particularly the relationship between correlated activity and behavior. The frontal eye fields (FEF) and superior colliculus (SC) are both considered to be important regions controlling eye movements. Because both areas contain neurons with a wide variety of response profiles (both visual and motor), they are ideal candidates for studying the relationship between correlated activity and the planning and execution of eye movements. We used linear electrode arrays to record from groups of FEF or SC neurons in alert rhesus macaque monkeys performing a conventional memory guided saccade task (FEF) or delayed visually guided saccade task (SC). We measured the spike count correlation (also known as noise correlation) between pairs of simultaneously recorded neurons during the delay period, after the visual stimulus was present but before the animal had made an eye movement. We found correlation in this epoch leading up to an eye movement varied depending on the reaction time of the animal's subsequent eye movement in pairs of both SC and FEF neurons. Additionally, the relationship between correlation and reaction time was dependent on the direction of the eye movement. This correlation structure shared a number of common features between FEF and SC populations, while the observed differences may be understood by considering their different levels in the oculomotor hierarchy.

**Title:** Integrated representation of reward and sensory information in the macaque caudate during a perceptual decision

**Authors: *T. DOI**, Y. FAN, J. I. GOLD, L. DING
Dept of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Decision making often requires processing uncertainty related to reward expectation and/or sensory input. For tasks with reward manipulations, some caudate neurons encode reward-related information, such as the reward context, reward expectation for a given choice alternative, and reward expectation for the chosen action. For tasks with sensory manipulations, some caudate neurons are modulated by the identity and strength of the stimulus. These diverse patterns of activity suggest that caudate neurons may combine reward and sensory information at a single-neuron level to support the selection and evaluation of choices. To test this hypothesis,

we recorded caudate activity in two monkeys performing an asymmetric-reward visual motion discrimination saccade task. For this task, the stimulus identity and strength are manipulated as motion direction and coherence, respectively, of a random-dot kinematogram, and reward context is alternated in blocks of trials such that, for a given block, one choice is paired with a large reward and the other is paired with a small reward.
Based on linear regression analyses, we found that ~60% of the recorded caudate units encoded both sensory and reward information, either additively or multiplicatively, during at least one task period. During stimulus viewing, “additive” neurons encoded the reward context as an offset of baseline activity, and “multiplicative” neurons showed reward-context modulation of how activity related to motion strength. After a saccade was made, the majority of “additive” neurons encoded reward expectations based on reward context and motion strength, but the fraction showing congruent modulation patterns (e.g., preferring large reward and stronger motion for both choices) was not above chance. Some neurons showed multiplicative reward size and coherence modulation consistent with reward expectation for both choices. We suggest that the caudate nucleus contributes to choice selection by integrating reward context as the baseline offset and by modulating accumulation rates during evidence accumulation. The caudate may also contribute to choice evaluation by providing signals that multiplicatively combine sensory and reward-size representations in a way consistent with the “common currency” idea.

**Title:** Visual receptive field changes dynamically across saccade in macaque lateral intraparietal cortex

**Authors: *C. ZHANG**[1], L. YANG[2], M. ZHANG[2]
[1]Institue of Neuroscience, Chinese Acad. Of Scien, Shanghai City, China; [2]Beijing Normal Univ., Beijing, China

**Abstract:** Primates perceive a stable visual world, unnoticed of the frequent displacement of retinal image caused by saccade. Since neurons in many brain areas encode spatial information

with their eye-centered visual receptive fields, the spatial reorganization of receptive fields around saccade may reveal the potential neural mechanism of visual stabilization. Previously, it is found that neurons in some brain areas respond in advance to visual stimulus which will be brought into their receptive field by an impending saccade. This anticipatory receptive field remapping may integrate the pre- and post-saccadic visual information, thus mediate visual stabilization. However, such theory has been challenged recently by findings that visual receptive field of most neurons in frontal eye field converged toward saccadic target instead of the location of future receptive field. Thus, there is an ongoing dispute regarding the function of perisaccadic change of visual receptive field: maintaining visual stability versus selecting saccadic target.
Here we recorded single neuron's activity extracellularly from macaque lateral intraparietal cortex (LIP) while monkeys were performing a modified visual-delay saccade task, in which a task irrelevant visual probe briefly flashed at various location of screen. Visual probe appeared at 4 epochs of the task, i.e., during fixation, during delay, just before saccade and long after saccade. We found that: 1) during delay period, while visual receptive field of minority neurons extended toward the location of future receptive field, visual receptive field of majority neurons expended toward the saccadic target. 2) just before saccade, visual receptive field of majority neurons expended toward the location of future receptive field, whereas visual receptive field of minority neurons expended toward the saccadic target.
Our results are consistent with previous findings of anticipatory receptive field remapping. In addition, we report a dynamic change of visual receptive field in LIP between delay period and just before saccade , which indicates the mixed function of LIP in spatial perception across saccades: target selection and visual stability.

**Title:** Transsaccadic perception of moving objects

**Authors: *S. PRIME**, L. NEUBURGER
Psychology, Univ. of Saskatchewan, Saskatoon, SK, Canada

**Abstract:** Most research on transsaccadic perception has focused on how static objects are spatially updated across saccades. Less is known about how and to what extent the visual system is able to keep track of the position of moving objects across saccades. Here, we investigated

how well subjects were able to detect when a moving object jumped either forward or backward along its motion path during a saccade. Subjects were presented with a dot stimulus moving with smooth continuous motion across a display as they maintained their gaze on a fixation point. Subjects were required to make a saccade when the fixation point moved to a different location. On some trials, the dot jumped forward or backward during the saccade. Subject made a 2AFC response to indicate if they detected a displacement or not. Based on previous findings showing that detection of intrasaccadic displacement of static stimuli is better with smaller displacements and saccade directions orthogonal to displacement direction (Niemeier, Tweed, and Crawford, 2003), we conducted a series of experiments where we systematically varied the displacement size and saccade direction relative to the dot's motion direction. Similar to previous findings with static stimuli, detection accuracy increased with displacement size, confirming that accurate transsaccadic motion tracking is also dependent on the amount of the intrasaccadic change in position. Although studies with static stimuli show a detection advantage for orthogonal saccades versus parallel saccades relative to the intrasaccadic displacement, we failed to find a similar advantage with moving stimuli. Instead, we found similar detection performance for all saccade directions, except significantly impaired detection when saccades were made towards the dot stimulus. We propose that the lower sensitivity in detecting displacements with saccades made toward the motion stimulus is consistent with evidence of spatial distortions in the area around the saccade target (Ross et al, 1997). Moreover, forward displacements were detected significantly less often than backward displacements, suggesting that the visual system is more likely to infer accurate post-saccadic target position and rely less on the internal computations extrapolating the future position of moving objects over the saccade when the displacement is in the direction of motion. These findings have important implications for incorporating motion tracking in models of transsaccadic perception.

**Abstract:** The emergence of the larval zebrafish as a model organism in systems neuroscience has spawned a variety of data recording techniques and stimulation hard- and software. Computer screens and projection cylinders have been used as visual stimulus surface in the past. However, larval zebrafish have large visual fields, subtending about 160° in azimuth for each eye. Therefore, an ideal stimulus apparatus would present stimuli on the surface of a sphere to accurately cover the visual field of the fish. For the combination of calcium imaging with large-field stimuli it is advantageous to use LED arrays to temporally interleave visual stimulation and calcium indicator fluorescence recording based on the timing of the scanning mirrors of the microscope. Here, we present a stimulus arena consisting of 240 8x8 LED tiles that have been assembled in a sphere using a 3D-printed scaffold and are operated by microcontrollers via MATLAB. Together with a rotation mount and a glass bulb stage developed for larval fish, animals can be stimulated with stimuli covering up to 75% of the spherical surface in studies of whole-field gaze stabilization behavior, such as the optokinetic response (OKR) and the optomotor response (OMR). We are studying the neural circuits underlying these behaviors and wanted to identify which spatial locations drive the optokinetic response best. We placed larvae (5-7 dpf) in the middle of the sphere and presented horizontally drifting gratings (spatial frequency: 0.06 cycles per degree azimuth, sinusoidal velocity modulation with max. velocity of 12.6°/s and period of 10 s) that covered different visual angles (full-field, half-field, 60°-wide disks) and were positioned at different azimuths and elevations (36 different positions for the 60° masks). Animals responded with optokinetic behavior and we found that the OKR gain of larval zebrafish strongly depended on stimulus position. Animals maximally responded to stimuli located fronto-laterally above the equator, which roughly corresponds to the previously published temporal-ventral position of the area centralis of the larval retina. Potential explanations for our findings include a) superior motion detection performance in the area centralis or b) a behavioral preference to minimize retinal slip in the area centralis. Our finding has important implications for future study designs investigating the OKR in larval zebrafish and it stresses the often neglected importance of the area centralis in zebrafish vision.

**Abstract:** Neurons in both the dorsolateral prefrontal cortex (PFC) and posterior parietal cortex (PPC) of the macaque monkey are known to jointly encode the direction of a planned saccadic eye movement. With strong reciprocal connections it is likely that the two areas exchange information during saccade planning and execution. The dynamics of this exchange are not yet well understood. To explore this relationship we used linear microelectrode arrays to simultaneously record from PFC and PPC during the memory-guided saccade task. We analyzed the spiking data by calculating the Pearson's spike-count correlation coefficient of all cross-area neuron pairs. We previously found that (Hall et al., in prep) if two neurons were selective for the same location and if the monkey was required to make a memory guided saccade to that location, then, during the period accompanying the execution of the saccade, the spike-count correlation decreased.

In the current study we looked to see if this interaction is also revealed during analysis of correlations between the local field potentials (LFPs) and spiking activity and LFP-LFP activity across areas. We found a parallel of the spike-spike correlation results within analysis of the LFP-LFP interactions. Because the activity of more than one neuron can be recorded on a single electrode contact, we first defined the spatial selectivity of each LFP signal. Then we calculated the magnitude-squared coherence between the LFPs that were selective for the same location. We found significantly less coherence when the monkey was required to make a memory-guided saccade to the preferred location than to the non-preferred location. Interestingly, our preliminary calculations of spike-LFP coherence do not parallel the spike-spike and LFP-LFP correlations. Our spike-field analysis reveals little coherent activity around the saccade for both target locations.

A plausible interpretation is that during generation of an action, such as execution of a saccade, the areas interact through their reciprocal connections and an indirect executive control loop. The executive control loop could explain the observation of negative spike-count correlation and decreased LFP-LFP coherence, as well as the non-coherent spike-LFP activity between prefrontal and parietal neurons during execution of the saccade.

**Abstract:** Pursuit eye movements allow the stabilization of moving objects on the retina by matching eye velocity to a selected target's velocity. This voluntary process requires target motion be separated from other motion signals in the world. This selection process has previously been linked to the acquisition of targets by saccadic eye movements in humans and macaques. Here we investigated if the common marmoset, a small New World primate, also exhibits changes in pursuit eye movements related to target selection. We measured tracking eye movements in two marmosets to motion of a single target or two targets, using the Rashbass step-ramp paradigm. In the single target task, animals were rewarded for successfully tracking a 4-6 deg/s moving target using a combination of saccades and smooth pursuit. In agreement with previous measurements in macaques (Lisberger, 1998), we found that a saccade to the target during pursuit initiation enhanced the amplitude of smooth pursuit (mean pre saccadic gain = 0.25, mean post saccadic gain = 0.74, gain = eye velocity/target velocity). Those trials in which saccades occurred early had a higher amplitude smooth eye velocity than those trials in which the saccade occurred late during initiation, but the gain during sustained pursuit did not depend on the saccade latency in this period. In trials in which two targets were presented, marmosets could track either target, and selection was marked by saccade direction. Saccade latencies were similar for single and two target conditions. The gain of pursuit eye movements increased following saccades to the selected target, and the presence of the second target nonetheless altered pursuit. We computed the weight of each target's influence on pursuit eye movements before and after saccades. Before the saccade occurred the weight of the two targets was near equal, consistent with a vector averaging computation being performed, whereas after the saccade occurred weights shifted to 0.68 for the selected target and 0.32 for the nonselected target. These results indicate that marmosets perform a similar selection procedure to track objects as other primates.

**Title:** Tradeoff between expectations and evidence for visual continuity across saccades

**Authors: *D. SUBRAMANIAN**[1], Z. M. ABZUG[2], M. A. SOMMER[3]
[1]Neurobio., [2]Biomed. Engin., [3]Biomed. Engin. and Neurobio., Duke Univ., Durham, NC

**Abstract:** The image of the external world is displaced across the retinas with every saccade, and yet our visual perception is coherent and continuous. We showed previously that the mechanisms of transsaccadic visual continuity are influenced by expectations about objects (Rao, Abzug, & Sommer 2016). If an object is not expected to move during a saccade but does, its movement is detected with higher visual sensitivity (d'). The real-world implication is that, for example, we would notice the transsaccadic movement of a rock more than a bird. We hypothesized that the system is Bayesian in the sense that the brain relies more on these priors when visual evidence is less certain. To test this, we ran human subjects (n=16) on a modified saccadic suppression of displacement task. On every trial, subjects fixated a central cross for a fixed duration, made a saccade to a peripheral target, and reported whether it had moved or remained stable during the saccade. The critical manipulation was to vary the quality of visual evidence (blurriness of the target) and determine if this affected the use of priors (expectation that the target would move). Each session consisted of two phases: training and testing. In the training phase, probability of target movement (10%, 50%, 90%) corresponded to the color of the fixation cross (e.g. red, white, green). Subjects were provided with trial-by-trial feedback on their performance in this phase. Targets were convolved with a very low-variance Gaussian blur (0.01 deg.) so that they appeared near-punctate. Subjects implicitly learned and used the color-associated priors about probability of target movement (confirmed by changes in d'). In the testing phase, two levels of visual uncertainty were introduced by convolving targets with low and high noise Gaussians (0.0625 and 0.25 deg. variance, respectively). Total luminance of all targets was constant. Fixation cross colors associated with 10% and 90% priors during training were randomly interleaved, although the actual probability of movement was 50% to isolate effects of the learned priors on subjects' responses. Supporting our hypothesis, we found that subjects relied on their learned priors significantly in the high noise condition but not the low noise condition. This reliance on priors was most prominent when subjects were least certain (near the 50% threshold level of psychometric curves; i.e. equally likely to report movement or

stability). We conclude that, consistent with a Bayesian framework for transsaccadic visual continuity, subjects rely on prior expectations about object movement more when the evidence is less reliable.

**Title:** Bold fMRI and somatosensory evoked potential response to electrical stimulation of tibial nerve: TBI pilot study

**Authors: *S. H. SALEH**[1], D. ALLEXANDRE[1], B. S. MAAS, 07052[2], D. A. CUNNINGHAM[3], A. HOXHA[2], G. H. YUE[4]
[2]Human Performance and Engin., [3]Biomed. Engin., [1]Kessler Fndn., West Orange, NJ; [4]Human Performance and Engin., Kessler Fndn. Res. Ctr., West Orange, NJ

**Abstract:** Damage to cortical and subcortical structures after traumatic brain injury (TBI) leads to many physical deficits. Electrical stimulation (ES) is conventionally used to test somatosensory evoked potentials (SEP) using EEG, and to stimulate muscle activity in functional ES interventions. However, brain activity in response to ES of peripheral nerves has not been studied in TBI survivors. In an ongoing study, we used ES to study SEP and brain excitability using EEG and fMRI. To date, we collected data from 6 individuals with disabilities due to TBI (age 56±4, 4 severe, 2 mild TBI); participants provided informed consents approved by Kessler Foundation ethical review board. ES was applied on the Tibial Nerve (medial malleolus), with a rate of 1.9Hz, and pulse width of 1 msec. The stimulus amplitude was individually adjusted to get a threshold that can be tolerated by the subject (uncomfortable but not painful) and induce consistent toe muscle twitching. In the EEG session, ES was applied continuously for 3 minutes on each foot. In the MRI session, ES was applied in 4 blocks (40 seconds rest, 20 seconds ES). ES on the left and right foot were applied in separate scan runs, duration of each was 5 minutes. fMRI data was collected using a 3T Siemens scanner (EPI sequence, TR=2seconds, TE=30ms, FA=90º) and MRI-compatible electrodes were used for ES. Preliminary fMRI results show activity in the following areas in response to Tibial nerve ES: bilateral posterior and anterior insular cortex, bilateral supramarginal and angular gyrus, bilateral thalamus, contralateral sensory and motor foot area, and contralateral supplementary motor area. These findings are consistent with studies that show a role of these regions in processing touch

and pain. Interestingly, two of the 6 TBI subjects (severe TBI) who require assistance to stand or use a cane to walk, did not show activity in the foot area during ES, and they did not show a strong SEP in the EEG experiment. In these participants, we noticed postcentral gyrus activity more lateral than the foot area, suggesting that TBI caused reorganization in the somatosensory networks of these individuals. While the data based on the small sample size are immature to make a conclusion about the relationship between TBI severity and excitability of somatosensory network during ES, the study is ongoing and additional data from newly enrolled participants may make the results more conclusive to help better understand the effect of TBI on somatosensory networks. The data may eventually help guide development of neuromodulation-based rehabilitation interventions to promote neuroplasticity for speedy and more complete recovery of sensorimotor function.

**Title:** Characterization of sensory and motor representation across rodent sensory, association, and motor cortices

**Authors: *M. KAWABATA**, S. SOMA, A. SAIKI, J. YOSHIDA, A. RIOS, Y. SAKAI, Y. ISOMURA
Brain Sci. Institute, Tamagawa Univ., Tokyo, Japan

**Abstract:** The cerebral cortex, consisting of sensory, association and motor cortices, receives sensory information such as visual and auditory senses, and transforms it into motor information to control muscles appropriately. Although specific functions of these cortices have already been known individually, the whole picture of the sensorimotor transformation across them remains unclear at a single-cell level. Here, we characterized sensory and motor representations across the primary visual cortex (V1), posterior parietal cortex (PPC), and secondary motor cortex (M2)

in rats behaviorally responding to visual and/or auditory stimuli. The rats performed a behavioral task under head-fixation, in which they had to push a spout-lever with right forelimb quickly in response to a brief cue presentation (light and/or sound) to get reward water. The behavioral task repeated a block of trials with a light cue or with a sound cue alternately, and trials with both cues were added occasionally at random. We obtained multi-neuronal recording from the three cortical areas during their task performance. To compare sensory and motor representation among these cortical areas, we analyzed the functional correlation of spike activity with the behavioral task (using task relevance index) and the temporal preference of spike activity for the sensory cue or pull response (using cue-response preference index) in each neuron. We also examined the dependence of spike activity on the reaction time, sensory modality and combination, and test/correction. We found that PPC neurons represented motor (pull response), rather than sensory (cue), information predominantly as a group, which was very similar to M2 neurons, but not V1 neurons. Nevertheless, a considerable number of PPC and M2 neurons displayed an intermediate form of cue-response preference, implying their higher-order functions in sensorimotor transformation. Moreover, we found that V1 neurons sometimes represented motor information in the spike increase evoked by the visual cue, suggesting that sensorimotor transformation might begin in the primary sensory cortex. Our results suggest that sensorimotor transformation is widely spread across cortical areas for functional integration and processing of information.

**Title:** Interrogating sensorimotor circuits of orientation: From lamprey to mouse

**Authors: J. PÉREZ-FERNANDEZ**, S. GRILLNER, *A. A. KARDAMAKIS
Karolinska Inst., Stockholm, Sweden

**Abstract:** (Re)directing our line of sight in space is a function of the stimulus, internal state and our task at hand. These sensory-based decisions for gaze reorientation involve the complex interaction of several brain areas, including the active engagement of subcortical and cortical circuits.
Over the past years, we have explored tectal function by using a conserved vertebrate system, the

lamprey, as a reductionist organism that has offered the necessary accessibility allowing the development of a series of preparations for the study of sensorimotor control for gaze reorientation at the cellular and circuit level. In particular, by focusing on the conserved brain area essential for multisensory integration and motor control of orientation, the optic tectum, we found a dual motor response system within its deeper layers that contains projections neurons that target contralateral and ipsilateral brainstem zones causal to orienting and avoidance gaze movements, respectively. These neurons receive two types of sensory inputs, vision and electroreception (in lamprey), which converge onto each projection neuronal subtype with spatiotemporal correspondence. These computations are elaborated by a well-organized local GABAergic network within the superficial and intermediate layers of tectum, thus, mediating disynaptically multisensory inputs and projection neuron output controlling gaze.
Following this phylogenetic model, the circuit configuration giving rise to these rules we postulate to be similar in later vertebrates. We are now testing the validity of this prediction in the superior colliculus by using mice as a generic mammalian model. To do this, we are using Cre-dependent mouse lines (VGlut & VGat) combined with tools that include electrophysiology, optogenetics and motor behaviour. Our results show the striking similarity of this conserved dual motor system arising from glutamatergic projection neurons located in the deep layer and terminating in the pontine reticular formation along with the functional impact of these connections with and without local inhibition. Our overarching aim is to use circuit comparisons across a greater range of taxa by following the phylogenetic model to connect them and infer basic principles of sensorimotor integration.

**Title:** Deactivation and activation of dorsal visual information processing pathway gates perception-action coupling

**Authors: *D. RAY**, N. HAJARE, A. BANERJEE
Cognitive Brain Lab., Natl. Brain Res. Ctr., Manesar, Gurgaon, India

**Abstract:** Dual stream hypothesis is a pre-eminent theoretical approach to conceptualize visuo-motor information processing. Subtle variations of the model exist often leading to fundamentally divergent explanations of underlying neural mechanisms. For example, the Mishkin-Ungerlieder (MU) model suggest that the *input* information decides the neural pathway for processing. Position related information ('where') takes the dorsal stream comprising MT/V5 and parietal cortex whereas finer feature processing ('what') comprising color, face, etc. takes the ventral stream involving V4 and inferior temporal areas. Concomitantly, the Milner-Goodale (MG) model suggests that the task *goal* decides the processing pathway, with dorsal stream areas needed for visual (sensory) guidance of action that doesn't involve active perceptual processing whereas the ventral stream is recruited for perceptual object processing. No single study has evaluated the viability of each model in a overarching experimental design. Furthermore are the models subject to neuroplastic changes is an open question.

We addressed these issues in an fMRI experiment involving 20 right-handed human volunteers (20-34 years, 12 females). Participants were scanned with TR=2 s TE= 35ms, flip angle =90° while each of them was performing 3 visual perception tasks and 3 visuo-motor action tasks inside a 3T MRI scanner. For both categories, 2 tasks were designed to involve "what" (color, face) processing and 1 task required processing of "where" (position) information. The fMRI scans were repeated after seven days of the practice session outside the scanner to explore the neuroplastic changes.

In all perception tasks, bilateral ventral stream areas are activated, whereas all action tasks shows prominent activations in bilateral primary visual cortices, ventral and dorsal stream regions. Unlike color and face perception, position perception elicits additional activations in dorsal stream areas. Deactivation of BOLD signals were observed in medial dorsal stream areas and in few primary visual and ventral stream regions. Analysis of reaction times established the positive effect of practice. Number of voxels activated decreased with practice but no such decrease was observed for deactivated voxels.

Dorsal stream activations in orientation perception could not be explained by the MG model whereas ventral stream activation in same condition violated the MU model predictions suggesting the need for a coupled perception-action model of visual processing. Deactivation found in perception tasks further points towards the role of feedforward and feedback interactions between both streams.

**Abstract:** Immediate-early genes (IEGs) have been indicated in neuronal plasticity events and play a critical role in visual development. Using transgenic mice expressing GFP under IEG promoter control, we chronically recorded both neural activity (using a red shifted calcium indicator) and IEG expression levels during visual development in primary visual cortex. Animals were born and reared in complete darkness and we imaged calcium activity and IEG expression levels every 12h over the course of 6 days both before and after first visual exposure. On the first two days activity in V1 was recorded in complete darkness while mice were head-fixed and free to run on a spherical treadmill. On the third day of imaging we exposed them to visual feedback (first light exposure) in a virtual reality tunnel in which visual flow was coupled to the locomotion of the mouse. Outside of the imaging sessions mice were still housed in complete darkness. Starting on day 5 mice were then subjected to a 12/12h light/dark cycle. We found that IEG expression levels only weakly correlate with average neuronal activity, but expression patterns exhibited changes both at the onset of first visual exposure and light cycle onset. We also found that different IEGs are preferentially expressed in different functional cell types in layer 2/3 of mouse visual cortex. Neurons that exhibit strong motor-related activity express higher levels of EGR1, while neurons that exhibit visually driven activity express higher levels of Arc. These findings suggest that different IEG expression levels might correlate with plastic changes in the functional type of input a neuron in layer 2/3 receives.

**Title:** Previous trial effect in visuomotor integration depends on an implicit short-term memory mechanism in premotor cortex and hV5/MT+

**Authors: *R. M. DE AZEVEDO NETO**[1,2,3], E. AMARO, Jr.[2], A. BARTELS[3,4,5,6]
[2]Radiology Dept., [1]Sch. of Medicine, Univ. of São Paulo, São Paulo, Brazil; [3]Ctr. for Integrative Neurosci., [4]Dept. of Psychology, Univ. of Tuebingen, Tuebingen, Germany; [5]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [6]Bernstein Ctr. for Computat. Neurosci., Tuebingen, Germany

**Abstract:** The so-called previous trial effect has been reported from perception to motor output in human behavior. For example, the speed from previously experienced moving targets biases movements on the current trial in coincident timing tasks. The precise mechanism underlying the previous trial effect is still under debate. In the present study, we tested the hypothesis that previous encounters with moving targets leave a neural trace of the information experienced, i.e. an implicit short-term memory mechanism. This information could be stored in either premotor or visual areas associated with the task, and influence neural processing of the current trial. We assume that injecting noise by means of transcranial magnetic stimulation (TMS) would interfere and degrade such short-term memory and hence reduce or abolish the previous trial effect if TMS is applied over neural sites involved in the mechanism. To test this hypothesis and to identify brain regions involved in mediating the previous trial effect, we asked healthy participants (n = 20) to perform a coincident timing task and applied a burst of TMS pulses (10 Hz) 500 ms into the inter-trial interval and 3500 ms before the next trial to disrupt the activity in right hV5/MT+, in left dorsal premotor cortex, and in the control position Vertex. Trial speed was counterbalanced in a way that allowed every speed to be equally often preceded by all speeds. As expected, participants presented a bias towards the speed of previous trial when intercepting moving targets without receiving TMS pulses. TMS applied over dorsal premotor cortex decreased the previous trial effect in comparison to Vertex stimulation. TMS applied over hV5/MT+ decreased the temporal bias only mildly, reaching significance when compared to

performing the task without TMS, but only a trend when compared to Vertex stimulation. These results provide causal evidence that the previous trial effect is mediated to a large extent by inter-trial interval activity in the left dorsal premotor cortex, and to a lesser extent by right hV5/MT+, in a visuomotor integration task with moving objects. Absence of difference in overall timing error between TMS sites indicates that the TMS pulses did not affect processing on the current trial. This suggests that an implicit short-term memory mechanism keeps information from one trial to the next, and that this information — motor or visual — is blended with current trial information so that it biases behavior.

