sensory space

**Authors: *A. T. MORGAN**[1], L. S. PETRO[2], L. MUCKLI[2]
[1]Inst. of Neurosci. & Psychology, [2]Univ. of Glasgow, Glasgow, United Kingdom

**Abstract: Introduction:**
Comparing information processing properties of different cortical areas is a fundamental challenge for systems neuroscience and can provide key insights to the interactions and information transformations executed by the brain. Information-based methods such as Representational Similarity Analysis (RSA; Kriegeskorte, at al. 2008) are powerful approaches that capitalize on multi-variate properties of neuroimaging signals to model the informational structure of brain areas. However, we show that examining model weights from V1 and V2 fMRI responses in visual space provides additional detail about retinotopically localized processing in each area compared to using RSA alone.
**Methods:**
We presented 24 partially occluded scenes to 18 participants and modelled V1 and V2 response differences in three image quadrants using RSA (Walther, et al. 2015). We projected models to visual space by weighting each voxel's population receptive field function (Dumoulin & Wandell, 2008) by its corresponding average model weight in each scene and summing across the visual field (Kok and de Lange, 2014; Thirion, et al. 2006). For comparison, we projected voxel response differences from the mean response to all images.
**Results:**
RSA model weight projections corresponded substantially more to visual features in the visible portions of scenes than response projections (Figure 1). In occluded portions of scenes, responses

did not vary much from their mean. However, model weight projections showed consistent retinotopic information sources across subjects, even in the absence of feedforward scene information, and these information sources differed between V1 and V2.

**Conclusions:**

We have shown that examining RSA models weights as visual space projections provides important detail about scene features that enable multi-voxel scene decoding. Importantly, this method is compatible with data from any sensory modality, and viewing weights in sensory space enables subject-, cortical area-, cortical layer-, task-, and computational model-based comparisons of information maps.

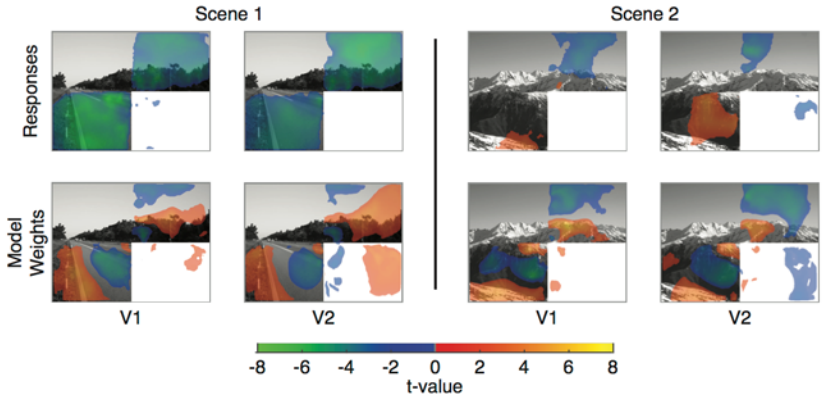

**Figure 1:** We calculated population receptive fields (pRF; Dumoulin & Wandell 2008) for V1 and V2 voxels from an fMRI dataset consisting of 18 subjects viewing 24 partially occluded visual scenes (Morgan, et al. 2016). For response projections (first row), voxel responses were projected by calculating a weighted average of all voxels' pRFs, where weights were each voxel's response amplitude with the mean response to all scenes removed. For model weight projections, the relative contributions to an LDA solution were averaged for each voxel (for significant classifications involving each scene) and weights were projected similarly to responses. In both projection types, a two-tailed t-test was conducted across subject maps at each pixel location to obtain t-value maps ($p < 0.05$ threshold). In response projections, warm colors show above-mean responses and cool colors show below-mean responses. In model weight projections, warm colors are visual areas where voxel activation is indicative of the respective scene and cool colors are areas where voxel activation is indicative of a different scene (across comparisons to 23 other scenes).

**Abstract:** The ability to map brain networks in living individuals is fundamental in efforts to chart the relation between brain and behavior in health and disease. We present a framework to encode brain connectomes and diffusion-weighted magnetic resonance data into multidimensional arrays. The framework goes beyond current methods by integrating the relation between connectome nodes, edges, white matter fascicles and diffusion data. We demonstrate the utility of the framework for in vivo white matter mapping and anatomical computing by evaluating more than 3,000 connectomes across thirteen tractography methods and four data sets in normal and clinical populations.
We show that this framework allows mapping connectivity matrices, edge anatomy, and microstructural properties of the white matter tissue in each connectome edge. The framework is based on statistical evaluation principles introduced with the Linear Fascicle Evaluation and virtual lesions methods (LiFE; Pestilli et al., 2014). In short, instead of building networks by relying uniquely on the terminations of fascicles into the cortex, we exploit the full measured signal available for each connectome edge and node by extracting a forward-prediction of the biological tissue properties of the edge. We validated the framework by comparing results with measures standard connectome measures (fiber count and density). To do so, we generated ten repeated-measures connectomes in each individual brain in various datasets, using different tracking methods. For each connectome estimated in an individual brain, we computed the mean network clustering coefficient across repeated measures. We demonstrate the high reliability of the clustering measures in individuals. We also demonstrate profound differences in connectomes across brains, beyond what can be captured using standard measures (fiber density). We also show that the proposed method is highly sensitive to differences between individuals by improving subject classification into various diagnostic groups. Finally, we show that the framework is useful in clarifying fundamental properties of the human visual white matter as well as identifying useful network science biomarkers for predicting degenerative changes in the Alzheimer's brain.

We publish the method with software compatible with data from the Human Connectome Project, the Alzheimer Disease Neuroimaging Initiative, and Indiana Alzheimer Disease Center Data. The software integrates the Brain Connectivity Toolbox and is available open source GitHub.com/brain-life and stand-alone at hub.docker.com/u/brainlife.

**Title:** Cortical depth and profile modeling for laminar MRI

**Authors:** ***P.-L. BAZIN**[1,2,3], A. FRACASSO[1,4], S. O. DUMOULIN[1], N. PETRIDOU[5]
[1]Spinoza Ctr. For Neuroimaging, Amsterdam Zuidoost, Netherlands; [2]Social Brain Lab., Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [4]Radiology, [5]Radiology, Imaging Div., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

**Abstract:** Recent advances in ultra-high field MRI have enabled to probe intra-cortical details of structure and function in living humans at sub-millimetric resolutions. The laminar structure of the neocortex provides a natural coordinate system for intra-cortical mapping, with cortical layers defining depth and cortical profiles following the vertical organization of cortical columns, intra-cortical vasculature, and incoming white matter fibers. Unfortunately, the best achievable resolution in MRI is still very coarse with regard to these structures and cortical depth and profiles need to be defined from macro-anatomical information, namely the white matter boundary and pial surface.
Here, we present and compare computational strategies to 1) define cortical depth with a distance-preserving or volume-preserving model, 2) measure intra-cortical features along cortical profiles with local profiles and ROI-based spatial general linear model (GLM) methods, and 3) smooth data along cortical layers. Unlike current surface-based methods, our approach works directly in volumetric space and samples all available data according to their partial volume estimates. To study the impact of different modeling strategies on intra-cortical data, we applied the methods to two ultra-high resolution MRI data sets both acquired with a T2*-weighted 3DEPI sequence on a Phillips 7T scanner with a dedicated 32-channel surface receive coil. First,

a 0.3 mm isotropic resolution anatomical image of the occipital pole was acquired on a single subject, showing the Stria of Gennari as well as many intra-cortical draining veins. Second, a 0.55 mm isotropic resolution functional scan was acquired in four subjects while participants viewed an alternating left and right sided dartboard pattern to induce differential activation in visual areas.
Our results show that a volume-preserving model with a spatial GLM provides the best fit to small regions of interest, compared to pooling individual profiles. The distance-preserving depth model introduces a widening and shift of intra-cortical profiles in curved regions. Local profiles have lower contrast, however the limited resolution along cortical depth impacts the stability of the GLM estimation. While laminar smoothing did not increase stability and did reduce contrast, we show that a approximation of the GLM by partial volume mixtures removes the instability entirely while retaining the higher contrast. Taken together, these results indicate that the estimation of subtle intra-cortical signal in anatomical and functional MRI requires carefully optimized cortical depth and profile modeling strategies.

**Title:** Linear responses across lamina in early visual cortex using sub-millimetre resolution fMRI

**Authors: *J. VAN DIJK**[1,2], A. FRACASSO[1,2,3], S. O. DUMOULIN[1,2]
[1]Spinoza Ctr. For Neuroimaging, Amsterdam, Netherlands; [2]Utrecht Univ., Utrecht, Netherlands; [3]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

**Abstract:** A fundamental assumption of nearly all fMRI methods is that the relationship between local neuronal activity and the fMRI signal is linear. Experimental evidence supports this notion for fMRI at conventional resolutions (>1mm isotropic). Recent advances in ultra-high field MRI (7T) allowed for high-resolution (sub-millimetre) fMRI. A novel and promising application of sub-millimetre fMRI is laminar imaging, i.e. measuring fMRI-responses across the thickness of the cortex, in particular to dissociate feed forward and feedback signals as they arrive at different lamina. However, known blood supply differences across lamina strongly affect the signal and may also affect the linearity of the signal over cortical lamina.
We collected fMRI data at 0.7mm isotropic, using a GE 3D-EPI sequence on a Philips 7T

scanner with 32-channel surface receive coils. We additionally collected 5 extra volumes with the opposite phase encoding direction to correct for geometrical distortions induced by the static magnetic field. Participants viewed sine-wave gratings in a circular aperture (9.5deg diameter) for 12 seconds, with 5%, 20%, and 80% contrast. We computed percentage response amplitude for each contrast. The statistical maps were distortion-corrected, and coregistered to a high-resolution (0.65mm isotropic) anatomy. Computational cortical layers were defined using an equivolume approach. We selected V1 voxels using independent visual field mapping.
We obtained strong responses in V1 for all contrasts and for all subjects. Signal amplitudes increased with increasing stimulus contrast. This increase was non-linear, as expected from the known non-linear contrast response function in the visual cortex. The signals also increased systematically as a function of cortical lamina, where responses increased towards the pial surface. Having taken into account the non-linear contrast response function, the laminar profiles for each contrast could be accurately modelled as a scaled version of the response to any other contrast, suggesting strong linearity of response profiles across lamina.
Our results provide evidence for a linear response function across lamina, despite known blood supply differences across lamina. This suggests that the assumption that the BOLD response is linear holds not only for regular, but also for sub-millimetre fMRI and laminar imaging.

**Title:** A second-order orientation-contrast stimulus for population-receptive-field-based retinotopic mapping

**Authors: *F. YILDIRIM**[1,2], J. CARVALHO[1], F. W. CORNELISSEN[1]
[1]Univ. of Groningen, Groningen, Netherlands; [2]Biomed. Engin., Boston Univ., Boston, MA

**Abstract:** Visual field or retinotopic mapping is one of the most frequently used paradigms in fMRI. It uses activity evoked by position-varying high luminance contrast visual patterns presented throughout the visual field for determining the spatial organization of cortical visual areas. While the advantage of using high luminance contrast is that it tends to drive a wide range of neural populations – thus resulting in high signal-to-noise BOLD responses – this may also be a limitation, especially for approaches that attempt to squeeze more information out of the BOLD response, such as population receptive field (pRF) mapping. In that case, more selective stimulation of a subset of neurons – despite reduced signals – could result in better characterization of pRF properties. Here, we used a second-order stimulus based on local differences in orientation texture – to which we refer as orientation contrast – to perform retinotopic mapping. Participants in our experiment viewed arrays of Gabor patches composed of a foreground (a bar) and a background. These could only be distinguished on the basis of a difference in patch orientation. In our analyses, we compare the pRF properties obtained using this new orientation contrast-based retinotopy (OCR) to those obtained using classic luminance contrast- based retinotopy (LCR). Specifically, in higher order cortical visual areas such as LO, our novel approach resulted in non-trivial reductions in estimated population receptive field size of around 30%. A set of control experiments confirms that the most plausible cause for this reduction is that OCR mainly drives neurons sensitive to orientation contrast. We discuss how OCR – by limiting receptive field scatter and reducing BOLD displacement – may result in more accurate pRF localization as well. Estimation of neuronal properties is crucial for interpreting cortical function. Therefore, we conclude that using our approach, it is possible to selectively target particular neuronal populations, opening the way to use pRF modeling to dissect the response properties of more clearly-defined neuronal populations in different visual areas.

**Title:** Geostatistical mapping of high-resolution fMRI reveals size and arrangement of high-signal clusters of BOLD activity in visual cortex

**Authors: *A. J. PARKER**[1], H. BRIDGE[2]
[1]DPAG, Oxford Univ., Oxford, United Kingdom; [2]FMRIB, Nuffield Dept. of Clin. Neurosci., Oxford Univ., Oxford, United Kingdom

**Abstract:** Functional topography is present throughout the cerebral cortex, often in the form of columns or clusters of neurons with similar functional properties within identified cortical regions. Most of the evidence for these structures comes from work with non-human species. Using 7-Tesla functional MRI, with gradient-echo echo-planar imaging at 0.75 mm isotropic resolution in human visual cortex, we used a phase-encoded paradigm in which binocular stereoscopic depth was changed steadily over time from -0.21 to +0.21 degrees disparity in ramped sawtooth waveform. The BOLD signals showed significant clustering and topographical structure in extrastriate visual areas V2, V3 and V3a.
The definition of clustered structures is frustrated by the presence of a background of local spatial correlations in the BOLD signal across the cortical surface. This structured background, which we term 'neural dust', is a form of noise that imposes a fundamental limit on the detection of clustering and topography. We apply a novel analysis approach that quantifies these background, spatial correlations. We measure the variogram, a distant-dependent measure of variance, which is applicable to discrete pairs of sample points and analogous to the autocorrelation function for continuous data. For two observations $Z_i$ and $Z_j$ at points $u = (x_i, y_i)$ and $v = (x_j, y_j)$ the variogram $\gamma$ is given by $2\gamma(u, v) = var\ (\ Z(u) - Z(v)\ )$, where *var* is the variance. We divide the population of voxels into groups having low- and high-signal coherence (< 0.3 or >= 0.3 correlation with the disparity waveform). For low-signal voxels, the variogram rises to a plateau as distance increases. The range over which the variogram rises quantifies the spatial correlations, which limit the practical resolution of the MR images to approximately 1mm (Gaussian half-width), closely similar to the physical limit predicted for the imaging system. Variogram analysis allows reliable identification of high-signal clusters of activation in the human cortex. We show that high-signal voxels modulated by stimulus changes of binocular stereoscopic depth occur in clusters, resulting in a systematic mapping of disparity-defined depth in regions of human early visual cortex. These high-signal clusters, on a scale as large as 12-15mm, were reliably identified across the cortical surface of all subjects tested, predominantly within visual cortical area V3A. These methods provide an objective approach for defining the size and locations of clusters of cortical fMRI activation to enable comparison with invasive methods that are less affected by noise.

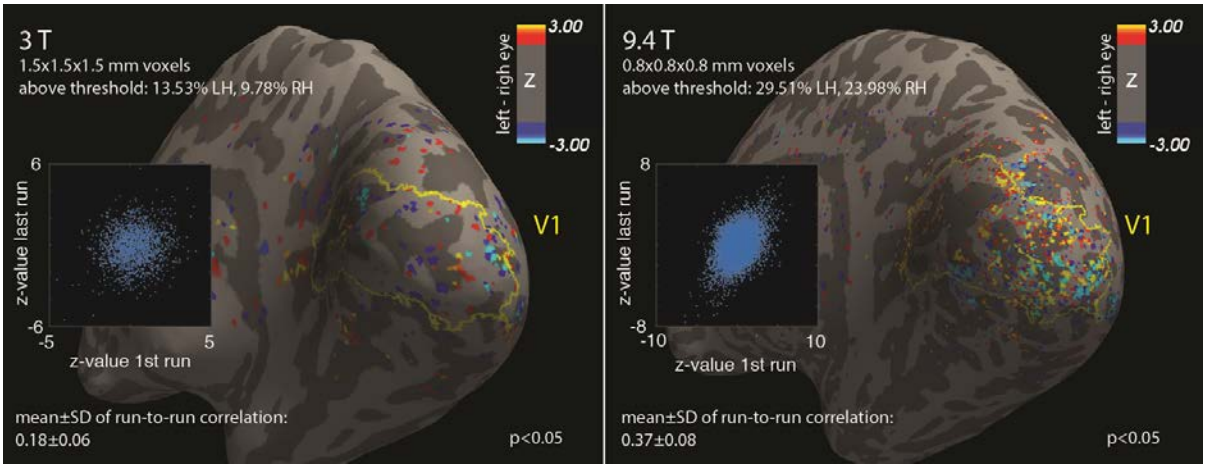
Sch., Charlestown, MA; [8]Harvard-MIT Div. of Hlth. Sci. and Technol., MIT, Cambridge, MA

**Abstract: Introduction**
The primary visual cortex of humans contains patches of neurons responding preferentially to stimulation of one eye (ocular dominance columns) (Adams et al., 2007). The majority of previous fMRI studies reporting eye-specific activity in V1 used magnetic field strengths of 4 T and higher (Cheng et al., 2001; Yacoub et al., 2007; Nasr et al., 2016). However, there have been reports of reliable eye-selective activations at 3 T (Haynes et al., 2005). Here we present preliminary results on the ability to detect eye-selective V1 activity using high-resolution fMRI at 3 T and 9.4 T.
**Methods**
BOLD signal of one healthy adult volunteer was measured at 3 T and 9.4 T using 2D GE-EPI (3 T: 1.5mm isotropic resolution, TR/TE/matrix/GRAPPA = 1720/30/128x128x24/R=3, 873 volumes; 9.4 T: 0.8mm isotropic resolution TR / TE / matrix / GRAPPA=2 s / 22 ms /230×230×40 / R=5, FLEET autocalibration (Polimeni et al., 2016), 900 volumes). Each eye was stimulated separately with a checkerboard flickering at 2 Hz for 18 s with 18 s breaks, viewed through a prism stereo display (Schurger, 2009). Structural scans (1mm$^3$ for 3 T and 0.6 mm$^3$ for 9.4 T) were acquired in each session for cortical surface reconstruction.
All analyses were performed using FreeSurfer 6.0 and FS-FAST (Fischl, 2012). Functional data

were motion-corrected, co-registered to the anatomy using boundary-based registration (Greve and Fischl, 2009) with 6 DOF for 3 T and 9 DOF locally constrained to V1 for 9.4 T, and analyzed using voxel-wise GLM with left eye, right eye and baseline regressors. Surface-based prediction of V1 location (Hinds et al., 2008) was used to label volume voxels belonging to V1 gray matter, and z-statistics of the contrast “left eye vs. right eye” were extracted from those voxels.

**Results**

We observed a more than two-fold increase in the percentage of eye-selective voxels and in run-to-run correlation of eye preference at ultrahigh field.



**Conclusion**

Increase in spatial resolution and improved BOLD point spread function at 9.4T allows for better detection of eye-selective signal related to ocular dominance columns.