**Title:** Vergence responces induced by Radial flow motion visual stimulus in monkey

**Authors: *Y. KODAKA**
Natl. Inst. AIST Tsukuba Central 2, Ibaraki, Japan

**Abstract:** Radial flow motion with sigmoidal contrast circular pattern induced the vergence eye movement in monkey. Expansion motion induced the increasing vergence angle and the motion toward the contraction induced the decreasing vergence angle response with short latency. The Opposite direction of the vergence eye movement was induced by the Missing Fundamental pattern motion stimulus, which was also induced in Human subject (Kodaka et al., 2007). The response to the radial flow motion induced with the short latency (<100ms) and the Gain of the response show the contrast dependency and spatial frequency dependency. The threshold of the contrast dependency was 2 -4 %, which was little bit higher than the human data (0.5 -1%). These characters of the response are very similar with the human data. Our result suggests that the vergence response system in monkey has the similar visual information processing in human, and the monkey can use for the human visual process model.

**Abstract:** The lamprey lateral pallium, corresponding to the mammalian cortex, is conserved in terms of its efferent connectivity, with projections to the basal ganglia and the brainstem (Ocaña et al., 2015). Here, we delineate the architecture of pallium and examine visual and olfactory input.
The lamprey has a three-layered pallium with a molecular layer and a cellular layers. The innermost layer contains a high density of GABAergic cells and an almost equal number of presumed glutamatergic cells, while in the outer cellular layer the glutamatergic cells dominate. 22% of the cells are GABAergic. Calbindin- and calretinin-expressing cells are well represented in the innermost layer. The glutamatergic projection neurons (PT, pyramidal tract, IT, intratelencephalic and Th-r, thalamo-recipient cells) are located in the cellular layer and their spiny dendrites extend into the molecular layer. Thalamic input reaches PT-type cells polysynaptically, and to Th-r cells monosynaptically. The PT-type cells are concentrated in the dorsolateral parts of pallium and the Th-r cells are present in its ventral part.
Primary visual is relayed to pallium via thalamus, along with processed visual information from pretectum/tectum. Extracellular multi-unit recordings showed that neurons in the dorsomedial pallium are activated by input from the retina - "visual" pallium. This visual region is separate from pallial motor regions. Stimulations of specific retinal quadrants elicited response in separate visual pallial areas, indicating possible retinotopic organization. Local injections of gabazine in the visual pallium resulted in the loss of this retinitopic organization indicating that the

GABAergic neurons are responsible for maintaining specificity. Whole-cell recordings of pallial neurons during optic nerve stimulation elicited EPSP's and recruited inhibition.
Olfactory bulb input to pallium is relayed through two routes – directly and via a relay nucleus (dmtn), both of which traverse in distinct layers in the molecular layer. Large areas of pallium respond to extracellular stimulation of the olfactory nerve including motor regions. Moreover, olfactory input to pallial neurons is monosynaptic.
The lamprey pallium, thus has a three-layered microcircuit *bauplan* that includes many features of the three-layered reptilian cortex, the mammalian olfactory cortex and the neocortex and can be regarded as a primordial vertebrate cortex. This in turn means that the origin of the layered cortex can be moved back from the currently assumed reptilian cortex, to the very dawn of vertebrate evolution, when the lamprey diverged from the main vertebrate line over 500 million years ago.

**Title:** The lateral parabrachial neurons contribute to pain-respiratory coordination in pons-medulla-spinal cord preparation

**Authors: *S. TONOMURA**[1,2], M. TANAKA[2], K. NOGUCHI[1], A. ARATA[2]
[1]Dept Anat and Neurosci, [2]Dept Physiol., Hyogo Col. Med., Nishinomiya, Japan

**Abstract:** The sensation of pain signals projects to the lateral parabrachial nucleus (LPB) of the pons via the dorsal horn; and LPB is also known as the system of inspiratory-expiratory (I-E) phase switching; that contributes to the control of respiratory rate. Previous study reported that increase respiration was observed after noxious stimulation in humans. Thus, the tightly interaction between respiration and pain signals as a pain-respiratory coordination were expected in LPB. In this study, we investigated the pain-respiratory coordination system using the pons-medulla-spinal cord preparation intact forelimb (including Th1 level) isolated from postnatal 0-4 days-rats. Spontaneous inspiratory activity was recorded from cervical 4$^{th}$ (C4) ventral nerve root. And then we examined the responses of C4 activity when a small amount of 2% capsaicin was injected into forelimb as a noxious stimulation. The C4 inspiratory rate increased significantly with noxious stimulation in the preparation with pons, but removal of pons had no effects ($P < 0.01$). Moreover, we examined the properties of LPB neurons in the pons-medulla-spinal cord preparation. First, the responded area of LPB from C8 dorsal root stimulation was

detected by optical imaging using voltage-sensitive dye; then the LPB neurons (n=32) were recorded from the responded area using whole-cell patch-clamp. Three of 32 LPB neurons were I-E neurons which were synchronized with I-E phase of C4 ventral root activity. The other type of neurons (n=29) were spontaneous or non-spontaneous firing neuron which were not synchronized with C4 activity; so-called non-respiratory neurons. All I-E neurons and 8 non-respiratory neurons, which existed in the responded area by optical imaging were received excitatory input from C8 dorsal root stimulation. Each neuron tested current-voltage (I-V) relationship in current clamp mode. According to the responses of hyperpolarizing current pulses, post-inhibitory rebound (PIR) was observed in 13 non-respiratory neurons. These results suggested that 1) the pons contribute to increase of respiratory rate by noxious stimulation; 2) I-E neurons could directly receive noxious information, so I-E neurons were thought to be the core mechanism of pain-respiratory coordination; 3) the non-respiratory LPB neurons which expressed PIR might be contributed to the onset-switching mechanism of the pain-respiratory coordination network.

Cognitives Marc Jeannerod, CNRS / Univ. Claude Bernard Lyon 1, Bron Cedex, France; [4]Dept Psychiat - Univ. Maryland, Baltimore Sch. Med., Baltimore, MD

**Abstract:** Intranasal administration of the hormone oxytocin (OT) facilitates prosocial behaviors, emotion recognition and cooperation between individuals. Recent electroencephalography (EEG) investigations have reported enhanced mu rhythm (8-13Hz) desynchronization during the observation of biological motion and social stimuli or during tasks that require social coordination in a dyad, after the administration of intranasal OT. It has also been hypothesized that this social hormone may target specific cortical circuits involved in

higher cognitive functions, which might include the Mirror neuron system (MNS). However, this hypothesis remains still largely unexplored. Here, in a double-blind, placebo-controlled, between-subjects study, we investigated whether intranasal OT might modulate the cortical activity from sensorimotor areas during the observation and the execution of social and non social grasping actions. Thirty-five adult male subjects participated in the study after being randomly and equally assigned to the OT (N=17) or the control (CT, N=18) group. Participants underwent EEG testing 45 minutes after receiving 24 IU of either intranasal OT or saline solution (Placebo). Each subject completed a visuo-motor task which included a social and a non-social condition. Both conditions started with the grasping of an object while they differed for the final goal of the action. In the social condition the grasping action was aimed at giving the grasped object to another person; while in the non-social condition the grasped object was placed into a container. During the observation task, participants observed video clips depicting the two types of action. During the execution task, subjects performed social and non-social grasps themselves. EEG mu power in the 8-13 Hz frequency band was computed by means of a Fast Fourier Transform. Results revealed greater mu desynchronization in the social condition compared to the non-social condition in the OT group, especially over central (C3, C4) and parietal (P3, P4) electrodes, although a modulation of mu frequencies was observed also across the scalp. No differences between the social and the non-social condition were found in the CT group. These results suggest a possible action of intranasal OT on sensorimotor circuits involved in social perception and action understanding, thus facilitating the possible prosocial effects typically reported by other studies.

**Abstract:** In persons with hemiplegia due to stroke, mirror visual feedback (MVF) of movements performed with the unaffected limb can recruit brain areas controlling the stroke-affected limb, potentially facilitating recovery. Given evidence that target-directed movements, relative to target-free, elicit stronger bilateral activation, we ask here if target-directed training with MVF may likewise elicit stronger activation in the untrained hemisphere. Following informed consent, 20 healthy subjects performed finger flexion movements using their dominant right hand, with feedback presented in a virtual environment (VR). Visual feedback was presented in real time VR as either veridical feedback with (VT+) and without (VT-) a target, and MVF with (MT+) and without (MT-) a target. Functional Magnetic Resonance Imaging (fMRI) contrasts (FDR-corrected) revealed significant activation in the ipsilateral intraparietal sulcus for the main effect of MVF and significant bilateral superior parietal activation for the main effect of target. Importantly, we noted significant and robust activation lateralized to the ipsilateral parietal cortex in the MT+ contrast with respect to the other conditions, suggesting that combining MVF with targeted movements may redirect bilateral activation to ipsilateral visuomotor processing areas. These findings may have important implications for understanding how it may be best to deliver MVF for rehabilitation purposes.

**Abstract:** Human infants with congenital Zika virus (ZIKV) infection exhibit a range of symptoms including microcephaly, intracranial calcifications, macular atrophy and arthrogryposis. More importantly, prognosis data have lagged far behind the recent outbreak of ZIKV in 2015. In this work, we allow congenitally ZIKV-infected mice to grow into puberty. These mice exhibited motor incoordination and visual dysfunctions, which can be accounted by anatomical defects in the retina and cerebellar cortex. In contrary, anxiety level of the ZIKV-infected mice is normal. The spectrum of anatomical and behavioral deficits is consistent across different mice. Our data provided evidence that may help predict the public health burden in terms of prognosis of ZIKVrelated congenital brain malformations in an animal model. Our study provided behavioral evaluation for the prognosis of congenital ZIKV infection and provides a platform for screening and evaluation of drugs candidates and treatment aiming at improving regeneration of infected neurons to prevent sequelae caused by ZIKV infection of fetus.

**Title:** Brain areas involved in consciousness of a sensorimotor conflict

**Authors: *M. CORAZZOL**[1], G. LIO[2], A. SIRIGU[2]
[1]Inst. of Cognitive Sci. Marc Jeannerod,UMR5, Bron Cedex, France; [2]Inst. of Cognitive Sci. Marc Jeannerod, Bron Cedex, France

**Abstract:** The ability to correct our movements is fundamental for motor learning. This competence is under the control of a conscious action-monitoring system. However, motor compensation does not always need consciousness. For instance, subjects show limited or no consciousness at all when experiencing a mismatch between vision and proprioception. Here we investigated neural changes associated with a sensorimotor conflict (SMC) while subjects shifted from unconscious to conscious states. We asked participants (N=20) to draw a straight line on a graphic tablet without seeing their hand and to look at the unfolding trajectory on the screen. Angular perturbations were visually introduced thus forcing subjects to modify their movement in order to maintain a straight line. After each trial participants reported if they felt a perturbation. Using a staircase procedure, we computed subjects' detection threshold of the SMC. EEG recordings were acquired simultaneously to estimate the cortical sources involved in the unconscious to conscious transition of movement correction. Our results show that the supplementary motor area (SMA), the visual cortex (V3A) and the medial parietal cortex are involved in action monitoring during a sensorimotor conflict. Interestingly, the SMA and area V3A were found to correlate with movement correction. In particular, while activity of the SMA encoded the magnitude of the proprioceptive error, V3A reacted to the visual perturbation regardless of hand position. Importantly, medial parietal cortex did not encode specific movement features but activity in this area was principally linked to subjective awareness of the sensorimotor conflict. Our findings suggest that the medial parietal cortex is a key area for bringing movements into consciousness.

**Title:** Action decisions correlate with visuo-haptic matching errors

**Authors: *I. A. KULING**, J. B. J. SMEETS
VU Univ. Amsterdam, Amsterdam, Netherlands

**Abstract:** People make systematic errors when matching the location of an unseen index finger with the location of a visual target. These visuo-haptic matching errors are idiosyncratic [1,2] and consistent over time [2]. So far, it is unknown whether and how these perceptual mismatches directly influence action decisions.
In this study, participants were asked to reach towards the closer of two visual targets with the index finger of their unseen hand from a varying unseen starting position. We hypothesized that the visuo-haptic matching errors would be reflected in the action decision on reaching to the closer target as a shift in the psychometric curve. Our results support this hypothesis since there is a correlation between the visuo-haptic matching error and the shift of the action decision.
Two additional findings are worth mentioning. For the outer starting positions participants are more likely to reach to the visual target that is closer to the center of the screen. This might be a visually induced bias towards the center of the screen, or a bias in the action decisions towards the body midline. Secondly, when comparing the steepness of the psychometric curves with the variability found in the matching errors to the target, variability of the decisions were lower than those of matching, in line with other visuo-haptic matching studies [1,2] and in action decision studies [3]. This combination of results suggests that position matching is less based on a prior than actions decisions are.
The results from this study suggest that visuo-haptic matching and action decisions use the same visual and proprioceptive information, but different priors.

**Title:** Contrasting effects of exogenous attention on saccades and reaches

**Authors: *A. MALIENKO**, A. Z. KHAN
Univ. De Montréal, Montreal, QC, Canada

**Abstract:** Planning saccades or reach movements to a specific location in the environment relies on attentional mechanisms to select a relevant location and on motor systems to correctly guide

the movements to their destination. However, it remains unknown whether movement planning of different effectors, eyes or arm, interacts with a single attentional mechanism or whether there exist multiple attentional selection mechanisms that are specific to the different effectors.
To test these two alternative hypotheses at the behavioural level, we recruited 13 participants (M = 22.8, SD = 1.5) to perform a task involving exogenous attentional allocation and movement planning. The participants were asked to fixate and hold their hand at an initial position on a screen in front of them (left or right of screen centre) and then, at the disappearance of the fixation cross, perform an eye or arm movement, or both, to a target square (mirror location of fixation cross). A distractor appeared momentarily just before the appearance of the target at one of seven equidistant locations on the horizontal meridian. Saccade reaction times (SRTs), reach reaction times (RRTs) and amplitudes were calculated.
Compared to the neutral condition (no distractor was presented), distractors overall did not result in a facilitation of SRTs at any location (shorter SRTs), rather only a strong inhibition (longer SRTs) as a function of distractor-target distance. In contrast, RRTs showed strong facilitation at the target location and less inhibition at further distances. However both SRTs and RRTs followed a similar pattern in that RTs were shortest closer to the target position and were increasingly longer as a function of distractor-target distance. In terms of amplitude, there was no effect of the distractor on reach endpoints, whereas, for saccades, there was an averaging effect of distractor position on saccade endpoints, but only for saccades with short SRTs. These effects were similar when either effector movement was performed alone or together.
These findings suggest that attentional selection mechanisms have both similar and differential effects providing evidence for both effector-independent and effector-dependent attentional selection mechanisms. This study provides understanding of the operating mechanisms of attention on eye and arm movements and the interaction between sensory and motor systems.

**Title:** Coordination of eye, head and hand movements during visually guided reaching in head unrestrained Rhesus monkeys

**Authors: *H. K. ARORA**[1], V. BHARMAURIA[2], X. YAN[2], H. WANG[2], S. SUN[2], J. D. CRAWFORD[2]
[1]Biol., York Univ., Brampton, ON, Canada; [2]York Univ., North York, ON, Canada

**Abstract:** Non-human primates have been used extensively as animal models for human eye-head coordination and eye-hand coordination within a 2-D plane, but the more natural condition of eye-head-hand coordination during a 3-D reach has not been studied in monkeys. Our goal here was to determine if reaching influences eye-head coordination, and vice versa, in the monkeys. Eye, head, and hand motion were recorded in two rhesus monkeys using search coil and touch screen technology, respectively. Animals were seated in a customized 'chair' which allowed the head to move freely and the hand to reach in both depth and direction. In the standard reach condition, monkeys were trained to initially touch a central LED at the waist level and maintain gaze for 400-800 ms on a central fixation point. When the fixation light was extinguished, animals were required to reach toward a target appearing at one of 15 locations in a 40° horizontal x 20° vertical (visual angle) array. In other conditions, initial hand and gaze position were varied in the horizontal plane. Animal were rewarded for touching the target, but otherwise allowed to move the eyes and head freely. The gaze- control condition, animals were rewarded for fixating the target for variable durations in the same conditions with the reach blocked. Preliminary observations included: 1) animals generally produced coordinated eye-head gaze shifts toward the reach target and then maintained fixation until it was touched, 2) saccade reaction times reduced from means of 185/131 ms in the gaze control to 152/109 ms in the reach condition in animals A/B respectively, and 3) the head moved more in the reach condition for some targets, especially in the vertical dimension, as if it was disinhibited and/or driven more by gaze position during reaches. These data suggest that reach influences gaze kinematics, and will be further quantified to provide a more complete spatiotemporal description.

**Title:** The effects of varying cognitive and motor demand on an attention-mediated reaching task in older adults

**Authors: *L. PETROVSKA**, C. FUEGER, W. E. HUDDLESTON
Kinesiology: Integrative Hlth. Care & Performance, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

**Abstract:** Every day, vision guides one's actions to facilitate successful navigation through a complex environment. The efficiency of how our visual and motor systems interact may decline with age. We examined the effects of increased cognitive and motor demand on behavior during an attention-mediated reaching task. We hypothesized that as cognitive and motor load increased, performance would decline at a greater rate for older participants. Thirty-one healthy older adults (67-84 years, 8 females, 3 left handed) and twenty healthy younger adults (20-29 years, all female, 1 left handed) participated. The trial sequence was as follows: a brief location cue in 1 of 8 peripheral targets presented on a screen in front of the participants, a delay, and a central go cue. Participants performed each of two trial types. The first was a simple reach (SIMPLE) to the previously cued location. The second involved touching a target 3 locations clockwise from the initial cue (SPatial REmapping; SPRE). Participants performed the 2 types of delayed reaches under 4 task conditions. The two BASELINE conditions included either only SIMPLE or SPRE trials. The CHOICE condition included both trial types. The final condition was the same as CHOICE; however, during the delay participants touched 4 cued targets (i.e., a motor mask; MOTOR). Generally, older adults were slower in both reaction times ($F(1,48) = 25.10$, $p < .001$) and movement times ($F(1,48) = 31.73$, $p < .001$) in all trial / task conditions, with a significant group by task interaction (RT $F(2,47) = 6.46$, $p = .003$; MT $F(2,47) = 4.20$, $p = .021$). Conversely, older adult reach endpoints were more accurate ($F(1,48) = 15.41$, $p < .001$), and were less variable ($F(1,48) = 16.61$, $p < .001$), than the younger adults; while path lengths were not significantly different ($p>.05$). Thus, increases in both cognitive and motor load significantly and negatively influenced older adults' temporal performance to a greater degree than the younger adults. These results show that strategies to mitigate movement-related injuries in this population should consider task difficulty, and perhaps temporal constraints, as a rehabilitation strategy.

**Abstract:** Neurons in LIP, an area in the macaque posterior parietal cortex, robustly code saccade direction under many but not all conditions (Mooshagian et al., SFN abstract, 2016). Firing of individual neurons has been shown to be affected by contralateral arm movements, and this has been taken to imply a role in eye-hand coordination (Hagan et al., 2012). We recorded from single LIP neurons while animals made visually-guided saccades, combined saccade and reaches with either the left or right arm to a single target, or reaches with both arms to one or two targets. We find that at the population level, activity is slightly higher when the contralateral arm moves into the receptive field along with the eyes compared to a saccade without a reach. Ipsilateral arm movements have very little effect on population activity, alone or in combination with a contralateral arm movement. At a single cell level, however, a subset of cells respond differently to different movements, such that a support vector machine can distinguish each type of movement. Thus, information about complex patterns of reaches is present in LIP, although the net effect on neuronal firing is modest.

**Title:** Don’t watch where you are going: Cognitive-motor integration development in children and adolescents

**Authors: *M. DALECKI**[1], D. J. GORBET[2], L. E. SERGIO[3]
[1]Sch. of Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Ctr. for Vision Res., York Univ., North York, ON, Canada; [3]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto, ON, Canada

**Abstract:** The spatial locations of guiding sensory information and the required motor action are often in alignment, representing a direct interaction task. However, once we decouple vision and action, they can be misaligned, e.g., when reaching for an object from memory while looking away, or using a computer mouse. This ability requires rule-based visuomotor transformations,

or “cognitive-motor integration” (CMI), often used in every-day life. Both cognition and motor development in the young brain have been fairly well characterized. However, it is not known when and how the ability to control rule-based, decoupled action emerges. Here we investigate CMI development by measuring direct and decoupled visuomotor control across a range of ages. We hypothesize that the rate of CMI development will be constrained by cognitive development rather than motor development, given the later development of cognitive spatial versus goal-directed reaching abilities in children. The actual age of CMI maturation is an exploratory question. Youth in two age groups (children, n=29, 8-12 yrs, mean 10 yrs; adolescents, n=33, 13-15 yrs, mean 14 yrs) performed two eye-hand coordination tasks. In the direct interaction task, participants slid their finger on a vertical touchscreen to move a cursor from a central target to one of four peripheral targets. In the CMI task, targets were in a different plane from hand motion, and feedback was 180° reversed (i.e. decoupling of vision and action in two ways). We analyzed whether movement planning, timing, and trajectory variables differed between age groups. In accordance with our hypothesis, we observed no age-group effects for any movement planning, timing, or execution variables on the direct interaction task ($p<0.05$). However, in the CMI task, we observed that adolescents’ movement planning and timing was significantly shorter than that of children in the CMI task condition which required integration of cognitive information into the visually guided action. Subdividing the child group (8-10 & 11-12 yrs.), we further demonstrated that CMI maturation emerged mainly in the latter period. Our results quantify an important milestone during childhood for the development of CMI, i.e., the ability to decouple vision from action. CMI seems to develop strongly during late childhood, leading to better rule-based motor performance in early adolescence. Based on previous animal, human, and imaging studies, we propose this CMI development is mainly due to frontal lobe development and the strengthening of fronto-parietal networks, networks well known to heavily contribute to the successful integration of rule-based visually guided movement.

**Title:** Rotated visual feedback of self-movement affects long-latency stretch reflex

**Authors: *S. ITO**, H. GOMI
NTT Communication Sci. Labs., Atusgi-City, Kanagawa-Pref., Japan

**Abstract:** Stretch reflexes, quick motor responses evoked by rapid extension of muscles, play a key role in postural control and movement correction. Previous studies have shown that long-latency stretch reflex in particular is flexibly modulated depending on various contexts including physical environments, movement intention or task goal. It is unclear, however, how the stretch reflex is affected by a discordance in motion between one's own limb and manipulated objects as in a situation where one uses complex tools. Here we tackled this issue by measuring the stretch reflex from wrist flexor muscle while introducing directional transformation into visual feedback of self-movements. In experiment 1, human participants repeated wrist flexion movement toward a visual target. In separated experimental blocks, locations of the target and direction of cursor movement were rotated around the center of a display (0, 45, 90, 135, 180 [deg]), while wrist movement was not changed. On the random trials, mechanical perturbation was applied on the wrist joint to evoke stretch reflex during the wrist flexion. We found significant reduction of the long-latency stretch reflex in the experimental blocks with larger visual rotation angles (> 45 [deg]). These results suggest that difference in movement direction between visual cursor and actual limb causes the suppression of stretch reflex. In experiment 2, participants performed a similar movement task, turning their heads toward left. Visual feedback was also rotated 90 degrees in a counterclockwise direction around the head axis so that the cursor motion was unchanged in eye-centered coordinate system. Stretch reflexes did not differ from control condition where direction of the head and visual feedback remained in front of the body. In other experimental block, visual feedback was additionally rotated 90 degrees in a clockwise direction on the center of visual field with participants' head turned. Though the direction of displayed cursor movement coincided with actual wrist movement in external coordinates, we found significant decrease in the stretch reflex. Those results indicate that observed reduction of the stretch reflex occurs depending on a body motion represented in eye-centered or head-centered coordinate system rather than external coordinate system. In conjunction with our previous observation of stretch reflex in a mirror-reversed visual feedback condition, our results suggest that somatomotor transformation for generating a long-latency stretch reflex is not solely coordinated within the somatosensory processing, but is established with a great contribution of visual information.

**Title:** Haptic feedback from stabilization of the hand on an underlying surface facilitates the initial development of visually-guided finger movements for reaching and grasping in 12-month-old human infants

**Authors: *J. M. KARL**, A. M. WILSON, C. WILSON, N. S. SHUBEAR
Thompson Rivers Univ., Kamloops, BC, Canada

**Abstract:** Traditional theories posit that development of the reach-to-grasp movement is dependent on visual guidance, proceeds in a proximal to distal fashion with reach movements of the upper arm maturing before grasp movements of the hand and digits, and is largely complete by 12 months of age. In contrast to this traditional view, recent research suggests that separate reach and grasp movements undergo significant developmental refinement based on somatosensory input long before they are integrated together under visual control. A precise description of how separate reach and grasp movements might transition from somatosensory to visual control during human development is currently lacking. The present study used the ethological task of reaching to grasp small ring-shaped pieces of cereal (Cheerios) to investigate the extent to which the reach and grasp depend on somatosensory versus visual guidance in twelve-month-old human infants. Twelve-month-old infants, sighted adults, and blindfolded adults reached to grasp Cheerios, which were located on either a flat table or on the top of a narrow pedestal. Their arm and hand movements were recorded from three different angles using time-synchronized high speed video cameras and analyzed offline using frame-by-frame video analysis. The reach and grasp movements of infants differed significantly from that of both sighted and blindfolded adults. When reaching to a Cheerio on a table, infants resembled blindfolded adults in that they almost always contacted the table with an open hand before they contacted the Cheerio; after table contact however, infants resembled sighted adults in that they used the tip of an appropriate grasping digit to establish first contact with the target. Despite unrestricted vision of the target and their own hand, infants were much less likely to use the tip of an appropriate grasping digit to establish first contact with the Cheerio when the Cheerio was located atop a narrow pedestal. The results suggest that the development of visual guidance of the reach-to-grasp movement might actually originate at the distal tip of the digit and be facilitated by initial haptic contact between the hand and an underlying table or surface. Contact with the underlying surface likely serves to: provide a haptic signal that the hand has reached the general target location, stabilize the endpoint of the reach at that location, and free up vision to attend to the interaction between the tips of the digits and the target.

**Title:** Grasping 2D targets: The influence of shape and position on gaze and grasp accuracy

**Authors: *R. W. LANGRIDGE**, J. J. MAROTTA
Psychology, Univ. of Manitoba, Winnipeg, MB, Canada

**Abstract:** A stable grasp is one in which a grasp line connecting the index finger and thumb would bisect the target object's center of mass. When grasping either 2D or 3D stationary rectangles, our lab has seen this achieved by placing the index finger on the top edge, close to the horizontal center. However, when grasping horizontally translating targets with the right hand, we see a final index finger position that lands *to the left* of the target's horizontal center (Bulloch, Prime, & Marotta, 2015; Langridge & Marotta, 2016), regardless of direction. Individuals may be unconsciously adjusting their reaches and grasping ahead of a leftward moving target's center to account for the increased mechanical risk present when executing a grasp 'across the body' for a target moving away from the hand. This study investigated how target shape and position influence preferred grasp location. **Methods:** Participants executed right handed reach-to-grasp movements for stationary 2D shapes positioned on the left, right, or in the center of a computer screen. Shapes were either square (Fig. 1), or were missing part of the top and bottom edges, intended to force a choice between grasping the left or right side of the target (Fig. 2). **Results:** Final gaze and index placement was positioned further rightward when grasping 'complex' shapes compared to controls. Participants fixated on the right side of targets positioned on the left, the left side of targets presented on the right, and the center of central targets, regardless of shape. Index finger placement corresponded with gaze: A rightward bias was observed when grasping left and central targets, whereas a leftward bias was observed when grasping targets on the right. **Conclusions:** When reaching for 2D targets, individuals prefer to choose grasp locations that require the least amount of mechanical effort. Both the shape of the target and its position in relation to the reaching hand influences where gaze is directed and the preferred index finger placement when grasping.

**Title:** Potential models of allocentric coding for reaching in naturalistic visual scenes

**Authors: *P. ABEDI KHOOZANI**[1], M. KLINGHAMMER[2], P. R. SCHRATER[3], D. ENDRES[4], K. FIEHLER[2], G. BLOHM[1]
[1]Queen's Univ., Kingston, ON, Canada; [2]Justus-Liebig Univ. Giessen, Giessen, Germany; [3]Univ. Minnesota, Minneapolis, MN; [4]Philipps-University Marburg, Marburg, Germany

**Abstract:** We use both allocentric and egocentric information when planning to reach to visual targets. Previous studies showed that contextual factors can modulate the integration of allocentric information, Klinghammer et al. 2015, 2016, 2017: e.g. when humans are exposed to similar scenes at two phases in a memory task, encoding for memorizing the scene configuration and decoding for reaching to a missing object, random shifts in objects of the scene lead to less contribution of allocentric information and higher variability in reaching compared to consistent object shifts. However, the principles of this integration and the impact of different parameters are not clear. Therefore, our aim is to examine potential principles for allocentric coding, using a modeling approach, to explain the reported data as well as make predictions for future experiments. We propose three models to estimate the position of a missing object using a

naturalistic scene. At the encoding phase the goal is to code and store the position of each object with respect to the other objects in working memory. The first two models perform this task by creating a cluster point and calculate the distance of objects from this cluster (first model is logistic Bayesian and the second model is generative Bayesian). The third model performs this task by creating Barycentric coordinates and encodes the position of the target object with respect to local clusters of objects. At the decoding phase, the goal is to infer the position of the missing object from the new scene and remembered information from encoding. In the first two models, this inference is done by combining the remembered egocentric cluster point, from encoding, and the new allocentric cluster point extracted from the new scene. The third model estimates the allocentric position of the missing object based on the new scene and then combines it with remembered egocentric position. All models reproduced the reported human data, but each model has different implications: Based on the first two models, the required computational and memory resources can be greatly decreased by creating a global cluster point, however, any misestimation in retrieving this cluster point, due to changes in the scene, can dramatically affect the final estimation (the first model in more efficient computationally while the second model Is more robust due to making less assumptions). In contrary, the third model uses a more redundant coding strategy (requiring more resources) by creating local clusters and therefore changes in the scene. Future experiments should be carried out to examine which of these strategies, if any, the brain might use.

**Title:** Short-latency stimulus-locked responses on human upper limb muscles are preferentially evoked by low spatial frequency stimuli

**Authors: *R. A. KOZAK**[1], C. GU[2], K. D. JOHNSTON[3], B. D. CORNEIL[3]
[1]Neurosci., [2]Psychology, [3]Dept Physio & Pharmacol, Western Univ., London, ON, Canada

**Abstract:** To reach to a visible target, visual information ultimately has to be transformed into motor commands. Neural processing within numerous frontal and parietal cortical areas is likely important for such a sensorimotor transformation, with the outcome typically being relayed to the motor periphery via the corticospinal pathway. Recently, we have described stimulus-locked

responses (SLRs) on human limb muscles, which are brief bursts of muscle recruitment that evolve at time-locked latencies within ~100 ms of visual target onset, even if eventual reach is temporarily withheld or moves in the opposite direction. These observations have led us to hypothesize that SLRs arise from a fast visuomotor system mediated by the tecto-reticulo-spinal pathway, which runs in parallel to the corticospinal pathway. Very little is known about the nature of visual input that feeds into the fast visuomotor system.
To address this question, we examined whether the SLR is preferentially evoked by visual stimuli composed of either high-spatial frequency (HSF) information, which is primarily mediated by the parvocellular visual pathway, or low-spatial frequency (LSF) information, which is primarily mediated by the magnocellular visual pathway. Human subjects placed in a robotic exoskeleton generated planar arm movements toward visual stimuli to the right or left as surface electrodes recorded electromyographic (EMG) activity from the clavicular head of the right pectoralis major muscle. Visual stimuli consisted of perceptually contrast matched Gabor patches, spanning 0.26 to 4.44 cycles per degree of visual angle. LSF stimuli evoked the shortest-latency and largest magnitude SLR. Approximately 70 percent of participants presented with detectable SLRs at ~100 ms for LSF stimuli (SLR+). Further, SLR latency increased and SLR magnitude decreased for progressively higher spatial frequency stimuli. In the SLR+ participants, not all presented with detectable SLRs for the highest frequency stimuli, significant responses were only detected after 125 ms. Off-line analyses confirmed that these results were not due to concomitant changes in movement reaction time. Overall, our results demonstrate that the SLR, which represents the earliest wave of upper limb muscle recruitment in a visually-guided paradigm, is preferentially evoked by LSF stimuli carried by the magnocellular pathway.

**Title:** Temporal development of an interaction effect between internal motion and contour signals of drifting target on reaching adjustment

**Authors: *H. UEDA**, N. ABEKAWA, H. GOMI
NTT Communication Sci. Labs., Atsugi, Kanagawa, Japan

**Abstract:** When a moving object containing internal motion is seen in the visual periphery, the perceived position of the object is often distorted towards the direction of its internal motion. This phenomenon is known as motion-induced position shift (MIPS) and observed also in motor actions such as manual reaching and saccades. A recently proposed object-tracking model (Kwon et al., 2015) describes that MIPS is caused by a bidirectional coupling between position and motion perception. In particular, at high positional uncertainty (e.g., in peripheral vision), most of the retinal motion signal including internal pattern motion is mistakenly attributed to the object's global motion/position, and vice versa. Although many evidence of MIPS has been found, most studies so far have ceased to verify under what conditions MIPS occurs and almost no study has been focusing on the temporal development of MIPS. The present study, therefore, aimed to examine an open question that, in what time course, such MIPS (or integration of object's internal and external motions) occurs.
In the experiment, the stimulus of the curveball illusion (Shapiro et al., 2010), which deviates the perceived trajectory of a moving visual target from its actual trajectory towards the direction of internal motion, was adopted as a target stimuli, in which positional uncertainty levels were controlled by the aperture boundary: soft, moderate, or hard. In each trial, participants started forward reaching to the target stimuli which initially located at 25 cm away from the start position. Shortly after the reaching initiation, the target either moved 5 cm to the left or right or stayed the initial position accompanied by the onset of internal motion. All the combinations of external and internal motion directions (rightward, leftward, and no motion), except for incongruent directions, were tested. Participants were required to make online reaching adjustment in response to the target motion.
The results showed that the reaching adjustment started approximately 190 ms after the external/internal motion onset in all the motion conditions, even in the condition of internal motion only. The early phase of the reaching adjustment (< 225 ms) was not affected by the contour type. The late phase of the adjustment (> 250 ms), on the other hand, was greatly affected. These results suggest that MIPS is also observed in the reaching adjustment, but is slowly developed, compared to the direct effect of visual motion on the reaching adjustment. That is, the adjustment would be initiated prior to the integration of motion and position information, and effect of integration on the motor response would appear after a certain period of time.

**Title:** Modulation difference in visuomotor responses in implicit and explicit motor tasks depending on postural stability

**Authors: *N. ABEKAWA**, H. GOMI
NTT Communication Sci. Labs., Kanagawa, Japan

**Abstract:** In our daily life, we reach for target objects accurately under various postural environments. If body posture is not stable, we should make online corrections of reaching rapidly to compensate for body motion. Recent studies have shown that a large-field visual motion applied during reaching induces rapid and unintentional manual following response (MFR) in the direction of visual motion (Gomi, 2008). Considering that retinal motion occurs when our body moves, the visuomotor system can use visual motion signals arising from body movements to rapidly adjust reaching against unpredictable body motion. This functional view regarding the MFR can raise a fundamental question of whether the brain optimally modulates the implicit visuomotor response according to postural environments. Here, we tested this issue by examining the effect of postural condition (unstable or stable) on the MFR. Standing participants made reaching movements to a visual target on a vertical screen. On the random trials, large-field vertical gratings (size: 80 [hor.] x 66 [ver.] deg., Fs: 0.1 c/d) started to move rightward or leftward (velocity: 100 d/s) just after the initiation of reaching. Participants performed reaching under the two different postural conditions. In the UNSTABLE condition, participants were standing on the motor-driven platform with viewing static gratings, and were asked to maintain their posture during every trial interval (for approx. 5 sec.) against the instability induced by platform motion. In the STABLE condition, they were standing on the wood box, and there was no postural disturbance. Note that between both conditions, body posture was identical during the reaching (i.e. motor platform did not move during the reaching). We quantified the amplitude of the MFR implicitly induced by visual motion, and found that the MFR was significantly larger for the UNSTABLE than for the STABLE. In the follow-up experiment, participants performed the choice-reaction task where they pressed the right or left button as fast as possible according to the direction of visual motion. There was no significant reduction of reaction time for the UNSTABLE compared to for the STABLE. This would rule out the explanation that the change in the MFR results from postural condition affecting early visual processing commonly used in the implicit and explicit visuomotor tasks. Rather, our data suggest that the visuomotor transformation specific for the MFR is flexibly modulated by external environments according to the postural stability. In unstable environments, the brain would rely on implicit visuomotor controller more in order to effectively adjust reaching movements.

**Abstract:** Human observers always fixate certain landmark positions in a visual scene in which objects have to be grasped and moved to a different location, and the grasp site on the object is invariably fixated prior to grasping. However, the neural basis of eye-hand coordination in object manipulation is not well understood. Previous studies have shown that parietal regions such as MIP, LIP and AIP, which are heavily interconnected with frontal areas, may play a pivotal role. Frontal areas are involved in controlling different effectors such as the eye, arm and hand, but it is not clear how these different areas interact during naturalistic behavior involving eye, reach and grasping movements.
Two monkeys were trained in a sequential saccade-reach-grasp task, in which the animals had to first fixate a spot on a display, after which an object was illuminated in peripheral vision. After a variable delay, the animals had to make a saccadic eye movement to the illuminated object, and after a second delay, the animals were instructed to reach towards, grasp and pull the object. Both animals were implanted with a chronic 96-channel microdrive (Gray Matter Research) with individually-movable electrodes above frontal cortex, allowing access to primary motor cortex, dorsal premotor cortex, ventral premotor cortex (F5a, F5p), Frontal Eye Fields and area 45B. We recorded in 80 sessions during 4 months with over 1500 recording sites in each monkey. Electrode position was confirmed by repeated CT-MRI co-registration in which individual electrodes could be visualised.
We did not observe a clear separation of visual-, saccade-, reach- and grasp-related activity across frontal cortex. In contrast, we observed very similar response profiles in all frontal areas: an initial visual response to light onset, then a sustained increase in neural activity after saccade onset followed by an additional increase in activity in the epoch before the hand started moving towards the object. This cumulative effect of visual-, saccade-, reach- and grasp-related responses was present across all recording channels, from primary motor to the most anterior

parts of ventral premotor cortex. These results suggest that frontal areas work in concert during a saccade-reach-grasp task that mimics natural prehension behavior.

**Title:** Multi-electrode recordings in the macaque parietal cortex reveal common processing of eye-, arm- and hand movements

**Authors: *P. JANSSEN**, E. PREMEREUR
KU Leuven, Leuven, Belgium

**Abstract:** Hand actions are usually performed in coordination with eye movements. For example, the grasp site on an object is invariably fixated prior to grasping. However, the neural basis of eye-hand coordination in object manipulation is not well understood. Previous studies have shown that parietal regions such as MIP, LIP and AIP may play a pivotal role. The latter areas are involved in controlling different effectors such as the eye, arm and hand, but it is not clear how these different areas interact during naturalistic behavior involving eye, reach and grasping movements. Two monkeys were trained in a sequential saccade-reach-grasp task, in which the animals initiated a trial by fixating a spot on a display, which was followed by the illumination of an object in peripheral vision. After a variable delay, the fixation spot dimmed, indicating to the animals to make a saccadic eye movement to the illuminated object. A second go-cue instructed the animals to reach towards, grasp and pull the object. Both animals were implanted with a chronic 96-channel microdrive (Gray Matter Research) with individually-movable electrodes above parietal cortex, allowing access to AIP, MIP, LIP, area 5 and PFG. We recorded in 171 sessions (monkey S: 87; 4187 recording sites, monkey O: 84 sessions; 4544 recording sites), and the electrode position was confirmed by repeated CT-MRI co-registration in which individual electrodes could be visualized. We found significant task-related multi-unit activity in 1460 sites (monkey O: 798 sites, monkey S: 662). A minority of these recording sites was responsive during object illumination (monkey O: 293 sites, monkey S: 167), and these recording sites were typically located more anteriorly in the IPS. On the majority of channels, however, we obtained an initial sustained increase in neural activity after saccade onset followed

by an additional increase in activity in the epoch before the hand started moving towards the object. We did not observe a clear separation of saccade-, reach- and grasp-related activity across parietal cortex. In contrast, we observed very similar response profiles in all parietal areas. These results suggest that parietal areas work in concert during a saccade-reach-grasp task that mimics natural prehension behavior.

**Title:** Development of locomotor skills in children

**Authors: *M. F. LEVIN**[1,2], D. CHAN-VIQUEZ[1,2], N. A. TURPIN[3,2], A. LAMONTAGNE[1,2], A. G. FELDMAN[3,2]
[1]McGill Univ., Montreal, QC, Canada; [2]Ctr. for Interdisciplinary Res. in Rehabil., Montreal, QC, Canada; [3]Neurosci., Univ. of Montreal, Montreal, QC, Canada

**Abstract:** The study of neurological control mechanisms underlying movement maturation is important for the understanding of how motor skills are acquired during early childhood and the identification of motor milestones. Maturation of locomotor skills in typically-developing (TD) children was studied in the framework of the referent configuration (RC) hypothesis, an extension of equilibrium-point theory. Identification of mature patterns would be associated with the presence of periods of minimal activity in multiple muscles of the body when the actual configuration (AC) of the body coincides with the referent one (RC) during rhythmical movement. The objective of the study was to determine whether locomotor maturation was associated with the presence of EMG minima in 3 locomotor tasks of increasing complexity (walking, jumping, jumping forward). **Methods:** Ten TD children (aged: 3.9±0.9 yr) and 10 adults (aged: 21.7±1.3 yr) were recruited after signing informed consent forms approved by the local ethics committee. Children underwent a clinical evaluation of gross movement performance (Test of Gross Motor Development-Gross Motor Quotient, GMQ). Kinematics (12-camera Vicon 512 system, 24 markers on trunk and legs) and EMG from 5 muscles on each leg (Wave Wireless EMG) were recorded while subjects performed 3 locomotor tasks: walking (W), vertical jumping (VJ) and jumping forward (JF). EMG minima were identified across muscles of one (W) or both (VJ, JF) legs. The number of minima and the location at which they occurred in the leg movement cycle (measured by the ankle marker) for each task were determined. **Results:** GMQs ranged from 115-136 out of 160 (mean 121.9±6.5). For the 3 tasks, children tended to have fewer EMG minima per cycle (W: 0.8±0.3, VJ: 0.4±0.2, JF: 0.7±0.3) compared to young

adults (W: 1.0±0.0, VJ: 0.9±0.2, JF: 0.9±0.1). The percentage of the leg movement cycle at which the minima occurred differed between groups. Less mature children had no or fewer minima. Minima, when present occurred more frequently between 20-29% (W), 40-59% (VJ) and 50-69% (JF) compared to young adults (W: 60-70%, VJ: 50-70%, and JF: 30-50%). The number of EMG minima during the VJ task was correlated with GMQ ($r=0.71$, $p=0.03$). **Conclusions:** Less mature children had fewer minima that occurred in different locations compared to adults, while EMG minima in children with more mature movement patterns were similar to those in young adults. EMG minima may be indicators of locomotor maturation defined as the specification of an RC by the nervous system. Understanding the mechanisms underlying locomotor maturation in young children can help identify developmental disorders and delays.

Paris Descartes, Paris, France; [4]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada; [5]Ecole de Readaptation, Univ. of Montreal, Montreal, QC, Canada

**Abstract:** Our postures and movements are oriented with respect to the direction of gravity. Body orientation changes when we lean forward from quiet standing position. The role of the vestibulospinal system in this process was investigated by assuming that this system should increase the spatial thresholds of anti-gravitational ankle muscles to let the gravitational torque

lean the body forward thus transferring body balance and stability to a new posture. Eight healthy subjects aged 19-40 yrs. old participated. Galvanic vestibular stimulation (GVS) was applied to compare the vestibulospinal influences during quiet standing, after intentional forward body leaning and after returning to quiet standing. Binaural stimulation (step impulse of 2mA current, duration 0.4s) was applied with the anodal electrode placed over the right mastoid process, after subjects turned their head to the left and closed their eyes at each position tested. Medium-latency EMG responses (MLRs; latency about 80-100ms) to GVS were recorded in ankle muscles (tibialis anterior and soleus of both legs) by post-stimulus averaging over 20 trials and normalized to the pre-stimulus EMG level. Compared with quiet standing, soleus MLRs were significantly reduced (by about 45%, paired t-test, $p=0.022$) at the position of forward leaning despite a substantial increase in the EMG levels in soleus muscles at this position. There was no change in tibialis anterior MLRs (paired t-test, $p>0.05$). Thus, during forward leaning, vestibulospinal facilitation of motoneurons of anti-gravitational ankle muscles was reduced. As a consequence, the EMG activity of these muscles initially diminished and then increased with reaching the final position of the forward leaning at which the increasing gravitational torque was balanced. Results support the prediction that to lean the body, the system changes the referent body orientation by shifting the spatial thresholds at which muscles of the body begin to be activated. Monotonic change in the body orientation gives rise to the observable non-monotonic EMG pattern without pre-programming. In contrast, direct specification of the EMG pattern without resetting the spatial thresholds for muscle activation would evoke resistance of posture stabilizing reflexes, preventing body leaning. This study advances the understanding of the role of the vestibulospinal system in the control of posture and movement by identifying a major control variable, the referent body orientation, underlying such control without direct pre-programming of motor commands to muscles and kinematics.

**Abstract:** This study addresses the question of how posture and movement are oriented with respect to the direction of gravity. It is suggested that neural control levels coordinate spatial thresholds at which multiple muscles begin to be activated in order to specify a referent body orientation (RO) at which muscle activity is minimized. Under the influence of gravity, the body is deflected from the RO to an actual orientation (AO) until the emerging muscle activity and forces begin to balance gravitational forces and maintain body stability. Postural corrections are produced by changing the RO, whereas the changes in muscle activity , forces and kinematics emerge, without pre-programming, due to deviation of the AO from RO. We tested several predictions of the hypothesis. (1) Dduring quiet standing on differently tilted surfaces, the same RO and thus AO can be maintained by adjusting activation thresholds of ankle muscles according to the tilt; (2) Intentional forward leaning of the body results from respective monotonic ramp-and-hold shifts in the RO. (3) Rhythmic oscillation of the RO about the ankle joints during standing results in body swaying; thereby at certain sway phases the AO and RO may transiently overlap, resulting in minima in the activity of multiple muscles across the body. EMG kinematic patterns in the 3 respective tasks were recorded and explained based on the RO concept that implies that these patterns are caused by referent control without being pre-programmed. In addition, as predicted, we confirmed the occurrence of minima in multiple muscles across the body at different body configurations during swaying. The role of the vestibulo- and corticospinal systems in the control of the body orientation in the gravity field is considered based on the notion of referent control of posture and movement.

**Title:** Experts use the brainstem more for movement than non-experts: Evidence from startle-evoked-movement during typing

**Authors: *B. M. BARTELS**, M. QUEZADA, M. SANTELLO, C. F. HONEYCUTT
Arizona State Univ., Tempe, AZ

**Abstract:** Recent evidence suggests that the brainstem is utilized more heavily following intense training. Bilateral motor cortex lesions do not disrupt the ability of rats to perform highly trained reaching (Kawai et a. 2015) - highlighting the importance of subcortical structures following learning. While provocative, this study was completed in rats and translation to humans is unclear. Startle-evoked-movement (SEM or startReact) represents a non-invasive way to evaluate the use of the brainstem (specifically the reticulospinal tract). We have previously demonstrated that SEM can detect the shift from cortical to brainstem usage following intensive training of finger abduction (Kirkpatrick et. al. 2017). Our objective here was to evaluate differences in brainstem usage between expert and non-experts. We hypothesized that the brainstem would be utilized more heavily in experts (showcased by the presence of an SEM in all fingers). We evaluated 8 expert (86.5 ± 12.9 WPM) and 8 non-expert typists (40.25 ± 14.6 WPM) with right handed dominance. The subject's right hand rested on the j, k, l, semi-colon, and space keys of a keyboard. A soft acoustic stimuli (80dB), informed the subject to prepare task execution. A go cue of either 80dB or 113dB was delivered 2-3 seconds later and directed them to press a specified key. The 113dB stimulus was intended to evoke a SEM. Keystroke and EMG data are collected. Analysis of the keystroke data revealed that SEM was present in all fingers of expert typists but none of the fingers of non-experts. In experts, SCM+ trials were faster than SCM- trials for the thumb ($\Delta$=0.024s; P=0.003), index ($\Delta$=0.029s; P=0), middle ($\Delta$=0.014s; P=0.04), ring ($\Delta$=0.029s; P=0.002), and little ($\Delta$=0.029s; P=0). There was no difference for any of the fingers in the non-expert population: thumb ($\Delta$=0.005s; P=0.618), index ($\Delta$ = -0.004s; P=0.677), middle ($\Delta$=-0.001; P=0.823), ring ($\Delta$=-0.006s; P=0.37), and little ($\Delta$=0.018; P=0.054). Importantly, there was no difference in the probability of evoking a startle between the populations. We conclude that experts utilize the brainstem to execute highly trained tasks indicating that the result from rats pertains to humans as well. Our results emphasize the importance of task familiarity towards an individual's ability to plan the execution of movements in subcortically.

**Title:** Does startle enhance unrestricted, 2D reaching movement in stroke survivors?

**Authors: *M. RAHIMI**[1], C. F. HONEYCUTT[2]
[2]Sch. of Biol. and Hlth. Systems Engin., [1]Arizona State Univ., Tempe, AZ

**Abstract:** Seventy-Five percent of stroke survivors have upper extremity deficits after acute stroke (Lawrence et al, 2001) which cause difficulty in essential movements like reaching and grasp. Recent work (Honeycutt & Perreault, 2012) has shown that startle can enhance stroke survivors' movements suggesting that startle can be used as a therapy tool. However, these studies evaluated single joint movements; therefore, it is unknown if startle will enhance movements when the arm is unrestricted allowing the full expression of abnormal muscle synergies and spasticity to affect movement quality. The objective of this study was to evaluate startle-evoked-movement during unrestricted, two dimensional reaching tasks. We hypothesized that startle would 1) decrease onset latency of muscle activity, 2) decrease movement reaction time and 3) increase the maximum speed of movement in stroke survivors. Moreover, we hypothesized that individuals who were not able to reach the targets would see increased movement distance.

Four eligible stroke subjects (Fugl-Meyer's ranging: 20 - 55 and Modified Ashworth scores ranging: 0 - 3) and two control subjects participated. Subjects reached to 3 different targets: mostly elbow, mostly shoulder, and both elbow and shoulder targets. Subjects were instructed to plan their movements and move from a home position to one of the targets following an auditory "GO" cue. "GO" cues were randomly replaced by a loud startling acoustic stimulus. EMG was collected in brachioradialis, biceps, triceps, pectoral, anterior and posterior deltoid muscles.

We found that startle decreased onset latencies of all muscles ($\Delta = 143.0 \pm 90.2$ ms) and decreased the reaction time ($\Delta = 139.2 \pm 113.0$ ms) in all subjects. Moreover, startle increased the maximum speed of the movement ($\Delta = 9.9 \pm 5.8$ cm/s). The most severely impaired individual (Fugl-Meyer = 20, Modified Ashworth = 3) saw the most dramatic enhancement of movement. Specifically, muscle onset latency decreased by $\Delta = 264.1 \pm 21.7$ ms. Furthermore, this individual only had quantifiable EMG activity in 37.3% of the trials during voluntary movement and 98.6% of the trials during startle. In addition, startle increased the movement distance of this individual ($\Delta = 2.8 \pm 0.3$ cm).

In conclusion, startle was able to enhance the movement of stroke survivors even in unrestricted

workspace. Further, the most significant improvements were seen in the most severely impaired individual who had high spasticity. This indicates that startle has the potential to play a role in therapy. Future work should evaluate how different levels of impairment and spasticity would affect the enhancements in stroke survivors.