**Title:** Improvements for periodic intrinsic signal imaging of mouse visual cortex

**Authors: *J. BOLZ**[1], M. TEICHERT[2]
[1]Univ. Jena, Jena, Germany; [2]Inst. Für Allgemeine Zoologie Und Tierphysiologie, Jena, Germany

**Abstract:** One major aspect of neuroscience is to characterize responses of sensory cortices evoked by external stimuli. A well-established technique allowing such investigation is optical imaging based on intrinsic signals. It enables non-invasive measurements of cortical activity over large brain areas with a high spatial resolution (Kalatsky and Stryker, 2003). Intrinsic imaging is a frequently used method for characterization and measurement of stimulus evoked responses e.g. in the primary visual cortex in mice (Kaneko et al., 2008; Isstas et al., 2017). For stable and reproducible results it is particularly important to control the anesthetic state of the animal during the recording session. Here, we examined how cortical maps are influenced by cardiopulmonary alterations. For this, we increased the concentration of isoflurane stepwise from 0.5% to 1.25% during one imaging session. At each step we measured the respiration rate (RR), the heart rate (HR) and the amplitude of visual cortex responsiveness evoked by visual stimulation. Our results demonstrate that the RR is a suitable and reliable indicator for anesthetic depth under isoflurane anesthesia which highly correlates with the strength of elicited visual cortex activity at the level of individual animals. In contrast, the HR appeared to be only a weak indicator for the anesthetic depth. Furthermore, we developed a novel technique which enables to determine the cortical visual acuity and contrast sensitivity using periodic imaging in a fast and simple manner. To validate this new method, we first determined contrast sensitivity and visual acuity in the visual cortex dependent behavioral visual water task (VWT). Then, we measured these attributes of vision with our adapted intrinsic imaging method in the same mice. Strikingly, our results showed that the data obtained in the VWT and by intrinsic imaging were almost identical, even at the level of individual animals. In conclusion, compared to established behavioral or electrophysiological methods for the determination of visual performance and perception in rodents which are time consuming or require complex and invasive surgeries (Porciatti et al., 1999; Prusky et al., 2000) our novel approach is quasi non-invasive and speeds up the experimental time to about 2 h. Taken together, we show that periodic intrinsic imaging is a powerful method for determining reliable values of visual perception in mice which provides clear advantages above conventional methods to measure mouse visual perception.

**Title:** Anion channelrhodopsin suppresses neural activity in awake monkeys

**Authors: *S. DEBES**[1], A. R. ANDREI[2], R. JANZ[3], V. DRAGOI[4]
[1]Neurobio. and Anat., Univ. of Texas At Houston, Houston, TX; [2]Neurobio. & Anat., McGovern Med. Sch., Houston, TX; [3]UT-Houston Med. Schl, Houston, TX; [4]Dept Neurobiol/Anat, Univ. of Texas at Houston Dept. of Neurobio. and Anat., Houston, TX

**Abstract:** Optogenetic methods allow for causal, cell specific perturbation of neuronal circuits. While ChR2 is widely used as a cation channelrhodopsin, we have yet to find an anion channelrhodopsin with similarly robust qualities for optogenetic suppression. Effectively suppressing neural firing would allow the investigation of neuronal circuit function in behaving animals. In this study we used a novel anion channelrhodopsin, *Gt*ACR2 to suppress neural responses of glutamatergic cells in the primary visual cortex (V1) of two awake, behaving rhesus macaque monkeys (*macaca mulatta*). *Gt*ACR2 is a light-gated chloride channel, packaged in a lentivirus vector with a CaMKIIα promoter and injected into multiple sites of V1. After waiting six weeks for the virus to express, laminar probes were used to collect single and multi-unit activity. Recordings were performed in parallel with optical inactivation using a laser-connected fiber optic cable. Monkeys completed a contrast detection task in which they maintained fixation on a central point while gratings of various contrasts were presented at parafoveal locations. Animals signaled the presence or absence of a stimulus. On half of the trials, optical stimulation was continuously presented during the entire stimulus presentation (300 ms). Across cells, we found that neuronal firing during stimulus presentation was suppressed by an average of 5.7 spikes per second (± 4.1) during the laser trials compared to control trials. Additionally, we found that the largest response suppression (laser vs. control) was 9.3 spikes per second (± 4.7); this difference was statistically significant ($P$=0.0058, Student's t-test). The largest suppression magnitude occurred 221.8 ms (± 16.3) after laser onset, however, this difference did not return to baseline until 258.8 ms (± 27.6) after laser offset. Overall, our results indicate that *Gt*ACR2 is an adequate tool for optogenetic suppression *in vivo* in the non-human primate brain.

**Abstract:** Many animals orient using visual cues, but how a single cue is selected from among many is poorly understood. *Drosophila melanogaster* are known to display a wide variety of innate and learned visual behaviors, including visually guided spatial navigation. Here we show that ring neurons—central brain neurons implicated in compass navigation—display a form of visual stimulus selection. By using *in vivo* two-color two-photon imaging with genetically encoded calcium indicators GCaMP6f and jRGECO1a, we quantitatively compared visual responses of individual ring neurons to those of their upstream partners. Ring neurons inherit their simple-cell-like receptive fields from these upstream inputs. Visual responses of both populations were systematically suppressed in the presence of an identical stimulus presented in parts of the contralateral visual field, but this suppression was more pronounced in the ring neurons. The spatial profile of contralateral suppression was consistent with inhibition arising from the summation of the receptive fields of the identical population of neurons on the contralateral side. Finally, the strength of this suppression depended on when the contralateral stimulus had been presented, an effect stronger in ring neurons than their upstream inputs. The history-dependent effect on the temporal structure of ring neuron responses, which was well modeled by a simple biphasic filter, may determine how landmarks are selected as references for the fly's internal compass. Our approach also highlights how two-color calcium imaging can be used to localize the origins of sensory transformations across synaptically connected neural populations.

**Abstract:** Historically, most studies of receptive fields were undertaken using electrophysiology, with a notable, recent shift towards calcium imaging as a method of choice. Extracellular electrophysiology and $Ca^{2+}$ imaging both constitute noisy observations of the underlying neural activity. However, the statistical properties of the raw signals, as well as the sources and effects of the introduced noise are quite distinct. To interpret receptive field maps derived from $Ca^{2+}$-imaging in the context of existing literature, it is therefore crucial to understand how these differences are reflected in the detectability and properties of receptive fields derived from extracellular spike trains as compared to those obtained from $Ca^{2+}$-dependent fluorescence traces, respectively. To address this issue, we first compute receptive fields from extracellular spike trains recorded in mouse V1 directly using the spike-triggered average. In a second step, we auto-calibrate a biophysical (forward) model that relates spiking activity to observed fluorescence (MLspike, [1]) on data from the Allen Brain Observatory (http://observatory.brain-map.org/visualcoding/), a public resource, which provides a standardized in vivo characterization of single neuron activity in the mouse visual cortex based on $Ca^{2+}$-imaging. Following this calibration, we then compute model calcium activity for above spike trains. The obtained synthetic fluorescence traces are subsequently analyzed using a method developed for mapping of classical receptive fields in the Allen Brain Observatory, based on responses to a locally sparse noise stimulus.
We find that this analysis readily yields receptive fields that largely agree with those identified directly from the electrophysiological recordings, and investigate the sensitivity of the obtained receptive field structure to the parameterization of the forward calcium model. In the future, this data-driven modeling approach may provide a Rosetta Stone for receptive field comparison across recording modalities, as well as inspire improvements to algorithmic receptive field fitting procedures.

**Title:** Measuring cellular-level interactions across multiple areas in mouse visual cortex using parallel silicon probe recordings

**Authors: *J. H. SIEGLE**, X. JIA, D. J. DENMAN, R. DIETZMAN, C. KOCH, S. R. OLSEN
Allen Inst. for Brain Sci., Seattle, WA

**Abstract:** The Allen Institute has performed an extensive characterization of the response properties of cells in individual visual areas using 2-photon imaging of genetically encoded calcium sensors (http://observatory.brain-map.org/visualcoding). But to understand how the visual system achieves dynamic coordination between brain regions, it is necessary to monitor the activity of multiple areas simultaneously with single-spike temporal resolution. To study this, we built a rig capable of targeting arrays of extracellular electrodes to retinotopically matched regions of mouse cortical visual areas, including AM, PM, RL, LM, and V1. Using miniature 3-axis linear stages from New Scale Technologies, we are able to align up to six 384-channel Neuropixels probes to area maps obtained via intrinsic signal imaging (wild-type mice) or though-skull widefield imaging (Emx1-IRES-Cre; Camk2a-tTA; tetO-GCaMP6s mice). We recorded spiking activity across all 6 cortical layers in response to a variety of visual stimuli, including drifting gratings, white noise, and natural scenes. We measured functional connectivity between layers and areas using cross-correlograms, mutual information, conditional firing rate correlations, and Granger causality. In the future, we plan to scale this paradigm into a pipeline capable of collecting highly standardized experiments across large numbers of mice.

**Abstract:** Morphology and connectivity are two defining features of cell types. We use large-scale Transmission Electron Microscopy (TEM) to characterize such features of neocortical neurons. In this study we describe our efforts to create samples that allow the reconstruction of the wiring diagram of neocortical circuits at synapse resolution of mice and humans, as well as characterization of their cell types.
We developed *en bloc* staining protocols to prepare tissue for large-scale (> 1 $mm^3$) serial-section TEM. We are incorporating methodology from different reduced osmium (rOTO) protocols (Hua et al., Nature Communications 2015), to see what permutations will break the "osmium shell" caused by the formation of physical barriers to diffusion. These permutations include the addition of formamide, substitution of pyrogallol for thiocarbohydrazide (Mikula and Denk, Nature Methods 2015), and lengthening of the OTO (osmium-thiocarbohydrazide-osmium) step. We demonstrate the use of this protocol in both perfused mouse visual cortex and from drop-fixed human surgical biopsies.
Circuit-level electron microscopy connectivity studies would also benefit from cell-type specific markers that would link morphological descriptions to genetic tools. The Allen Institute has developed a transgenic mouse reporter line (Ai133) expressing the genetically encoded peroxidase APEX2. When bred with the Scnn1a-Tg3-Cre driver line, APEX2 is expressed in the cytosol of select neurons in layer 4 of primary visual cortex. Combining the APEX2 protocol with our refined *en bloc* rOTO staining protocol produced tissue with high contrast membranes and cytosolic contrast in the genetically tagged cells, permitting auto segmentation of the final image stacks.
All samples showed well-preserved ultrastructure with well-defined membranes, clear synaptic structure, and high contrast. It is critical to avoid on section staining of the serial thin sections on films mounted on copper grids or grid tape. These protocols eliminate the need to post section stain and avoid the risk of contamination by precipitate and dirt. The high contrast enables the short imaging times necessary for our large-scale, high throughput imaging method.

**Abstract:** Modern genetic approaches have allowed for unprecedented access to diverse types of neurons within the mammalian brain and have greatly facilitated the study of their function. In parallel, the development of highly sensitive sensors and optical tools has enabled the labeling of diverse cell types, the perturbation of neuronal activity with precise temporal control and the visualization of distinct neural states. Over the last several years we have developed multiple gene expression platforms in mice using various molecular genetic approaches that achieve high levels of fluorescent proteins, sensors, and optogenetic tools within selective cell populations, defined largely by unique Cre driver lines. The TIGRE locus (Zeng, H et al., PLOS Genetics 2008) represents one of our favored platforms for transgenic production because it is uniquely permissive for tetracycline-inducible regulatory elements and because it achieves transgene expression comparable to that achieved with viral methods. Here we will report our newest TIGRE 2.0 Cre-dependent reporter lines that were generated using our previously published strategy (Madisen L et al., Neuron, 2015). This new collection of reporters include tools that will enable optical physiology, optogenetics, and sparse labeling of genetically defined cell populations. TIGRE 2.0 reporters offer several key advantages compared to our first generation of TIGRE lines such as a more simplified breeding strategy and robust transgene expression within different populations of interneurons and neuromodulatory cell types. Anatomical and functional data for several TIGRE 2.0 reporter lines will be presented and the lines currently under development will be described. These novel transgenic lines will greatly expand the repertoire of high precision genetic tools available to effectively identify, monitor, and manipulate distinct cell types within the mammalian brain.

**Title:** Cell-type-dependent relationship between *In vivo* calcium events and spiking activity in transgenic mouse lines

**Authors: U. KNOBLICH**, *L. HUANG, P. LEDOCHOWITSCH, M. A. BUICE, J. WATERS, C. REID, C. KOCH, H. ZENG, L. LI
Allen Inst. for Brain Sci., Seattle, WA

**Abstract:** Genetically encoded calcium indicators (GECIs) have been widely used with two-photon (2-p) imaging to report action potentials (spikes) within local populations of neurons in vivo. However, the relationship between observed calcium events and spiking activity is not yet fully understood, making it difficult to link these studies to the large body of existing knowledge about neuronal activity. This spike-to-calcium transfer function depends on several factors including the properties of the GECIs, the neuronal cell-types expressing GECI (due to differences in intracellular calcium dynamics), GECI expression level, and the behavioral state of the animal (due to changes in calcium dynamics, e.g. by neuromodulators). Recent advancement in transgenic mouse lines offers better opportunities, compared with the viral expression, to achieve more uniform expression of GECIs in genetically defined populations of neurons, enabling a more straightforward comparison of activity across cells and animals. Using our newly developed intersectional transgenic mouse lines expressing GCaMP6f or GCaMP6s in a Cre-dependent manner, we perform concurrent 2-p calcium imaging and 2-p targeted cell-attached recordings in the same neurons to simultaneously measure spiking and calcium activity to directly characterize their transfer function. These results will be beneficial for interpreting existing as well as future calcium imaging data such as the output of the Allen Institute's Allen Brain Observatory.

**Title:** Recording from large ensembles of neurons with high-density electrophysiology and two-photon calcium imaging in primate primary visual cortex

**Authors: *A. K. GARG**[1,2], P. LI[1], E. M. CALLAWAY[1]
[1]Systems Neurobio. Labs., Salk Inst. for Biol. Studies, LA Jolla, CA; [2]Neurosciences Grad. Program, UCSD, La Jolla, CA

**Abstract:** Decades of previous work have revealed the functional and anatomical organization of primate primary visual cortex (V1) at the level of cortical layers and columns. However, recent technological advances in extracellular electrophysiology and two-photon calcium imaging have allowed for investigation of more detailed cortical organization at the cellular level. We aim to develop and further refine approaches to link large ensembles of neurons in V1 to their laminar identity, cell types, functions, and connectivity. In this study, we demonstrate the ability of high-density Neuropixels electrode arrays and two-photon calcium imaging using GCaMP6f to increase our understanding of the principles and mechanisms by which large populations of neurons transform sensory input to give rise to patterns of neuronal activity in macaque V1. Integrating multiple imaging and recording technologies enables us to perform detailed studies revealing computational and organizational principles of functional cortical connectivity.
Using next-generation Neuropixels electrode arrays, we demonstrate the ability to simultaneously record from 50-100 V1 neurons across all cortical layers. In these experiments, we present a series of chromatic and achromatic visual stimuli consisting of stationary and moving gratings, which allows us to characterize cellular receptive fields of a wide array of cell types. Simultaneously recording from large ensembles of neurons enables us to use reverse correlation and cross-correlation analyses to reveal circuit mechanisms between functionally connected pairs or groups of neurons. Combining these results with current source density (CSD) analysis, in which we assign a laminar identity to each recorded neuron, enables us to reveal the laminar organization of color-responsive neurons in macaque V1.
In combination with our work using extracellular electrophysiology, we robustly express GCaMP6f in V1 using the TET-Off inducible gene expression system, allowing simultaneous imaging of calcium responses from hundreds of neurons. Using these results, we can align the calcium imaging responses with postmortem cytochrome oxidase staining to identify the locations of blobs and inter-blobs, and compare the differences between neuronal activity in each of these locations in response to a variety of visual stimuli.

**Abstract:** Visual motion is encoded both within the retina and in higher visual areas [1]. Direction selective cells in the retina encode visual motion along the four cardinal directions [2] and drive specific behaviours such as the optokinetic reflex [3]. However, the system of brain regions that process retina-encoded direction selective signals is not well understood.
In order to reveal this system we used functional ultrasound imaging [4] to record activity across the whole brain of awake mice and parsed the signals into distinct brain regions. When wild type mice were stimulated with visual motion along the four cardinal directions, a stimulus that evokes the optokinetic reflex, an extensive set of brain regions was activated. We clustered brain regions based on response properties into functional groups: symmetrically responsive, direction selective, anti-correlated with visual motion stimulation or exhibiting different responses across hemispheres.
To find brain regions whose activity depends on retina-encoded horizontal direction selective signals, we specifically perturbed the detection of horizontal motion in the retina using *FRMD7* mutant mice [5] and compared whole brain activity maps across wild type and mutant mice. In *FRMD7* mutant mice, visual stimulation evoked no horizontal optokinetic reflex. Furthermore, activity in spatially distributed brain regions was significantly reduced during horizontal motion. The vertical optokinetic reflex and the activity in brain regions activated by vertical motion did not change.
Thus we reveal a brain-wide system of nuclei that process retina-encoded horizontal motion. Furthermore, we show that whole-brain functional ultrasound imaging can identify brain regions affected by circuit perturbations in awake mice.

**Title:** Mapping of the cerebral structures involved in visual information processing with ultrafast functional ultrasound imaging in rodents

**Authors: *K. BLAIZE**[1], M. GESNIK[2], T. DEFFIEUX[2], J.-L. GENNISSON[2], J.-A. SAHEL[1], M. FINK[2], M. TANTER[2], S. PICAUD[1]
[1]Inst. De La Vision, PARIS, France; [2]Inst. Langevin, Paris, France

**Abstract:** The development of innovative therapies for vision restoration requires measuring visual cerebral activity with highest spatial and temporal frequencies as possible. A new functional imaging technique using ultrasounds for a fast acquisition of Cerebral Blood Volumes, which is a functional indicator of the neuronal activity, has been recently developed. Here we investigated whether we could use this new imaging technique to accurately map different visual areas as Visual Cortex (VC), Superior Colliculus (SC) and Lateral Geniculate Nucleus (LGN). We have mapped these structures after measuring the influences of flickering frequency and contrast on functional responses. We examined the responses of visual areas of anesthetized Long-Evans rats (n=8) to different visual stimuli. To do this, we first performed a craniotomy to expose the visual cortex of the animals so the ultrasound probe was approached at approximately 500 µm of the brain. Visual stimuli were flashed on a computer screen placed in front of the animals (~ 8 cm). Our visual stimulations consist in 5 repetitions of 30s visual stimulations followed by 30s of black screens. We have tested different visual parameters as flickering frequency, stimulus contrast or spatial frequency. Then, we compared the CBV recorded during visual stimulations to a baseline CBV. Using this technique, we could image with a high spatial resolution (~100µm x 100µm, FOV = 13 x 13mm²), and with an acquisition of 1 frame/s. The cerebral blood volume increased in a correlated fashion with the visual stimulation reaching up to 47% increase in SC (SEM: 1.8%), 46% in LGN (SEM: 1.6%) and 18% in VC (SEM: 2.4%) with correlation coefficients r=0.7 in SC, LGN and r=0.6 in VC. We also have demonstrated a lateralized activation of visual areas by flashing stimuli in one visual hemi- field. A retinotopy map has also been constructed. By shifting the ultrasound probe position by steps of 500 µm, we obtained 3D reconstruction functional maps of visual brain (VC, LGN and SC). Together, these results show that functional ultrasound imaging is an interesting technique to study the cerebral visual system. Spatial and temporal resolutions are high enough to discriminate and accurately monitor these structures - and substructures - involved in the

visual information processing. The anesthetic greatly disrupts brain activity, that's why it could be interesting to develop methods for awake animal's experiments.

**Abstract:** We determined the spatial-temporal dynamics of neural propagation across lower- and higher-order visual systems, by intracranially measuring neural responses elicited by single-pulse stimulation. The present study included patients with focal epilepsy who underwent extraoperative electrocorticography (ECoG) recording as part of presurgical evaluation. The cortical surface was parcellated using FreeSurfer on individual MRI data. Trains of electrical stimuli were delivered to a contiguous pair of subdural electrodes at a frequency of 1 Hz for 40 seconds. Each electrical stimulus consisted of a square wave pulse of 0.3 ms duration, 5 mA intensity, and biphasic polarity. ECoG signals were averaged time-locked to the onset of each electrical stimulus; this analytic process yielded cortico-cortical evoked potentials (CCEPs) in electrode sites distant from the stimulated pair. In addition, time-frequency analysis was performed to determine the dynamics of stimulation-elicited neural modulations in given sites. Thereby, augmentation and attenuation of gamma (40-70 Hz) and high-gamma (70-110 Hz) activities were treated as summary measures of cortical activation and deactivation at given moments, respectively. We found that CCEPs generally consisted of an early negative wave (N1) followed by a late negative wave (N2). Stimulation of the lingual gyrus elicited CCEPs in the lateral occipital region. Stimulation of the lateral occipital region elicited CCEPs in the posterior-fusiform region, whereas that of the posterior-fusiform region elicited CCEPs in the lateral occipital and anterior-fusiform region. Time-frequency analysis revealed that brief gamma augmentation co-occurred with N1, whereas prolonged high-gamma attenuation co-occurred with N2. The present study provided unique evidence of feed-forward-preferential propagation

from the primary visual cortex to lateral occipital region as well as reciprocal propagation between the posterior fusiform and lateral occipital regions. The results of our time-frequency analysis support the notion that N1 component on CCEPs reflects an excitatory process while subsequent N2 reflecting an inhibitory one.

**Title:** Local origins of electrocorticogram (ECoG) in visual cortex

**Authors: *A. DUBEY**, S. RAY
Ctr. For Neurosci., Indian Inst. of Sci., Bangalore, India

**Abstract:** Brain signals are recorded from humans and animals using a variety of electrodes of varying sizes. For example, local field potential (LFP) is obtained by low-pass filtering the raw signal obtained from a microelectrode (tip diameter of a few microns) inserted in the brain. Another signal is the electrocorticogram (ECoG), obtained by placing macroelectrodes (~2.3 mm diameter) on the exposed surface of cortex, which is widely used by neurosurgeons to identify the focus of seizure in epileptic patients. In this procedure, part of the brain (epileptic zone) that initiates the seizure is determined based on the distribution of epileptogenic activity on the ECoG electrodes, and is subsequently surgically removed. Therefore, it is critical to determine the cortical area that contributes to the ECoG (known as its 'spatial spread'), which is currently unknown.
To address this, we recorded brain signals from the primary visual cortex of three awake monkeys using both microlectrodes and ECoG electrodes. A small stimulus was flashed at different locations on the screen in a random order to estimate the visual spread for each recording site. Subsequently, the spatial spreads of ECoG and LFP (measured in micrometers) were estimated from the visual spread using a model proposed by Xing and colleagues (2009). The spatial spread of LFP was local (few hundred microns), consistent with some of the previous studies. Surprisingly, we found that the spatial spread of ECoG was on average only 3-4 times

greater than the LFP spread, suggesting that ECoG signal was also local, with a standard deviation approximately equal to the diameter of the electrode (~2.5 mm). Further, we compared the tuning characteristics of gamma oscillations in ECoG and LFP by presenting a full screen Grating stimulus. The tuning profiles of Gamma oscillations to orientation and spatial frequency in ECoG was comparable to LFP, further indicating that ECoG had a local origin. Our results justify the use of the usual grid spacing of 1 cm between ECoG electrodes commonly used in epilepsy surgeries, and in general the use of ECoG recordings from a particular brain area to infer local network properties of that area.

**Abstract:** Knowing where sources of activity are in the brain can help diagnosis. Locating the sources of electroencephalography (EEG) signals acquired on the scalp, the inverse problem, is an ill-posed problem since there are an infinite number of source configurations that can result in a potential distribution on the head surface. Therefore, additional constraints to the source space must be used to find a unique solution. Equivalent current dipole methods utilize a discrete source space in which a small number of dipoles are assumed to generate the given surface potential. Distributed source methods constrain the source space to a larger number of dipoles distributed either on the cortical surface or within the brain. Both methods have their advantages, but discrete source spaces yield an overdetermined solution while the solutions of distributed source methods are underdetermined.

In the present study, the increased spatial resolution of tri-polar EEG [1] (tEEG) improved the focality of the underdetermined results found in distributed source localization methods with respect to visually evoked potentials (VEPs). Subjects (n=5) were concurrently recorded with both EEG and tri-polar concentric ring electrodes (TCREs) during periods of checkerboard polarity reversal stimulus presentation. The stimulus was presented at 1.93 Hz for approximately 5 seconds followed by a 10 second pause. Said stimulus train was repeated for 5 minutes for a total of 3 times with a 60 second break between each, yielding a total of 600 trials. Due to hardware limitations, electrodes were placed on 16 of the standard 10-20 locations, excluding A1, A2, F7, F8, and T4. Surface potentials related to the visual stimulus were filtered with a low-pass filter (40 Hz cutoff) and segmented into epochs. Epochs containing artifacts were removed with a peak-to-peak threshold, and remaining epochs were averaged per subject. The subsequent average VEPs were localized using distributed source methods on the ICBM152 head model derived from a non-linear average of MRI scans of the 152 subjects in the MNI152 database. Using the open-source data analysis application Brainstorm, a linear L2-minimum norm estimates algorithm was used to localize sources to a source space constrained normal to the cortical surface.
Localization results obtained from tEEG appear to be much more focal when compared to those of EEG. Thus, the underdetermined nature of distributed source localization methods is decreased when used with tEEG, alleviating this drawback and producing a more accurate representation of the VEP source signal.

**Abstract:** Our research has focused on the functions and anatomical organization of the primate visual pulvinar. Here we are interested in the specific roles that higher order nuclei of the pulvinar play in the visual system. Recent work has shown that there are two mirrored retinotopic maps in the pulvinar, one located dorsally and the other located ventrally. The presence of these two maps in the pulvinar raises important questions regarding the functional roles that this seemingly redundant nuclei might have. To examine the differences between cortico-thalamic projections to the two retinotopic maps of the pulvinar, we conducted a retrograde tracer study and examined labeled cortical cells.
Dual retinotopic maps of the pulvinar were distinguished electrophysiologically in two prosimian galagos (Otolemur garnettii) and were differentially labeled by pressure injections of either red or green fluorescently tagged cholera toxin subunit B (CTB) into each map. Special care was taken to ensure that each 4μL injection was made in locations that correspond retinotopically without allowing for overlap between the two injection sites. This was done to ensure that any double labeled cortical cells explicitly project to both of the pulvinar's retinotopic maps. After a 14-day survival period, the animals were perfused and cortex was sectioned coronally into 50μm sections. Tissue slides were imaged, cortical locations were determined via CO staining, and labeled neurons were localized and counted.
Results indicate that different populations of neurons in V1 and V2 project to the two pulvinar maps. Few, if any neurons were double labeled. Neurons within V1 and V2 were labeled by injections in either pulvinar map, but neurons in V1 were almost exclusively in layer 6, while neurons in V2 were in both layers 5 and 6. Furthermore, injections in the dorsal map labeled many more neurons in V2 than V1. These results support the view that the two pulvinar maps have different functions, and that neurons in V2 are important in driving the dorsal map. In monkeys, the dorsal map is located in the lateral pulvinar (PL) and the ventral map in the central lateral nucleus of the inferior pulvinar (PIcl).

**Title:** Causal role for the pulvinar in shaping cortico-cortical interactions

**Authors: *M. K. ERADATH**[1], M. A. PINSK[1], S. KASTNER[1,2]
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

**Abstract:** The pulvinar is the largest nucleus in the primate thalamus and has topographically organized connections with multiple cortical areas, thereby forming extensive cortico-pulvino-cortical input-output loops. Neurophysiological studies have shown a role for the pulvinar in regulating information transmission within and between these cortical areas. However, the neural mechanisms underlying these cortico-pulvino-cortical interactions are not yet clear. Here, we explore the functional role of pulvinar in resting state connectivity between cortical areas V4 and LIP in macaques. We performed pharmacological manipulations by injecting muscimol ($GABA_A$ receptor agonist) and bicuculline ($GABA_A$ antagonist) into the pulvinar, immediately followed by simultaneous recordings from areas V4 and LIP, both in awake and anesthetized conditions. We used an MRI-guided approach for injectrode placement and further confirmed the extent of injection by visualizing Gadolinium MR contrast agent mixed with the pharmacological agent. Our preliminary results suggest that inactivating the pulvinar causally affects both V4 and LIP, possibly by similar neural mechanisms. The phase locking between lateral pulvinar and cortical areas was reduced in alpha frequencies following the muscimol injection. The alpha phase gamma amplitude coupling between V4 and LIP was decreased after the muscimol inactivation of the lateral pulvinar. These results further characterize the functional mechanisms with which the pulvinar regulates cortico-cortical interactions.

**Title:** Effects of selective visual attention on macaque lateral, medial, and inferior pulvinar neurons

**Authors: *R. LY**[1], M. A. PINSK[1,2], S. KASTNER[1,2]
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

**Abstract:** Recent studies suggest that the pulvinar nucleus of the thalamus plays an important role in visual attention. The pulvinar can be subdivided into lateral, inferior, and medial pulvinar. Firing rates in the lateral pulvinar increase with covert visual attention to a cued stimulus (Zhou et al., 2016) and to a cued location without a visual stimulus (Saalmann et al., 2012). Deactivation of the lateral pulvinar leads to attentional impairments (Petersen et al., 1987, Desimone et al., 1990). Whereas the lateral and inferior pulvinar are strongly connected with ventral visual stream areas, the medial pulvinar is strongly connected with higher order areas, including the frontoparietal attention network. If the medial, lateral, and inferior pulvinar are interconnected, attention signals from frontoparietal cortex could influence ventral stream areas through the pulvinar. Few studies have looked at the effects of attention on medial pulvinar neurons, and no studies have established whether the medial, lateral, and inferior pulvinar are interconnected.
We simultaneously recorded from tens of single units and multi-units in lateral, medial, and inferior pulvinar (15-30 per session) using linear microelectrode arrays in a macaque monkey while the animal performed a spatial attention task. We computed spatial receptive fields and attention indices for each unit and compared response properties of neurons in the three pulvinar subdivisions. Across the population, we computed cross-correlations of spiking activity as well as spike-field coherence to investigate functional connectivity within and between pulvinar subdivisions. In addition, using pairwise correlations between simultaneously recorded units, we developed a maximum entropy model to ask whether spiking of individual lateral and inferior pulvinar units can be predicted from the population activity of the pulvinar during different task states. These results extend the basic pulvinar mapping performed by Petersen et al. (1985) to demonstrate the population dynamics of the pulvinar during selective visual attention.

**Title:** Pulvinar inactivation modifies the dynamics of visual cortical responses

**Authors: *N. CORTES**[1], B. OLIVEIRA FERREIRA DE SOUZA[1], C. F. CASANOVA[2]
[1]Ecole d'optometrie, Univ. De Montreal, Montreal, QC, Canada; [2]Univ. Montreal, Montreal, QC, Canada

**Abstract:** It is well known that the pulvinar establishes reciprocal connections with areas of the visual cortex, allowing the transfer of cortico-cortical signals through transthalamic pathways. However, the exact function of these signals in coordinating activity across the visual cortical hierarchy remains largely unknown. In anesthetized cats, we have explored whether pulvinar inactivation affects the dynamic of interactions between the primary visual cortex (a17) and area 21a, a higher visual cortical area, as well as between layers within each cortical area. We found that pulvinar inactivation modifies the local field potentials (LFPs) coherence between a17 and 21a during a visual stimulation. In addition, the Granger causality analysis showed that the functional connectivity changed across visual areas and between cortical layers during pulvinar inactivation, the effects being stronger in layers of the same area. We observed that the effects of pulvinar inactivation arise at two different epochs of the visual response, *i.e.* at the early and late components. The proportion of feedback and feedforward functional events was higher during the early and the late phases of the responses, respectively. We also found that pulvinar inactivation facilitates the feedback propagation of gamma oscillations from 21a to a17. This feedback transmission was predominant during the late response. At the temporal level, pulvinar inactivation also delayed the signals from a17 and 21a, depending on the source and the target of the cortical layer. Thus, the pulvinar can not only modify the functional connectivity between intra and inter cortical layers but may also control the temporal dynamics of neuronal activity across the visual cortical hierarchy.

**Title:** Potentiation of the pulvinar leads to reorganization of direction preference maps in the cat visual cortex

**Authors: *S. I. SHUMIKHINA**, A. A. POTEKHINA, M. M. SVINOV
Inst. of Higher Nervous Activity and Neurophysiol. RAS, Moscow, Russian Federation

**Abstract:** The lateral posterior-pulvinar complex (LP-Pulv) sends direct fibers to areas 17 and 18 in cats. It is shown that LP-Pulv can modulate cortical activity influencing response magnitudes, cortical gamma oscillations, synchronization between cortical neurons, and orientation selectivity. Here we hypothesize that LP-Pulv complex may also modulate such an important cortical property as its directional selectivity. Optical imaging of intrinsic signals was performed on the adult cat visual cortex. Monocular stimulation with moving square-wave gratings that changed continuously their orientation and direction was employed (method of Kalatsky and Stryker, 2003). Fourier decomposition was performed on the temporal signal to obtain orientation and direction maps. The phase and magnitude maps of the first harmonic were associated with directional components while such maps of the second harmonic were related to orientation components. After control direction maps were acquired, the high-frequency electrical stimulation of the LP-Pulv (200 Hz) was used for 10 s and post-tetanisation direction maps were recaptured. The degree of similarity between maps was measured on the pixel-by-pixel basis in the region of interest (ROI). It was observed that direction maps after the LP-Pulv tetanisation were markedly reorganized. Correlation coefficients between direction maps were strongly decreased to -0.1-0.2. Anisotropy in direction preference reversed or markedly increased. Computing orientation distribution histograms revealed large shifts in preferred orientation for each stimulus direction. Up to 68% of neuron populations acquired responses to opposite direction. The changes were not equally expressed for different orientations. The directional selectivity index also showed not equal changes for different orientations after LP-Pulv tetanisation. These preliminary results demonstrate that the LP-Pulv complex can modulate the directional selectivity of visual cortical neurons that can be important during attention processes.

**Title:** Modulation of the mouse primary visual cortex neuronal activity by the pulvinar

**Authors: *U. KEYSAN**, C. CASANOVA
École d'optométrie, Univ. de Montréal, Montreal, QC, Canada

**Abstract:** Information about the visual world is processed by an ensemble of cortical visual areas, which follow a hierarchical organization. The primary visual cortex (V1) first receives most of this information through the lateral geniculate nucleus (LGN), before being conveyed to higher-order cortical areas. Aside from this connectional route, there is also a complex network of bilateral connections between areas of the visual cortex and the pulvinar, considered as the largest extrageniculate visual thalamic nucleus. Despite an increasing number of studies on pulvinar, the exact function of this thalamic complex remains unknown. In this study, we investigated the functional impact of the lateral posterior (LP) nucleus, the homologue of the primate pulvinar, on the activity of neurons in the primary visual cortex in mice using optogenetic stimulation. A channelrhodopsin-2 gene-carrying viral vector (AAV5.CaMKII.hChR2-eYFP.WPRE) was injected into the LP of wild-type (C57BL/6) mice. Extracellular recordings of the activity of V1 neurons were carried out using 16 and 32-channel silicon probes. The stimulation of LP was achieved with light pulses (470 nm, 20 pulse trains of 5 ms each at 10 Hz) delivered by a 4-channel optrode, which also recorded the thalamic activity. Visual stimuli consisted on drifting sinewave gratings of varying parameters (direction, contrast, spatial or temporal frequency and size). Our preliminary data shows that LP stimulation performed in conjunction with the visual stimulation decreases the amplitude of neuronal responses up to 50 %. To date, results indicate that this inhibitory effect is only observed in neurons in the infragranular layers. The response profiles of V1 neurons to size-increasing stimuli were also affected. These findings suggest that the pulvinar nucleus can exert layer-dependent contextual modulation on the activity of neurons in the mouse primary visual cortex.

**Title:** Functional and anatomical subdivisions of mouse visual thalamic area LP

**Authors: *C. BENNETT**, S. D. GALE, S. R. OLSEN
Allen Inst., Seattle, WA

**Abstract:** The lateral posterior nucleus of the thalamus (LP) is highly interconnected with all known regions of mouse visual cortex. Additionally, LP receives a dense projection from the superficial layers of the superior colliculus (SCs) and is thought to act as the main conduit through which information from the SCs reaches cortex. However, the role that LP plays in visual processing remains poorly understood, in part because previous studies have focused on

limited portions of LP. Here, we used high density silicon (Neuropixel) probes to conduct a broad survey of mouse LP visual responses, recording from >1000 units distributed throughout LP. By mapping these units to the Allen Institute's Common Coordinate Framework, we were able to register functional maps derived from our recordings to the anatomical projection maps in the Allen connectivity atlas. We found a striking correspondence between these functional and anatomical maps, supporting a coarse partitioning of LP into at least two subregions: a posterior SCs-recipient region (pLP) and an anterior non-SCs-recipient region (aLP). Neurons in these two zones differ in their visual response properties, and receptive field mapping reveals a clear reversal in elevation between aLP and pLP suggesting the existence of at least two retinotopic maps in LP. Properties of pLP neurons are similar to those of the SCs neurons that project to LP: large, horizontally-elongated receptive fields, strong surround suppression, spatiotemporal tuning for slow speeds, and stronger responses to object motion than to background motion. Conversely, aLP neurons have smaller receptive fields, weaker surround suppression, spatiotemporal tuning for high speeds, and stronger responses to full-field motion. Using these visual response properties alone we performed a clustering analysis on LP neurons and found two major functional clusters that segregate spatially into posterior and anterior populations. Thus, combined functional and anatomical evidence together point to the existence of multiple regions in LP that may support distinct visual processes.

**Title:** Interactions between population activity in cortex and striatum

**Authors: *A. J. PETERS**, N. A. STEINMETZ, K. D. HARRIS, M. CARANDINI
Univ. Col. London, London, United Kingdom

**Abstract:** The striatum receives input from the entire cortex, and its outputs are routed both to other subcortical structures and back to the cortex. Corticostriatal connectivity has been shown to

be important for learning and decision-making, but the functional relationship between the cortex and striatum remains largely unknown.
To investigate this functional relationship, we combined widefield calcium imaging of the entire dorsal cortex with simultaneous high-density electrophysiological recordings in the striatum of awake mice. The use of 1 cm-long Neuropixels probes (ucl.ac.uk/Neuropixels) allowed us to record from a coronal trajectory spanning from the dorsomedial to dorsolateral edges of the striatum. Hundreds of units were sorted for each recording with Kilosort (Pachitariu et al, bioRxiv, 2016). We characterized the spatiotemporal patterns of cortical activity accompanying striatal firing using regularized linear regression.
Consistent with previously described corticostriatal connectivity, we found that cortical activity predicted striatal spiking in a topographic manner, such that dorsolateral striatum was most closely related to anterior cortex while dorsomedial striatum was related to progressively more posterior aspects of cortex. Spiking in the most medial band of the striatum was predicted by activity in the visual cortex. Moreover, responses in that band could be elicited by passively viewed visual stimuli. Large flickering gratings elicited the most reliable visual striatal responses, although receptive fields could sometimes be mapped also using sparse noise. Conversely, responses in more lateral regions of the striatum were neither elicited by visual stimuli nor predicted by visual cortical activity.
Corticostriatal topography and stimulus-driven responses were observed at both the multiunit and single-unit scale, but there was substantial heterogeneity in cortical fluorescence accompanying individual striatal units. Single units in the striatum could be parsed into cell types by waveform duration, firing rate, and inter-spike intervals, and included putative medium spiny neurons, tonically active neurons, fast spiking interneurons, and unknown interneurons. Preliminarily, there did not appear to be qualitative differences in the relationship between cortical activity and these different classes of cells.
These results confirm the functional relevance of corticostriatal anatomical projections and characterize the relationship between cortical and striatal activity at a mesoscopic scale.