**Title:** Startle is able to evoke nearly identical movements in unrestricted, two dimensional reaching space

**Authors: *M. R. OSSANNA**, S. Y. SCHAEFER, C. F. HONEYCUTT
Arizona State Univ., Tempe, AZ

**Abstract:** Startle-evoked movement—or the ability of startle to involuntarily release planned movement—has recently become a fixture in the literature due to its robust nature across numerous populations (i.e. stroke, Parkinson's) and joints (i.e. wrist, elbow, ankle). In addition, SEM has been shown to enhance single joint elbow movements and whole hand grasping in stroke survivors (Honeycutt et al, 2014, 2012). Still, almost all work to date has focused on single joint tasks while other joints were restricted. Indeed, others have often cited that SEMs were less precise than voluntary movements (Carlsen et al, 2004b) or exhibited differences in movement kinematics (Maslovat et al, 2011). Therefore SEM's ability to elicit multi joint movements of the whole arm is unclear. The objective of this study was to evaluate the ability of SEM to evoke unrestricted, two-dimensional movement. We hypothesized that SEM would be readily accessible across all directions even though we expected SEM movements to be less precise.

Ten right-handed subjects performed a reaching task to five targets that were equally spaced in a semi-circle to create a two-dimensional workspace. Target placement was chosen based on where arm stability is maximized (Hu et al, 2012). Subjects reached to each target following a sequence of two non-startling acoustic stimuli (60dB) cues: "Get Ready" and "Go". A loud acoustic stimuli (113dB) was randomly substituted for the "Go" cue with the intention of eliciting a SEM. Muscle activity during the performed movement was recorded using EMG for

bicep, triceps lateral, brachioradialus, pectoral, anterior and posterior deltoids. Movement time, acceleration, and position were also recorded during each reaching task.
We found that SEM was evoked in all five target directions as demonstrated by faster muscle onset latencies and movement start times. Muscle onset latency averaged across all 6 muscles and all targets had a delta value of 36.07ms ± 11.08 between SEM and voluntary movements. For movement start time, the average delta value between SEM and voluntary movements across all targets was 39.028 ms± 6.42. Interestingly, no differences were reported between voluntary and SEM trials in movement kinematics (i.e. total movement time, movement start time, linear deviation, average velocity, time to peak velocity) (all $p>0.05$). This result indicates that SEM can evoke functionally relevant movements. Our results represent the first step towards validating SEM as a potential therapy tool following stroke.

**Title:** Generalization of complex motor skills: the transfer of dance movement sequences from trained to untrained contexts

**Authors: *E. MCKENNA**[1], R. NORTH[2], E. PRICE[3], S. SHIELDS[3], W. M. JOINER[2]
[1]Neurosci., [2]Bioengineering, [3]Dance, George Mason Univ., Fairfax, VA

**Abstract:** Motor generalization refers to the ability to transfer learning from a trained context to an untrained context. Generalization of motor adaptation (e.g., induced by perturbing arm reaching movements with robotic manipulandums) has been widely studied through the variation of movement speed and extent (Goodbody and Wolpert, 1998; Mattar and Ostry, 2010; Joiner et al. 2011), configurations (Shadmehr and Mussa-Ivaldi, 1994; Shadmehr and Moussavi, 2000; Malfait et al. 2002), effectors (Criscimagna-Hemminger et al. 2003; Malfait and Ostry, 2004; Taylor et al. 2011; Joiner et al. 2013), and directions (Donchin et al. 2003; Thoroughman and Taylor, 2005; Hwang et al. 2006; Fernandes et al. 2012). These studies, however, investigated the transfer of motor learning using confined, simple movements. In the current study, we examined motor generalization using more complex motor skills. Specifically, we observed dancers' ability to transfer learning of an intricate movement sequence from a rehearsed to an

unrehearsed spatial orientation. This task is familiar to dancers as they are often required to learn movement sequences in a studio and later perform them on a stage with different spatial constraints given little, if any, practice. In our study, three dancers performed a movement sequence in three different spatial orientations: 1) a rectangular space (7.5 m by 5 m) serving as the trained orientation, 2) an untrained rectangular space with different dimensions (5 m by 7.5 m), and 3) an untrained circular movement pattern (radius of 2.5 m). While dancers performed the movement sequence in each spatial orientation, we tracked the position of the dancer using motion capture (OptiTrack). With these data we were able to 1) quantify the position of the dancers throughout the movement sequence in each spatial orientation and 2) quantify how these positions were adjusted in order to comply with the different spatial constraints in each orientation. Our results demonstrate that dancers have the ability to adjust their movements in accordance with varied spatial constraints. In addition, dancers were able to transform the movement sequence from a Cartesian coordinate system in the rectangular spaces to a polar coordinate system in the circular movement pattern. Our data suggest that the mechanisms underlying the motor generalization patterns studied in simple motor adaptation paradigms may also apply to more complex movement sequences.

**Title:** Presence and absence of prediction errors during action observation induce distinct motor contagions

**Authors: *T. IKEGAMI**[1], G. GANESH[2], H. NAKAMOTO[3]
[1]Natl. Inst. of Information and Communications Technol., Suita City, Osaka, Japan; [2]CNRS-AIST JRL (Joint Robotics Laboratory), UMI3218/CRT, Intelligent Systems Res., Natl. Inst. of Advanced Industrial Sci. and Technol. (AIST), Tsukuba, Japan; [3]Fac. of Physical Education,, Natl. Inst. of Fitness and Sports in Kanoya, Kagoshima, Japan

**Abstract:** Motor contagions are implicit effects induced in one's actions by watching of other's actions (Blakemore & Frith, 2004). The popular belief is that motor contagions such as automatic imitation, emulation, or outcome mimicry (Heyes, 2011) cause features (like kinematics, goal, outcome) of one's action to become similar to that of an observed action. On the other hand, Ikegami & Ganesh (2014) has recently reported a motor contagion that changes one's action but may not necessarily induce a similarity in it to the observed action. This contagion is induced not simply by observation, but by the presence of *prediction errors*- differences between actions one observes and those one predicts. To determine whether these two contagions are indeed distinct, here we examined the differences in the motor contagions induced by the observation of a same set of actions, in the presence and absence of prediction errors.

30 varsity baseball players took part in our study. In alternating sessions, the subjects observed a video of a baseball pitcher throwing a ball aimed for the upper right corner of a target strike zone (observation session), and threw a baseball themselves (throwing session) aimed for the center of the target. The throwing sessions were performed wearing a shutter goggle that shut when they released the ball from their hand, and prevented them from seeing where their throws hit the target. The subjects were divided into three groups (n=10 for each)- No prediction error (nPE), Prediction error (PE), and Control (CON) groups. The prediction error was manipulated by a difference of instructions between nPE and PE groups before each observation session. nPE group was correctly informed that "the pitcher is aiming for the upper right corner", which was expected to suppress prediction errors. PE group on the other hand was misinformed that "the pitcher is aiming for the center of the target" which was expected to generate prediction errors. CON group performed only the throwing sessions and not the observation sessions.

Even though only few words of instruction differed between the two groups, they showed completely different changes in motor performance. The throws by nPE group progressively deviated towards the upper right corner, similar to previously reported motor contagions. However, the throws by PE group progressively deviated towards the lower left corner, opposite to the direction of the observed throws. No deviation was observed in CON group. Our results clearly show the presence of two distinct types of motor contagions: one induced by features of the observed actions, and another by prediction errors related to the observed actions.

**Abstract:** Our research examines cognitive-motor integration during eye-hand coordination. Such integration is often required when performing non-standard visuomotor tasks, where a rule is used to align the required motor output to the guiding visual information. We propose that cognitive-motor integration provides a simple, fast behavioural measure to track functional recovery following concussion. Previous cross-sectional research from our laboratory[1,2,3] has shown cognitive-motor integration declines in elite-level, university-level, child, and adolescent athletes who have a history of concussion (but were deemed recovered at the time of evaluation). To extend our research into concussion recovery, the current longitudinal study examines cognitive-motor integration (CMI) in young adult athletes at two time points during their return-to-play protocol following concussion. Participants were tested on two visuomotor transformation tasks using an ASUS tablet touch-sensitive computer attached to an external monitor or external touchpad. They made movements from a central target to one of four peripheral targets (up, down, left, right) by sliding their finger across the horizontally-placed touch-sensitive tablet displaying the targets. In condition one, participants viewed the targets on the touch-sensitive tablet. In condition two, participants viewed the targets on the upright, vertically oriented external monitor, with the cursor feedback 180$^{o}$ reversed so that the motion plane and cursor alignment were decoupled from guiding visual information (requiring CMI). We observed that, compared to their own baseline, these athletes continued to show performance impairments at the time they were cleared to return to their sport based on current return-to-play protocols[4]. Specifically, we found movement path length, movement time, and accuracy impairments relative to baseline during CMI, a skill that is often needed on the field of play. As well, some athletes showed deficits as long as three months following injury. These data suggest that the current return to play protocols do not fully capture functional abilities needed for many sports, and that their impairment may underlie an increased vulnerability to further concussion.

**Title:** Engagement with a virtual clinician encourages gesture usage in speakers with aphasia

**Authors: S. L. SNELL**[1], N. MARTIN[2], *E. A. KESHNER[1]
[1]Dept. of Physical Therapy, [2]Dept. of Communication Sci. and Disorders, Temple Univ., Philadelphia, PA

**Abstract:** Aphasia is an acquired communication disorder that affects the ability to speak and understand spoken language. The use of gestures during speech is an important nonverbal means of communication that may facilitate speech production. We hypothesized that active engagement with a virtual clinician that produces natural gestures will support the emergence of more upper extremity and coordinated postural actions in patients with aphasia. Five speakers with aphasia (49 to 65 yrs) engaged in several communication tasks following instructions from a virtual clinician that: 1) did not use gestures, 2) exhibited gestures, and 3) again did not use gestures. Motion of the affected and unaffected thumb, index finger, wrist, shoulder and head of the patient were collected (Qualisys, Sweden) and analyzed off-line. Magnitude of upper extremity motion and trunk motion was determined by deriving the 95% confidence ellipsoid volume (CEV) of all of the gestures per condition for each subject. The Wilcoxon rank sum test was used to determine significant differences ($p<0.05$) between the CEV values according to trial condition. A taxonomy of gestures was created to identify whether each gesture was communicative or manipulative. Frequency of appearance of type of gesture was calculated. The number of gestures produced and the amount of time spent producing meaningful gestures was not significant between conditions. Magnitude of motion was significant between Pre-Gesture and Gesture conditions ($p\leq0.01$, $Z=-3.56$). Specifically, the non-affected index finger, thumb and wrist markers significantly differed ($p\leq0.01$, $Z=-3.10$) between Pre-Gesture and Gesture. No significance was found when comparing Pre-Gesture and Post Gesture conditions of the affected upper extremity ($p>0.05$, $Z=-1.50$). No significance was found between Pre-Gesture and Post-Gesture conditions. Results indicate that Individuals with aphasia did produce larger gestures after the clinician produced gestures with more forward trunk motion suggesting that they became more engaged with the virtual clinician over time. The results support the use of gestures with virtual clinicians for rehabilitation purposes.

**Title:** Antiseptic Dorogov's Stimulator skin application effect on the animal's behavioral response

**Authors: *G. A. PIAVCHENKO**[1], R. BULTHUIS[2], L. BACHDASARIAN[2], V. I. NOZDRIN[1]
[1]Histology, Cytology and Embryology Dept., Orel State University, Med. Inst., Orel, Russian Federation; [2]Metris B.V., Hoofddorp, Netherlands

**Abstract:** Antiseptic Dorogov's Stimulator 3 fraction (ASD) is a thermal processing of animal-origin tissues drug that is used for psoriasis, dermatitis and eczema treatment. Two doses of 5% drug (0,5 g/day and 4 g/day - groups 1 and 2 respectively) and drug base (Zn paste - control group) were applied on the shaved interscapular skin surface of Sprague Dawley male rats (age: 2 month, n=18) in a period of one week. Two hours after the last application the rats were recorded with the Laboras and Sonotrack research instruments (Metris, Netherlands) for identification of the behavioral responses. After intracardiac perfusion of the rats on frozen brain sections the c-Fos-positive cells were revealed by the avidin-biotin method using a 3,3'-diaminobenzidine detection (Santa Cruz, USA). The neuronal activation was observed in brain regions with reference to the Paxinos and Watson Rat Brain Stereotaxic Atlas (2013) on 13-15 section levels. Some activated cells in the motor cortex associative layer and a significant number of cells in the sensory cortex were observed in the control group. For the drug groups c-Fos positive neurons were found in the sensory cortex (same amount as in control group), and a significant activation of cells was registered in the motor, cingulate and piriform cortex and striatum. A high number of c-Fos-positive cells were observered in the caudate nucleus head, cingulate cortex and globus pallidus (drug group 1), and in the motor cortex and putamen (drug group 2). Although no local irritating action was mentioned, the average speed, the distance traveled and the number of behavioral acts increased, as well as the ultrasound vocalizations frequency decreased in according with the control groups in both drug groups. Finally it is concluded that ASD application on the skin causes c-Fos expression and an increase of motor activity, which may be interpreted as an indirect drug action on brain structures and behavior.

**Title:** Reasoning about errors in humans and nonhuman primates

**Authors: *M. SARAFYAZD, JR**[1], M. JAZAYERI[2,1]
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]McGovern Inst. for Brain Res., Cambridge, MA

**Abstract:** Reasoning about errors is a key computational component of adaptive goal-directed behavior. An integral component of this computation is to dissociate internally- and externally-triggered sources of errors (e.g., “did I make a mistake, or were the instructions inaccurate?”). Here, we designed a novel behavioral task to investigate the computational principles of error monitoring in humans and monkeys. Subjects had to judge whether an interval demarcated by two flashes, one at the fixation point and one peripheral, was shorter or longer than an internal criterion, and report the decision by regulating a top-down inhibitory control to make either a prosaccade toward the second visual flash or an antisaccade away from it. The response contingencies were governed by two possible rules, either prosaccade (“Pro”) for “Short” and antisaccade (“Anti”) for “Long”, or vice versa, and the rules were switched during each behavioral session randomly after 10-26 trials. We tested subjects in two conditions. In the “External” condition, the color of the fixation point indicated the rule so that subjected had explicit information about the times of rule switch. In the “Internal” condition, the rule was not cued and subjects had to infer the times of rule switch from the pattern of feedbacks. To receive positive feedback, subjects had to correctly report the rule (which we solicited at the beginning of each trial) and make the correct response (Pro versus Anti). Subjects were able to perform the task in both External and Internal conditions and for both rules. As expected, performance was worse in the Internal condition, although an analysis of responses indicated that temporal judgements were similar across conditions, and the drop of performance was due to uncertainty about the rule. Subjective rule switches occurred after errors and increased systematically with

confidence about temporal judgment. Furthermore, the probability of switch increased with the number of errors indicating that subjects integrated evidence across trials in support of a potential rule switch. We were able to capture these results by an observer model that has structural knowledge about both internal sources of error related to timing, and externally-triggered sources of error due to the nonstationarity of the environment (rule changes). This indicates that monkeys, like humans, are capable of abstract rational reasoning about the various sources of errors. This opens the possibility of investigating the mechanisms of reasoning about errors at the level of single neurons.

**Title:** Cortico-cortical functional connectivity between the primary motor and somatosensory cortical areas during grasp

**Authors: *S. LEE**[1,2], J. M. GOODMAN[1,2], S. J. BENSMAIA[1,2], N. G. HATSOPOULOS[1,2]
[1]Dept. of Organismal Biol. and Anat., [2]Committee on Computat. Neurosci., Univ. of Chicago, Chicago, IL

**Abstract:** Primary motor (M1) and somatosensory (S1) cortical area of primates are known to be anatomically interconnected. However, very little is known how proprioceptive signaling in S1 interact with motor cortex to control naturalistic motor behavior such as grasping. By statistically analyzing the spatiotemporal interactions between the spikes with the local field potentials (LFPs) recorded across the areas, we tested the hypothesis M1 and S1 sites that shared similar somatotopic representations of the hand would exhibit stronger functional connections than pairs with dissimilar representations. Macaques were trained to grasp over 30 different objects and multi-camera Vicon motion capture system tracked the kinematics of reflective markers placed on the hand and arm of the monkey, from which we reconstructed the joint kinematics. High-density multielectrode arrays were used to sample single unit activity and LFPs from rostral and caudal motor cortex, area 3a, and area 2. Generalized linear models (GLM) were used to estimate the receptive/projection fields of each M1 and S1 neuron using various hand joint kinematics as predictors of firing rate of the neuron. We used a LASSO regularization technique which effectively isolated the most crucial joint kinematic features from the highly correlated joint movements of the hand. Having computed the somatotopy of neurons, we then inferred

functional connectivity by using the LFP signal from a site (as a proxy of the recorded neuron from that site) in one cortical area to predict the spiking response of neuron recorded in the other cortical area. By comparing model performance of the full model (GLM with LFP and joint kinematics covariates) and the reduced model (GLM with only joint kinematics covariates) on test data not used to build the models, we characterized the statistical significance of adding the LFP covariate in predicting the neural spiking. From a total of 72 pairs (38 similar and 34 dissimilar somatotopic pairs), 71% or similar somatotopic pairs showed significant model performance improvement whereas only 38% of dissimilar somatotopic pairs showed significant model performance improvement ($p<0.02$, t-test). We conclude that such functional connectivity structure maybe facilitates sensorimotor coordination of similar somatotopic representations.

**Title:** Temporal dynamics of neural tuning to kinematics in primary motor cortex during reach-grasp-manipulation

**Authors: *A. G. ROUSE**[1], R. A. JACOBS[2], M. H. SCHIEBER[1]
[1]Neurol. and Neurosci., [2]Brain and Cognitive Sciences, Computer Sci., Univ. of Rochester, Rochester, NY

**Abstract:** Neurons in the primary motor cortex (M1) are known to represent kinematic features of upper extremity movement (Moran & Schwartz, J Neurophysiol, 1999). Though these representations commonly are considered time invariant, the improved linear encoding of movement fragments suggests a more complex temporospatial representation (Hatsopoulos et al., J Neurosci, 2007). We recently found that when subjects reach to different locations to grasp and manipulate various objects, neural activity evolves over time, being related more to location early and object later (Rouse AG & Schieber MH, J Neurosci, 2016). Here, we explore whether kinematics explain this neural modulation in a linear, time-invariant fashion, or whether kinematic representations encoded by M1 neurons show temporal dynamics.
Initially, we built encoding models in which each sorted unit's firing rate was predicted by the

position and velocity of six kinematic features: 1) the translation of the wrist in XYZ Cartesian space, and 2) the first three principal components of angular motion at 13 wrist and digit joints. These kinematic features were used to model firing rates at 20 evenly spaced time points across the entire movement time from movement onset to peripheral object contact (median movement time = 255 for monkey L, 235 ms for monkey X).
For 20 single time-point linear models at the appropriate times, the average R-squared for predicting firing rate was 0.30, whereas all-time linear models had an average R-squared of 0.23, only 78% of that explained by single time-point models. When single time-point models were used to predict the firing rates at other times > 100 ms earlier or later, however, these models had little predictive value (R-squared = 0 for a majority of sorted units).
We therefore built a mixture density neural network consisting of: i) multiple linear models, and ii) mixing coefficients that estimated the probability of each linear model for a given set of kinematics at each time point. The mixing of only two linear models predicted firing rates with an average R-squared of 0.29, explaining > 95% of the variance explained by the 20 single time-point models. ANOVA showed that 59% of the mixing coefficients' explained variance depended on time sample, 16% on location, and 25% on object, suggesting that neural encoding of kinematics shifts substantially with time rather than showing temporally invariant relationships to particular locations or objects. Our results highlight the temporal dynamics of the relationship between kinematics and M1 activity during naturalistic movements.

**Title:** Reconfiguration of population responses between normal and reversed-vision reach planning in monkey sensorimotor cortex

**Authors: *H. GUO**[1,2], S. KUANG[3], A. GAIL[1,2,4]
[1]German Primate Ctr., Goettingen, Germany; [2]Univ. of Goettingen, Goettingen, Germany; [3]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [4]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

**Abstract:** Neurons in parietal reach region (PRR) of rhesus monkeys encode reach motor goals. A recent study disassociated physical goals from visual goals by using center-out reaches conducted under reversed vision. Statistics on the numbers of motor-goal neurons suggested

predominant but not exclusive encoding of physical goals in PRR (1). However, how neural population encoding during movement planning accounts for the perturbed feedback in motor control is still unclear. Under reversed vision, the spatial representation of a visual cue needs to be translated into an opposite-side physical goal. If monkeys by default initially plan a reach towards the visual cue location, then a spatial motor-goal remapping is required under reversed vision, equivalently to anti-reach planning. Intrinsic direction selectivity of each neuron could be preserved in this case, and remapping be achieved by selectively activating neurons with opposite selectivity. Alternatively, neurons might adapt their intrinsic direction selectivity to planning under reversed vision. In the first case we expect population activity during normal and reversed viewing to occupy the same subspace in neural state space; in the latter case we expect a re-configuration in state space. We tested our hypothesis in two monkeys conducting a memory guided reach task in both viewing contexts by analyzing neural dynamics in response to a motor-instructive spatial cue. Most neurons exhibited direction selectivity for the normal and the prism viewing context, ruling out recruitment of complementary subpopulations. But the subspace capturing the neural dynamics best in the normal-viewing captured only little variance of activity in reversed vision, which means the two subspaces are significantly misaligned. The result rejects the hypothesis that reversed reaching is achieved by simple remapping, which would happen in the same subspace. In contrast, pro and anti-reach planning is characterized by a much higher alignment of the corresponding subspaces, supporting the remapping model. Further, we show that task-related directional dimensions of the normal and reversed-viewing subspaces are close to orthogonal, while the time-related dimensions stay parallel, suggesting that misalignment between the normal and reversed subspace is endowed by the orthogonality of direction-related dimensions. We conclude that PRR exploits different neural dimensions for reach planning under reversed vision. Neural population responses are reconfigured to account for the perturbed feedback, instead of motor-goal encoding just being remapped as in spatial cognitive remapping tasks. (1) Kuang et al. **Title:** Selectivity of posterior parietal cortex for observing action exemplars: A 100 actions fMRI study

**Authors: *S. FERRI**, G. A. ORBAN
Univ. of Parma, Parma, Italy

**Abstract:** Recent evidences showed that regions of human of posterior parietal cortex (PPC) are selective for observing exemplars of specific actions classes (Abdollahi et al 2013, Ferri et al 2015; Corbo and Orban 2017). The occipito-temporal (OT) regions activated in the same studies were very similar for all classes. However the selectivity for action classes of PPC regions was only proven using a restrict set of actions, typically 3x4 exemplars. To address this shortcoming we runs an fMRI action observation experiment using video clips of 100 different actions exemplars - like swimming, running, eating, measuring writing, manipulating an object, communicating with another person- covering all classes of the human repertoire, except those involving uro-genital apparatus, and recorded in a natural environment and involving only natural objects. 24 runs were recorded in three different fMRI sessions in right-handed, healthy subjects instructed to fixate a central target on the screen while passively viewing the videos. In each run we presented twice 25 actions exemplars plus fixation condition in 9s blocks (3TRs and 3 videos with the 3 actors). A single voxel analysis was performed on phAIP (419 voxels, Jastorff et al 2010), OTS (470 voxels) and MTG (417 voxels) ROIs (Ferri et al 2015) of the left hemisphere. After a first level analysis with 9 no-interest regressors (6 from realignment, session, motion and luminance), we contrasted the 100 actions with fixation to extract the corresponding fitted bold (in the last 2 TRs of a block) to obtain 2x2x3= 24 values for each of the 100 actions. These 24 values were used in a split analysis with 100 permutations to first determine the rank of the 100 actions and then the fitted bold corresponding to each rank. The average Bold-rank curve was fitted with a second-degree polynomial function to determine the rank corresponding to the 50 % of the maximum of BOLD response, as an index of selectivity.
The distribution of indices included significantly more small values (<40) in phAIP than in the OT ROIs in all three subjects analyzed (2x3 $\chi^2$ = 128.7, 135.1 and 145.3, all <0.001). These data show that phAIP voxels are activated by a smaller number of observed actions of the human repertoire than LOTC voxels, confirming the greater selectivity of the representation of observed actions at the PPC compared to the OT level.

**Abstract:** The ability to discriminate between observed actions is a fundamental aspect of social behavior in primates (Platonov and Orban Sci Rep 2016). It is known that visual information on observed action is processed in temporal brain regions and conveyed to premotor cortex by inferior parietal areas (Nelissen et al J Neurosci 2011). Among these, the anterior intraparietal area (AIP) is gaining increasing interest because its human homologue is specifically activated by the observation of manipulative actions (Ferri et al Hum Br Mapp 2015). However, despite the rich knowledge about the capacity of area AIP neurons to process objects features, a detailed description of their tuning to different manipulative actions is still lacking. To address this issue, we recorded single neuron activity from two macaque monkeys (MK1 and MK2) while they observed video portraying 7 different manipulative action exemplars (drag, drop, grasp, push, roll, rotate and squeeze) performed by two actors (male and female) on two objects of different colors (orange and magenta). Neurons were recorded from 4 linear silicon multi-electrode probes (32-Chs each one) chronically implanted in the right (MK1) and left (MK2) hemispheres, along the entire rostro-caudal extension of AIP. We found that about 20% of AIP neurons showed action selectivity (significant 7x2 repeated measures ANOVA). Although all actions were represented, fewer neurons preferred rotate and squeeze exemplars. Furthermore, in a control experiment carried out on MK2, the 7 actions were presented in 9 different positions within the visual field, one at the fixation point and the remaining 8 at 3° eccentricity. This experiment showed that about 30% of the tested neurons were action selective (significant 9x7x2 repeated measures ANOVA). Among these action selective neurons, 67% showed tuning for the relative position of the observed action in the visual field, whereas the remaining 33% were just action selective. These findings constitute the first single neuron evidence in macaque that area AIP, besides underlying visuomotor coding of object features, also plays a role in discriminating between observed manipulative actions exemplars, suggesting that it could constitute a crucial node in the cortical action observation network.