**Title:** Visual response properties and receptive field structure in the thalamic reticular nucleus of the mouse

**Authors: *U. M. CIFTCIOGLU**[1], F. T. SOMMER[2], J. A. HIRSCH[1]
[1]USC, Los Angeles, CA; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA

**Abstract:** Before reaching cortex, retinal signals are processed by two separate inhibitory circuits in the visual thalamus. Local interneurons in the lateral geniculate nucleus (LGN) receive retinal input and provide feedforward inhibition to relay cells and each other. Gabaergic cells in the visual sector of the thalamic reticular nucleus (TRN) receive input from relay cells and project back to them in return to form the first feedback loop in the visual pathway. The TRN likely serves different roles, including bottom-up sensory processing and top-down control of spatial attention. To understand how the TRN influences relay cells and their targets in cortex, it is important to understand stimulus selectivity in the nucleus. While early studies suggested that reticular cells had limited sensitivity to stimulus shape, size or contrast, later work in cat and primate showed that reticular neurons are selective for complex visual features and that their receptive field sizes are comparable to those in the LGN, at a given eccentricity. The overall shape of receptive fields in the TRN is not altered by removing cortex and thus is likely sketched by geniculate afferents. However, the question of how these inputs are integrated with each other and influenced by connections among reticular cells is not understood and is experimentally difficult to explore in higher mammals. The mouse is a more tractable preparation and also offers advantages such as cell-type selective targeting through optogenetic means. Thus, we began to explore visual responses in the reticular neurons in anesthetized mice, using two experimental approaches. We made extracellular recordings to map receptive field structure, and used the (difficult) technique of whole-cell patch recording in vivo to study the underlying pattern of synaptic inputs. The receptive fields we mapped ranged widely in shape, from large (~50-60$^0$) and diffuse to smaller (~10-15$^0$) and structured, recalling the diversity recorded across the visual field in cat and monkey. There was also a wide range in spike-timing precision. Intracellular recordings revealed pronounced EPSCs, consistent with powerful afferent input, and pronounced hyperpolarizing currents, consistent with a strong influence of inhibitory connections. Taken together, our preliminary results suggest that the mouse may serve as a useful model to understand visual processing in the TRN.

**Title:** Functional characterization of distinct cortical inputs to higher-order visual thalamus

**Authors: *M. A. KIRCHGESSNER**[1,2], E. M. CALLAWAY[1,2]
[1]Salk Inst., La Jolla, CA; [2]Neurosciences Grad. Program, UC San Diego, La Jolla, CA

**Abstract:** The lateral posterior nucleus of the thalamus (LP), which is the mouse analog of the primate pulvinar, is a higher-order visual thalamic nucleus that is thought to play an important role in visual attention. A key difference between LP/pulvinar and the first-order visual thalamic nucleus LGN is that LP/pulvinar receives two distinct cortical inputs: one from layer 6 that it shares with LGN, and one from layer 5 that avoids LGN. Prior studies of the morphological and physiological characteristics of these inputs have suggested that the two corticothalamic (CT) populations may have very different effects on activity in LP/pulvinar. In particular, it has been hypothesized that the layer 5 CT group, which has large synaptic terminals in LP/pulvinar that resemble retinal ganglion cell terminals in LGN, provide the primary "driving" input to LP/pulvinar and shape its visual response properties. Meanwhile, the layer 6 CT population, which has more numerous but smaller terminals in LP/pulvinar, may contribute "modulatory" input (e.g., Sherman 2016). However, whether layer 5 and layer 6 CT cells are functional drivers and modulators, respectively, of LP/pulvinar has never been directly tested. To answer this question, CT neurons in mouse V1 were selectively targeted for optogenetic manipulations using Ntsr1-Cre transgenic mice (layer 6) or wild-type mice with a retrograde virus encoding Cre injected into superior colliculus (layer 5). Multi-shank neural probes with high-density microelectrode arrays were used to record extracellular single-unit activity in LP of awake mice viewing drifting gratings while optogenetically manipulating the activity of either layer 5 or layer 6 CT neurons. This was used to determine each CT population's effect on visual and spontaneous firing rates and visual response characteristics in LP. The morphology and spatial distribution of each CT population's axon terminals relative to recording sites in LP was also examined. Preliminary results are consistent with the model of layer 5 and layer 6 CT neurons as functional drivers and modulators of LP, respectively, although they do not uniformly affect activity across the spatial extent of LP. For example, the effects of layer 6 CT activation can be facilitating or inhibitory depending on the recording location in LP. The results from this work not only address a longstanding question about the functional consequences of distinct cortical inputs to LP, but also provide the most complete characterization of visual response properties in the mouse LP to date. Overall, this work has implications for understanding LP/pulvinar's role in visual processing through its interactions with visual cortex.

**Title:** Differential volume loss of thalamic nuclei across aetiologies of cerebral visual impairment

**Authors: *L. MERABET**[1], E. BAILIN[2], C. M. BAUER[2]
[1]MEEI-Harvard Med. Sch., Boston, MA; [2]Mass. Eye and Ear -- Harvard Med. Sch., Boston, MA

**Abstract:** Cortical/Cerebral Visual Impairment (CVI) is the leading cause of pediatric visual deficits in the developed world. It is often observed in children with early developmental brain damage, in particular those individuals born preterm who experienced a hypoxic-ischaemic event with resulting periventricular leukomalacia (PVL). Reduced neuronal number of the thalamus is often implicated in histology studies of PVL; however, it is not known whether MRI morphometry studies are sensitive enough to detect volume changes associated with PVL in specific thalamic nuclei. Thus, the current study examined volume of thalamic nuclei based on the Morel Histological Atlas.
A total of 7 individuals with CVI (Ages 14-24, mean 18.4 years, 4 PVL, 2 seizure, 1 neonatal infection) and normally-sighted and developed controls (Ages 15-24, mean 19.75 years) underwent a neuroimaging protocol on a 3T Philips Achieva system using an 8-channel phased array head coil. Two T1-weighted scans were acquired for each subject and analyzed in Freesurfer. Thalamic nuclei from the Morel MRI atlas (Krauth et al., 2010) were reverse transformed into each subject's anatomical space. Volume was calculated for each nucleus and assessed for CVI-related differences using t-tests and ANOVA in SAS.
Compared to controls, the CVI group showed an overall significant reduction in bilateral thalamus volume (CVI=4993.8 (1824.1); control=7607.7 (686.6), p = 0.02), which was likely driven by individuals with CVI due to PVL (PVL=3907.5 (813.9); non-PVL=7167.5 (689.4), p = 0.0087). Decreased volume in PVL compared to non-PVL causes of CVI were observed in the following thalamic nuclei: mediodorsal (PVL=101 (53); non-PVL=267 (181), p = 0.02), central lateral (PVL=654 (65); non-PVL=980 (613), p=0.015), paraventricular (PVL=4.2 (0.7); non-PVL=9.3 (3.2), p = 0.04), habenula (PVL=25 (9.1); non-PVL=74 (61), p=0.038), pulvinar (PVL=819 (387); non-PVL=1923 (1064), p = 0.013), medial geniculate (PVL=96.5 (24.6); non-PVL=240.5 (151), p = 0.016), lateral geniculate (PVL=92.7 (18); non-PVL=200.5 (92.6), p = 0.007), and ventral posterior (PVL=30 (4); non-PVL=86 (54), p = 0.009). All results are

presented as mean volume (sd) $mm^3$.
Overall, these results support the hypothesis that CVI is associated with reductions in specific thalamic nuclei, particularly those in the medial and posterior portions of the thalamus. Individuals with CVI due to PVL showed more widespread losses in thalamic nuclei compared to those without PVL. Thalamic damage in PVL may contribute to poor prognosis in children with CVI.

**Title:** Development of a visual pathway model to optimize sensory stimuli for brain-computer interface

**Authors: *C. TREMMEL**[1], F. SOBREIRA[1], S. H. WEINBERG[3], D. J. KRUSIENSKI[2]
[2]Electrical & Computer Engin., [1]Old Dominion Univ., Norfolk, VA; [3]Biomed. Engin., Virginia Commonwealth Univ., Richmond, VA

**Abstract:** Typical brain-computer-interfaces (BCIs) consist of devices to provide a sensory stimulus (e.g., video monitor, speakers, vibrotactors), an EEG measuring headset, and a computer processing unit for the decoding and feedback control. Common approaches such as the P300 Speller and steady-state visual evoked potential (SSVEP)-based interfaces use brain responses to visual stimuli to identify the user's intended target to achieve device control. BCI decoding algorithms have been researched for decades and have evolved to become more sophisticated. Rather than a continued focus on decoding algorithms, an alternative approach is to enhance brain response characteristics through the optimization of the stimulus patterns. This study aims to develop an extended model of the human visual pathway from the stimulus incident on the retina, through the lateral geniculate nucleus (LGN), to the electrode interface over the visual cortex. Information theoretic techniques will be used to create and test improved stimulus sequences based on the resulting visual pathway model. This model will leverage and combine existing work on modeling various components of the visual pathway and cortex. While models for some parts of the pathway such as phototransduction, single cortical neurons, and the electrode interface are already well-developed, the LGN and the visual cortex have a high complexity and only estimates about specific functions are possible. In order to create the best possible output, existing standalone models will be linked together by models of cortical

neurons. The more complex parts will consist of artificial neural networks (ANN) that will be trained with real-life data to match their function, with an emphasis on preserving physiological forms, connections, and positions. In preliminary experiments image sequences were presented to a virtual retina model that performs a spatio-temporal linear filtering, resulting in spike trains that are subsequently applied an ANN composed of three hidden layers with thirty hidden units each. The ANN is trained to simulate a 660 ms of an EEG response from a single channel over the visual cortex (i.e., Oz). The results show that this model successfully reproduces EEG responses to a simple contrast image stimulus at the input.

**Abstract:** The primate pineal in macaca fasicularis, is a bipartite structure (right left), each with dorsal and ventral regions seen at its posterior extent. Anterior projections of each part are highly topographic, extend primarily ipsilaterally but the more medial regions comprise both ipsilateral and crossing elements prior to exiting the gland. Clear multi - tract projections are seen to most components of the primary visual system as well as bilaterally to shared and distinct regions of V1/BA 17. Specifically, other regions include the optic chiasm and suprachiasmatic nucleus where both ipsi and crossed tracts continue in thin bands on the superior aspect of the optic nerves, likely to the retina. Projections also pass through the LGNs, bilaterally in distinct lateralized regions that connect in part in close association with the posterior inferior aspect of the optic chiasm. In humans, using the Connectome Lifespan pipeline acquisition sequences,

both left and right pineal elements project predominantly to the left hemisphere, similar to Zebrafish. These results provide a revolutionary view of human brain lateralization in a gland that regulates much of the limbic system and may provide a new origin and therapeutic targets for mental illnesses including autistic spectrum disorder and schizophrenia.

**Title:** Ultrastructural analysis of synaptic connectivity of local interneurons in the ferret visual thalamus

**Authors: *S. AHN**[1,2], V. SURESH[2], A. KUMAR[2], J. K. DAMRON[3], J. A. HIRSCH[1,2], M. E. BICKFORD[3]
[1]Neurosci. Grad. Program, [2]Biol. Sci., USC, Los Angeles, CA; [3]Anatom. Sci. and Neurobio., Univ. of Louisville Sch. of Med., Louisville, KY

**Abstract:** The lateral geniculate nucleus (LGN) of the thalamus transforms the retinal signals it receives before sending visual information to cortex for further processing. The intrinsic circuits of the LGN comprise relay cells and local interneurons. Both types of cells share a similar, center-surround, receptive field structure but integrate synaptic inputs in different ways. Excitatory visual stimuli drive trains of unitary EPSCs in relay cells, but not in interneurons. Conversely, suppressive stimuli evoke serial IPSCs in interneurons but not in relay cells. Computational analyses suggest that these complementary patterns of response help to preserve information encoded in the fine timing of retinal spikes and to optimize the amount of information transmitted to cortex (ref Wang et al., 2011). While it is clear the trains of unitary EPSCs recorded from relay cells are produced by retinal afferents, the source of the serial IPSCs recorded from interneurons is not known. To reveal the potential synaptic circuits that underlie these distinct responses, we prepared ferret LGN tissue for ultrastructural analysis. Blocks of tissue including all layers of the LGN were cut into ultrathin sections, stained with an antibody against GABA tagged with gold particles, and imaged using an electron microscope.

GABAergic profiles were identified based on gold particle density. Both the dendrites and axons of interneurons form connections with neighboring cells. It is possible to distinguish synapses made by dendrites from those made by axons by the relative density of vesicles in the presynaptic element. Postsynaptic GABAergic elements were categorized as somata, dendritic shafts, or dendritic terminals. Retinal inputs were identified using the unique ultrastructural features of their mitochondria. Preliminary data (from 217 synapses) indicate that the large majority of presynaptic GABAergic profiles contact nonGABAergic profiles, presumed relay cells. Analysis of inputs to GABAergic profiles indicates that interneurons receive the majority of their input from two sources--retinal terminals and GABAergic terminals, including those from both dendrites and axons. This result suggests that synaptic coupling of interneurons generates the serial IPSCs that are recorded from interneurons during vision.

**Abstract:** Contour elements of static and dynamic visual stimuli are more accurately detected and discriminated when aligned with the horizontal and vertical axes than when obliquely oriented. This phenomenon, known as the "oblique effect", has been observed in a great variety of visual tasks and for animal species as diverse as goldfishes, octopuses, pigeons, cats and

monkeys. To date, the neural basis of this asymmetric processing of visual information remains elusive. In mammals, optical imaging and single-unit recording studies provided evidence for an overrepresentation of cardinal orientations in the early visual cortex, which suggests that the latter may mediate the oblique effect. With the aim of providing comparative insights into this issue, the present study seeks to determine whether such an overrepresentation is also present in the avian homologue of the primary visual cortex, namely the visual wulst. Previously, we and others have shown that most wulst neurons in owls are highly selective for the orientation and direction of simple stimuli like bars and sinusoidal gratings (Baron et al., 2007, *European Journal of Neuroscience*, 26 , 1950-1968). Here, we reassess this finding in a large dataset of isolated cells (n = 689) sampled from 11 awake burrowing owls (*Athene cunicularia*) and lightly sedated barn owls (*Tyto Alba*). Orientation/direction selectivity was quantified by a set of standard indexes, curve-fitting parameters and vector-based measures computed on neuronal responses to gratings drifting in 16 different directions (22.5 deg. increment steps) during 2000 ms. Our results reveal a clear heightened prevalence of neurons preferring near-horizontal orientations and downward motion in the visual wulst of both burrowing owls and barn owls. Unlike in area 17 of cats, this bias was not more pronounced for simple cells than for complex cells. Indicators of tuning precision tended to be more uniformly distributed in both orientation and direction spaces. The challenges for future research will be to understand the behavioral implications of these findings and the factors underlying the anisotropy of orientation and direction tuning preferences in the owl visual wulst.

**Abstract:** The lateral geniculate nucleus (LGN) is commonly portrayed as a passive way station between the retina and the visual cortex. However, growing research suggests that the human LGN is involved in more sophisticated visual and cognitive processes, showing modulation by covert attention (O'Connor et al., 2002) and evidence of orientation-selective processing (Ling et al. 2015). Here, we examined the role of the LGN in figure-ground processing, using high-resolution fMRI at 7 Tesla to record human brain activity. We investigated whether the LGN might show sensitivity to figure-ground organization in response to orientation-defined figures, as has been previously found in the early visual cortex. In two experiments, we asked 1) whether directed spatial attention is necessary for figure-ground modulation in the LGN, and 2) if feedback from cortical visual areas likely contributes to the enhancement of LGN responses to orientation-defined figures. We measured fMRI responses to orientation-defined figures presented to the left and right of fixation, cuing participants to spatially attend to one figure while ignoring the other. Spatial attention led to enhanced responses in the LGN, consistent with prior work, but more importantly, orientation-defined figures produced elevated responses even in the absence of attention. In a second experiment, we manipulated whether the figure and the surround stimuli were presented to the same eye or to different eyes. This design leverages the binocular organization of the early visual system: V1 is considered the first stage along the visual hierarchy in which signals from the two eyes are strongly integrated. Nevertheless, we found that the LGN was reliably modulated when figure and ground were presented to different eyes, implying that top-down feedback from binocular cortical neurons contributes to figure-ground modulation in the LGN.

**Title:** Photoreceptor-resolved receptive fields of parafoveal macaque LGN neurons

**Authors: *L. C. SINCICH**[1], A. MEADWAY[2], P. TELLERS[3]
[1]Vision Sci., Univ. of Alabama Birmingham, Birmingham, AL; [2]Optometry and Vision Sci., [3]Univ. of Alabama at Birmingham, Birmingham, AL

**Abstract:** The receptive fields of neurons in the lateral geniculate nucleus (LGN) are primarily determined by signals arising from a small number of cone photoreceptors in the retina. For LGN neurons that represent visual space near the center of gaze, the number of cones serving the receptive field center can be quite small, ultimately thought to be just one cone for central foveal neurons, though this has not been directly measured. Ordinarily, optical constraints limit such measurements. A prior study that bypassed the optical limits using interference fringes found that parafoveal parvocellular neurons had field centers comprised of 2 or more cones (McMahon et al. 2001), suggesting a role for intraretinal circuitry in delimiting the fields. Adaptive optics can also be used to minimize optical constraints, and offers the advantage that the cones themselves can be targeted for stimulation. We used a multiwavelength adaptive optics scanning laser ophthalmoscope to simultaneously image the cone mosaic and present micron-scale movie stimuli for mapping LGN receptive fields in anesthetized macaques undergoing neuromuscular blockade. Imaging was performed with 840 nm light. Two stimulus channels were independently modulated to drive L and M cones equally (543 nm) or L cones preferentially (710 nm). In these green and red channels, binarized Gaussian noise movies were shown concurrently, at a spatial resolution of either 100 or 150 pixels/deg, with frames refreshing at 30 Hz, and using real-time retinally-stabilized delivery. Spatiotemporal receptive fields were constructed by reverse correlation of spike-triggered average (STA) movies. In 28 neurons recorded in 2 macaques, the noise movies yielded 22 receptive fields located between 0.4° and 4° from the foveal center. Receptive field center sizes were measured in the STA frame occurring 66 msec before the spike, based on stimulus pixels that had signals greater than 3 SDs of the noise in the STA frame 33 msec after the spike. For all cells at all eccentricities, field centers were less than half the diameter of those reported previously (Croner & Kaplan 1995; Levitt et al. 2001). In some cells, likely parvocellular, the field centers were of the same dimensions as the cone spacing measured at the site. Our data suggest that, with optical aberrations and eye motion minimized, the smallest parafoveal LGN receptive field centers may be revealed as being defined by inputs originating from one cone.

**Title:** Lateral geniculate neurons in adult mice show robust ocular dominance plasticity

**Authors: *T. ROSE**, J. JÄPEL, S. WEILER, M. HÜBENER, T. BONHOEFFER
Max Planck Inst. of Neurobio., Muenchen, Germany

**Abstract:** The change in ocular dominance (OD) after monocular deprivation (MD) is one of the most prominent models of experience-dependent plasticity in the neocortex. MD is known to evoke an OD shift in the binocular part of primary visual cortex (V1), but robust OD changes in the dorsolateral geniculate nucleus (dLGN) of the thalamus have not been reported so far. This led to the view that OD plasticity in the visual system is exclusively cortical in the mature brain. However, none of the recordings in dLGN to date have been performed chronically with single-cell resolution. Hence, changes in the eye-specific responsiveness of individual thalamic relay cells (TRCs) could have easily been missed. Furthermore, in contrast to the classical view of strict eye-specific segregation in dLGN, recent studies have reported that a fraction of TRCs integrates input from both eyes, which could provide a substrate for competitive TRC plasticity. This led us to re-evaluate thalamic binocularity and experience-dependent OD plasticity using chronic two-photon $Ca^{2+}$ imaging of TRCs projecting to binocular V1 of adult mice.
We conditionally expressed the genetically encoded $Ca^{2+}$ indicator GCaMP6m in the dLGN of Scnn1a-Tg3-Cre mice using adeno-associated virus and followed the visually evoked $Ca^{2+}$ signals of the same individual TRC axonal boutons in layer 1 (L1) of binocular V1 for up to 4 weeks before and after 6-8 days of contralateral eye MD. This provided a reliable and minimally-invasive longitudinal readout for the activity of TRCs in dLGN. We found that most (86%) dLGN cell boutons in L1 of binocular V1 were stably monocular during baseline. Following deprivation, however, more than half (55%) of the TRC boutons showed significant OD shifts, leading to population OD changes comparable in magnitude to those in cortical L2/3 neurons. Similar to cortex, TRC boutons that were exclusively responsive to the contralateral eye during baseline showed a prominent decrease in contralateral eye-evoked activity after MD. However, very different from cortex, initially monocular contralateral boutons also showed the most prominent increase in ipsilateral eye responsiveness. We are currently performing *in vivo* cortical silencing and *in vitro* optogenetic circuit mapping experiments to disentangle the contribution of feedback (i.e. corticothalamic) and feedforward (i.e. retinogeniculate) contributions to dLGN plasticity. Regardless of the mechanism, our results show that eye-specific responses in the

mature rodent dLGN can undergo substantial changes. We therefore conclude that purely cortical interpretations of OD plasticity need to be taken with a grain of salt.