**Title:** Anatomo-functional evidence on the role of pre-supplementary motor area F6 in the extended cortical grasping network

**Authors: *M. GERBELLA**[1], M. LANZILOTTO[2], M. MARANESI[1], A. LIVI[3], C. G. FERRONI[5], L. BONINI[4]
[1]Italian Inst. of Technol., Genova, Italy; [2]Dept. of Neurosci., [3]Deparment of Med. and Surgery, [4]Univ. of Parma, Parma, Italy; [5]Univ. degli Studi di Parma, Unità di Neuroscienze, Parma, Italy

**Abstract:** The macaque mesial premotor area F6 is an arm-related area involved in the specification of “whether” and “when” to perform an intended action, particularly in complex “cognitive” situations, but it has been recently proposed to constitute an additional node of the cortical grasping network (Lanzilotto et al. 2016). In this latter study, we recorded neural activity along the rostro-caudal extent of area F6 from two monkeys (Mk1 and Mk2) with chronic linear multielectrode probes during a reaching-grasping go/no-go task with three different objects as targets, to be grasped with different types of grip, in the light and in the dark. Many of the recorded neurons showed task-related visual and/or motor responses, and a set of them (26%) also exhibited visual and/or motor selectivity for the target object. To further support from an anatomical point of view the proposed involvement of area F6 in the cortical grasping network we performed an anatomical tracing study of the functionally characterized F6 sectors. To this purpose, at the end of the recordings the probes were removed and 2 neural tracers for each investigated hemisphere of Mk1 were injected at different anatomical positions within the functionally characterized region. We found that all the injections showed a common pattern of connections compatible with that reported in a previous study (Luppino et al. 1993). In the frontal lobe labeling was found in adjacent area F3, dorsal premotor areas F7 and F2, ventral premotor areas F5 and F4, prefrontal area 46 as well as in the cingulate motor cortex. In the parietal lobe, connections were observed with the intraparietal areas AIP and MIP as well as with the inferior and mesial parietal areas PFG, PG, V6A, PGm, and PEc. Additional prefrontal connections with area 8Ad were observed only after the more rostral injection. More interestingly, the stronger connectivity of the posterior/middle part of F6 with the hand-and-

mouth related ventral premotor areas F5 and F4, as well as with the grasping-related parietal areas PFG and AIP, fits well with its robust neuronal tuning to motor and visuomotor processing of objects relative to the more rostral part. In turn, the more rostral part of F6 showed stronger connectivity with visual and reaching/grasping-related parietal area V6A, reaching-related premotor area F7, and eye-related prefrontal areas 8Ad and 46d, suggesting its anatomo-functional involvement in the online control of reaching-grasping motor acts and their integration with eye movement. Altogether, these findings highlight the anatomo-functional correlations underlying the recently proposed contribution of area F6 to the extended cortical grasping network.

**Abstract:** The processing of observed actions involves several parietal and frontal areas. Recent findings revealed that neurons of the anterior intraparietal area (AIP), in addition to their well-established role in the extraction of object affordances for hand-grip selection, can become active when monkeys observe videos of both grasping actions and of an isolated hand moving in the visual field (Pani et al J Cogn Neurosci 2014; Maeda et al J Cogn Neurosci 2015), suggesting that these neurons may constitute a first step in the cortical recognition of observed actions. However, action recognition may still be possible even if the available information is partial, e.g. when only the hand (without the object) is visible, or when the action is presented in a static image. To investigate this issue, we have compared macaque monkey's AIP single neuron activity during 1) the observation of dynamic videos and pantomimes of grasping actions and 2) the observation of a static image (single frame) taken from each video during the real (or

pantomimed) hand-target interaction phase. Recordings were carried out with linear multielectrode silicon probes, chronically implanted in area AIP of one monkey trained to keep fixation during the presentation of visual stimuli. Stimuli depicted a hand grasping a little sphere (with precision grip) or a big sphere (with power grip), and pantomimes of the same actions (with no object). We recorded 130 neurons. Among them, 89 showed a response to at least the static and/or dynamic stimuli and were therefore classified as task-related: most (85.4%) responded to dynamic stimuli, with half of them encoding static pictures as well (46.1%). A few neurons responded selectively to static stimuli (14.6%), whereas almost all task-related neurons discharged during the observation of both action and pantomime. In a few cases, they showed a differential activation depending on the grip type during both action and pantomime (i.e. the object did not seem to be essential): interestingly, these differences occurred more frequently with dynamic (22.4%) than static (6.3%) stimuli. Altogether, these findings revealed that a moving hand is generally sufficient to trigger the activity of AIP neurons, even if it is not directed to an object, and they also suggest that the neuronal response cannot be accounted for by object presentation. The observation that static hand-grasping stimuli (with or without the object) can trigger AIP neurons discharge is an important step for using static stimuli to better investigated AIP neural dynamics underlying visual processing of observed hands.

**Abstract:** Primates use vision to guide their actions in everyday life. In macaques, visually guided object grasping is known to rely especially on intraparietal area AIP, which contains various classes of motor and visuo-motor neurons. Indeed, its anatomical connections with caudal intraparietal (CIP) and posterior intraparietal (PIP) areas, sensitive to both structural and

positional stereo information on objects, makes it a crucial node of the parieto-frontal network underlying visuomotor transformation for object grasping. In addition, the strong link with the inferotemporal (IT) cortex renders AIP a core area of the parieto-frontal action observation network. MR-based studies suggested the existence of a visual-to-motor gradient in AIP (Janssen et al. 2015; Durand et al. 2009). In order to obtain further evidence for such a gradient we recorded neuronal activity from 2 hemispheres of 2 monkeys (Mk1 and Mk2) using linear multielectrode silicon probes, chronically implanted at different antero-posterior levels of the area. Monkeys were trained to perform a reaching-grasping go/no-go task with three different objects as targets, to be grasped with different types of grip, in the light and in the dark. In addition, they also observed the same task done by an experimenter. At the end of the recordings, probes were removed and 3 different neural tracers injected at different rostro-caudal positions of the functionally characterized region in the right hemisphere of Mk1. We found that all the injected sectors of AIP showed connections with adjacent inferior parietal areas, superior parietal area MIP, the hand region of SII, premotor area F5, and prefrontal area 46v, in line with a previous study (Borra et al. 2008). Further labeling was observed in the dorsal premotor area F2, in the cingulate motor cortex, and in mesial parietal areas PGm and V6A, likely due to injection sites that also involved adjacent areas PFG and PG. In IT and in the caudal intraparietal areas LIP, CIP, and PIP relatively strong labelling was found only after the most caudal injections, whereas these connections were very weak following rostral injections. This rostro-caudal connectivity pattern appears to match with the distribution of functional properties. Indeed, the caudal portion of the investigated region showed more visual responses and visuo-motor selectivity for the target object and observed actions relative to the most rostral ones. These data support the existence of a caudo-rostral visual-to-motor gradient within area AIP.

**Title:** Barriers in the brain: Pragmatic representation of objects by single neurons of the cortical grasping network

**Authors: *A. LIVI**[1], M. LANZILOTTO[1], C. G. FERRONI[1], M. MARANESI[2], L. BONINI[1]
[1]Deparment of Med. and Surgery, Univ. of Parma, Parma, Italy; [2]Inst. Italiano di Tecnologia, Parma, Italy

**Abstract:** Brain processing of objects around us involves visual areas as well as the parieto-frontal motor system. This latter extracts from the object visual image the various motor possibilities for interacting with it (object affordances). The visual-to-motor transformations underlying object affordance processing rely on a circuit encompassing the anterior intraparietal area AIP, the ventral premotor area F5 and the pre-supplementary motor area F6 (cortical grasping network). In everyday life, contextual and physical barriers can prevent an observer from interacting with objects, though leaving unchanged their visual image: how does single neuron activity in the cortical grasping network represents objects behind a barrier?
Here, we answered this question by recording single neurons activity from area AIP, F5 and F6 of 3 macaques while they performed a visuomotor reaching-grasping task with three different target objects, each graspable with a specific type of grip: a ring (hook-grip), a small cone (precision grip) and a big cone (power grip). Object presentation responses were tested 1) during Go trial, which instructed the monkey to reach and grasp the target, 2) during No-Go trial ("contextual barrier"), which instructed the monkey to stay still, as well as 3) in the presence of a transparent plastic screen interposed between monkey's hand and the target ("physical barrier"). We recorded a total of 781 neurons from the three areas. Besides single neuron responses, we also decoded the activity of the whole neuronal populations of each area by means of a pattern classifier. The results revealed several interesting differences among the investigated areas in terms of 1) percentage of visually responsive neurons (about 63% in AIP and 30% in both F5 and F6), 2) distribution of neural selectivity for the different objects and 3) most importantly, effect of barriers. Indeed, contextual and, even more, physical barriers reduced both the magnitude of activity and object selectivity of premotor areas, particularly area F5, where object classification accuracy based on population activity dropped down to near-chance levels. These findings reveal that premotor areas provide a pragmatic description of potential target objects, depending on the agent's intention and possibility to interact with them. In contrast, AIP neural responses showed greater invariance to both contextual and physical barriers, suggesting a more visual-based encoding of object features. These findings shed light on how physical and contextual barriers affect neural processing of observed objects in the cortical grasping network.

**Abstract: Mirror neurons** (MN) located in ventral and dorsal premotor and primary motor cortices (PMv, PMd, MI, respectively) are thought to play an important role in understanding and imitating actions of others. These neurons are active both during performed and observed actions. The proposed mechanism through which MNs mediate action understanding and imitation hinges on similarity in activity patterns during similar observed and performed actions. So far, no experiment has tested these hypotheses directly.
Here we trained macaque monkeys to perform a cued reach-to-grasp task with various object and grasp options. In addition, experimenters performed the same actions with cues invisible to the monkeys and the animals had to repeat the movement in order to receive a reward. The addition of action imitation to the experiment ensured that the monkey paid attention to the experimenter's movements.
We estimated information about target object and grasp type present in neural activity of single neurons and ensembles during observed and performed actions by computing trial-by-trial decoding performance. We found that **information about observed actions** is indeed present in PM and MI neurons, however information **is not limited to MNs** (i.e. neurons with significant changes in firing rate for both action observation and execution). In fact, non-MNs and even neurons whose firing rate distributions are not significantly different between pre-movement and movement times have grasp and object information at levels comparable to MNs. We also found that observed movement information can only be decoded during a short time window at object contact. This suggests that information about the movement to be imitated is stored in short-term memory elsewhere until retrieved again during movement execution.
We employed spike train similarity space (SSIMS) projections of single unit and ensemble activity to compute task-relevant information at different time points. This analysis is sensitive to both differences in spike rate and spike patterns. In our ongoing research, we investigate under which conditions rates or precise timing dominate information transfer in motor cortex.
In summary, we developed a task ensuring the animal's attention during observed movements. We show that **information about observed movements is widespread across** the **PM and MI** population. Non-MNs carry information comparable to MNs, and even units classically considered 'unresponsive' are task-informative through firing pattern variations.

**Abstract:** Acquired brain injuries, such as stroke or traumatic brain injury, are often associated with persistent motor deficits. Following a lesion to motor cortex, reorganization occurs throughout the remaining brain regions, and is thought to underlie motor recovery. Unfortunately, the neurophysiological and neuroanatomical endpoints typically associated with reorganization do not directly monitor the relevance of these changes to specific motor behaviors. This study examined the neural activity associated with execution of rodent reaching movements on a ms by ms time scale. Specifically, we developed a novel rodent reaching task consisting of a ‘gross’ lever press that allows access for performing a ‘fine’ pellet retrieval. The ‘gross’ and ‘fine’ movements have similar limb trajectories but the pellet retrieval requires both finer control of the distal forepaw and increased sensorimotor integration for successful task completion. We trained 5 healthy, male, Long-Evans rats (*Rattus norvegicus*) to perform the task. Each animal was able to learn to successfully perform the task with baseline accuracies exceeding 50%. In each animal, two chronic, 16-channel microeclectrode arrays were implanted in motor cortex contralateral to the reaching forelimb, with one array implanted in the caudal forelimb area (rodent primary motor cortex or CFA) and a second implanted in the rostral forelimb area (rodent premotor cortex or RFA). By collecting multichannel recordings of multiunit spiking activity, we were able to systematically analyze of the neural correlates of each individual motor behavior across cortical areas and task conditions. Specifically, approximately 60% of channels with multi-unit spiking activity had statistically significant ($p<0.01$) changes in firing rate time locked to both the button press and pellet retrieval events. An additional 30% of

channels had significant firing rate changes time locked to the pellet retrieval but not the button press. Firing rate modulations were greater in amplitude during the pellet retrieval relative to the button press with an overrepresentation of channels modulated only during the button press within RFA relative to the total number of channels. These results add to the existing literature describing the importance of RFA, particularly in more complicated motor tasks involving fine control of the distal forepaw and increased demands for sensorimotor integration. Furthermore, this study helps to characterize the normal task-related activity of RFA and CFA respectively, establishing a baseline for future comparisons in injured animals.

**Title:** Properties of mirror neurons in the dorsal premotor cortex of the macaque brain. Comparison with F5 mirror neurons

**Authors: *V. PAPADOURAKIS**[1,2], V. RAOS[1,2]
[1]Computat. Neurosci., FORTH/IACM, Heraklion, Greece; [2]Univ. of Crete Sch. of Med., Heraklion, Greece

**Abstract:** Neurophysiological studies have reported the existence of dorsal premotor cortex (PMd) neurons that discharge both when a monkey executes a conditioned task (moving a cursor to capture targets on a computer screen) and when the monkey observes the visual stimuli associated with the performance of the same task either replayed or executed by the experimenter. Although these neurons display motor and observation evoked neural activity as F5 and parietal mirror neurons (MirNs) do, it is still debatable whether PMd contains MirNs. This is mainly due to the lack of evidence on whether the observation of the interaction between

a biological effector and an object (the standard visual stimulus evoking the discharge of typical MirNs) would also be effective for triggering the discharge of these PMd neurons. Here, we investigated whether PMd contains neurons that respond during both the execution and observation of reaching-to-grasp actions performed by the experimenter and compared their properties to those of F5-MirNs in terms of timing, response selectivity and action representation.
We identified neurons in PMd of the macaque brain that respond during the execution and observation of reaching-to-grasp actions, thus fulfilling the criterion for being considered MirNs. Cross-correlation between the single neurons' responses in the two conditions revealed that both PMd- and F5-MirNs neurons fire earlier in execution than in observation. During observation, PMd contained as many action selective MirNs as F5 and this resulted in similar selectivity indexes in the two areas. During execution, more F5 than PMd-MirNs neurons were selective and this was reflected also on the higher selectivity indexes in F5 than in PMd. In both areas the grip selectivity tended to be higher in execution than in observation, and the onset of action selectivity occurred later in observation than in execution for the majority of the neurons. The matching between the execution and observation discharge of MirNs in the two cortical areas was evaluated both at the single neuron and the population levels and was low in the former and high in the latter case. Furthermore, representational similarity analysis revealed that encoding of actions in PMd and F5 is alike, during both observation and execution. Besides the many similarities shared by PMd and F5 MirNs we found that PMd is not only activated but also displayed action related information earlier than F5 during both conditions.
The existence of MirNs in PMd that are recruited earlier than the akin F5-MirNs dictates the need to revise not only the nodes of the MirN circuit but also the flow of information within it and inevitably the sub-served functions.

**Title:** Adaptation of grip forces to 3D printed surface textures

**Authors: *S. BILALOGLU**[1], C. TYMMS[3], E. P. GARDNER[2], P. RAGHAVAN[4]
[2]Dept Physiology/Neuroscience, [1]New York Univ. Sch. of Med., New York, NY; [3]Computer Sci., New York Univ., New York, NY; [4]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY

**Abstract:** Friction at the skin surface is an important aspect of haptic perception that is used to adapt the fingertip forces to the grip surface to prevent use of inadequate or excessive grip forces. Previous work on grip force adaptation has used non-parametric natural materials or a narrow range of artificial substances. The advent of high-resolution 3D printing technology provides the ability to fabricate arbitrary 3D shapes and textures of precise surface geometry to be used in tactile studies. Using high resolution stereolithography 3D printing and parametric modeling, we created nine different surface textures, where the texture elements ("textons") were truncated cones with 0.1, 0.3, or 0.5 mm diameters spaced 0.75 mm, 1.0mm, or 1.25mm apart. In previous studies, Tymms et al (2016) found that surfaces with small wavelengths and large textons are judged smoothest, and textures with large wavelengths and small textons are judged least smooth. In this study we measured changes in friction and grip force adaptation during precision grasp and lift using an instrumented grip device with 3D printed grasp surfaces. Ten healthy adult subjects grasped the instrument using bare hands or with a thin layer of plastic (Tegaderm) applied to the fingertips. Adaptation of fingertip forces was quantified using the peak grip force rate (PGFR), and the coefficient of friction (COF) of the surfaces was computed as the inverse of the slip ratio (grip force/load force at the moment of slip). When grasped with bare hands, surfaces with large wavelengths and small textons were perceived as rougher, and produced lower PGFR, and a significantly higher COF. Friction was negatively correlated with subjective smoothness estimates in which small wavelengths and large textons were rated smoothest. This study also confirms previous findings that the tegaderm changes COF between the fingers and the tactile surface, and impairs the efficiency of grip force adaptation to the spacing and texton size. Textures generated with different texton sizes and wavelengths using stereolithography 3D printing can be used to generate a variety of quantified frictional surfaces that can be used in studies of tactile roughness perception and in related neurological applications. Additionally, we note that covering the fingertips with the tegaderm membrane effectively impairs tactile discrimination and adaptation of grip forces.

**Title:** Level of arm motor impairment predicts sensory modalities that optimize learning with the Bimanual Arm Trainer in patients with severe stroke

**Authors: *A. TANG**[1], S. BILALOGLU[1], C. BAYONA[1], J. STONE[1], M. WILFRED[2], C. HUNG[3], A. YOUSEFI[1], P. RAGHAVAN[1]
[1]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY; [2]Rehabil. Med., New York Univ. Lutheran Med. Ctr., New York City, NY; [3]Icahn Sch. of Med. at Mount Sinai, New York City, NY

**Abstract:** Few options exist for training arm movements in patients with severe chronic hemiparetic stroke who have very little active range of motion in their affected arm. Coupled bimanual training can prime the ipsilateral motor cortex for subsequent training with the affected arm and has shown to promote greater improvement in arm function as compared to training with the affected arm alone. The purpose of this study was to test the extent to which motor learning can be enhanced using specific sensory stimuli during coupled bimanual arm training, and whether level of impairment predicts which sensory stimuli will optimize learning in the affected arm in a given patient. The Bimanual Arm Trainer (BAT, Mirrored Motion Works, Inc.) links the movements of the affected and unaffected arms to perform external and internal rotation at the shoulder, which is combined with auditory and visual stimuli to enhance movement provided by a customized video game. 15 subjects with chronic post-stroke hemiparesis were tested on the BAT for 30 minutes. Subjects completed 4 sets of 10 trials. Each trial consisted of 30 second bouts of shoulder movements performed alternatively with both arms (bimanually) or unimanually with the affected arm alone. Each set presented a different sensory condition for movement in a random order, consisting of: (1) rhythmic auditory stimuli, (2) visual stimuli, (3) both auditory and visual stimuli, and (4) no additional stimuli. Upper limb motor impairment was assessed using the Fugl-Meyer Scale and active range of motion on the BAT. The slope of the learning curve for trials with the affected arm was computed for movements under each of the 4 conditions. We found that as the level of motor impairment increased, the sensory modality that produced the highest learning curve changed: subjects with the lowest Fugl-Meyer scores and range of motion showed steeper learning curves with auditory stimuli, followed by no additional stimuli, then visual stimuli and finally, those with the highest Fugl-Meyer scores and range of motion in the cohort responded best to both auditory and visual stimuli. The results suggest that patients may have different thresholds for processing sensory information for motor learning across the various stages of recovery. Motor learning may be optimized by providing the appropriate sensory stimulus based on an individual's stage of recovery post stroke.

Ctr., New York, NY; [6]Dept. of Applied Statistics, Social Sci. and Humanities, NYU Steinhardt, New York, NY; [7]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY

**Abstract:** Efficient grasp requires proper planning grounded on visual perception of object shape. In this study, we explore the relationship between gaze location, finger position, and hand shaping during reach-to-grasp for objects of various shapes. Seven neurologically intact subjects sat at a table and reached towards and grasped an object positioned at 75% of their arm's length for seven times. They repeated the task for nine different shapes while their gaze, hand, and fingers were tracked. Reach-to-grasp was divided into pre-reach, acceleration, deceleration, and grasp based on wrist velocity. The finger position on the objects was relatively consistent across the subjects. Gaze location on the object was predominantly above the center of mass, corresponding most closely with the final position of the index finger. During the first trial, subjects fixated on the object most in the acceleration phase, but there were fewer fixations of longer duration. In the practiced trials, they fixated on the object the most in the deceleration phase and showed a larger number of fixations. The gaze location was measured as the distance between the fixation point and the final finger position on the objects. From the time of eye-opening, across all shapes, the gaze-finger distance was consistently smallest for the index finger followed by the thumb, and it was the longest for the little finger. The gaze-finger-distance was significantly smaller on the practiced trials for all fingers compared to the first trial. Since gaze was primarily directed at the index finger, we focused on the gaze-index distance as a measure of eye-hand coordination. Hand shape was computed as the difference between the final position of the fingers and the real-time position during reach-to-grasp. On the first trial, object shape determined the initiation, termination and the pace of the hand shaping. For the convex shapes, hand shaping started immediately at pre-reach and ended at grasp, although the hand shape was achieved earliest for the planar rectangular shape. In contrast, for the concave shape, hand shape began to occur after a delay. Shape-specific differences were less prominent in the practiced

trials as hand shaping started early reach and shaped fast as for the rectangular shape on the first trial. The results suggest that simultaneous examination of gaze patterns and finger positions can disclose eye-hand coordination which enables us to improve treatment strategies for patients who may have impaired eye or hand function. This information can serve as a benchmark for the assessment of eye-hand coordination in neurologically impaired patients such as stroke.

**Title:** Enhanced upper limb motor control with intramuscular hyaluronidase injections in pediatric patients with cerebral injury

**Authors: *V. A. TSETLINA**[1], S. KWON[3], M. MIRCHANDANI[1], S. BILALOGLU[2], Y. LU[4], R. SUKHOV[5], A. STECCO[1,6], P. RAGHAVAN[5]
[1]RUSK Rehabil., [2]New York Univ. Sch. of Med., New York, NY; [3]Rehabil. Med., NewYork-Presbyterian Hosp., New York, NY; [4]New York University, Steinhardt Sch. of Educ., New York, NY; [5]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY; [6]Univ. of Padua, Padua, Italy

**Abstract:** Brain injury frequently leads to debilitating upper limb dysfunction. Following cerebral injury patients develop muscle weakness and spasticity which is followed by development of muscle stiffness and, if untreated, contractures of the joints. The cause of the muscle stiffness is not fully understood. We proposed the hyaluronan hypothesis, which postulates that stiffness can develop as a result of accumulation of the glycosaminoglycan hyaluronan in the extracellular matrix (ECM) of the muscle, leading to increased ECM viscosity and impaired sliding of muscle fibers during movement. The objective of this study was to determine the extent to which multiple off-label intramuscular injections of the enzyme hyaluronidase, which hydrolyses hyaluronan, could reduce upper limb muscle stiffness, and increase both passive and active joint movement in pediatric patients with brain injury.
In this pilot study ten children (age 7-17) with various etiologies of brain injury, who developed chronic muscle stiffness, received repeated injections of intramuscular human recombinant hyaluronidase into selected upper extremity muscles depending on their clinical presentation, and were followed for 4-24 months following initial intervention. Muscle stiffness, and passive and active range of motion (ROM) at the shoulder, elbow, forearm and wrist were assessed pre-injection, and at a several time points post injection. Muscle stiffness was assessed using the

modified Ashworth scale (MAS) and ROM was video recorded and analyzed using Dartfish video analysis software by two independent researchers. One patient had an allergic skin reaction in the upper arm after the second injection, which required a dose of steroids. All the other patients tolerated the injections without adverse effects.
Muscle stiffness declined by 1 point or more on the MAS after each injection and remained low (0-1 on MAS) at follow up. Overall, 80 passive movements (10 patients, 4 joints, movements in each direction) were analyzed, of which 15 movements had less than 80% of normal range pre-injection. 73.3% (11/15) of these movements improved to within the normal range.
Of the 72 active movements that were analyzed (from 9 patients), 44 were impaired. 61.4% (27/44) of the movements showed significant improvement in extent and control of active range of motion, defined as 20% increase in age-normalized ROM values, or increase by 30 degrees or more, or initiation of movement when there was none pre-injection.
The results of our pilot study suggest that repeated intramuscular hyaluronidase injections can enhance upper limb motor control in patients with muscle stiffness in the chronic stage after brain injury.

**Abstract:** Effective hand function requires a great deal of coordination and control, also an integration of kinesthetic, tactile and visual sensory information with motor output. Over 85% of stroke survivors with hemiparesis have difficulty performing skilled everyday tasks and - despite conventional rehabilitation - have persistent deficits in hand function that severely affect their

quality of life. In previous studies we found that patients post-stroke did not adapt their fingertip forces to object weight with their affected hand. The purpose of this study was to define patient subgroups based on performance on a grasp-and-lift task before and after alternate hand training with objects of varying weights over a single session, and their motor and sensory impairments (in kinesthetic, tactile and visual domains). We recruited 40 patients to perform a grasp and lift task under eight different learning conditions, each involving a different combination of tactile, kinesthetic and visual cues. Each patient practiced the task under each of the treatment conditions with the affected hand only in one session, and then alternating hands in a different session. The measurements include grip and load forces, as well as several clinical tests of tactile, visual, kinesthetic and motor impairment, along with imaging data on brain lesion location and motor tract density. We used a rank-based clustering algorithm to delineate statistically significant patient subgroups which exhibit therapy specific structure. Each of these subgroups will correspond to a 'tricluster' involving not only a specific subset of the patients, but also a specific subset of sensory feedback conditions and grip task outcome measures that respond to alternate hand training. This method pinpoints triclusters within the positively-responding patients that exhibit structure which is not reflected within the non-responding patients. A cluster of patients with primarily motor and tactile deficits on their affected hand showed positive changes in grasp control with alternate hand training under tactile-kinesthetic, tactile-vision-kinesthetic for loading phase (LP), deceleration time (DT) and pre load phase duration (PLD) outcomes. Our results suggest that the patients with different degrees of motor and sensory impairments are likely to require different types of therapeutic regimens and patients with common sensory-motor characteristics may form subgroups that respond preferentially to certain training regimens. Also, the alternate hand training method may allow subjects to use tactile and kinesthetic information from their unaffected hand to improve grasp control in the affected hand.

**Title:** The influence of prior expectation on movement variability for two different movements

**Authors: *I. C. WEINBERG**[1], S. BESTMANN[2]
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom; [2]Inst. of Neurol., London, United Kingdom

**Abstract:** Preparing multiple movements incurs a cost: movement variability increases when two movements must be planned rather than one (Wijdenes et al., 2016). This can be understood as motor planning using a limited neural resource; when there is more than one motor plan, this limited resource must represent more information, and hence the variability of each representation increases.
We often plan multiple movements which have unequal likelihoods of being executed. An expectation to make one movement over another leads to a reaction time advantage (e.g. Rahnev et al., 2011). A possible explanation is that expectation to move may direct the distribution of a limited resource. We hypothesised that when expectation to make one movement over another is higher, more of the limited resource is allocated to the expected movement and the movement variability is lower.
We tested this in an experiment in which human subjects were required to make a quick, accurate movement to hit one of two visual targets. On each trial, the target that the subject should move to was cued prior to movement. This was preceded by a probability cue, which indicated accurately the relative likelihoods of the target cue being correct (expect left (80:20), expect right (20:80), or expect either (50:50) probability). The two targets were oriented at 45° leftward or rightward in a 2-D plane relative to starting position. Movements were made with the right hand. We were thus comparing a two-joint movement to a single-joint movement (van Beers et al., 2004).
To assess movement variability, we calculated variability in reach angle for movements following the different probability cues. For a leftward, two-joint, movement, early reach angle was indeed less variable when expectation was higher, as hypothesised. The influence of prior expectation ended ~40% through the movement, in line with an effect on motor planning which is strongest early on.
Interestingly, there was no effect of expectation on the early reach angle variability of rightward, single-joint, movements. The different biomechanical properties of one-vs two-joint movements may lead to differing optimal control policies and thus different effects of expectation.
Preliminary results suggest that, for the leftward movement, early position is a stronger determinant of later position than in the rightward movement. This supports the hypothesis that execution noise is less strongly controlled for the rightward movement early on.
We thus propose that a stronger expectation to move influences planning, reducing movement variability, and this effect is dependent on an interaction with the feedback control policy.

**Title:** Perception-action linkage in top athletes during batting

**Authors: *D. NASU**, M. YAMAGUCHI, T. FUKUDA, N. SAIJO, M. KASHINO, T. KIMURA
NTT Communication Sci. Labs., Kanagawa, Japan

**Abstract:** Sports frequently involve severe time constraints. For example, in baseball and softball, a batter is required to judge the characteristics of a pitched ball (i.e., speed and trajectory) and hit it with his/her bat within about 500 ms from the time of pitcher's ball release. Since the pitcher intentionally change the ball speed and trajectory, it is not easy to adjust the timing and position of the bat in relation to an uncertain ball in such a short time. This study evaluated the movement and cognitive features that occur during actual softball batting as regards two types of pitched balls (fastball and change-up), whose different respective ball speeds (approximately 90 and 75 km/h) resulted in a difference of approximately 150 ms in the time between the pitcher's release and bat contact (400 and 550 ms). A superior batter should probably be able to adjust the swing onset to compensate for this time difference. Furthermore, such a superior reaction may result from a superior ongoing ability to perceive ball types traveling with different speeds and trajectories. In this study, we paired the perception task with a real batting task and investigated whether perceptive performance is linked to batting performance. Elite woman's softball players participated in the experiments, and some of them have been members of the national team. In the batting task, the participants were asked to hit randomly pitched fastballs and change-ups. At this time, the batters were not informed of the type of ball would be thrown. The whole body movements of both the batter and pitcher were recorded simultaneously with a motion capture system. In the perception task, the participants stood in the batter's box and faced the same pitcher. They were asked to respond by pressing a button as rapidly as possible whenever the pitcher threw a fastball, but not when the pitcher threw a change-up. As expected, superior batters clearly adjusted the timing of the swing motion to the ball impact according to the pitch type. Specifically, when the pitcher threw a change-up, they paused their swing motion about 300 ms from the time the ball was released and restarted their swing. This was not the case with inferior batters because their swing timing was more variable. The average perception time determined by the participants pressing the button was about 250 ms for superior batters. These times were extremely stable, whereas those for inferior batters were unstable, as was their swing timing. These results indicated that perceptive

repeatability is linked to action stability in a batting situation. It is likely that top athletes have highly reliable perception, which is the underlying basis of high motor performance.

**Title:** Attentional modulation of visual search alters visuomotor performance without altering limb movements

**Authors: *J. R. NORKITIS**[1], C. PERRY[2], A. HARRISON[2], J. J. FRIDRIKSSON[3], S. L. FRITZ[4], T. M. HERTER[1]
[1]Dept. of Exercise Sci., [3]Communication Sci. and Disorders, [4]Exercise Sci., [2]Univ. of South Carolina, Columbia, SC

**Abstract:** Many daily motor tasks, such as driving, use visual search (patterns of eye movements that actively gather visual information) to guide planning and control of limb movements. Visual search is modulated by attentional mechanisms, including “bottom-up” mechanisms that direct eye movements to salient objects and “top-down” mechanisms that direct eye movements to task-relevant objects. The purpose of this study was to examine how attentional modulation of visual search impacts visuomotor task performance. Young adults, older adults, and stroke survivors (left-hemisphere) used a KINARM robot with integrated eye tracking to perform a bimanual visuomotor task, Object Hit and Avoid, in an augmented reality environment. Participants used virtual paddles to hit away Targets objects (n=150) and avoid hitting Distractor objects (n=150) that moved towards them in the horizontal plane. We manipulated the saliency of Targets (task relevant) and Distractors (non-relevant) by altering their brightness relative to the black background (nonsalient, 15% white; salient, 80% white) in five experimental conditions: all objects nonsalient (control), all targets salient (AT), all distractors salient (AD), half targets salient (HT), and half distractors salient (HD). Relative to the control condition, young and older adults exhibited significant increases in task performance (Target Hits) in AT and AD, but similar task performance in HT and HD. Young and older adults also exhibited significant increases in visual search efficiency (Target-Distractor Foveation Bias) and extrafoveal visuomotor performance (Nonfoveated Target Hits) in AT and AD, but not in HT and HD. Measures of limb-motor control were similar across all conditions in the young and older adults. Changes in task performance were strongly correlated with changes in visual search efficiency (young, r=0.65; older, r=0.80) and extrafoveal visuomotor performance (young,

r=0.64; older, r=0.80). Surprisingly, stroke survivors did not exhibit task-dependent modulation on any measure. Our results indicate that: 1) visual search and extrafoveal vision can directly influence visuomotor performance, and 2) post-stroke deficits in attentional mechanisms and/or visual search may contribute to impaired visuomotor performance.

**Title:** Injecting instructions into premotor cortex using intracortical microstimulation

**Authors: *K. A. MAZUREK**, M. H. SCHIEBER
Dept. of Neurol., Univ. of Rochester, Rochester, NY

**Abstract:** When approaching a stop sign, a law-abiding driver responds by moving his or her foot to the brake pedal to stop the car. This is one example of how the nervous system processes information based on learned associations between instructional cues and specific actions. In individuals with neurologic injuries, the ability to process instructions and elicit the associated movements may be damaged or impaired. Instructions typically enter the nervous system through primary sensory modalities, such as vision, hearing, or touch. Recent studies have demonstrated that intracortical microstimulation (ICMS) in the primary somatosensory cortex (S1) can evoke somatotopically localized sensations. ICMS in S1 also has been used to instruct movements, presumably because the subject learns to associate the sensation evoked by ICMS at different S1 sites with particular actions. Can ICMS outside of the primary sensory areas also provide instructions? Here we show that ICMS in the premotor cortex (PM) can instruct specific movements through arbitrary, learned associations. Two monkeys learned to perform particular reach-grasp-manipulate movements instructed by ICMS in PM. The current amplitudes we used for the PM ICMS instructions were too low to evoke muscle activity (confirmed by stimulus-triggered averaging) indicating that the monkeys were not detecting muscle twitches and using them as instructions. Our results show that instructions can be delivered with ICMS in a cortical area not conventionally considered sensory. Additionally, the ICMS did not need to mimic the

natural activity of PM neurons to successfully instruct the movements. The ability to deliver instructions in PM expands the potential territory available for introducing information into the brain artificially. Identifying cortical areas where useful information can be delivered with ICMS eventually may enable development of cortico-cortical neuroprosthetic devices that reestablish communication between areas of a damaged brain.

**Abstract: Introduction**: Direct cortical stimulation (DCS) may provide a means of delivering somatosensory feedback in a brain-computer interface (BCI) through electrical stimulation of the primary somatosensory cortex (S1). Previous work has demonstrated that human subjects can perceive and discriminate the intensity of DCS based on varied current amplitude or frequency, and that subjects can use DCS as feedback in a motor task. To effectively integrate somatosensory feedback via DCS into a BCI we must first gain a better understanding of the DCS parameters that can elicit percepts. Here we explore human subjects' DCS perceptual thresholds and their just noticeable differences (JND) in stimulation amplitudes.
**Methods**: Human subjects were implanted with electrocorticography (ECoG) grids (Ad-tech,

Racine, WI) and monitored for long-term seizure activity. We used Tucker-Davis Technologies hardware to deliver bipolar, constant-current stimulation using trains of biphasic square pulses. We varied the current amplitude to quantify subjects' perceptual thresholds and JNDs. We used a staircase method to determine subjects' perceptual threshold and fit the resultant data with a Weibull function using a maximum likelihood method. For the JND assessment we used a two-alternative forced-choice (2AFC) task in which we delivered two 200 ms DCS trains with different current amplitudes separated by 1 s and asked subjects to report whether the "first" or "second" train was more intense.

**Results**: Subjects generally localized the percept to one area on their hand. Subjects' perceptual thresholds ranged from approximately 0.75 mA to 2.0 mA. One subject converged to a 50% perceptual threshold of approximately 0.77 mA (Fig. 1). While this research into the psychophysics of human DCS is ongoing, we anticipate variations in perceptual thresholds between additional subjects. We are continuing to study the effects of current amplitude and other stimulation parameters on subjects' DCS percepts.

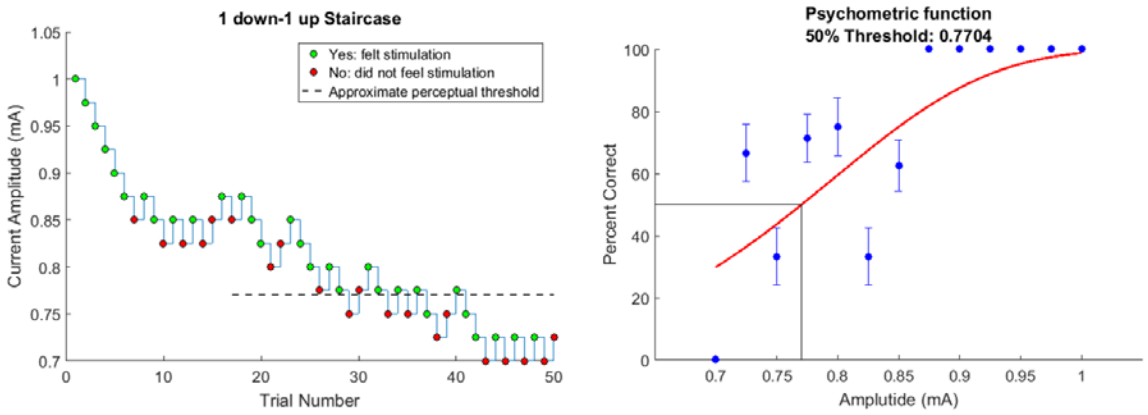

**Figure 1.** Example thresholding staircase and psychometric function for one subject. The 1 down-1 up staircase converges on a 50% threshold which was fit to a Weibull function using a maximum likelihood method. The best fit psychometric function yields a 50% perceptual threshold of approximately 0.77 mA, which is shown on each plot.

**Abstract:** Current users of brain-computer interface (BCI) technology must rely on visual feedback of cursor or robotic arm movement. The inherently long delays of visual processing likely contribute to relatively slow and unnatural control of BCIs. Despite increasing numbers of electrode sites and ever growing complexity of control algorithms, BCI technology has yet to achieve a rapid, dexterous control signal comparable to an intact human system. We believe the lack of tactile perception and proprioceptive input imposes a fundamental limit on speed and accuracy of BCI controlled prostheses or re-animated limbs. By artificially recreating this comparatively low-latency pathway via Intra-Cortical Microwire Stimulation (ICMS) or micro-ElectroCorticoGraphy (µECoG), BCI stability and control will be improved. Towards this aim, we will explore cortical sensitivity of modulating stimulation parameters to further understand the critical stimulation features which best encode sensory intensity. Given the hi-dimensional parameter space of electrical stimulation, BBCI designers have many options for presenting grated sensation. Parameters such as amplitude, frequency, pulse-width, stimulation train duration, and electrode site could all be modulated to vary the intensity of a percept. Using our novel center-out task for rodents as a behavioral metric of perceived intensity, we can compare the perceptual resolution of modulating these parameters, both individually and combinatorically. Rodents perform discrimination tasks to measure just-noticeable-differences (JNDs) and perceptual thresholds. By understanding the mapping between parameter modulation and sensory perception of intensity, we can identify the critical parameters which sensory cortex cues off when presented with electrical stimulation, either through penetrating micro-wires or on the surface of the brain.
Our overarching goal is to formulate a general pattern for providing a high resolution sensory signal which can be mapped to any sensory modality. Through electrical stimulation, either on the surface (µECoG) or through penetrating wires (ICMS), we will repair/create this low-latency sensory feedback in our BCI control loop. This will enable patients with a wide range of impairments, from spinal cord injury, stroke, to any user of BBCI technology. By improving their control of a prosthetic (or re-animated) limb, we can integrate this into existing BBCI implementations and increase our knowledge of augmented sensory prosthetics.

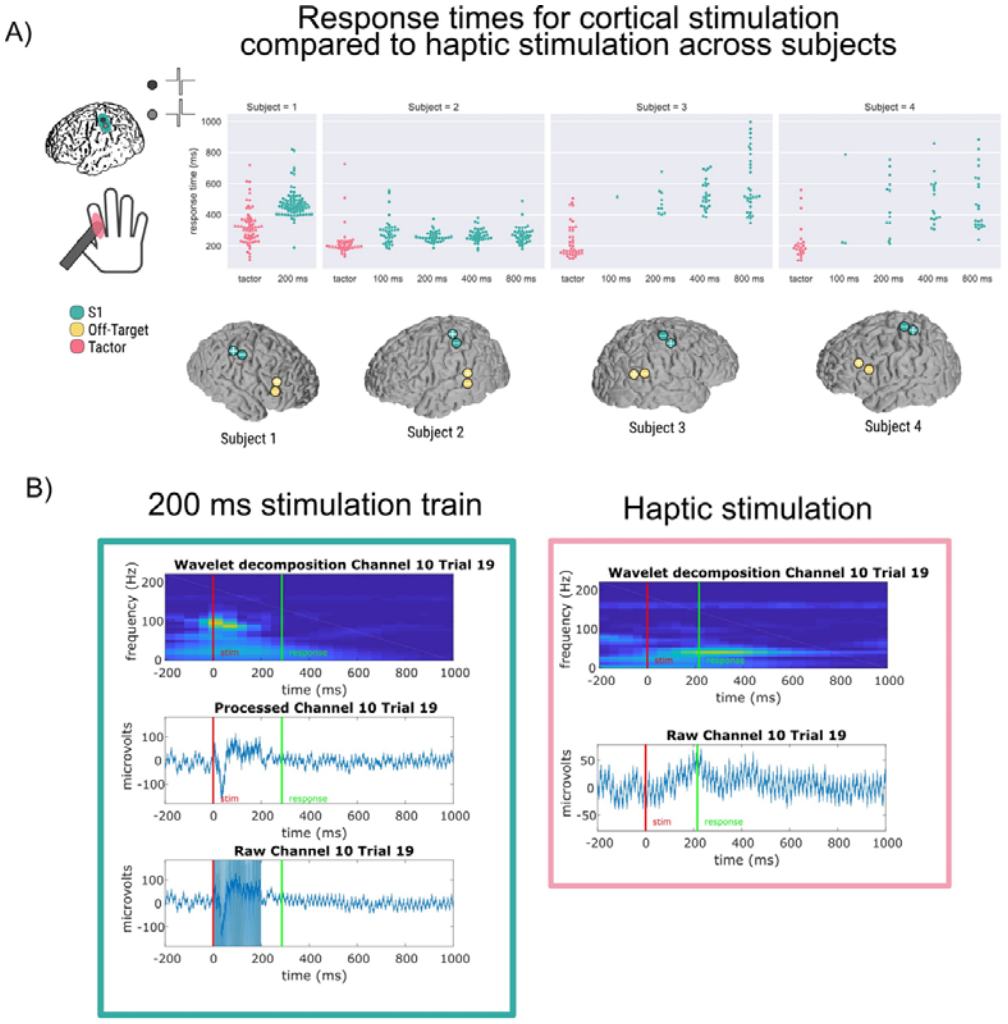
**Abstract:** Objective: Direct cortical stimulation (DCS) may help close the loop in human brain computer interfaces. Previous efforts have shown that humans can respond to and utilize DCS to somatosensory (S1) cortex to perform a task while non-human primate work using intracortical stimulation revealed a delayed reaction time for cortical stimulation compared with haptic stimulation. However, the comparison of human S1 DCS to haptic stimulation has not been explored. In this study we examine and compare psychometric response timings and spectro-temporal analyses of human electrocorticographic (ECoG) signals for DCS of hand somatosensory cortex and haptic stimulation. Methods: Humans (n=4) were implanted with ECoG grids for epilepsy monitoring. We provided haptic stimulation through digital touch probes (tactors) to the same cutaneous region where sensation was reported through DCS (200 Hz, biphasic, bipolar stimulation) to S1 hand cortex. Train lengths of 200 ms DCS were applied to one subject, with trains of 100, 200, 400 and 800 ms in the subsequent 3 subjects in 2 separate blocked trials. In the 3 later subjects, off-target stimulation of a region outside of S1 was used as a control. An optimized ICA algorithm was used for post-hoc neural signal extraction during

stimulation trials. Spectrotemporal analyses were performed with wavelets. Results: Haptic stimulation elicited significantly faster reaction times (RT) than cortical stimulation across all subjects (Fig. A). DCS trains of different lengths did not result in significantly different RTs. No significant block wise differences were seen. Individual trial spectrotemporal analyses demonstrate post-stim signal differences between haptic and stimulation conditions (Fig. B). Conclusions: These results show that the perception of direct cortical stimulation in humans is significantly slower than haptic stimulation. Different spectral responses to haptic relative to cortical stimulation are suggestive of non-native patterns of neural activity elicited by cortical stimulation, potentially explaining slower response times.



A) Individual subjects' response times and cortical reconstructions showing S1 and off-target stimulation sits. Only one off-target stimulation was responded to in Subject 2, with no other responses in the other subjects. Individual points represent individual response times per trial.

B) Example trial with optimized ICA processing for neural recording extraction during the stimulation period, compared to a haptic stimulation trial in an electrode adjacent to the stimulation electrodes in Subject 2.

**Title:** Hind-limb motor responses to microstimulation of the dorsal root ganglia in behaving cats

**Authors: *M. A. URBIN**, A. C. NANIVADEKAR, K. K. KING, W. D. CUSACK, M. F. LIU, R. A. GAUNT, L. E. FISHER, D. J. WEBER
Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

**Abstract:** A lack of cutaneous and proprioceptive feedback impedes the ability to control lower-limb prosthetics, thus, impairing gait and increasing the risk of falls. Recent work has demonstrated that microstimulation of the dorsal root ganglia (DRG) selectively recruits major hind-limb nerve branches early (Gaunt et al., 2009; Ayers et al., 2016) and months after implantation (Fisher et al., 2014). Patterned microstimulation of the DRG may therefore provide a means to generate sensory percepts for an advanced lower-limb neuroprosthetic. Since patterns of lower-limb muscle activation during gait are largely mediated by somatosensory inputs (Duysens & Stein, 1978), the ability to drive motor responses may further increase the functionality of such a device. Here, we report on motor responses evoked by DRG microstimulation in awake, behaving animals. Penetrating, 32-channel microelectrode arrays were implanted chronically in the L6 and L7 DRG of four male cats. EMG electrodes were implanted in the ipsilateral flexor and extensor muscles of the knee and ankle, and the sciatic nerve was instrumented with a five-contact nerve cuff. A binary search procedure was performed on stimulating channels during anesthetized experiments each week to determine sciatic nerve recruitment threshold. A stimulating electrode with low threshold for recruiting Group I afferents was selected for delivering 10-ms, 100-Hz pulse trains at 1.5x (ie, stimulation-low) and 2.0x (ie, stimulation-high) threshold while the cat was standing on a platform in subsequent experiments each week. Motor-evoked responses were defined as a sustained change in the EMG signal ($\geq$20 ms) that was $\geq$2 standard deviations above/below the mean of the pre-stimulation window (200 ms). Over the course of testing (15.8±1.3 weeks), motor responses were observed in stimulation-low (25.1±10.5%) and stimulation-high (26.7±14.8%) conditions. Across both conditions, a comparable response rate was found in knee (33.5±16.1%) and ankle (38.3±20.1%) muscles with flexor (37±18%) or extensor (31.9±19.2%) joint actions. Motor responses exhibited were mostly facilitatory (63.6±15.2%) and fewer were inhibitory (19.5±15.6%). Some responses consisted of

both facilitation and inhibition (16.8±16.6%). The various patterns of motor responses likely reflect activation of multiple spinal reflex circuits, including those involved with monosynaptic Ia excitation, disynaptic reciprocal inhibition, and recurrent inhibition. Further work is needed to understand how DRG microstimulation can selectively activate each spinal circuit to allow for maintenance of balance and effective sequencing of gait transitions.

**Abstract:** We have previously demonstrated brain-computer interface (BCI) control of a robotic arm using signals recorded from motor cortex (M1) and that intracortical microstimulation (ICMS) of human primary somatosensory cortex (S1) can evoke tactile percepts. We wish to combine these results in a closed-loop BCI system, which must be capable of continuously recording and stimulating adjacent regions of cortex. This problem is non-trivial due to the presence of large amplitude electrical stimulus artifacts, which mask smaller-amplitude extracellular potentials generated by active neurons. Additionally, filtering of the recorded signals, an essential step for spike detection, can compound the problem by distorting artifacts in time such that the signal is corrupted for a duration longer than the stimulus pulse width. We developed a simple artifact elimination (AE) scheme to record in M1 during ICMS of S1 without complex real-time processing.
A man with a C5/C6 spinal cord injury was implanted with two recording microelectrode arrays in M1 and two stimulation microelectrode arrays in S1. During each 700 µs biphasic stimulus

pulse, a sample-and-hold digital filter was applied to the raw recorded signal to eliminate stimulus artifacts prior to additional filtering. A 750 Hz first-order high-pass Butterworth filter was then applied to the signal prior to thresholding for spike detection. These parameters were chosen to meet the specifications of a fast return to baseline after perturbations, elimination of filter ringing in the step response, and an overall increase in signal-to-noise.
This AE scheme allowed for reliable spike detection as soon as 800 μs after the offset of each stimulus pulse, corresponding to a 15% loss of neural data when stimulating at 100 Hz. We demonstrated the effectiveness of the AE scheme in a closed-loop BCI task. A 5 DOF velocity decoder was trained to control a robotic arm. The subject was instructed to use the robotic arm to transfer an object across a 20 cm region as many times as possible during a two-minute period. During ICMS trials, 8 electrodes were simultaneously stimulated between 18-46 μA at 100 Hz when the fingers generated torque against the object. A one-way ANOVA found significant differences in performance between baseline (no ICMS), ICMS, and ICMS+AE conditions ($p < .01$). Post-hoc tests revealed a significant decrease in performance with ICMS without AE compared to baseline ($p < .01$), but no significant difference between baseline and ICMS+AE conditions ($p = .621$).
The proposed system is relatively simple to implement and requires minimal parameter tuning to produce reliable recordings during ICMS for closed-loop BCI control.

**Abstract:** Intracortical microstimulation (ICMS) is a powerful tool both to probe neural circuits and to produce artificial sensations in a brain machine interface (BMI) for a variety of modalities, including vision, audition, touch and proprioception. In addition to conscious perception, the role of somatosensation in the control of movement in bidirectional BMIs is of potentially great importance. When used to provide somatosensory feedback, ICMS through an array of electrodes implanted in the somatosensory cortex (S1) could be used to evoke neural activity that closely imitates that of natural limb movements. This biomimetic approach is appealing as it may elicit intuitive sensations that require less learning to master. To maximize the effect of biomimetic approaches, it is important to understand the response of cortical neurons to ICMS. This is a challenge, as the electrical artifacts associated with ICMS typically prevent obtaining electrical recordings for several milliseconds after the stimulation pulse. We evaluated the effect of various front-end electronics, post-processing techniques, and stimulation profiles on the electrical artifact generated by ICMS when using chronically implanted 96-channel electrode arrays in S1 of rhesus monkeys. We varied the timing and amplitude of the pulse charge balance, resulting in stimulation profiles that decreased the duration of the artifacts on both the stimulated and non-stimulated electrodes. Additionally, by using a lower gain pre-amplifier, we reduced the loss of signal due to saturation. This is most critical immediately after stimulation pulses end, as avoiding saturation improves linearity and reduces the latency at which it is possible to resume recording neuronal activity. To make the post-stimulus data more accessible, we used acausal, time-reversed filtering to attenuate slowly decaying artifacts without contaminating the post-stimulus period with the filter transient response to the stimulus. We implemented this process in quasi-real time with about a 70 ms delay. Using these approaches, we developed methods that allowed stimulation and recording at sub-millisecond latencies even within an array of electrodes. We were able to record on non-stimulated electrodes about 0.4 ms after the end of the stimulation pulse and on the stimulated electrode about 1 ms after the end of the pulse. Using these tools, we have begun to explore the spatial pattern of neural responses to stimulation. This work enables the development and validation of models to design stimulation patterns to evoke biomimetic cortical activity that closely imitates that of natural limb movements.