**Title:** Different modes of visual integration in the lateral geniculate nucleus revealed by single-cell-initiated transsynaptic tracing

**Authors: *S. ROMPANI**[1], F. MUELLNER[2], A. A. WANNER[2], C. ZHANG[3], C. ROTH[2], K. YONEHARA[4], B. ROSKA[2]
[1]Friedrich Miescher Inst. For Biomed. Resear, Basel, Switzerland; [2]Friedrich Miescher Inst. for Biomed. Res., Basel, Switzerland; [3]Dept of ASNB, Univ. of Louisville, Louisville, KY; [4]Nordic EMBL Partnership for Mol. Medicine, Aarhus Univ., DANDRITE- Danish Res. Inst. of Translation, Aarhus C, Denmark

**Abstract:** The thalamus receives sensory input from different circuits in the periphery. How these sensory channels are integrated at the level of single thalamic cells is not well understood. We performed targeted single cell-initiated transsynaptic tracing to label the retinal ganglion cells that provide input to individual principal cells in the mouse lateral geniculate nucleus (LGN). We identified three modes of sensory integration by single LGN cells. In the first, 1-5 ganglion cells of mostly the same type converged from one eye, indicating a relay mode. In the second, 6-36 ganglion cells of different types converged from one eye, revealing a combination

mode. In the third, up to 91 ganglion cells converged from both eyes, revealing a binocular combination mode in which functionally specialized ipsilateral inputs joined broadly distributed contralateral inputs. Thus the LGN employs at least three modes of visual input integration, each exhibiting different degrees of specialization.

**Title:** Fractal property and non-Gaussian dynamics of maintained spiking activity in parvocellular, magnocellular and koniocellular cells of marmoset lateral geniculate nucleus

**Authors: *B. MUNN**
Univ. of Sydney, Sydney University, Australia

**Abstract:** Purpose: In absence of patterned visual stimuli, LGN neurons fire quite irregularly. We analyse the dynamics of spiking activity in LGN neurons for fractal properties and also compare these spiking dynamics with those described in cortical neurons. While, maintained activity in macaque retinal ganglion cells shows Poisson-like renewal statistics at sub-second timescales (Troy & Lee, 1994), at multi-second timescales, activity shows fractal (self-similar) characteristic in cat lateral geniculate nucleus (LGN) (Teich et al., 1997). Here we analyse the dynamics of spiking activity across long and short timescales in marmoset LGN neurons, specifically comparing parvocellular (P), magnocellular (M) and koniocellular (K) populations. We also show their diverse levels of coupling between local neuronal populations - ranging from highly correlated "choristers" to weakly correlated "soloists" (Okun et al, 2012), and a lognormal distribution of firing rates (Buzsaki, 2014).Method: Extracellular action potentials of visually-responsive cells were recorded in sufentanil-anaesthetised marmosets using a Neuronexus (16x2) silicon array probe. The visual stimulus was a uniform grey 20 deg. field, intensity ~50 cd/m2. The instantaneous firing rate, spike-triggered population rates (stPRs) and variability relative to Poisson process (Fano factor) over time windows between 0.1 s and 100 s were calculated.Results: The Fano factor of parvocellular (P, n =11/12), magnocellular (M, n=5) and koniocellular (K, n=26/29) neurons is close to unity for time windows less than 1 s (i.e. Poisson-like property) but rises monotonically with window width for time windows > 10 s (scale-free/Fractal property). Transition from Poisson-like to Fractal behaviour occurs at shorter time windows for K cells than for P and M cells ($p < 0.01$, Kruskal-Wallis test). Further, the distribution of firing rates of all LGN neurons follows a log-normal distribution and there was no

difference amongst neurons across stPR. Conclusion: Maintained firing activities of LGN neurons exhibits non-Gaussian dynamics, which are comparable to those described for cortical neurons (Churchland et al., 2010). This similarity suggests that thalamus contributes to cortical dynamics, and that to get a fundamental understanding of brain dynamics, an integrative investigation of thalamocortical interaction is required.

**Abstract:** Relay neurons in the mouse lateral geniculate nucleus of the thalamus (dLGN) exhibit diverse and distinct visual tuning. Some mouse dLGN neurons can be sensitive to location, lights on, lights off, stimulus direction and/or orientation, while others are broadly suppressed by any stimulus contrast (Piscopo et al., 2013; Zhao et al., 2013; Suresh et al., 2016). Selective visual coding in relay neurons could result, in part, from specificity of retinal ganglion cell (RGC) input. Indeed, more than 30 functional types of RGC have been estimated in a recent imaging study in the mouse retina (Baden et al, 2016), providing a rich palette of visual feature tuning across RGC inputs to dLGN. How are different RGC axons organized in the dLGN and how do they converge to contribute to the selective tuning properties of the relay neurons? Technical limitations have prevented direct investigation of these important questions. Here we mapped the

functional organization of RGC axonal boutons with subcellular resolution in the dorsal region of mouse dLGN. By implanting a chronic cannula and cranial window above the dLGN, we could reliably record calcium events in hundreds of RGC axons and assess their visual tuning properties. With these preliminary data, we have begun to address several questions: how precise are retinotopic maps across RGC boutons in dLGN? Is there spatial organization to direction/orientation tuning? More specifically, do nearby boutons from different RGC axons show functional convergence that might give rise to specific receptive field properties in dLGN neurons?

**Abstract:** The basic response properties of neurons in the lateral geniculate nucleus (LGN) are supposed to inherit from those of retinal ganglion cells. However, there is difference in spatial frequency (SF) tuning between LGN and retina, in which LGN neurons exhibit a band-pass type of tuning to SF, while the tuning of retinal cells is more low-pass. We recently found that intrageniculate GABAergic inhibition contributes to the transformation of SF tuning from retina to LGN (Kimura A et al., 2013). To understand how GABAergic inhibition elaborates the band-pass SF tuning property, we performed extracellular single-unit recording in the LGN of cats and examined the effects of blocking GABAergic inhibition on the SF tuning properties of visual responses by iontophoretical administration of gabazine, GABAA receptor antagonist, to neurons recorded. There are two sources of intrageniculate GABAergic inhibition, interneurons in LGN (feedforward inhibition) and perigeniculate nucleus (PGN) neurons (feedback inhibition). To obtain the clue of the sources of GABAergic inhibition, we focused on the temporal

characterisitcs of gabazine's action on SF tuning property and analyzed early (0-50ms) and late (50-100ms) responses separately. Administration of gabazine increased the visual responses of neurons, and changed the shape of SF tuning curve from band-pass to low-pass in both early and late responses. However, the effect of changing SF tuning curve was stronger in early than late response, suggesting that GABAgic inhibitory action via GABAA receptor is early and phasic. The detailed temporal analysis demonstrated that the inhibitory effect starts within 15ms after response onset. Therefore, the feedforward inhibition in LGN was thought to attribute to the inhibition because the feedback inhibition from the PGN takes more than 20 ms after LGN activation (Eysel, 1986). We conclude that GABAergic inhibition reshapes the SF tunings of early visual responses from LGN to retina via GABAA receptor, and the possible source of the inhibition is intrageniculate interneurons.

**Title:** The effects of stage II retinal waves on retinal ganglion cell projection to lateral hypothalamic area

**Authors: *P.-C. CHEN**[1], C.-T. WANG[1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

**Abstract:** The function of retinal ganglion cells (RGCs) can be divided into visual and non-visual function, mainly through their axon projection to thalamus and hypothalamus, respectively. Retinohypothalamic projection consists of medial retinohypothalamic tract (RHTm) and lateral retinohypothalamic tract (RHTl), the latter transferring environmental luminance to the lateral hypothalamus area (LHA), i.e, the retinorecipient region of the ventral zone of the rostral region of LHA (LHAavr). Previous studies showed that LHAavr mainly receives the inputs from the contralateral eye in adult rodent. However, it remains unknown whether this retinohypothalamic projection to LHAavr can be regulated during the developmental critical

period, when patterned spontaneous activity propagates through the developing visual system termed retinal waves. Particularly, stage II retinal waves (postnatal day P0-P9 in rodent) have shown critical for establishing the eye-specific segregation of the retinogeniculate projection. In this study, we determined the role of stage II retinal waves in pruning the retinohypothalamic projection to LHAavr. Stage II waves are generated by starburst amacrine cells spontaneously releasing acetylcholine (ACh) to the entire ganglion cell layer. Here, to block the stage II retinal waves, we injected the ACh receptor inhibitor (1 mM epibatidine in PBS) into binocular vitrea every 48 hr, starting from P1 to P9. Subsequently, the eyes were anterogradely labeled by CTB-488 and CTB-647 at P9 for 24 hr and the rats were scarified at P10 to examine the retinohypothalamic projection to LHAavr. Our results showed that the blockade of stage II retinal waves interferred the eye-specific segregation in the dorsal lateral geniculate nucleus (dLGN). By contrast, the LHAavr still received the main inputs from the contralateral eye, suggesting that stage II retinal waves may play a minor role in pruning the retinohypothalamic projection to LHAavr.

**Title:** Gain-control interactions in the lateral genicualte nucleus of the alert macaque monkey

**Authors: *D. ARCHER**, W. M. USREY
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

**Abstract:** In the early visual system, nonlinear gain control mechanisms differentially modulate neuronal responses to visual stimuli. In the lateral geniculate nucleus (LGN) of primates, cell-class specific differences in the expression of nonlinear gain control are particularly apparent. Notably, contrast gain control is robust in magnocellular layers, where individual neurons show greater response gain at low stimulus contrasts and lower response gain at high stimulus contrasts. Two related manifestations of gain control, also reported to be most robust for magnocellular neurons, are extraclassical surround suppression and contrast-dependent phase advance (CDPA). Mechanisms that contribute to extraclassical suppression and CDPA in the primate LGN likely rely on multiple circuits including feedforward input from the retina, local thalamic inhibition, and feedback from the cortex. To gain insight into the circuits involved, we performed experiments aimed at identifying interactions between extraclassical suppression and

CDPA. Single-unit recordings were made from LGN neurons in the alert, fixating macaque monkey, and we measured responses to stationary and drifting sinusoidal gratings, varying in size and contrast, and centered over the receptive fields of recorded cells. Temporal profiles of responses evoked from suboptimal, optimal, and large size stimuli over a range of contrasts were compared. Consistent with the literature, response onset latencies advanced as stimulus contrast increased and as stimulus size increased from suboptimal to optimal size. We determined preferred response phase across stimulus size and across stimulus contrast, and CDPA (i.e., change in preferred phase across contrast for a given size) was compared across size to gain insight into the potential interaction between stimulus size and CDPA. While our results reveal a range of effects across our sample of cells, evidence for cell-class specific interactions were observed. CDPA was evident in most of the cells and contingent on stimulus size—observed more often and stronger when using suboptimal and optimal size stimuli than with large stimuli. Taken together, these results indicate differential interactions between the mechanisms that underlie extraclassical suppression and CDPA.

**Title:** A model of multivalent distribution of bouton volumes reveals selective targeting of synaptic inputs on dendrite segments in lateral geniculate nucleus

**Authors: S. IMTIAZ**[1], E. N. KESKINÖZ[3], A. M. BAYA[2], C. LALA[3], E. E. MAHER[2], *A. ERISIR[2]
[1]Neurosci. Undergraduate Program, [2]Psychology, Univ. of Virginia, Charlottesville, VA; [3]Dept. of Anat., Acibadem Univ. Sch. of Med., Istanbul, Turkey

**Abstract:** From Ray Guillery's electron microscopy characterization studies in the 1960s, to more recent complete circuit reconstruction analyses (Morgan et al., 2016), the synaptic circuitry in the visual thalamic nucleus, dLGN, has been one of the most intensely studied systems. Accumulated knowledge on its inputs, including from the retina, cortex, brainstem cholinergic neurons, inhibitory interneurons and thalamic reticulate nucleus (Erisir et al, 1997; Van Horn et al, 2000), where these inputs synapse (i.e., type of neuron; location on dendrite; in or outside of glomeruli), and the divergence/convergence of retinal fibers on geniculate targets, continue to reveal the structural basis for the dynamics of sensory information processing at the neuronal

level, and for maintaining the specificity of information flow in parallel pathways. Morphological characteristics of terminals seen with electron microscopy provide an invaluable tool in identifying origin-specific inputs without using track tracing or immunochemical approaches. This is particularly useful in utilizing serial EM imaging techniques, which enable accurate measurements of terminal volumes and other morphometric features. We have used SBEM stacks to develop a simple estimation tool that combined precision of 3D measurements and the reliability of unbiased sampling approaches. A multivarient analysis in R (mclust, mclustbootstrap) of terminal bouton volumes that make up randomly sampled dLGN terminals reveals five normally distributed subpopulations and confidence levels that represent five inputs (means varying $0.2\mu m^3$ to $15.4\mu m^3$). We have applied this analysis to identify the selectivity of different inputs on segments of relay and interneuron dendrites in the dLGN. We focused on axo-somatic inputs and several dendritic segments: appendage forming interneuron (F2) and relay dendrites, proximal and distal dendrites, and dendrite branching. Using *Reconstruct* software, we measured the volumes of terminal boutons that synapse on identified dendritic segments that were at least 30um in length. By comparing the volumes of terminals that were specific to each segment, to the subpopulations of the multivariate distribution, we determined the most probable origin of each bouton. We analyzed several features for each dendrite segment, including synapse density and clustering, terminal source, presence and complexity of glomeruli, and glial enclosure selectivity. We suggest this approach provides a less time- and resource-prohibitive alternative to complete circuitry reconstructions, while also yielding more specific information on the inputs that make up the geniculate circuitry.

**Title:** Organization of the retinofugal pathway in the nine-banded armadillo (Dasypus novemcinctus)

**Authors: *B. E. SKINNER**, A. K. YORK, J. PADBERG
Biol., Univ. of Central Arkansas, Conway, AR

**Abstract:** Previous research has shown that animals with forward facing eyes, such as predators and primates, exhibit partial crossing over of the retinofugal pathways at the optic chiasm. In

contrast, animals with laterally positioned eyes, such as rodents, exhibit almost exclusively crossed pathways; the retinal pathways terminate overwhelmingly on contralateral thalamic nuclei. The aim of the current study was to determine the organization of retinofugal pathways in the nine-banded armadillo (*Dasypus novemcinctus*), a member of the Xenarthra superorder and the only species of armadillo found in North America. Extant xenarthrans lack cone photoreceptors, and it has been suggested that stem xenarthrans became rod monochromats, in conjunction with a fossorial lifestyle. Based on their relatively lateral eye position, we predicted that the retinofugal pathways would exhibit nearly exclusively contralateral projection. Monocular injections consisting of twenty microliters of fluorescent anterograde tracer (.5-1% WGA+CTB Alexa-Fluor 555 with 2% DMSO) were placed into the vitreous humor of the eyes of armadillos. Cytoarchitectural stains such as Nissl and cytochrome oxidase (CO) histochemistry, along with immunocytochemical techniques using antibodies to calbindin, parvalbumin, and nonphosphorylated neurofilament protein, were used to identify the thalamic nuclei. The dorsal and ventral divisions of the lateral geniculate nucleus (LGN) stained intensely for CO, with a thin intrageniculate leaflet separating the two. Tracer label was observed contralaterally in both the dorsal and ventral divisions LGN and in the most superficial layer of the superior colliculus. An area within the dorsal portion of the contralateral LGN was void of label, which is indicative of the recipient zone of projections from the ipsilateral eye, as there was a corresponding patch of label on the ipsilateral side. This overall pattern resembles the organization found in marsupials and eutherian mammals with laterally placed eyes, and thus, it is likely that armadillo vision is predominantly monocular. Future functional studies are likely to reveal the extent to which a frontal binocular field, if any, is present in this species.

**Abstract:** Direction selective ganglion cells (DSGC) enable vertebrates to perceive directions of moving objects. While cellular mechanisms of DSGCs have been extensively studied within the retina, downstream pathways of DSGCs have not been fully understood. It is believed that DSGCs form a distinct pathway, in parallel with X-cells, Y-cells, color coded ganglion cells, and melanopsin-containing ganglion cells. Genetic labeling and tracer injections revealed that DSGCs converge onto the shell of dorsal lateral geniculate nucleus (dLGN) before projecting to layer 1 of the primary visual cortex (V1), while X and Y neurons cluster in the core of dLGN before reaching layer 4 of V1. However, it is still unclear which layer of V1 cells receive the direction information first, since both layer 2/3 and layer 4 neurons stretch out their dendrites to layer 1 and both layers are comparably direction selective. We therefore hypothesize that both layer2/3 and layer 4 receive inputs from the shell of dLGN. We approach this problem with chronic in vivo two-photon microscope, chemogenetics and anterograde viral tools. Calcium traces from V1 layer 2/3 and layer 4 neurons are recorded while head-restrained awake mice run on a cylindrical treadmill, watching gratings waves moving at different directions through the contralateral eye. Silencing different parts of dLGN affects direction selectivity of layer2/3 cells in V1. Anterograde trans-synaptic tracers are injected into the shell and core dLGN respectively. Histological reconstruction shows that V1 layer 4 receives more input from shell dLGN than layer 2/3.

**Title:** Alpha (α) oscillations in the alert macaque lateral geniculate nucleus

**Authors: *H. J. ALITTO**, W. USREY
Ctr. For Neurosci., Univ. of California Davis, Davis, CA

**Abstract:** Neural oscillations are hypothesized to play an active role in sensory processing as well as higher-order cognition. The most ubiquitous oscillations present in the mammalian brain are alpha (α) oscillations (8-14 Hz). Past studies using scalp EEG recordings over visual cortex report α-oscillations occur during periods of low-arousal and inattentiveness, and can influence performance on visual detection tasks. While the perceptual and behavioral states associated with α-oscillations have been extensively investigated, the underlying neural circuitry remains largely unknown. Previously, our laboratory demonstrated that corticothalamic feedback from primary visual cortex (V1) to the lateral geniculate nucleus (LGN) of the dorsal thalamus is strongly coherent in the α-band. Given that the LGN is the primary source of visual input to the cortex, receiving monosynaptic input from the retina and, in turn, projecting to V1, cortically driven α-oscillations could modulate retinogeniculate communication, determining in part which retinal spikes are transmitted through the LGN to visual cortex.
To investigate the influence of α-oscillations on visual processing in the geniculostriate pathway, we recorded from both the visual thalamus and V1 in three alert rhesus macaque monkeys using a combination of electrophysiological and viral driven, optogenetic techniques. As we have previously reported, α-oscillations are a robust feature of local field potentials (LFPs) in the LGN, while higher frequency band activity (e.g., gamma band) did not significantly differ from the "1/f" prediction. Contrary to the hypothesis that α-oscillations may strongly influence retinogeniculate communication, LGN neurons displayed little coherence with local α-oscillations and retinogeniculate spike efficacy was invariant to α-oscillation phase. Intriguingly, unlike α-oscillations recorded from scalp EEG, those present in LGN and V1 LFPs were present regardless of visual task engagement, were only weakly modulated by visual stimulation, and did not increase in amplitude when the eyes were closed. We propose that geniculostriate LFP α-oscillations are present during attentive visual processing and that the amplitude of α-oscillations is stable across a wide range of behavioral states. Ongoing studies are examining whether or not spatial coherence of α-oscillations changes with shifts in attention and/or behavioral state.