**Title:** A neuromodulation integrated circuit for high-channel count, bidirectional, and minimally invasive neural interfaces

**Authors: *S. JUNG**, E. ALON, J. RABAEY
Electrical Engin. and Computer Sci., Univ. of California, Berkeley, Berkeley, CA

**Abstract:** We present a neuromodulation integrated circuit (IC) as a key building block in realizing a neural interface. The IC has 64 low-power small-area digitally programmable recording channels (<3uW/channel, 150umx150um/channel, variable BW, variable gain, AC-coupled), two digitally programmable stimulators (current digital-to-analog converter, variable phase, variable amplitude, variable pulse width, and variable pulse rate, multiplexed to eight different sites), and digital blocks for wired communication between the IC and a field-programmable gate array (FPGA). On-chip powertrains provide regulated supply voltages to recording channels and digital communication blocks, and also high-voltage supplies to the stimulators. This tight integration makes the IC as one of the most dense (4.78mm$^2$) and low-power (<1mW) hardware.
By attaching the low-power dense neuromodulator IC and fine flexible microelectrodes on a small flexible printed circuit board (PCB), we get a prototype hardware that can be implanted on a brain with being minimally invasive. We target to separately insert >1000 flexible microelectrodes, increasing observability and controllability of electrical neural signals. Multiple ICs and PCBs are deployed to support 1000-channel recording. All the recorded signals are first serialized in the ICs, and the FPGA time-multiplex data streams of each IC to relay the data to a PC. For stimulation, commands are asserted from the PC, relayed by the FPGA, and get activated in the IC. USB3.0 link is used between the FPGA and the PC for this purpose. This integrated system realizes the microelectronics part of a 1,000-channel bidirectional neural interface we envision.

**Title:** Study on the deep brain stimulation to induce voluntary locomotion of a rat

**Authors: *N. SUDO**, O. FUKAYAMA, K. MABUCHI, Y. ABE
Univ. of Tokyo, Tokyo, Japan

**Abstract:** The brain-machine interface (BMI) with transcranial electrodes is a powerful method to extract motor commands in the brain to control the body. Supervised estimators have been generally used to correlate neural activities with the voluntary intentions to move the limbs. However, it is not easy to regulate the intentions of experimental rodents, commonly used for invasive BMI experiments, to move the body parts. This work proposes a method to motivate a rat to make a voluntary locomotion by applying electrical stimuli in the deep brain region. For surgical preparation, a pair of wire electrodes implanted in the deep brain of a rat, 2.5 mm posterior, 2.0 mm lateral, and 8.0 mm ventral from the brain surface of the bregma point in the stereotaxic coordinate system. Then, the rat was connected to an electrical stimulator (Multichannel Systems STG-4008) while it behaved freely on a plain field of 150 cm wide and 150 cm depth. An optical recorder system tracked two LEDs attached to the top of the head to detect forward body movements. The locomotion velocity over the 15 cm/s threshold drove the stimulator to flow biphasic spike trains of electric currents in the brain. The rat initially had a sham period of 15 minutes followed by an active period of 15 minutes where the stimuli were applied. The set were conducted twice to 3 times per a day. As a result, close to half out of the tested rats increased frequency of the voluntary locomotion in the active periods. They tended to walk around the field to earn more stimuli in the brain, which ceased as the stimuli were stopped in the next sham period. The tendency repeated in the sets on the following days. Meanwhile, continuous stimuli asynchronous to the body movement were ineffective. The others which failed to gain the tendency to walk included a subject which learned to shake its head instead of walking to earn false detection of the LED movements, a subject which showed involuntary movement of the neck to interfere with walking. The remainders showed no responses to the stimuli regardless of the active and sham periods. These results suggest that stimulation in the deep brain changed behavioral tendency of the rats. Its reason was considered that they learned walking as a behavior to get reward because the tip of the electrodes located in the lateral hypothalamus, known as a reward area. The failed subjects were supposed to have electrodes placed in inappropriate positions. Our method could have temporarily induced the locomotion without altering the original circuits of the rats, and may be utilized to train BMI estimators.

**Abstract:** It is difficult to grasp and manipulate objects without tactile feedback, and yet prosthesis users must work with this limitation. To work towards a solution, we implanted microelectrode arrays in primary motor (M1) and primary somatosensory (S1) cortices in a person with a cervical spinal cord injury to enable closed-loop prosthesis control. Using neural activity decoded from M1, our participant can control a dexterous prosthetic limb while sensory feedback is delivered through intracortical microstimulation (ICMS) in S1. Microstimulation on more than 60 of the 64 implanted electrodes reliably evokes sensations in the hand, but the perceived intensity of the stimuli evoked can vary significantly from electrode to electrode. We have previously shown that stimulation amplitude has a linear relationship to perceived intensity, but the stimulation frequency was always 100 Hz. In non-human primates increasing stimulation frequency decreases detection thresholds, but has little effect on discriminability. [1] It has also been suggested that increasing stimulus frequency could increase perceived intensity. Here we explored the effects of stimulus frequency on perceived magnitude in a human participant. To test this, we used a free magnitude estimation task where varying stimulus amplitudes (20, 50, and 80 uA) and frequencies (20, 100, and 300 Hz) were paired and presented in randomized order. For each stimulus pair, the participant reported the perceived intensity on a self-selected scale. We found that that perceived intensity increased with stimulation amplitude on all electrodes at all frequencies, as expected. However, stimulus frequency changed the perceived intensity in idiosyncratic ways that were electrode dependent: when comparing between 20 and 100 Hz, on 3 of 8 stimulated channels, 20 Hz was associated with increased perceived intensity, while on 5 of 8 stimulated channels, 100 Hz was associated with increased perceived intensity and these relationships generally held across all stimulus amplitudes. Understanding the relationships between stimulus frequency, perceived intensity, and other perceptual characteristics could help us improve the perceptual quality of ICMS and develop prostheses that provide a rich sensory repertoire. Ultimately, these techniques could also help us understand how inputs are processed more generally in the somatosensory cortex. [1] S. Kim, T. Callier, G. A. Tabot, R. A. Gaunt, F. V. Tenore, and S. **Abstract:** Brain-computer interfaces (BCI) have enabled users to achieve high degree-of-freedom control of a prosthesis even though limb state feedback has been limited to information available through vision. In tasks such as object manipulation however, providing tactile sensory feedback is an important step to improving control as vision provides less salient cues. Intracortical microstimulation (ICMS) of area 1 of primary somatosensory cortex (S1) can convey spatially selective tactile percepts that are graded over a range of perceived intensities and may therefore be sufficient for providing information about object contact force. Here we demonstrate that ICMS in S1 can be used during continuous control of a BCI to provide task-relevant feedback about both the location and intensity of object contact.
In this study, a twenty-eight year old participant with a chronic C5 motor and C6 sensory spinal cord injury was implanted with two intracortical microelectrode arrays in primary motor cortex (M1) and two arrays in S1. The M1 arrays were placed in the upper limb representation and used to continuously control various BCI end effectors. The S1 electrode arrays were targeted to the hand region of area 1 in the left hemisphere based on presurgical imaging. The goal was to elicit cutaneous percepts that project to the fingers of the right hand.
In a first task, we found that simple cursor control tasks where the subject attempted to locate an unseen target that provided ICMS feedback could be completed under the guidance of stimulation alone. Further, functional tasks, such as object transfers, were performed with and without ICMS feedback. In these tasks, robot finger torques were read every 20 ms and linearly mapped to ICMS pulse amplitudes to relay information about object contact. These tasks were performed at least as well with ICMS feedback as they were without it. We have found that simple tasks where vision is obscured and task feedback is only available through ICMS clearly

show the value of providing ICMS feedback. However, in more complex tasks where vision is available, ICMS feedback has not always improved performance. While our participant prefers having ICMS turned on, functional gains are currently difficult to quantify. Significant future work remains in identifying non-trivial tasks that are within the motor control capacity of current BCIs and the end effectors they control, yet can still benefit from cutaneous sensory feedback.

**Abstract:** A major technological barrier to ubiquitous and chronic brain-machine interfaces or peripheral nerve electroceuticals embedded deeply in soft tissue is a bi-directional, wireless system on a sub-mm scale. To address this challenge, we circumvented the size-scaling issues and energy absorption losses associated with conventional EM systems and developed an ultrasonically powered neural stimulator, Stimulating Neural Dust (StimDust). Each StimDust mote consists of a 750μm x 750μm piezocrystal for power harvesting and communication packaged with a 1mm x 1mm power-efficient control ASIC (application specific integrated circuit) on a flexible printed circuit board.
Previous implementations of ultrasonically-powered stimulators provided uncontrolled stimulation sensitive to received power and electrode impedance. StimDust, however, rectifies and stores power harvested from the piezocrystal and utilizes a current-mode stimulator to deliver a controlled charge independent of electrode size and impedance. Furthermore, the stimulation waveform is dynamically reconfigurable via the structure of the input ultrasound, where lengths of ultrasonic packets encode commands for amplitude, frequency, pulse width, and interphase gap. This enables temporally precise (sub-microsecond) control of pulse width, interphase gap, and pulse interval. Another advantage of using ultrasound to encode control

signals is the flexibility and inherently high dynamic range afforded to the stimulation frequency (e.g. 1mHz to 10kHz) without relying on internal clock dividers which consume power and are sensitive to the resonant frequency of the piezocrystal. The system can deliver up to 350μA of stimulation current at a wide range of pulse widths and frequencies, resulting in a >80% conversion efficiency from received power to delivered stimulation power.

**Abstract:** Brain-Computer Interface (BCI) systems have been developed that allow users to control devices such as computer cursors, robotic manipulators, and advanced upper limb prosthetics such as the Modular Prosthetic Limb (MPL). Typically, the only information available to the BCI user regarding the state of the device is from the visual system. However, recent studies have shown that intracortical microstimulation (ICMS) can be used to provide feedback about the state of the BCI. Many questions remain, however, about the potential of ICMS to convey information about complex actuators that can adopt many states (e.g. upper limbs).
We explored whether a BCI user with tetraplegia could position the hand of a virtual MPL (vMPL) over an invisible, randomly positioned target in a 2D plane when guided solely by ICMS. The vMPL hand position was controlled via neural signals recorded from multi-electrode arrays implanted in primary motor cortex, while ICMS was delivered through multi-electrode arrays implanted in primary somatosensory cortex. Two approaches were used to provide

information to the subject regarding the position of the hand relative to the target: proximity and direction. In the proximity mapping, ICMS amplitude on a single electrode increased in six discrete levels as the vMPL approached the target. In the direction mapping trials, target position relative to the vMPL's current location was conveyed through three ICMS channels. Each channel was assigned a particular angular direction ($90^O$, $210^O$, $330^O$). The amplitude for each channel was scaled (in six discrete levels) by relating the angle of an ideal target movement (given current vMPL position) to the channels' associated directions. Stimulation frequency was 100 Hz, and charge-balanced pulses with a cathodal phase of 200 µs were used. The BCI user was able to learn to use the ICMS to guide movements using both the proximity and direction mappings. In both cases, the subject achieved accuracies which significantly outperformed chance (*p* < 0.05). While the BCI user achieved higher target accuracies using the proximity-based encoding scheme, the distribution of vMPL movements during direction-encoded trials still showed a clear bias toward the angles communicated via ICMS. Our results highlight that encoding strategy is critical in designing feedback for BCIs: some strategies are more intuitive and thus easier to learn.

**Abstract:** More than 40% of women suffer from lower urinary tract (LUT) disorders including deficient bladder emptying and urinary incontinence. Electrical stimulation of the S3-S4 root or the pudendal plexus that innervate several pelvic and perineal targets is considered currently a viable alternative treatment of several LUT dysfunctions. However, this therapy seems to increase urinary retention in some patients, and urinary voiding in others. These contradictory effects seem to be, at least in part, due to the indiscriminatory activation of both efferent and afferent fibers in the sacral or pudendal plexi in the pelvic floor. We sought to investigate whether stimulation of the specific motor efferent innervating the ischiocavernosus, (Ism) and bulbospongiosus (Bsm) muscles in the pelvic floor would modulate the bladder emptying response. Since our previous studies demonstrated that, these muscles deploy asynchronous activity during urine storage and bladder emptying. Nulliparous adult young female rabbits were implanted acutely with a novel wireless miniature cuff electrode (WMCE) that uses RF at a 10.7 MHz frequency to power a 1 mm transistor-less device attached to a custom nerve cuff. A diode in the WMCE was used to produce a 400 us cathodic pulse and deliver a 400 mV potential to the target nerves. The animals were stimulated for 30 seconds at 2 Hz and repeated 3 times with a 10-minute inter-stimulation delay. Cystometrograms were recorded before and during the WMCE stimulation and the threshold volume of the bladder, voided and residual volume, and the voiding efficiency were quantified. The results showed that wireless stimulation of the Bsm and Ism nerves the increase the maximum pressure of the bladder. These results demonstrate the efficacy of wireless neuromodulation of perineal muscle nerves for affecting bladder function and suggest that this approach might offer a more selective treatment for urinary incontinence.

**Abstract:** The trigeminal nerve (CN V) is divided into three branches, opthalmic (V1), maxillary (V2) and mandibular (V3), and carries most of the tactile, proprioceptive and nociceptive information from sensors in the face to the central nervous system via nuclei in the brainstem and thalamus. In recent years, the V1 branch of the trigeminal has become a popular target for neuromodulation therapies to treat of a variety of neurologic and psychiatric disorders (i.e. epilepsy, depression, attention deficit hyperactivity disorder and traumatic brain injury) due to its integration with the sympathetic and parasympathetic nervous system. Despite promising preclinical and clinical data, the mechanism of action trigeminal nerve stimulation (TNS) remains in question. In this work, we describe the development and evaluation of a neural interface targeting the mouse trigeminal nerve with the goal of enabling future mechanistic research on TNS. We performed separate experiments designed to: 1) identify the best stimulation target for TNS in the mouse and 2) evaluate the ability of a cuff electrode to stimulate the nerve. Using fresh cadavers, we investigated the course and measured the size of each branch of the trigeminal nerve, and found that V2 (infraorbital branch) was the best candidate for a neural interface to its accessibility and size (0.7mm diameter). In contrast, V1 is easily accessible (supraorbital branch) but rather small (0.2mm diameter), while the course of the V3 branch (behind the lower jaw) makes access problematic. To evaluate our ability to engage the infraorbital nerve, mice were anesthetized with isoflurane (1-2.5%) and implanted with a custom bipolar cuff electrode (1.5mm spacing, 0.05mm wire diameter) on the infraorbital nerve distal to the infraorbital foramen. Electrical stimulation of the infraorbital nerve was performed using single, monophasic or biphasic (cathode leading) pulses (50-800uA, 100-300us per phase) initiated at pseudorandom intervals (varying between 3-4 seconds). Following surgery, anesthesia was switched from isoflurane to a ketamine (25-100mg/kg) - dexmedetomidine(0.05-0.1mg) cocktail. We measured changes in cortical activity in the barrel cortex (somatosensory evoked potentials [SSEPs]) elicited by stimulation using a uECoG array (16 channel, 200um site diameter, 500um inter-site spacing). The magnitude of SSEPs increased monotonically until saturation with increases in stimulation current and activation thresholds decreased with increases in phase duration. These preliminary results suggest that an infraorbital nerve interface is a suitable candidate for examining the neural mechanisms of TNS in the mouse.

**Abstract:** Oscillations in field potentials provide insight to the underlying information processing within regions of the brain. A huge catalog of experimental evidence has shown that coordination of oscillations across and within brain areas is critical for learning and performance in memory tasks. While a large amount of work has focused on the generation of neural oscillations, the effect that these oscillations have on the spiking activity of neural populations and the extent to which these rhythms have a direct role in the learning process has not been evaluated. In the present work, we propose that a neuronal property, sub-threshold resonance, interacts with oscillating input to ensure that networks of neurons properly map the information represented in external inputs the weights of recurrent synaptic connections. We demonstrate using a biophysical neuronal model that when individual cells display an input-current dependent shift in their resonance response, populations will arrange their phases of action potential firing to represent the differences in the strengths of their respective inputs. As networks learn (i.e. change synaptic strengths to compensate for the differences in external input) the firing phase difference is reduced to a minimum. Consequently, learning saturates when the network has successfully mapped the input distribution to the synapses. Additionally, we show that by bringing consecutive subsets of neurons into and out of resonance with an oscillating input allows networks to accurately store and reproduce sequences of activation in both the forward and reverse direction, as seen in numerous experimental studies. As validation for our proposed mechanism we show *in vivo* that periodic stimulation of hippocampal cells coordinates network

activity and functional connectivity in a frequency-dependent manner that is qualitatively reproduces the effect seen modeled networks. We argue that sub-threshold resonance provides a emergent network level mechanism to accurately encode and retrieve information without over-strengthening connections between neurons.

**Abstract:** Neural interfacing technologies have the potential to significantly improve the quality of life of patients that are severely disabled or suffering from a variety of neurodegenerative conditions. To recapitulate proper physiological function, motor commands and sensory feedback must be considered. The spinal nerve is a unique location at which these complementary systems can be accessed. In this study, the dorsal root ganglion-ventral root (DRG-VR) complex was targeted with floating microelectrode arrays (FMAs) designed either to record from the VR or test stimulation paradigms in the DRG. Extensive characterization of the tissue response to these chronically implanted microelectrode arrays was performed to determine the reliability of these peripheral locations for interfacing applications. To accomplish these analyses, hematoxylin and eosin and Nissl/Luxol fast blue staining along with antibody-based stains [NF200 (axons), S100 (Schwann cells), vimentin (fibroblasts, endothelial cells, astrocytes), MAC387 (monocytes/macrophages), GLUT1 (glucose transport proteins)] were employed, regions of interest representing the entire area of the implanted array defined, and pixel-based image analyses specific for each stain utilized. Implanted roots were compared to the non-implanted (i.e., contralateral) roots from the same cohort of animals. The results indicate

that the inflammatory reaction elicited with array insertion is not significantly greater than what is observed in a control (i.e., non-implanted) spinal nerve. The absence of a significant immune response to these arrays suggests some level of immune privilege in the spinal nerve and bodes well for long-term applications. In addition, no significant decreases in neuronal density or myelination were observed in the area associated with the array indicating that both neuronal cell bodies and axonal projections are maintained. Observations related to the status of the blood-nerve barrier suggest it is preserved and/or reestablished at the chronic time points examined. Our data indicates that targeting the DRG-VR complex is a viable option and that the associated tissue response in this location is an opportunity to achieve the overall goal of a long-term, reliable interface with prosthetic limbs.

**Abstract:** Nerve stimulations require careful optimization of waveform parameters, whether for sensory feedback or central neural network activation. Pulse width and amplitude are two parameters investigated often. Charge balanced symmetric pulses tend to appear most frequently in central nervous stimulation paradigms. While this convention tends to hold for peripheral nerve stimulation, this study assesses the possible utility of asymmetric pulse-width encoding in peripheral nerve stimulation. Toward this end, a series of asymmetric sequences were designed to determine what, if any, effect asymmetric stimuli have on compound neural action potentials (CNAPs).
Experiments were conducted in vivo, stimulating in the rat Tibial nerve and recording in the Tibial and Peroneal nerves. Stimulations were delivered via a microwire electrode with CNAPs captured via cuff electrodes downstream. The sequences were asymmetric in pulse-width and amplitude but were kept charge balanced. The stimuli were presented cathode leading first and

then followed by the reverse of the sequence with anode leading pulses. The effect of the interpulse period was not investigated in this study and therefore was fixed at zero. To expand the parameter space and investigate the role of asymmetry in the stimuli, six base stimuli amplitudes were delivered. The stimuli ranged logarithmically from 50 microamperes to 200 microamperes.
After stimuli delivery, the compound neural action potentials were sorted and averaged. From the data strip, stimulus artifact was removed from the leading edge and noise introduced from the muscle was removed from the trailing end. The remaining data strip was considered the contribution from neural activity. To determine the efficacy of each stimulus, the root mean square (RMS) of the signal was calculated. The RMS of the signal is proportional to the number of recruited fibers within a nerve fascicle; the RMS of individual stimuli were then compared against each other to determine which stimulus gave the highest recruitment value. Recent results have shown that varying the degree of asymmetry has had no significant effect on the RMS of recorded CNAPS.

**Title:** Optimal spatial and frequency parameters of subthalamic neurostimulation for the neural and kinematic signatures of gait impairment in freely moving Parkinson’s subjects

**Authors: *C. ANIDI**, J. O'DAY, M. F. AFZAL, J. SYRKIN-NIKOLAU, A. VELISAR, T. MARTIN, H. BRONTE-STEWART
Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

**Abstract: Objective**: Gait impairment and freezing of gait (FOG) are severe complications of Parkinson’s disease (PD) and are characterized by specific kinematic and subthalamic neural signatures. We investigated the effect of low versus high frequency STN deep brain stimulation (DBS) through the ventral versus more dorsal STN electrode(s) on synchronized neural and kinematic recordings in freely moving PD subjects.
**Methods**: 6 PD subjects (11 STNs), off-medication, performed a forward walking (FW) task, a stepping in place (SIP) task on dual force plates, and a FW turning and barrier course (TBC), during which synchronized local field potentials (LFPs) and kinematic data were recorded. Tasks were completed during NO, 60 Hz and 140 Hz DBS at a clinical equivalent voltage. STN LFPs

were recorded bilaterally from electrodes 0 - 2 and 8 - 10 of the left and right STN DBS leads (model 3389, Medtronic, Inc.) on to an investigational sensing neurostimulator (Activa® PC+S, Medtronic Inc., FDA-, IDE-, IRB-, and CA Medicare-approved) before and during DBS through electrode 1 and 9 respectively. During the SIP task, kinematic data was recorded during 60 and 140 Hz DBS on the most ventral electrodes at the same voltage as the more dorsal electrode paradigm. Kinematic data was recorded using wireless Opal® inertial measurement unit (IMU) sensors (APDM, Inc.). Angular velocity signals from IMUs on the lower legs were used to determine gait cycle duration, swing phase duration, and swing angular range. Angular velocity signals from the lumbar IMU were used to determine forward direction and delineate periods of straight walking and turning.
**Results**: 6 subjects (11 STNs) completed FW, SIP, and TBC while off stimulation and during 60 and 140 Hz DBS. STN DBS at 60 and 140 Hz decreased the number of freezing episodes (FEs) in freezers and attenuated beta band power compared to the off stimulation state. In all subjects, there were fewer FEs of shorter duration during 60 Hz compared 140 Hz DBS. Preliminary results from 3 subjects during the SIP task demonstrated greater improvement in both gait arrhythmicity and asymmetry during both frequencies of DBS on the most ventral electrodes when compared to the more dorsal electrode.
**Conclusions:** Low and high frequency STN DBS improved FOG and simultaneously attenuated beta band power. Preliminary analysis suggested that 60 Hz DBS was more efficacious and in the ventral STN region may be a better target than more dorsal STN regions to treat FOG in PD. Optimizing spatial and control policy parameters will be important for closed loop DBS systems.

**Title:** Subthalamic neural closed-loop deep brain stimulation in Parkinson's disease using patient specific functionally relevant frequency bands

**Authors: *M. AFZAL**, C. ANIDI, A. VELISAR, J. SYRKIN-NIKOLAU, J. O'DAY, H. BRONTE-STEWART
Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

**Abstract: Objective**: Exaggerated neural synchrony in the beta band (13-30Hz) in the subthalamic nucleus (STN) is a pathophysiological marker in Parkinson’s disease (PD), the

attenuation of which is related to the improvement in bradykinesia. We compared the efficacy of neural closed-loop deep brain stimulation (NCL-DBS) for bradykinesia using patient-specific beta sub-bands that were more or less attenuated by deep brain stimulation compared to the off DBS state. **Methods**: To determine the upper and lower voltages for NCL-DBS and the beta band control variables, 6 akinetic-rigid consenting PD subjects (10 STNs), off-medication performed a repetitive wrist flexion-extension task (rWFE) during randomized presentations of 140Hz contralateral STN open loop (OL-)DBS at 0%, 25%, 50%, 75% and 100% of their maximum tolerable voltages. Synchronized wrist angular velocity and STN local field potentials (LFPs) were recorded during the task. Angular velocity was recorded using wearable gyroscopic sensors and LFPs were recorded from electrodes 0 -2 or 1 -3 of the DBS lead (model 3389, Medtronic, Inc) on to a sensing implanted neurostimulator (Activa®PC+S, FDA-, IDE-, IRB-, and CA Medicare-approved). LFP power spectral density identified two LFP bands between 8-30 Hz in each STN that were more or less attenuated during the voltage range used for NCL-DBS; these were used independently to drive NCL-DBS (Activa®PC+S and Nexus-D3/E system; Medtronic, Inc). **Results**: 6 PD subjects have completed WFE during randomized presentations of contralateral OL-DBS, 2 of whom have also completed a trial of 60 minutes of NCL-DBS driven by the beta sub-band that was maximally attenuated during OL-DBS. Preliminary results demonstrated that for each subject compared to off DBS, the root mean square angular velocity ($V_{rms}$) increased by 631% and 1692%; the coefficient of variation (CV) of $V_{rms}$ decreased (more regular) by 66% and 86%; the mean frequency of movement increased by 362% and 442%; and the CV of frequency decreased by 79% and 83% during NCL-DBS. $V_{rms}$ and frequency were greater on NCL-DBS compared to OL-DBS in both subjects. The total electrical energy delivered decreased by 43% and 63% during NCL-DBS as compared to their clinical OL-DBS.**Conclusions**: Neural closed loop STN DBS using LFP power in a patient specific, functionally relevant beta sub-band improved the velocity, frequency and regularity of progressive bradykinesia in akinetic rigid PD subjects and was more efficacious and efficient than their clinical open loop DBS. Further comparison of efficacy, side effect profile, and efficiency of patient specific NCL-DBS will be made with functionally irrelevant beta bands and with OL-DBS.

**Abstract:** Closed-loop neuromodulation systems, which deliver therapeutic microstimulation based on the real-time neural state of the patient, aim to provide on-demand therapy and reduce side effects, while also extending battery life. These technologies must be able to simultaneously record neural signals, remove stimulus artifact from recorded data, and extract neural biomarkers and behavioral states to optimally and automatically deliver microstimulation. To address these needs we have developed OMNI, a wireless and autonomous neurotechnology for closed-loop neuromodulation and continuous, high-throughput streaming of neural data.
OMNI utilizes two custom 64-channel ASICs for recording and stimulation, whose outputs can be dynamically assigned to any of 128 electrode channels. The ASICs provide highly reconfigurable stimulation parameters and nearly artifact-free recording during stimulation, resulting in real-time closed-loop computation on local neural activity during stimulation. On-board computational components enable neural signal processing and closed-loop control algorithms, and wireless data communications allow for operation during natural behavior with 11+ hours of battery life.
OMNI has been deployed in a nonhuman primate (NHP) subject for closed-loop microstimulation during a manual-control delayed reach task. The device records local field potential (LFP) activity and determines when the NHP is performing different sub-stages of the task by thresholding the power in different frequency bands, with all computation done on-board. The reaction time is increased by delivering targeted microstimulation in dorsal premotor cortex (PMd) during the delay-hold periods of the task, prior to the onset of movement. The OMNI device was also used for overnight cortical and subcortical recording during free, natural behavior. The pilot NHP study demonstrates the comprehensive recording and closed-loop functionality of the OMNI device.