**Title:** Wavelength-specific single cone responses in macaque LGN neurons

**Authors: *P. TELLERS**[1], L. C. SINCICH[2]
[2]Vision Sci., [1]Univ. of Alabama at Birmingham, Birmingham, AL

**Abstract:** Color coding by neurons in the lateral geniculate nucleus (LGN) arises from the wavelength opponency signals created by intraretinal circuity, ultimately originating from cone photoreceptors with different spectral sensitivities. Using adaptive optics retinal microstimulation, we have previously shown that LGN neurons can be driven to fire action potentials with high probability when stimuli are as small as the size of a cone (Sincich et al., 2009). In that study, it was not possible to supply stimuli with different wavelengths, nor to determine if the variation in LGN responses from one cone to the next was due to variation in cone weighting. Thus, it was not clear if cone signals are all weighted the same, a feature that would impact color coding. Recent psychophysical evidence in humans suggests that single cones can have different weights (Bruce et al., 2015) and can signal wavelength-specific responses (Sabesan et al, 2016). Here we examine how LGN neurons respond to equivalent cone-targeted stimuli. We used a multiwavelength adaptive optics scanning laser ophthalmoscope to simultaneously image the cone mosaic and to deliver cone-sized stimuli to identified photoreceptors. Extracellular recordings from individual LGN neurons were made in anesthetized macaques undergoing neuromuscular blockade. Imaging was performed with 840 nm light, and two stimulus channels were used to deliver red (710 nm) or green (543 nm) stimuli, the latter wavelength selected to equally activate L and M cones. Transverse chromatic aberration correction was incorporated to allow stimuli to land on cones identified in the infrared movie images running at 30 Hz. Trials consisted of stimuli flashing at 3 Hz, with each flash randomly selected between the two wavelengths and from 5-7 intensities. Stimulus delivery was retinally stabilized in real time. In 5 neurons recorded in one macaque, receptive fields were located between 0.9° and 2.2° from the foveal center. Among groups of 4 cones tested for each neuron, we found that cones varied in functional weight by a factor of up to 3 for green stimuli that should drive L and M cones equally. This result agrees with cone weight differences found in retinal ganglion cells (Li et al., 2014). We also found differential responses to red stimuli, consistent with activity derived from M versus L cones. These preliminary data suggest that cone-targeted microstimulation may be used to resolve wavelength sensitivity at the photoreceptor level in vivo, once cone weighting is taken into account.

**Title:** Stimulus selectivity of macaque middle and anterior superior temporal sulcus body patches

**Authors:** *S. KUMAR[1], ***S. KUMAR**[1], I. D. POPIVANOV[2], R. VOGELS[1]
[1]KU Leuven, Leuven, Belgium; [2]New Bulgarian Univ., Sofia, Bulgaria

**Abstract:** Monkey fMRI studies demonstrated two body selective patches in the Superior Temporal Sulcus (STS). One body patch, labeled MSB, is in the middle of the STS, close to face patches ML and MF, and was examined in a series of single unit studies (Popivanov et al., 2014, 2015, 2016). The anterior STS body patch, ASB, is close to face patch AL. Vogels and Kumar (SFN, 2016) observed a greater viewpoint-tolerant encoding of body posture and identity in ASB compared with MSB. That study employed only monkey bodies and did not examine ASB single units for other stimulus categories. Here, we recorded single unit spiking responses and local field potentials in ASB of the same 2 rhesus monkeys to the same stimulus categories as in our previous MSB studies (Popivanov et al., 2014): headless monkey bodies, headless human bodies, four-legged mammals, birds, H. Moore sculptures, monkey faces, human faces, fruits/vegetables and two sets of manmade objects (matching in aspect ratio to monkey and human bodies). As in MSB, the ASB LFP gamma power (30 -150 Hz) was greater for the body images (monkey bodies; human bodies; mammals; birds) compared to the other classes, including faces. The mean normalized firing rate was greater for bodies compared to non-bodies in ASB of each animal. The median Body Selectivity Index (BSI = [mean response to bodies - mean response to non-bodies] / [ |mean response to bodies| + |mean response to non-bodies|]) was similar in ASB (0.52; N = 159) and MSB (0.37; N= 214; Bayes Factor favoring null = 3.2). ASB neurons responded less selectively than MSB neurons to images of the same class: decoding (Linear Support Vector Machines (SVM)) of the individual exemplars of a stimulus class was significantly poorer in ASB compared with MSB, even when controlling for differences in Fano Factor between patches. Cluster analysis showed for MSB a body versus non-body clustering while a more heterogeneous clustering was present in ASB (e.g. human bodies distinct from monkey bodies). Linear SVM showed a significantly worse body versus non-body classification in ASB (84%) compared to MSB (92%). As in MSB, ASB neurons demonstrated size and position tolerance of their stimulus preference. A marked difference was the smaller degree of planar rotation selectivity of ASB compared with MSB neurons (Bayes Factor favoring

alternative > 10000). Surprisingly, given the more anterior location of ASB, the latency of the population responses and body category selectivity was similar in both patches. These data show that despite a similar overall body category selectivity at the single unit level, MSB and ASB differ in their stimulus selectivity, such as body orientation tuning.

**Title:** Sub-millimeter resolution fMRI reveals human-like fine-scale organization of body regions in macaque monkeys

**Authors:** ***X. LI**[1], Q. ZHU[1], W. VANDUFFEL[1,2,3]
[1]Res. Group Neurophysiology, KU Leuven, Leuven, Belgium; [2]A.A.Martinos Ctr. for Biomed. Imaging, MGH, Charlestown, MA; [3]Dept. of Radiology, Harvard Med. Sch., Boston, MA

**Abstract:** Previous monkey fMRI studies revealed two body-selective regions along the STS: the middle and anterior STS body complex (e.g. Pinsk et al. 2005, 2009; Popivanov et al. 2012). It is unclear, however, how they correspond to the human extrastriate (EBA) (Downing et al. 2001) and fusiform body areas (FBA) (Schwarzlose et al. 2005). Furthermore, high resolution imaging revealed that EBA consists of three separated compartments surrounding the MT cluster (Weiner and Grill-Spector 2011), but similar fine-grained structures have not yet been shown in macaques. Also, Lafer-Sousa and Conway (2013) showed interdigitating fMRI patches within IT cortex, selective for color, faces and places. It is unknown, however, how body patches are organized relative to other fMRI-defined patches at very fine scale. To address these questions, we studied the fine-scale organization of body regions in awake macaques using high resolution fMRI (0.6-0.7 mm isotropic voxels), and compared it with retinotopy, color, disparity and face activations at the same resolution in the same animals. To define body patches, we contrasted

monkey bodies with size-matched fruits, objects and monkey faces. To detect reliable activations, only reproducible regions across scan sessions were selected. Face patches were defined in the same way but with different contrasts (faces vs. fruits, objects and bodies). Color biased regions were localized using isoluminant color and achromatic radial gratings. A size-matched binocular disparity defined radial sine-wave grating and its monocular counterpart were used to activate disparity biased regions. Retinotopy was acquired using phase-encoded retinotopic fMRI mapping. Our results show multiple body activations surrounding retinotopically defined MT cluster in a crescent-like organization, surprisingly similar to the fine-grained organization of human EBA. Consistent body activations were found in V4d, V4t, PITd and rostral to MSTd, mostly corresponding to peripheral eccentricities as in humans. Similar face activations were found next to body activations corresponding to more foveal eccentricities. The latter form a crescent-like band around PITd body activations and were adjacent to the body patches. Several additional smaller body and face patches were found in anterior regions of IT and STS. Both body and face activations are largely separated from color and disparity activations, supporting parallel pathways in higher-level visual cortex. Together our results suggest that a surprisingly similar functional neuro-architecture exists in humans and monkeys for processing social relevant visual stimuli such as bodies.

**Title:** Cortical representation of body part relationships

**Authors: *A. BRATCH**, P. C. BURTON, S. A. ENGEL, D. J. KERSTEN
Psychology, Univ. of Minnesota, Minneapolis, MN

**Abstract:** Two regions critical for human body perception have been identified in human visual cortex: the extrastriate body area (EBA; Downing et al., 2001) and the fusiform body area (FBA; Peelen and Downing, 2005). While a wealth of evidence suggests that these areas process individual body parts and whole bodies, respectively, the regions' precise roles have yet to be elucidated. Here, we hypothesized that while neurons in the EBA represent individual body parts, neurons in the FBA also represent relationships, even at the level of pairwise connections,

between body parts. We tested this by measuring neural responses to body parts that were perceived as either forming a single, larger part, or as two disjoint parts. We used 3 Tesla fMRI (2.4 mm isotropic resolution, TE = 30.4 ms, TR = 2 s, multiband factor = 3) to measure neural activity in human subjects (N = 8). In an event-related paradigm, a hand and an elbow were presented within circular apertures on a gray background. The parts were presented either in their "normal" connected positions, or rotated within the apertures to induce the percept of an aligned arm or misaligned arm parts, respectively. Six rotations were used. We observed significantly higher activity in the FBA, but not the EBA, when subjects perceived the parts as aligned. When subjects did not actively judge alignment, and instead performed a task that demanded attention to individual parts, no difference between conditions was observed. Furthermore, a linear support-vector machine discriminated the pattern of activity for parts perceived as aligned vs misaligned at a level above chance in the FBA but not the EBA. These findings strongly suggest that the neural activity in the FBA underlies perception of relationships between body parts.

**Title:** Monkey brain fMRI responses to custom-designed animations of monkey hand- and tail-grasping actions

**Authors:** ***M. M. VISSERS**, S. SHARMA, P. A. FIAVE, S. KUMAR, K. NELISSEN
Lab. for Neuro- and Psychophysiology, Katholieke Univ. Leuven, Leuven, Belgium

**Abstract:** *Background*: Videos of human actions are widely used to study action recognition in humans and macaques. However, it is impractical to generate large, well-controlled batches of filmed videos to test various aspects of action recognition such as view invariance, generalization, coding of transitive versus intransitive actions, different effectors, action goals, etc. Moreover, creating such videos using monkey subjects to study conspecific action recognition is not straightforward.

*Methods*: We therefore designed (using open-source software Blender) an animated 3D monkey model performing various actions. Custom videos were created depicting a monkey grasping an object with its hand or tail. In addition, intransitive versions of these videos were made by removing the object from the animations. In order to validate these videos, fMRI brain responses were recorded in two macaques while they observed these animations in the scanner (Siemens 3T). Data were analyzed using SPM12 and Matlab.
*Results*: Consistent with previous monkey single cell (Caggiano et al., 2013; Kuravi et al., 2016) and fMRI (Nelissen et al., 2011) studies using videos of human actors, observing an animated monkey model performing transitive hand-grasping actions (compared to static controls), yielded significant activations throughout the action observation network, including extrastriate, STS, parietal, premotor and frontal regions. Interestingly, most of the regions responding to hand grasping observation (including those housing mirror neurons) also yielded significant responses for tail-grasping observation, as well as to intransitive hand or tail actions.
*Conclusion:* This study demonstrates the feasibility of using an animated 3D model to study brain responses to conspecific actions in monkeys. Our preliminary results suggest that typical motor regions containing grasping mirror neurons, also respond to observed motor actions that are outside the monkeys' own motor repertoire but share to same goal (grasping). The finding that even observation of intransitive actions yielded robust responses in these regions consistent with previous fMRI (Nelissen et al., 2005) and single cell data (Pani et al., 2014) suggesting that mere stimulus motion might be sufficient to drive at least a proportion of the neurons in these regions. More sensitive decoding and representational similarity analyses might shed light on the underlying organizational principle of these regions with respect to representing either immediate goals (Rizzolatti and Sinigaglia, 2016), causality (Caggiano et al., 2016) or the type of action effectors (Jastorff et al., 2010).

**Title:** Measuring neuronal selectivity for facial features in macaque inferotemporal cortex through adaptive sampling of feature space

**Authors: *A. P. MURPHY**, D. A. LEOPOLD
Section on Cognitive Neurophysiol. and Imaging, Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract:** For social animals like primates, faces are a behaviourally important class of visual objects, and they exhibit statistical variation across multiple dimensions. Previous studies have typically investigated the selectivity of single neurons in the inferotemporal (IT) cortex of macaques to variation of one or two facial features at a time, such as identity and head orientation. However, due to the high-dimensionality of the stimulus space and the time-constraints imposed by traditional recording methods, our understanding of how multiple facial features are encoded remains limited. To overcome these limitations and obtain a broader characterization of IT neuronal preferences for visual face features, we exploited two recent methodological advancements. First, we surgically implanted chronic microwire 'brush' electrodes, which allowed us to stably isolate single units over periods of weeks to months. The ability to record from the same neuron longitudinally increases the total number of visual stimuli that can be tested, thus improving coverage of stimulus space and characterization of the cell's selectivity across multiple stimulus dimensions. To leverage this, we developed an anatomically realistic three-dimensional virtual macaque avatar that offers continuous parametric control of over 50 variables (in addition to lighting, material and environmental varibles). To sample this high-dimensional feature space we used an adaptive approach whereby neuronal responses from one session were used to inform which regions of feature space to explore in the next session, with each generation of new stimuli being rendered offline using ray-tracing. Here we focused on a subset of possible variables that included head orientation, facial expression, identity, position in depth, depth profile, and virtual scale. We recorded from 128 channels in each of 3 macaque monkeys, targeting fMRI-localized IT 'face patches': ML, AF, and AM bilaterally. Monkeys viewed full-color 3D stimuli stereoscopically through a mirror haploscope, and maintained fixation while stimuli were presented. For most cells, firing rate was more strongly modulated by head orientation (azimuth and elevation angle) than by any other parameter tested, and this held true across all three face patches tested. However, a subset of cells showed highly specific selectivity for conjunctions of variables, such as head orientation and expression. The results demonstrate the value of adaptive sampling in a high-dimensional and parameterized feature space, thus improving characterization of the feature preferences of single neurons to complex stimuli.

**Abstract:** Face is a complex visual stimulus, and primates developed neuronal networks specialized for face recognition. In macaque monkeys, face-selective neurons were clustered in the inferotemporal cortices, constituting face patches that are mutually interconnected and process unique property of faces. Although a previous study showed that anterior inferotemporal neurons represent visual face stimuli by encoding difference from an average face (Leopold et al., 2006), it is still not clear whether the neurons in the face patches show this “norm-based” coding or not. Here we recorded single-units from two face patches located at the most anterodorsal (face patch AF) and anteroventral (AM) part of the inferotemporal cortices and examined their response tuning around an average face. The average face was created from 12 different identities of monkey faces by morphing technique. A series of stimuli was then computed based on the average face and each identity, producing “caricature faces” which has exaggerated features and “anti-faces” which has opposite features of the original identities. We recorded 30 face-selective AF neurons from three monkeys and 38 face-selective AM neurons from two other monkeys. Neurons from both face patches tended to respond weaker to the average face and respond stronger to caricature-/anti-faces, showing characteristic “v-shaped” tuning along the axis of anti-, average- and caricature-faces. Regression modeling of the response tuning showed that 76% of the face-selective neurons have the v-shaped tuning with its vertex around the average face. This tuning was not obvious in early transient response but became evident in later sustained responses starting 200 ms after stimulus onset. These results indicate a special role of the average face in both the AF and AM face patches, consistent with the concept of norm-based coding.

**Title:** fMRI mapping of retinotopy using complex objects in rhesus monkeys

**Authors: *A. MESSINGER**, B. JUNG, C. SPONHEIM, L. G. UNGERLEIDER
Lab. of Brain and Cognition, NIMH, Bethesda, MD

**Abstract:** Visual processing in the primate brain occurs along two main pathways: a dorsal visual stream that primarily processes the spatial location of visual stimuli (the "where" stream) and a ventral visual stream that primarily processes the form and identity of those stimuli (the "what" stream). Using neurophysiology and fMRI, early visual areas have been shown to be retinotopically organized, with different portions of the cortex responding to different portions of the visual field. Such retinotopy is less apparent or absent in later stages of the ventral visual stream, where many neurons have receptive fields that span much of the visual field. Neurons in these ventral areas are selective for particular shapes, with neurons preferring the same visual category (e.g. faces or objects) clustering together. It is unclear how much, if any, spatial information is retained in these later stages of the ventral visual stream.
We measured fMRI responses in two rhesus macaques to the presentation of static monkey faces (and objects) in each of four quadrants of the visual field during a central fixation task. Stimuli were 7x7 degrees and were presented in a block design at an eccentricity of 6 degrees.
We evaluated responses in anatomically-defined areas throughout the visual stream using a standard anatomical template and coordinate system (Seidlitz et al., *Neuroimage*, 2017). As expected, responses throughout the visual system were almost always greater when the complex shape stimuli were presented in the contralateral quadrants than in the ipsilateral quadrants of the visual field. In early visual areas (V1-V4), regions responding more to the upper field quadrants were distinct from (and typically located ventral to) regions that responded more to the lower field quadrants.
In anterior ventral stream areas, contralateral stimuli generally elicited greater responses than ipsilateral stimuli and voxels responding significantly more to stimuli in the lower quadrants than the upper quadrants were more common than the reverse. This result indicates that some information about the position of visual stimuli is retained even in the later stages of the ventral stream, where complex shapes such as faces and objects are processed. The bias for lower-field stimuli suggests that face and object recognition may be more accurate or efficient in the lower relative to the upper visual field.

**Title:** Experience-dependent development of the visual system is anchored to an innate retinotopic organization

**Authors: *M. J. ARCARO**[1], P. F. SCHADE[2], M. S. LIVINGSTONE[3]
[1]Neurobio., [2]Dept. of Neurobio., [3]Harvard Med. Sch., Boston, MA

**Abstract:** The adult primate visual system comprises a series of interconnected, topographically-organized areas arranged in two, dorsal and ventral, distributed hierarchies. This global organization, as well as the anatomical location and functional properties of individual areas throughout cortex, are similar across individuals, suggesting an early common program for the development of the visual system.
Here, we tracked the functional development of visual cortex over the first year of life in monkeys that were raised with normal or abnormal visual experience. We scanned monkeys using fMRI in a variety of visual tasks and under rest conditions starting as early as 8 days. To resolve the organization of visual cortex in infants, we characterized visual selectivity as well as patterns of functional connectivity (correlations).
Within the first two weeks of life, visual cortex was retinotopically organized in all monkeys regardless of visual experience. This organization preceded the emergence of other functional organization such as category-selective domains in inferotemporal (IT) cortex. When category-selective domains emerged, they were localized to retintopically-specific regions of visual cortex in each monkey. e.g., face domains developed within foveal regions of IT and scene regions developed within peripheral regions. However, visual experience shaped which domains developed. Specifically, monkeys raised without exposure to faces failed to develop face domains, but developed domains for other normally experienced categories such as hands and scenes. Functional connectivity patterns that overlapped with category domains emerged during early development in all monkeys. These connectivity patterns were localized to comparable

parts of IT across monkeys regardless of visual experience. However, category selectivity within these connectivity regions differed between monkeys based on visual experience, suggesting a dissociation between fMRI measured correlation patterns and underlying functional selectivity. Our results demonstrate a retinotopic organization present throughout the entire visual system, including IT, at birth. This organization is present even in monkeys raised with abnormal visual experience. Experience-dependent development is anchored to this retinotopic organization. Thus, despite substantial early organization, the primate visual system is immature at birth, and its organization is heavily modifiable through experience.

**Title:** The effects of early face deprivation on the macaque face-patch system

**Authors:** ***M. S. LIVINGSTONE**[1], M. J. ARCARO[2], P. F. SCHADE[2], J. L. VINCENT[2], C. R. PONCE[2]
[2]Neurobio., [1]Harvard Med. Sch., Boston, MA

**Abstract:** In humans and in monkeys, inferotemporal cortex is subdivided into domains that process different image categories, such as faces, bodies, or scenes. Here we asked whether experience is necessary for the development of category domains, specifically, the face patch system. We report that monkeys raised without exposure to faces did not develop face patches, but had normal domains for other categories, such as hands, bodies, and scenes. Furthermore, they showed normal retinotopic organization, indicating that their deficit was specific to the never-seen category. Therefore experience must be necessary for the formation of category domains. Our previous results had shown that intensive early experience can result in domains in monkeys for categories of objects that they normally never experience, indicating that experience is also sufficient for domain formation. Since face patches appear in foveally biased parts of IT, how monkeys view faces must be important in driving the stereotyped locations of face patches. Gaze tracking revealed that control monkeys looked preferentially at faces, even at ages prior to the emergence of face patches, but face-deprived monkeys did not. Thus selective early viewing behavior could bias category-specific visual responses towards particular retinotopic representations, thereby leading to domain formation in stereotyped locations in IT, without requiring category-specific templates or biases. We conclude that experience drives viewing

behavior, and viewing behavior precedes and sculpts domain formation. These results highlight the malleability of IT cortex early in life, and the importance of early experience on normal visual cortical development.

**Title:** Consequences of early face deprivation on viewing behavior in macaques

**Authors: *P. F. SCHADE**, M. S. LIVINGSTONE
Neurobio., Harvard Med. Sch., Boston, MA

**Abstract:** Human and non-human primates tend to fixate on salient features and behaviorally relevant information in their visual environment. During free viewing, human and non-human primates preferentially look at faces, presumably due to the high amount of behaviorally relevant information that can be found in a face, such as its identity, emotion, and direction of gaze. It is debated, however, whether preferential face looking behavior is learned or innate. To address this, we asked if experience with faces is necessary for preferential face looking behavior. Using eye tracking, we monitored the gaze of normal and face-deprived macaques over the first year of life. Consistent with prior studies, our normal infant monkeys showed preferential face looking behavior. In contrast, we found that face-deprived monkeys did not preferentially fixate on faces during free viewing, indicating that preferential viewing of faces must be a learned behavior, and that faces must not be intrinsically interesting. Instead, the face-deprived monkeys looked more often at hands, when both faces and hands were presented, probably due to hands being more behaviorally relevant to them. We additionally monitored the gaze of the face-deprived macaques subsequent to the year-long deprivation period. Following the introduction of the face-deprived monkeys to social housing with other juveniles, there has been a shift in the viewing patterns, so that they now attend more to faces, yet they still show enhanced attention to hands, compared to normal juveniles. These data show that early experience, not an innate face bias, is the driving factor in how non-human primates, and likely humans, sample their environment.

**Title:** Using electrical microstimulation to manipulate gaze following and face perception

**Authors: *I. CHONG**, H. RAMEZANPOUR, P. DICKE, P. THIER
Cognitive Neurol., Hertie Inst. For Clin. Brain Res., Tübingen, Germany

**Abstract:** Gaze following involves reading the eyes or head direction of an observed individual to identify possible objects of interest they are attending to and redirecting attention towards said objects. This is a process both humans and rhesus monkeys are capable of. We were able to circumscribe a “gaze following patch” (GFP) localized in the posterior superior temporal sulcus (pSTS) through human and monkey fMRI experiments, the latter followed by single unit neuronal recordings. That a highly specialized cortical area exists to extract directional facial information for redirecting the gaze of an observer highlights the importance of being able to follow gaze, yet it remains unknown what exactly the GFP is contributing to eye/head gaze following and to establishing joint and shared attention. Given the immense amount of socially relevant information we obtain from faces, one could imagine that the functional contribution of the GFP builds on information derived from various elements of the face processing network. The fact that one element of this face network, the middle face patch (mFP) lies in close proximity to the GFP (4-6mm) suggests a particularly important link. We used electrical microstimulation to perturb either the GFP or the mFP in the right hemisphere of two macaque monkeys trained in gaze following and identity matching tasks, and assessed subsequent effects on gaze following and face processing. In the gaze following task, the monkeys were presented with a portrait of one of four different monkey individuals, looking at one of four targets presented along a horizontal line. The monkeys were required to make a saccade towards the same target the portrait was looking at. In the identity matching task, the monkeys were required to direct saccades towards a spatial target unique to the identity of the monkey portraits they had been trained to associate. Here we report results from the first monkey as the experiments on the second one are still in progress. Our results indicate that the GFP and mFP are specifically relevant for gaze following and face processing respectively; stimulating the GFP led to impairments in gaze following whilst leaving identity matching intact, while targeting the mFP enhanced the ability of the monkey to match monkey identities without any significant effect on the ability to follow gaze. The evidence we provide here is a first step in establishing a causal role of the GFP in gaze following. The fact that stimulating the mFP did not disrupt gaze following does not necessarily contradict the assumed link between the mFP and the GFP;

possibly the latter may draw from redundant sources of face-related information and eventually also from the left mFP.

**Title:** The development and specialization of the visual system from infancy to adulthood

**Authors: *K. LESINGER**[1], G. ROSENTHAL[2], K. PIERCE[3], E. COURCHESNE[3], I. DINSTEIN[4], G. AVIDAN[5]
[1]Psychology, Ben-Gurion Univ. of the Negev, Tel Aviv, Israel; [2]Dept. of Brain and Cognitive Sci., Ben-Gurion Univ., Beer Sheva, Israel; [3]Univ. California San Diego, La Jolla, CA; [4]Ben Gurion Univ., Beer Sheva, Israel; [5]Dept. of Psychology, Ben-Gurion Univ. of the Negev, Beer Sheva, Israel

**Abstract:** **Background:** Little is known about how the face perception network develops during early life. Here we investigated the development of this network from infancy to adulthood (1-35 y.o.; N=131) using an innovative method which registered anatomical and functional MRI scans of infants, children, adolescences and adults into a common space. This enabled us to use the regions identified as belonging to the face or place networks in adults for analyses in the other age groups in which such data were not available. Functional correlations across the identified ROIs were examined in resting state fMRI scans obtained in all age groups. **Results:** Functional connectivity was measured across ROIs belonging to the core face network (fusiform face area, occipital face area, superior temporal sulcus) and the place network (parahippocampal place area, inferior temporal sulcus, transverse occipital sulcus, inferior parietal sulcus). Interestingly, connectivity in the core face network was stronger in the right hemisphere across all age groups (infants, children, adolescences and adults). In contrast, the place network connectivity was stronger in the left hemisphere compared to the right hemisphere only in infants, while no difference was observed in the connectivity of this network between the right and left hemispheres in the other age groups. **Conclusions:** These findings reveal key details regarding the developmental trajectory of physiological changes unique to face representation. Specifically, the core-face network exhibited an early rightward lateralization from infancy, which is a well-known marker of the face processing system in adults.

**Abstract:** In adults, the ventral visual stream contains category-specific regions that preferentially process faces, places and objects. The developmental origins of these regions were recently studied in infants using functional neuroimaging by Deen et al. (2017), who found regionally specific activation for faces and places, but not for objects. We aimed to characterise the development of these regions in a complementary way to Deen et al., by also characterizing the development of the broader networks that the category-specific regions participate in, using diffusion weighted images (DWI) (128 directions, 2 mm isotropic, no gap, b=0 mm $s^{-2}$) and applying diffusion tractography and machine learning. We used the parcellation of the ventral visual stream and fMRI localisers from the Human Connectome Project to identify the most face, place and tool selective regions, which were: the fusiform complex, the ventromedial visual area 2, and ventromedial visual area 3, respectively. We found that the face, place and tool regions could be localised through their unique signatures of connectivity. Using leave-one-subject-out cross-validation, three linear discriminant classifiers were trained to determine whether a voxel was inside or outside each of the three category-selective regions, from its strength of connectivity to regions across the rest of the brain. The classifiers' performance on identifying the regions was then tested on the left-out subject. All three regions could be robustly localised in adults ($p<0.001$). To test whether regions with similar category-specific signatures of connectivity were present in infants, we then acquired similar DWI data in infants between 1 and 9 months old (N=11, Mean Age=6.1 months) and performed tractography. The three classifiers trained on the full group of adults were then tested on each infant. We found that the classifiers

were able to localise all three regions in the infants ($p<0.01$). However, while the face and place regions were as strongly detected in infants as they were in adults (difference, $p>0.1$), the tool region was substantially more weakly detected (difference $p<0.01$). These results support Deen et al's findings that face and place specific activation is present in infants, but object specific systems are less developed, using a complementary neural measure. We further show that the broader networks of these category-specific regions are already connected in a way that is similar to adults. Our results are consistent with a broader framework that visual categories that are more passively perceived (faces and places) develop before those that are actively manipulated (objects).

**Title:** Image reconstruction reveals the impact of aging and medial temporal lobe damage on face perception

**Authors: *C.-H. CHANG**[1], A. NESTOR[1], A. C. LEE[1,2]
[1]Dept. of Psychology at Scarborough, Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Institute, Baycrest Ctr., Toronto, ON, Canada

**Abstract:** A number of studies have demonstrated that face perception, as measured by performance accuracy on a variety of visual discrimination tasks, is impacted by healthy aging as well as by anterior medial temporal lobe (MTL) cortex damage. To date, however, there has been relatively limited insight into how precisely aging and MTL lesions affect the representations that underlie face processing, and how the subjective experience of face perception is altered. Here, we sought to address these issues by turning to a recent image reconstruction method that capitalizes on the structure of multidimensional face space. Neurologically healthy young participants, older adults and an amnesic patient with focal MTL damage first provided similarity judgments for pairs of face images presented simultaneously, with participant-specific ratings then used to construct a face space for each individual. Significant facial features and corresponding dimensions were subsequently derived from face space for every participant, and

then used to reconstruct the appearance of each face image that was presented. Our findings indicated that image reconstruction was successful for all groups of participants. However, reconstruction accuracy varied systematically across groups, with best results achieved for young adults. Converging with this, a hierarchical clustering analysis revealed differences in the representational space of the older participants and MTL patient when compared to the younger group. Our findings provide novel insight into age- and MTL lesion-related changes in face perception and demonstrate the utility of image reconstruction approaches to understanding face recognition across a variety of participant populations.

**Title:** Behavioral mechanisms underlying visual expertise and their relation to face perception

**Authors: N. WEISS**[1], *G. AVIDAN[2]
[1]Psychology, Dept. of psychology, Ben-Gurion Univ., Beer-Sheva, Israel; [2]Dept. of Psychology, Ben-Gurion Univ. of the Negev, Beer Sheva, Israel

**Abstract: Background:** A major question in the face perception literature is whether faces comprise a distinct visual category that is processed by specialized cognitive mechanisms, or whether face processing merely represents an extreme case of visual expertise. A related question is whether objects of expertise are processed by the same cognitive mechanisms used for face perception. **Methods:** We address these issues by studying two groups of individuals with long-term visual expertise for either flowers or horses, naturally acquired due to personal interests and/or occupation. Using an eye-tracker, we conducted a gaze contingency experiment to examine whether these objects of expertise are processed holistically similarly to faces, as previously claimed in the literature. In this task, stimuli (flowers, horses and faces) are presented in three different conditions: 1. The whole stimulus is shown 2. An oval mask covers the visual field at the centre of the participant's gaze, concealing the local characteristics of the stimulus, and 3. An oval window is presented as a function of the participant's gaze, allowing only the presentation of local information. This behavioural task allowed fine-grained examination of the visual processes underlying perception of these stimuli, whether holistic or non-holistic. **Results**: Our findings revealed that experts did not necessarily use face processing mechanisms for objects of expertise. Specifically, a different perceptual process was used for each category of

expertise, as demonstrated by the different patterns of results obtained for each of these categories. **Conclusions**: The results imply that each visual category is processed as a function of its idiosyncratic characteristics. These findings shed new light on the seperability of the mechanisms mediating face processing compared to the processing of different categories of of visual epxertise.

**Title:** Developmental prosopagnosics show reduced category-selectivity in right hemisphere areas selective for faces and other categories

**Authors: *J. GUO**[1], H. YANG[2], B. DUCHAINE[1]
[1]Dartmouth Col., Hanover, NH; [2]Univ. of Massachusetts Med. Sch., Boston, MA

**Abstract:** Although many studies have investigated the neural basis of developmental prosopagnosia (DP), it remains unclear which face-selective areas are implicated in DP and whether their neural abnormalities extend to other category-selective areas. To address these issues, we scanned 22 DP participants and 27 controls with a dynamic localizer that effectively identifies posterior and anterior face-selective areas as well as areas selective for scenes, bodies, and objects. To avoid the complications inherent in comparing groups using typical ROI-based approaches, we analyzed each category-selective area by selecting a fixed percentage of the most selective voxels for each anatomical region that typically contains a category-selective response and then systematically probed the effect of ROI size on category-selectivity (Norman-Haignere et al., 2016). For faces, results showed significantly reduced face-selectivity in four face-selective areas in the right hemisphere (FFA, pSTS-FA, aSTS-FA, IFG-FA) along with weaker face-selectivity in OFA and ATL-FA. Face areas in the left hemisphere also tended to show weaker selectivity but only left FFA was significant. Results for other category-selective areas were mixed. DPs showed reduced selectivity in all three scene-selective areas in the right hemisphere (PPA, OPA, RSC), and weaker selectivity in left hemisphere areas but only the reduction in PPA was significant. For bodies, DPs showed reduced selectivity in right EBA and non-significant reductions in right FBA and left EBA. Object-selectivity in bilateral lateral occipital cortex (LO) was normal. In summary, our results show that posterior and anterior face-selective areas respond abnormally in DPs. The differences that reached significance were located primarily in the right hemisphere, which is consistent with the predominance of the right hemisphere in face perception. Reduced selectivity was also present in a number of areas

selective for non-face categories, and these reductions also tended be in the right hemisphere. Together, these findings suggest that many DPs have broad impairments across right hemisphere regions involved in visual recognition.

**Title:** Face perception: what we have learnt from face transplant patients

**Authors: *E. GÜLBETEKIN**[1], S. BAYRAKTAR[1], Ö. ÖZKAN[2], Ö. ÖZKAN[2]
[1]Dept. of Psychology, [2]Dept. of Plastic and Reconstructive Surgery, Med. Faculty,, Akdeniz Univ., Antalya, Turkey

**Abstract:** The face is an important information source about its owner's gender, age, race and emotional state. Therefore, specific brain regions -fusiform face area, superior temporal sulcus- have evolved for face perception. Self-face recognition is also crucial to recognizing the bodily self and actively represented in the human cognitive and emotional system (Martini et al., 2015). Face transplantation has the potential to understand the link between self and other face perception. Due to long term facial somatosensory deprivation and thus having less feedback from his own face, face perception is thought to be altered in people having facial injuries since infancy. We observed that facial recognition memory performance was poorer in two facial transplant patients (Gülbetekin et al., 2017). Another phenomenon related to self-other face perception is enfacement illusion (EI): By touching the face of subjects who were viewing simultaneous touches on a partner's face, Bufalari et al.(2010) induced a novel illusion of personal identity called ''enfacement''. We tested two FTPs and compared their data with 21 healthy individuals for EI. The participants were asked to watch the video clips from a viewing distance of 150 cm. While watching the video, participants were touched on their face at the same locations as observed in the video in two conditions: synchronous, and asynchronous. The results indicated that the healthy subjects experienced stronger EI when the right side of the face was stimulated $X2\ (2, 28) = 17.64$, $p = .001$; however, the two FTPs did not show the right-sided bias for the illusion. Additionally, the EI was weaker in FTPs. The third issue on self-other face perception link is the influence of facial feedback on emotion recognition. In addition to visual and contextual routes to emotion recognition, people might also make use of sensorimotor simulation" (Wood, Magdalena Rychlowska, Korb & Niedenthal (2016). Some studies indicated that populations lacking facial expressions showed poorer performance in recognizing emotional expressions. FTPs have also difficulties in conveying emotional expressions. Therefore, we

tested the FTP's performance in "Reading the Mind in Eyes Test" if their difficulty in expressing emotions has any influence on decoding the emotional expressions of other faces. We found that their scores were lower than the mean score for their education level. Altogether we propose that long-term facial somatosensory deprivation may alter FTPs' ability to recognize faces and decode facial expressions, therefore intact facial feedback from one's own face seems to be required for precise facial processing.

**Title:** Face ensembles and identity processing: Decoding facial summary statistics from ERP signals

**Authors: *T. ROBERTS**, J. S. CANT, A. NESTOR
Univ. of Toronto Scarborough, Scarborough, ON, Canada

**Abstract:** Previous behavioural work has demonstrated our ability to extract summary statistics from groups of faces such as mean identity, emotion, and sex. However, despite the abundance of behavioural research, we know very little regarding the extraction of summary statistics for facial identity within the human visual cortex. Here, we used electroencephalography (EEG) to explore the neural basis of summary statistics for facial ensembles and its reliance on individual face representations. To this end, we collected EEG data while participants performed a one-back repetition detection task either with face ensembles (i.e., displays of 6 different faces presented simultaneously) or with single faces presented one at time. Critically, stimulus ensembles were designed so that, though they consisted of different individual faces, they could lead to the same summary representation, that is, the same average face. Pattern analyses were then conducted across spatiotemporal signals recorded across 12 bilateral occipitotemporal electrodes. These analyses showed that event-related potential (ERP) data support individual face classification and, also, point to the feasibility of ensemble classification. Importantly, these analyses serve to characterize the neural sensitivity to summary statistics beyond the processing of individual faces while, conversely, they also evaluate the relationship between ensembles and their individual elements. Further, they characterize the time course of face perception and confirm the informational value of spatiotemporal patterns in the proximity of the N170 ERP component. Thus, theoretically, the present investigation sheds new light on the neural basis of

ensemble processing in the context of face perception. Last, from a methodological standpoint, it serves to confirm the ability of EEG data to uncover the neural dynamics of ensemble perception.

**Title:** Shape and surface-based facial image reconstruction: An evaluation of different neuroimaging modalities

**Authors: *D. NEMRODOV**, M. NIEMEIER, A. NESTOR
Univ. of Toronto Scarborogh, Scarborough, ON, Canada

**Abstract:** Neural-based reconstruction of image stimuli has been previously achieved with functional magnetic resonance imaging (fMRI) data as well as, more recently, with electroencephalography (EEG) data. However, a comparison of different modalities regarding their ability to support stimulus reconstruction along with their relative reliance on different classes of visual cues are yet to be explored. Here, we evaluate and compare the outcomes of facial image reconstruction based on fMRI, EEG and behavioral data. To this aim, we investigate the ability to reconstruct, from each modality, images of adult faces displaying different emotional expressions. Specifically, we aim to separately reconstruct face shape (i.e., a deformable configuration of fiducial points) and surface-based appearance (i.e., luminance and color properties of standardized 'shape-free' face morphs). Our results indicate that both shape and surface information can be recovered with above-chance accuracy from any of the modalities considered. However, surface is consistently retrieved with better accuracy than shape across all modalities. Interestingly, behavioral and fMRI-based reconstruction appear to perform equally well in terms of average accuracy, followed by their EEG counterpart. At the same time, EEG stands out by its ability to characterize the temporal dynamics of face encoding by supporting reconstruction for distinct time intervals. This investigation indicates that both shape and surface information can be recovered at multiple time points from the EEG signal and they are most effectively retrieved in the proximity of the N170 ERP component. Thus, our results speak to the feasibility and the relative success of stimulus reconstruction based on different data types while, theoretically, they shed light on the visual mechanisms for face recognition and their neural dynamics.

**Title:** Smaller, slower, and shorter-lived: Context-dependent temporal characteristics of visual adaptation in human ventral temporal cortex

**Authors: *V. RANGARAJAN**[1], K. S. WEINER[2], C. JACQUES[4], J. PARVIZI[3], R. T. KNIGHT[5], K. GRILL-SPECTOR[2]
[1]Psychology, UC Berkeley, San Francisco, CA; [3]Neurol. and Neurolog. Sci., [2]Stanford Univ., Stanford, CA; [4]Psychological Sci. Res. Inst. (IPSY), Univ. Catholique de Louvain, Louvain, Belgium; [5]Univ. of California Berkeley, Berkeley, CA

**Abstract:** Repeated presentations of visual stimuli produce decreased neural responses within human ventral temporal cortex (VTC) - a phenomenon known as repetition suppression or adaptation. Several neural mechanisms, including scaling, sharpening, and facilitation, have been proposed to explain this phenomenon. Different than scaling and sharpening, facilitation proposes that neural responses are comparable in amplitude, faster to peak, and shorter in duration for repeated than nonrepeated stimuli. To distinguish between proposed mechanisms of adaptation, we tested the dynamics of responses to repeated stimuli utilizing the high spatial and temporal resolution of electrocorticography (ECoG) from 6 subjects (2 female) implanted with intracranial electrodes over the right (n=4) and left (n=2) VTC. Subjects were presented with images of houses, bodies, cars and faces. We first identified which electrodes were face-selective in each subject. Then, using independent data, we quantified the functional dynamics of responses to repeated images presented either after intervening stimuli (experiment 1) or immediately (experiment 2).
We found a concentration of face-selective electrodes (n=43) in the lateral fusiform gyrus and inferior temporal gyrus. Many of these electrodes (54%) exhibited significantly reduced high frequency broadband (HFB: 70-150 Hz) power to immediate repetitions of faces. Contrary to predictions of the facilitation model, responses to immediate repetitions of a face were slower ($p<0.004$), smaller ($p<10^{-5}$), and shorter-lived than responses to the first presentation (area under

the curve for 1st vs 2nd presentation, $p<10^{-8}$, KS-test=0.6744). For repetitions with intervening stimuli, we also found reduced responses to repeated vs. first presentations, although less attenuation than for immediate repetitions. However, there were no significant changes to the onset ($p>0.05$) or duration (area under the curve, $p=0.057$, KS-test=0.2791). Together, these findings provide evidence that mechanisms other than facilitation likely underlie processing of repeated stimuli in human VTC and immediate and interleaved repetitions may involve different neural mechanisms. As adaptation is prevalent across the brain, these data have important implications for understanding neural mechanisms of repetition effects.

**Abstract:** We and others have previously shown that oculomotor dynamics serve as a valid biomarker for fatigue and high mental workload, and other brain states—measured in applied environments. We obtained eye movements from both instructor and trainee United States Marine Corps (USMC) combat aviators to determine the differences in dynamics as a function of expertise. The pilots flew different simulated mission types and we determined their ocular kinematics—as a function of mission type and cohort—across many dimensions. We observed

that there are differences in specific eye movement signals between novice and expert helicopter pilots. From this data we created a classifier of expertise, which performed with an accuracy of >70%. We then studied whether novice pilots benefit more from viewing movies of experts performing emergency procedures or the same movies with the expert's eye position scanpaths overlaid. As an innovation, we did not measure the benefit to novices as a function of performance, but instead measured their oculomotor dynamics as a function of the expert scanpaths—assessed by our objective expertise discriminator. We tasked novice pilots with repeatedly resolving an Emergency Procedure (dual engine failure cascade), followed by watching a video with the expert eye position indicated, and the other half watched the video without the eye movements superimposed. Pilots who were given access to the expert's scanpaths significantly changed, in comparison to pilots who saw the same movies without scanpaths. These results suggest that physiological biomarkers such as oculomotor dynamics may provide a rich source of data—in a short amount of time and within challenging operational environments. This also suggests that our oculomotor systems learn to use eye tracking information—even without being instructed to—very quickly. Future research will determine if the fast oculomotor learning we observed translates to true improvements of performance.

**Abstract:** Sensory deficits and cognitive impairments contribute to poor psychosocial functioning in patients with schizophrenia. These patients use inefficient visual search strategies and show reduced ability to make correct anti-saccades. Impairments related to the visual system can be quantified using psychophysical parameters of visually guided eye movements. This study aimed to verify the importance of higher versus lower order visual information processing

in schizophrenia patients and its relationship to specific cognitive domains. Therefore, we compared the performance of schizophrenia patients and healthy controls while executing two oculomotor tasks. The visual search task requires finding a vertical gabor target among several horizontal distractors with the same contrast (efficient search) and vertical distractors with a higher contrast compared to the target (inefficient search). The anti-saccade task requires looking to the direction (pro-saccade) or the opposite direction (anti-saccade) of a luminescent stimulus. Moreover, we performed correlations between the visual processing outcome measures and specific cognitive domains scores in the patients group. Patients made significantly more fixations to find the target in the visual search task (efficient search: t=2.16, p=0.04; inefficient: t=3.37, p=0.003) and showed elevated error rates for the anti-saccade task (pro-saccade: t=2.25, p=0.04; anti-saccade: t=2.11, p=0.05) compared to controls. The patients group showed a correlation between the inefficient search and spatial memory and learning scores (r=-0.64, p=0.04) and between anti-saccade error rates and verbal memory and learning scores (r=-0.85, p=0.001). These results confirm that patients with schizophrenia have deficits in visual search and anti-saccade neurobiological correlated processes, which may be associated to memory and learning cognitive domains. To remediate these impairments, we are currently testing the efficiency of a neuroplasticity-based cognitive training.

**Title:** Neural correlates of presaccadic compression: An ERP study

**Authors: *A. RODRIGUEZ**, S. M. LONG, M. A. GANNON, N. A. PARKS
Dept. of Psychological Sci., Univ. of Arkansas, Fayetteville, AR

**Abstract:** The perceptual consistency viewed across the large quantity of saccades made has been posited to be the result of a visual mechanism known as presaccadic visual remapping which updates visual representations prior to the execution of a saccadic eye movement. A byproduct of remapping is the occurrence of a significant spatial distortion prior to a saccade (known as presaccadic compression) in which there is a systematic mislocalization of targets toward the spatial location of a planned saccade. Several studies have illustrated such mislocalization, demonstrating that observers systematically report stimuli to appear spatially shifted toward a saccade target. Single-cell recordings in monkeys have demonstrated rapid alteration to receptive field dynamics in posterior parietal cortex and retinotopically organized

extrastriate visual cortices that are consistent with a remapping of visual space in anticipation of an impending saccade. Here, we use event-related potentials (ERPs) to examine the link between presaccadic neural activity and the percept of presaccadic compression in the human visual system. Observers performed a cued saccade task, requiring them to make leftward or rightward saccades when cued by an auditory tone. On 85% of trials, a probe stimulus (vertical line) briefly flashed at a pseudorandom delay following the saccade cue. After completion of the saccade, observers then used the mouse to indicate the perceived position of this probe. On the remaining 15% of trials, no probe stimulus was presented and observers simply made a saccade to the target location. These 'saccade only' trials were used to remove electro-ocular eye movement artifacts from probe trials. Trials were binned into three bins according to the relative timing of probe onset to saccade onset (-225 to -151 ms, -150 to -76 ms, and -75 to -1 ms). ERPs and mislocalization effects were calculated within each of these time windows. Preliminary results demonstrate a standard presaccadic mislocalization effect in the -75 to -1 ms time window leading up to the saccade and further indicate the occurrence of a potentiated visual N1 component of the visual evoked potential within this same time window. This reveals a potential correlate of presaccadic compression in human extrastriate visual cortex, and is consistent with single-cell work in monkeys.

**Title:** Population interactions between prefrontal and visual cortex during eye movement planning

**Authors: *M. A. SMITH**, S. B. KHANNA
Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

**Abstract:** During active vision, prefrontal regions of cortex that encode eye movement plans and are important in working memory interact continuously with visual cortex where the scene is parsed and salient information is identified. Anatomical studies have demonstrated connections between these regions of cortex, and some electrophysiological investigations have identified

functional interactions. However, very little is known about the way in which signals in these two regions interact at the population level. The spatial structure of these interactions is particularly important in active vision, where attention and eye movements can be directed rapidly across the visual landscape. One means of studying the language of this communication is through the correlated variability among pairs of neurons, a signature of functional interactions among neurons. It has been suggested that changes in correlated variability impact the ability of a given neural population to encode information, such as a visual stimulus. It is unclear, however, how correlated variability propagates across cortical regions and across large areas of visual space contingent on an eye movement plan. Visual cortical area V4, an intermediate level along the visual processing pathway, and dorsolateral prefrontal cortex (PFC), an area that represents working memory and eye movement signals in its delay period activity, both factor in the transition from visual stimulus to eye movement. We used two 96-channel “Utah Arrays” to record from groups of V4 and PFC neurons simultaneously in alert rhesus macaque monkeys performing a conventional memory guided saccade task. We measured the spike count correlation (also known as noise correlation) between pairs of simultaneously recorded neurons, both within and between V4 and PFC, during the delay period before the eye movement was made but after the visual stimulus had been presented. Correlations in V4 and PFC decayed with increasing spatial distance between recorded neurons, as observed previously in numerous cortical regions. Correlation between PFC and V4 neurons varied depending on the spatial relationship between the PFC and V4 receptive fields. Furthermore, PFC neurons with ipsilateral and contralateral receptive fields displayed distinct functional interactions with V4. These functional signatures may reflect the role of PFC in integrating and representing information about memory and motor planning across the entire visual field.

**Title:** The interaction between Bayesian prior and attention in visually guided eye movements

**Authors: *S. KIM**[1], J. LEE[2]
[1]Sungkyunkwan Univ., Gyeonggi-Do, Korea, Republic of; [2]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon-Si, Gyeonggi-Do, Korea, Republic of

**Abstract:** When we interact with the environment and make appropriate behavioral responses, our brain relies not only on the incoming sensory information but also on a prior knowledge based on recent experience. The influence of the prior knowledge becomes more prominent when the sensory evidence is weak or ambiguous. Because attention is a cognitive factor that is known to boost the gain of sensory representation, it is possible that attention interacts with the Bayesian prior and affects behavioral responses. To understand how attention interacts with the Bayesian prior to influence sensory-motor behavior, we asked human subjects to perform a smooth pursuit eye movement task while we controlled the strength of sensory motion and attention independently under the same prior condition. The pursuit target was a random dot patch whose speed was fixed at 16 deg/s, while the direction was randomly selected from three motion directions (pre-determined prior direction, ±30 deg). We controlled the strength of visual motion by randomly varying luminance contrast of the pursuit target (100% or 12%), while attention was controlled by manipulating the validity of a motion cue that was briefly presented before the onset of target motion. While the individual subjects were performing the task, we recorded their eye positions using an infrared video tracking system (EyeLink 1000 Plus, SR Research, Ltd.), and measured EEG activity using a 64-channel active electrode system (BrainAmp, Brain Products, GmbH) for later analysis. Consistent with the previous study on non-human primates (Yang, Lee, and Lisberger, 2012), we found an interaction between direction prior and the strength of visual motion. Specifically, pursuit directions were attracted towards the prior direction especially when the visual motion was weak (12% contrast). In addition, attention appears to nullify the effect of the prior. When the direction cue was valid, pursuit directions were closer to the target direction even if the contrast of the pursuit target was low. A simple Bayesian observer model may explain the behavioral data if attention works on the likelihood function in such a way that it reduces the standard deviation of a Gaussian distribution.

**Abstract: Introduction:** The study of fixational eye movements (FEM) has implications for the neural and computational aspects of visual perception. One component of FEM is tremor, a high frequency oscillatory jitter with an amplitude of a few seconds of arc. Tremor is often identified as an increase in the power spectrum of eye motion in a band of frequencies around 50-100Hz. The contribution of ocular tremor to visual perception is still not fully understood.
**Methods:** A novel eye tracking method using a Tracking Scanning Laser Ophthalmoscope (TSLO) was utilized to examine the characteristics of tremor on the retinal surface. The left eyes of 7 subjects were tracked while fixating a tumbling E. The contribution of ocular tremor to the retinal image motion was determined using spectral analysis of high resolution eye motion traces. The ability of the TSLO system to record high frequency motion and therefore detect tremor was validated in three ways: (i) spectral analysis methods were validated by analyzing synthetic eye motion traces composed of a tremor motion overlaid onto a random walk, (ii) eye motion traces and power spectra were computed from videos where high frequency motion was inserted digitally into real TSLO videos of a fixating eye, and (iii) eye motion traces and power spectra were computed from videos of a model eye with actual high frequency motion.
**Results:** The TSLO system was able to recover tremor in each of the three validation conditions. However, contrary to previous findings, the increase in power between 50-100Hz indicative of tremor was minimally apparent in the power spectra of motion on the retinal image of human eyes during active FEM. The amplitude of eye motion decreased monotonically as a function of frequency and, although there was a slight deviation from the typical 1/f pattern within the range of 50-100Hz, this increase never exceeded ~2 seconds of arc, much lower than previous reports of tremor.
**Discussion:** Most eye tracking methods that measure tremor rely on tracking the cornea or lens, and can only infer the movement of the image on the retina. The TSLO has the advantage of measuring the retinal image motion directly and unambiguously. The reported movement of the anterior segment of the eye induced by ocular tremor is greatly reduced at the level of the retina, and is therefore unlikely to contribute to the visual percept.

**Abstract:** Asthenopia or visual discomfort is a condition associated with near work tasks. Near work tasks consists of any task done within arms-length (i.e., texting, working on a laptop, reading a textbook). Individuals struggling with visual discomfort may experience symptoms such as headaches, blurred vision, and sensitivity to light. Due to the high demand on college students to perform near work tasks and the potential associated symptoms, we investigated whether visual discomfort had an impact on academic performance. Two oculomotor systems are involved in visual discomfort: the accommodation system and the vergence system. An insufficiency in either of these systems can be associated with visual discomfort. Two surveys have been developed to address insufficiencies in these systems. The Visual Discomfort Survey (Conlon et al., 1999) has been linked to accommodative insufficiencies and the Convergence Insufficiency Symptom Survey (Borsting et al., 2003) has been linked to insufficiencies in the vergence system. An academic problems survey was added to investigate whether visual discomfort symptoms are linked to perceived academic problems (Chase et al., 2009). We also wanted to assess an individual's ability to persevere despite their visual discomfort symptoms and we did this using the grit survey (Duckworth et al., 2007). Participants completed all four surveys and a demographic questionnaire. Results found that symptoms mediates the relationship between near work and academic problems. Ethnicity moderated the pathway between near work and discomfort and grit has a main effect on symptoms. These findings have widespread implications in the field of neuroscience, due to the dependency on computers and growing use of near work tasks it is important that we better understand visual discomfort. By better understanding visual discomfort and it's potential impact on students we can help find interventions to help students succeed in academics.

**Title:** Parsing the contributions of perception, motor planning, and cognition to anti-saccade performance in human subjects

**Abstract:** The anti-saccade (AS) task, which requires subjects to look ***away*** from a peripheral visual cue, is considered to be a sensitive assay of executive function. Its requirement to withhold responding to a salient, abruptly appearing visual cue in favor of programing a saccade to a diametrically opposed location is thought to rely heavily on frontal cortical mechanisms of cognitive control. However, as for all paradigms that begin with sensory input and end with motor output, it is a major challenge to discern the respective contributions of sensation, motor planning, and cognition to behavioral performance as typically measured in terms of accuracy and reaction time (RT). The present study deploys a novel task that combines the perceptual, motor and cognitive demands of the AS task with an urgency requirement in an effort to distinguish and quantify the relative contributions of these capacities to AS performance in human subjects. The Compelled Anti-Saccade (CAS) task required subjects to begin programming a saccade ***in advance*** and to use later arriving perceptual information about cue location to modify the ongoing motor plan. This urgency requirement generates a unique psychometric function — the tachometric curve — that tracks success rate as a function of perceptual ***processing time*** (PT), the interval between cue presentation and saccade onset. For the CAS task, the tachometric curve took on a characteristic shape that we interpret to reflect the interaction of perceptual (cue driven) and cognitive (internal planning). For PTs less than 50 ms, subjects performed at chance (50%), consistent with uninformed choices (guesses). However, PTs between 75-125 ms were associated with a pronounced dip to below-chance performance, which reflected the irrepressible “pull” of the salient stimulus that caused subjects to erroneously saccade to the cue. Performance recovery, a reflection of cognitively-guided motor planning, began at PTs of between 100-150 ms and was evident as a gradual rise in success rate as subjects directed a progressively larger proportion of saccades to the correct, “anti” location. The onset time and depth of the early PT performance dip assays the strength of low-level sensory

representations, and recovery from this perceptual vortex reflects the strength of cognitive mechanisms that resist its pull, perform the necessary mental rotation, and program an "anti-saccade". Together with RT distributions that independently assay motor function, the findings provide a detailed account of how a subject's perceptual, motor, and cognitive capacities interact in time to guide saccadic choice.

**Title:** Binocular alignment in mice during stereoscopic discrimination of depth

**Authors: *J. M. SAMONDS**[1], V. CHOI[2], N. J. PRIEBE[3]

**Abstract:** In order for animals with binocular vision to use retinal image disparity to infer depth, they must be able to maintain some alignment between the eyes. Primates and carnivores frequently make coordinated saccades, and when they fixate on an object, their eyes converge or diverge to align their retinal images at that point. Rodents do not have a fovea, saccade less frequently, and their eyes are directed laterally at an angle of 50 degrees. Nonetheless, neurons in the primary visual cortex of mice are tuned for binocular disparity and mice have 40 degrees of binocular overlap. Therefore, we examined the binocular eye movements of head-fixed mice to see whether they could use this disparity tuning. During free viewing of natural scenes, mice nearly always made coordinated saccades. The eyes generally converged slightly relative to their average gaze during the saccade and diverged back to the original alignment while fixating. The range of relative vergence angles during free viewing corresponds to the expected range of useful binocular disparities for mice. We also examined binocular eye movements of mice while they discriminated between relative near and far surfaces rendered in dynamic random dot stereograms. For both near and far surfaces, the mice would start converging their eyes seconds before stimulus onset and then diverge their eyes back to the natural gaze position once making a decision about whether the surface was near or far. We analyzed the vergence angle for correct

and incorrect trials and found that successful discrimination required the eyes to be slightly converged with the same alignment for near and far surfaces. This suggests that mice can align their eyes and successful stereoscopic discrimination depends on proper binocular alignment.

**Title:** Dynamically tracking the neural signatures of visual attention across a saccade

**Authors:** ***J. CHEN**[1], X. ZHANG[2], J. D. GOLOMB[1]
[1]Dept of Psychology, Ohio State Univ., Columbus, OH; [2]Psychology, The Ohio State Univ., Columbus, OH

**Abstract:** To maintain visual stability, the retinotopic coordinates of objects need to be remapped across each saccade. Recent evidence suggests that visual attention is also remapped. Research has reported two different stages of remapping: a fast remapping to the new retinotopic location (i.e., predictive remapping of attention; Rolfs, Jonikaitis, Deubel, & Cavanagh, 2011) and a slower disengagement from the prior representation (i.e., retinotopic attentional trace; Golomb, Chun, & Mazer, 2008). While there is some behavioral evidence for both stages (Jonikaitis et al., 2013), it remains unclear the temporal and neural dynamics of how these two stages relate to each other, and more generally how the focus of attention is dynamically shifted over the entire perisaccadic period. In the current study, we recorded steady-state visual evoked potentials (SSVEP) in human EEG to dynamically read out which objects subjects were attending to across each saccade. Three orientation gratings were displayed on the screen with two possible fixation locations between them ("O+O+O" pattern). Subjects maintained attention on the central patch and reported an occasional orientation change. In half of the trials, subjects also made a saccade from one fixation point to the other as soon as a saccade cue appeared. Thus, the central patch was the spatiotopic (attended) location, while the other two patches represented the "predictive-remapping location" and "retinotopic-trace location", respectively. All three patches flickered at different frequencies, such that each location was tagged with a unique SSVEP spectral peak. Time-frequency analysis was performed on EEG data to calculate inter-trial coherence (ITC) corresponding to each location over time. ITC was greatest at the

spatiotopic (attended) location during baseline periods (outside the perisaccadic window), indicating that subjects were successfully attending to the spatiotopic location. Immediately before each saccade, the ITC difference between the spatiotopic location and predictive remapping location was reduced compared with the presaccadic baseline, suggesting attention temporarily shifted to the predictive remapping location. Immediately after each saccade, the ITC difference between the spatiotopic location and retinotopic-trace location was smaller compared with the postsaccadic baseline, consistent with a temporary lingering of attention at the retinotopic-trace location subsequent to each saccade. The current experiment provides a new method to dynamically track the neural signatures of visual attention across a saccade.

**Abstract:** Trial-to-trial fluctuations in spiking activity, which give rise to correlated variability, are commonly observed between pairs of neurons in a wide variety of cortical areas. When processing a visual stimulus, for example, the correlation among neurons has been suggested to impact the amount of information a given neuronal population can represent. This stored sensory information is often used to then guide a motor output such as an eye movement. Very little is known, however, about the correlated activity in areas that bridge this sensory and motor divide,