**Abstract:** In 1997, deep brain stimulation (DBS) was approved by the FDA for treatment of essential tremor. In the following decades neuromodulation of the CNS became a active field and was applied for treating different conditions. Similar to the technological progress of cardiac pacemakers, concepts were developed to adapt the stimulation to the patient's need, making the devices responsive. Today, two of these closed-loop devices are approved for clinical use, Medtronic Activa PC+S and Neuropace RNS. Both devices work with eight electrode contacts on the surface or deep inside the brain and permit delivery of electrical stimuli initiated, or modified in intensity, based on neural recordings. Here, we present a closed-loop device that overcomes current application limitation by increasing the electrode contact number, minimizing the closed-loop response time and transferring the closed-loop algorithms to a device outside the body, allowing maximum freedom for clinical research. The design is inspired by today's cochlear implants: The implant is wirelessly powered by a body-external transceiver. Cortical electrode arrays and DBS electrodes can be connected to the hermetically packaged implanted electronics. The device records synchronously from 32 electrode contacts at 1kS/s (16bit) at a pass band of 0.5 to 450Hz. Data are wirelessly streamed to the body-external transceiver, which is connected to a laptop-PC, running the control software. The software can send instructions to the implant to generate electrical stimuli of up to 6mA on each of the 32 electrode contacts. Typically, it takes some 10ms for closing the loop of recording and recording-based stimulation, strongly depended on the signal analysis and decision-taking algorithms used.
The system was implanted in sheep (approved by the Regierungspraesidium Freiburg, Germany and the Animal Ethics Committee of the University of Freiburg) to investigate long-term functionality and biological acceptance. Excellent robustness of the implanted hardware, good biological acceptance and stable recording signal quality could be demonstrated. We present the

latest results from the animal studies and technical improvements developed based on prior results. In conclusion, the implant system presented has the potential for researching closed-loop therapies for the central nervous system. The validations towards clearance for clinical studies are currently on the way.

**Title:** Electrical brain stimulation causes patient to sing

**Authors: *A. C. CONNOLLY**[1], K. A. BUJARSKI[2], C. MARTIN[3], B. C. JOBST[2], D. W. ROBERTS[4]
[1]Dartmouth Col. Geisel Sch. of Med., Lebanon, NH; [2]Neurol., [4]Neurosurg., [3]Dartmouth-Hitchcock Med. Ctr., Lebanon, NH

**Abstract:** Electrical brain stimulation (EBS) can occasionally cause overt behavioral responses in patients. Nearly all of those reported in the literature represent simple behaviors including lip-smacking, unintelligible vocalizations, changes in muscle tone, or reflexive uncontrolled muscle movements. Here we present a case of EBS of the right non-language dominant cingulate gyrus during functional brain mapping for epilepsy surgery which resulted in the singing of spoken language. Stimulation at a single pair of electrodes reliably caused the patient to involuntarily switch from speaking to singing whole phrases and sentences. This observation provides evidence that the cingulate gyrus is directly involved in motor control of singing. We discuss this finding in the broader context of cognitive neuroscience research on singing. We conclude that the automatic and involuntary nature of the EBS-induced singing behavior supports recent claims that the singing faculty in humans is phylogenetically ancient and is supported by dedicated neural circuitry.

**Abstract:** Numerous studies indicate that sensory feedback could enhance the embodiment and ease of use of prosthetic limbs and potentially alleviate phantom limb pain (PLP). Electrical stimulation of the peripheral and central nervous system is the focus of extensive research as a means of providing this sensory feedback. In this study, we targeted stimulation to the dorsal spinal cord and roots (DSCR) to provide sensory feedback in upper-limb amputees. The DSCR provide a clear separation between the sensory and motor pathways, thereby avoiding any undesired concurrent activation of motor pathways that could contaminate a myoelectric interface. Also, the DSCR can be accessed through a minimally invasive surgical technique. Here, we present observations from human psychophysics experiments performed while stimulating the C5-C8 DSCR in two upper-limb amputees using FDA-approved spinal cord stimulation leads. Using percutaneous implantation techniques, we placed three 8 or 16-contact leads (Boston Scientific) in the lateral epidural space of the cervical spinal cord. Stimulation was delivered using a custom external stimulator for up to 4 weeks, after which the electrodes were removed. Information regarding the modality, location, and intensity of perceived sensations was provided by the subject using a structured reporting system. We found that stimulation frequency had a stronger effect than stimulus amplitude on the intensity of perceived sensations and often, dictated the perceptual modality of the sensation. However, across different electrodes, changes in intensity or perceived sensation area were not consistently monotonic with respect to changes in stimulus parameters. Using multivariate analyses, we determined which stimulus parameters could most reliably predict the intensity of a perceived sensation. This information will be useful in scaling the perceived intensity in accordance with sensor information during closed-loop tasks. To assess PLP, we asked the subject to report the PLP intensity after every trial of stimulation. Also, the McGill Pain Questionnaire (MPQ) was administered once before implantation, weekly during the stimulation phase and again one month after explantation. The

subjects reported a transient increase in PLP that was correlated in intensity and likelihood with stimulation amplitude and pulse width respectively, whenever sensory stimulation was delivered. However, in contrast, we observed a clinically significant reduction (>5 points) in PLP from baseline over the 4 weeks of stimulation as determined by the MPQ. This time-dependent modulation of PLP by sensory feedback will be explored in future experiments.

**Abstract:** Levodopa and deep brain stimulation alleviate most of the symptoms associated with Parkinson's disease. However, axial gait disorders are less responsive to these treatments. These deficits include short and slow steps, balance deficits and freezing of gait that involves episodes during which the affected persons are unable to initiate locomotion. Over the past decade, we have established a mechanistic and technological framework that guided the design of electrical spinal cord stimulation protocols engaging extensor and flexor muscle groups. We created an interface between the leg motor cortex activity and these spatially selective stimulation protocols, so as to engineer a brain-spine interface - a neuroprosthetic system that reinforced intended movements. As early as 6 days after spinal cord injury, this brain-spine interface restored weight-bearing locomotor movements of the paralyzed leg in nonhuman primates. Here, we show that the brain-spine interface effectively alleviates axial gait deficits observed in Parkinson's disease. These experiments were conducted in MPTP-treated Rhesus macaque monkeys, which is the gold standard model of Parkinson's disease symptomatology. After MPTP treatment, a rhesus macaque was implanted with the wireless brain-spine interface. Brain recordings of the left and right leg motor cortex were used to detect neural states related to flexion and extension movements of both legs while the animal walked freely overground or over a horizontal ladder. The detection of these gait events controlled an implanted pulse generator that delivered electrical stimulation through two e-dura (dura mater like) electrode array implants, which covered the dorsal aspects of the lumbar and sacral spinal cord. The brain-spine interface instantly improved gait execution when compared to non-stimulation condition. These improvements manifested in increased speed along the corridor and the ladder, and the absence of falls on the horizontal ladder, which contrasted to the frequent misplacements that occurred without stimulation. These preliminary results open promising avenues for evaluating the ability of the wireless brain-spine interface to alleviate gait deficits in people with Parkinson's disease.

**Abstract:** Loss of touch and proprioception, e.g., due to spinal cord injury, causes significant movement deficits, and the absence of sensory feedback limits the function of prosthetic devices. We are developing a biomimetic approach to evoke sensory percepts through intracortical microstimulation (ICMS) of somatosensory cortex (S1). One of the key challenges of the biomimetic approach is to determine the spatiotemporal pattern of multi-channel ICMS that results in neural responses that mimic those evoked by naturalistic sensory inputs. However, the response to multi-channel ICMS is not expected to be the superposition of responses evoked by individual channel stimulation due to strong nonlinear interactions. This results in an exceedingly large stimulus parameter space that cannot be searched by brute force, and we developed a systematic approach to design biomimetic patterns of ICMS.
We recorded multiunit activity (SPIKES) from area 2 of S1 in two rhesus macaques using a 96 channel multi-electrode array during a center-out reach task. The task spanned eight reach directions in a 2D space and the hand position ($PHYS_{prop}$) was continuously tracked. We also recorded SPIKES from S1 area 1 in a rhesus macaque during application of indentations ($PHYS_{tact}$) of varying amplitudes onto digits D3 and D4.
We implemented a computational model of a cortical hypercolumn (*slab* model) comprising 100 modules arranged in a 10*10 grid. Each module consisted of an anatomically realistic, layer-specific cortical minicolumn, following an existing model of multi-compartment cortical neurons (Traub et al., 2005). The layer-4 neurons were extracted from the *slab* model, and a simplified *sheet* model was used with a genetic algorithm to design spatiotemporal patterns of ICMS

(STIM). We identified optimal STIM patterns such that model-based responses (EVOKED) approximated the measured SPIKES. We tested the performance of sheet model-optimized STIM on the more complex slab model. The slab model EVOKED responses matched SPIKES for neurons <100 um from the electrode tip.
Finally, we developed a mapping function between PHYS and STIM – the sensory encoder to be integrated into a neuroprosthetic device – by training a recurrent neural network (RNN). The RNN was cross-validated using PHYS that were not included in training and evaluated the output STIM on the sheet model. The RNN-predicted STIM generalized well to untrained $PHYS_{prop}$ reach trials, with the degree of similarity between SPIKES and EVOKED being comparable to trial-trial variability between SPIKES.
This framework enables an encoder to evoke biomimetic patterns of neural activity and thereby naturalistic sensory percepts.

**Abstract:** Leg amputees do not have natural sensory information from commercial prostheses. As a consequence, amputees risk falls, and lose confidence in the prosthesis, so that patients exert counterbalancing movements with the sound leg increasing metabolic costs, and leading to catastrophic events as heart failures. Also, because of the lack of sensory feedback, 50 to 80% of amputees report phantom pain from the missing leg. Some efforts to restore sensory feedback in lower limb amputees have been conducted with non-invasive technologies, but they failed in addressing these problems. In this work we developed the first prosthetic leg, which restores sensory feedback to amputees by means of implanted intraneural electrodes, in order to reduce metabolic costs during walking and to decrease phantom limb pain. Two transfemoral amputees

underwent the implant of 4 TIME electrodes in the tibial nerve for three months. The response of the subjects to the nerve stimulation was characterized during the whole course of the study. We showed that natural sensations of touch and muscle contractions could be elicited on the phantom leg on the whole area of innervation of the tibial nerve. A commercial prosthetic leg with an encoder embedded in the knee was equipped with a custom made sensorized sole, giving pressure information from 7 positions of the foot sole. The readout of these sensors was used to drive wirelessly the stimulation of 4 active sites, eliciting natural touch under the foot sole and calf contraction, intuitively interpreted by the subject as knee flexion. The subjects were asked to walk with the prosthesis restoring sensory feedback at increasing velocity on a treadmill for 8 minutes. Then they were asked to walk outdoor for 6 minutes at a self-assessed speed on a fixed path on send and grass. These trials were repeated with and without restored sensory feedback, while the metabolic costs were measured. Finally, the subjects underwent sessions of 10-minutes continuous monopolar biphasic square stimulation. The volunteers replied to standard pain questionnaires before and after the stimulation. Remarkably, we measured significantly reduced metabolic costs both indoor and outdoor when the subjects walked with the prosthesis restoring sensory feedback. Furthermore, the subjects reported a significant decrease of phantom pain after the provision of 10 minutes stimulation. These results show that natural invasive sensory feedback restored by means of intraneural electrodes successfully addresses current limitations of prosthetic devices, opening the way for a dramatic improvement of amputees' life.

**Abstract:** In the last years several research groups have demonstrated that nerve stimulation by implantable peripheral nerve interfaces can be reliably used to restore sensory feedback to upper limb amputees. It has been shown that this improves the performance of controlling hand prostheses. Different strategies to transduce the readout of hand prostheses sensors have been tested. Recently, it has been demonstrated that the charge and frequency of neural stimulation have a linear relationship with the intensity of the elicited sensation. Here, we developed a bidirectional hand prosthesis, in which the readout of force sensors in the hand is linearly related or to the charge or to the frequency of intraneural stimulation. This was done in order to verify whether one approach produced better than the other in improving motor control performance. We implanted the median and ulnar nerve of a transradial amputee, above the elbow, with 4 TIME electrodes. We identified the active sites able to elicit the sensation of touch/pressure in the median and ulnar areas of the hand. The subject controlled the hand prosthesis using the residual arm muscles, whose activation was recorded by surface EMG electrodes. The acquired signals were pre-processed and fed to a KNN to classify, within 100 ms delay, the intention to open, close and not move the hand. The subject blind-folded and acoustically isolated was engaged in 4 tasks from the literature: force control, object location, compliance and shape recognition. In the first one, the subject was asked to control the force level he could exert by the prosthesis on a pressure sensor. 3 levels of force were required either in a casual order or in a ramp fashion from the minimum to the maximum one and back. In object location the subject had to recognize if an object was placed in the ulnar or median portion of the hand or in both. Finally, the volunteer had to distinguish among 3 objects of different compliance or shape. The subject successfully performed object location, compliance and shape recognition, with both charge and frequency modulation. During the force control task, instead, while the volunteer was perfectly capable of controlling three randomly required force levels with both stimulation strategies, she managed to execute the ramp only by means of charge modulation. When the frequency was modulated, indeed, it was impossible for the subject to control the force level from the maximum to the minimum one. This suggests that the intensity of sensations elicited by neural stimulation decays rapidly over time when high frequency is used, making charge modulation strategy a more reliable to exploit in bidirectional prostheses development.

**Title:** Learning object discrimination using electrotactile feedback

**Authors: *T. ARAKERI**[1], B. A. HASSE[2], A. J. FUGLEVAND[3]
[1]Bio-medical Engin., [2]Neurosci., [3]Physiol. and Neurosci., Univ. of Arizona, Tucson, AZ

**Abstract:** A variety of bioengineering systems are being developed to restore tactile sensations in individuals who have lost somatosensory feedback because of spinal cord injury, stroke, or amputation. These systems typically detect tactile force with sensors placed on an insensate hand (or prosthetic hand in the case of amputees) and deliver touch information by electrically or mechanically stimulating sensate skin above the site of injury. Successful object manipulation, however, also requires proprioceptive feedback representing the configuration and movements of the hand and digits. Therefore, we developed a simple system that simultaneously provides information about tactile grip force and hand aperture using current amplitude-modulated electrotactile feedback. We evaluated the utility of this system by testing the ability of five healthy human subjects to distinguish among 27 objects of varying sizes, weights, and compliances based entirely on electrotactile feedback arising from grip-force and hand-aperture sensors placed on the hand of an experimenter (not visible to the subject) grasping and lifting the test objects. We were also interested to determine the degree to which subjects could learn to use such feedback when tested over multiple sessions. The average percentage correct identifications on day 1 (25.9 ± 6.2% correct) was well above chance (3.7%) and increased significantly with training to 46.2 ± 13.6% on day 5. These results suggest that simple, non-invasive methods can provide useful multisensory feedback that might prove beneficial in improving the control over prosthetic limbs.

**Title:** Decoding articulatory representation of speech from cortical recordings: A preliminary study

**Authors: *F. BOCQUELET**[1], T. HUEBER[2], S. CHABARDES[3], B. YVERT[4]
[1]INSERM (U1205), Grenoble Cedex, France; [2]GIPA-lab, CNRS, Grenoble, France; [3]CHUGA, Grenoble, France; [4]Clinatec UA01, INSERM, Grenoble Cedex 9, France

**Abstract:** Brain-Computer Interfaces (BCIs) usually propose typing strategies to restore communication for paralyzed and aphasic people. A more natural way would be to directly control a speech synthesizer through a BCI. Neural activity from the speech motor cortex has been shown to be correlated to the articulatory features of produced speech. Thus, a BCI using neural activity from the speech motor cortex might benefit from decoding an articulatory representation of speech rather than an acoustic one. Such an articulatory representation could then be converted to an audible speech signal using an articulatory-based speech synthesizer. In a previous work, we built such a synthesizer and showed that it could produce intelligible speech from movements of the jaw, tongue, lips and velum, in real-time closed-loop condition. In this preliminary study, we recorded neural activity from several subjects undergoing awake surgery for a tumor removal using both electrocorticographic or intracortical micro-electrode arrays, during production of overt or covert speech. We then investigated the decoding of articulatory trajectories from the recorded neural activity, which was compared to a direct decoding of acoustic features. To perform this comparison, decoded articulatory trajectories were converted to acoustic features using our articulatory-based speech synthesizer.

**Abstract:** Objective: To analyze the color of the phosphenes elicited by AV-DONE.
Methods: The patient was a 44-year-old man with autosomal-recessive RP and bare light

perception. The patient had no other ocular diseases or systemic disorders that could have caused the visual loss. After a standard three-port pars plana vitrectomy, the electrode device with wires was inserted into the vitreous cavity through the silicon trocar. Then, the electrode tips were inserted into the optic disc. Next day biphasic, cathodic-phase-first, electrical pulse trains with a 1-s total duration were applied between one of the stimulation electrodes and the reference electrode. The duration of the stimulus pulses was 0.25 ms/phase, and the frequency was 320 Hz. The patient was questioned about perception of the phosphenes, their clock position (1 to 12 o'clock), and the color of the phosphenes.
Results: The patient identified electrically induced phosphenes through six of the seven stimulation. The phosphenes was distributed focally in the visual field. The average central position of the phosphenes differed for each electrode. The colors of phosphenes were red (13%), yellow (9%), white (8%), blue (31%), pink (19%) and green (20%).
Conclusion: The phosphenes elicited by AV-DONE have several variations of the color. With effective use of the phosphenes, AV-DONE could provide the blind patients with useful information.
The color of the phosphenes elicited by Artificial Vision by Direct Optic Nerve Electrical stimulation (AV-DONE).

**Title:** Evoking visual percepts via epicortical microstimulation of primary visual cortex

**Authors: *D. OSWALT**[1], D. ZHOU[3], P. DATTA[3], N. TALBOT[3], R. GREENBERG[3], Z. MIRZADEH[4], B. GREGER[2]
[2]Sch. of Biol. and Hlth. Systems Engin., [1]Arizona State Univ., Tempe, AZ; [3]Second Sight Med. Products, Sylmar, CA; [4]Dept. of Neurosurg., Barrow Neurolog. Inst., Phoenix, AZ

**Abstract:** Electrical stimulation of primary visual cortex (V1) is a potential means to restore limited vision to those with profound blindness. Early studies using epicortical macroelectrodes demonstrated this technique could evoke phosphenes and simple visual patterns. However, high levels of current were required, yielding unnatural sensations and a concern for initiation of seizure activity. The use of intracortical microelectrodes reduced the level of current needed to

evoke visual percepts, but presents other challenges. Since intracortical microelectrodes are inserted into the parenchyma and violate the blood-brain barrier, their use may comparatively increase tissue response and reduce longevity. With a large portion of V1 residing in the sagittal fissure, the complex geometry of intracortical arrays complicates surgical implantation for more peripheral visual field representation. Epicortical microelectrodes may improve longevity and visual field accessibility. Provided that epicortical microelectrodes can evoke visual percepts at lower current levels than macroelectrodes, they may provide an effective route to restore limited vison.
A 46-channel epicortical array (Second Sight Medical Products) with concentric rings was implanted in two rhesus macaques (macaca mulatta), NHP0 and NHP1, to determine what electrode diameters can evoke visual percepts and how thresholds change with diameter. The rings create diameters of .2, .75, 1.5, and 2 mm. Each array was placed in the sagittal fissure facing right hemisphere, with the caudal-most point of the array in close approximation to the pole, superior to the calcarine. Subjects were trained to respond to small flashes of light on a CRT monitor by using the left hand to indicate perception and the right hand to indicate no perception. Electrical stimulation was then applied to individual electrodes. Tissue damage was assessed by functional changes in the subjects' perception of photic stimuli.
Both subjects responded as perceiving a visual percept with currents in the range of 300-900µA applied to 200µm diameter electrodes. Psychometric data for NHP1 places the average 50% detection rate during stimulation on 200µm electrodes at 375.5µA. Following 12 months of daily stimulation NHP0 showed no significant changes in photic perception. Electrode impedances remained consistent during the 18 months NHP0 was implanted.
Epicortical microelectrodes can evoke visual percepts at lower levels than epicortical macroelectrodes. Percpts can be evoked several months post implant with consistent thresholds and steady electrode impedances, suggesting array stability and consistent charge delivery over time.

**Title:** An SSVEP-based brain-computer interface applied to patients with persistent vegetative state

**Authors: *Y. OKAHARA**[1,2], K. TAKANO[1], K. ODAKA[3], Y. UCHINO[3], M. ODAKI[3], Y. IWADATE[2], K. KANSAKU[1,4]
[1]Systems Neurosci. Section, Dept. of Rehabil. for Brain Functions, Res. Inst. of NRCD, Tokorozawa, Japan; [2]Neurolog. surgery, Chiba university, Chiba, Japan; [3]Chiba Ryogo Ctr., Chiba, Japan; [4]Brain Sci. Inspired Life Support Res. Center, Univ. of Electro-Communications, Tokyo, Japan

**Abstract:** Patients who represent no evidence of awareness of self and environment, and no evidence of volitional response to passive stimulus like an auditory, visual, and tactile have been diagnosed as persistent vegetative state (PVS, Plum and Posner, 1972), or recently as unresponsive wakefulness syndrome (UWS, Laureys, et al., 2010). Recent neuroimaging studies have suggested that some of the patients who diagnosed as PVS/UWS may be able to modulate their thoughts voluntarily (Monti, et al., 2010, Cruse, et al., 2011); however, brain-computer interfaces (BCIs) applied to patients with PVS/UWS have not been successful (Lule, et al., 2013, Pan, et al., 2014). In this study, we applied a steady-state visual evoked potential (SSVEP)-based BCI (Sakurada, et al., 2015) to patients with PVS/UWS. Four patients with PVS/UWS participated in this experiment (1 male, mean: 45.5 years old, JFK Coma Recovery Scale-Revised (CRS-R) mean: 6, ranged 5-7). Following verbal instructions, the participants were asked to attend to or ignore a green/blue flicker, which elicited SSVEPs from the occipital cortex (an attention/ignorance task). We calculated power spectral density (PSD) of target frequency to evaluate their classification accuracy. When asked to attend to, if the PSD of the frequency of the flickering light-emitting diode (LED) crossed over the threshold for 4 sec, the response was recognized as a correct answer. When asked to ignore, if the PSD was kept below the threshold for 30 sec, the response was accepted as a correct answer. Online accuracies were evaluated. Online feedback regarding the task performance was verbally delivered to the participants. In the attention/ignorance task, mean accuracy was 66.3% (n=4, total 90 trials). The mean accuracies were below 70% in 3 out of 4 patients, but a patient (female, 20 years old) achieved a reliable accuracy (mean 80%, 30 trials).The results showed that a patient who diagnosed as PVS/UWS was able to operate our SSVEP-based BCI system in a reliable accuracy, and suggested that some of the patients with PVS/UWS might be able to modulate their thoughts voluntarily and our system might detect volitional responses from the patient group.

**Title:** Motoneuronal and interneuronal control of rolling waves that mediate *Aplysia* locomotion

**Authors: *K. YU**[1], D.-D. LIU[1], S.-Y. YIN[1], G. ZHANG[1], W.-D. YUAN[1], E. C. CROPPER[2], K. R. WEISS[2], J. JING[1,2]
[1]Sch. of Life Sci., Nanjing Univ., Jiangsu, China; [2]Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

**Abstract:** Rolling waves are rhythmic activity that propagates from one location to another, and can mediate some forms of vertebrate and invertebrate locomotion. Here, we study *Aplysia* locomotion, which is mediated by pedal rolling waves propagating from front to back, and seek to characterize the locomotor circuit. We have identified a cluster of ~20 P1 root neurons on the ventral surface of the pedal ganglion that exhibit different activity phases during fictive locomotion elicited by stimulation of nerve P9 or command interneurons CC9-10. A majority of these neurons are motoneurons as they project their axons to the periphery through pedal nerves P1, P7, P8, P9, and can elicit contraction of foot muscles when stimulated. Electrical coupling between motoneurons that are active in a similar phase may contribute to the generation of different activity phases in rolling waves.
With the exception of cerebral C cluster interneurons that activate locomotor programs (e.g., CC9/10) (Fredman and Jahan-Parwar 1983, Jing et al 2008), few interneurons involved in the control of locomotion have been identified. Here, we describe several novel interneurons located in both pedal and cerebral ganglia. On the ventral surface of the pedal ganglion, there are two major classes of interneurons. All have processes that are in close contact with the P1 root neuronal cluster. However, axon projections patterns differ. One class of interneurons projects their axons in a medio-antero-lateral circle within the ipsilateral pedal ganglion. These neurons are rhythmically active during fictive locomotion and can speed up the locomotor rhythm. The second class of interneurons projects to the contralateral pedal ganglion (via the pedal commissure). These interneurons can either speed up or slow down the locomotor rhythm. Moreover, one of the second class of interneurons elicits monosynaptic EPSPs on a P1 root cluster motoneuron in the contralateral pedal ganglion through axo-dendritic electrical coupling. This interneuron does not speed up the locomotor rhythm. On the dorsal surface of the cerebral ganglion, a D cluster interneuron projects its axon to the contralateral pedal ganglion through the

contralateral cerebral-pedal connective (CPC). This neuron is rhythmically active, and can drive a locomotor rhythm, although not as effectively as CC9-10. An E cluster interneuron projects its axon to the ipsilateral pedal ganglion through the ipsilateral CPC, and can slow down the locomotor rhythm. Thus, we identified a number of interneurons that may function as a part of the central pattern generator of the locomotor rhythm. Alternatively they may function as rhythm drivers or modulators.

**Abstract:** During swimming the four paired swimmerets of crayfish's abdomen are coordinated in an anteriorly proceeding metachronal wave with a phase lag of ≈ 25% between each segment. Each swimmeret is innervated by local interneurons of the central pattern generator (CPG) and motor neurons. The intersegmental coordination of the CPGs is achieved by three neurons located in each hemisegment forming a coordinating circuit. One ascending ($ASC_E$) and one descending (DSC) coordinating neuron encode the information about the status of their home module and project it to other ganglia. A nonspiking neuron, Commissural Interneuron 1 (ComInt1), decodes this information transmitted by three coordinating neurons with a gradient of synaptic strength, where the biggest EPSP is always elicited by the neighboring $ASC_E$, the intermediate by the neighboring DSC and the smallest by the coordinating neuron which is the farthest away. Firstly we investigated how the gradient of synaptic strength in ComInt1 is achieved? We hypothesized that the different sized EPSPs are due to differences in the synaptic contacts between ComInt1 and the three coordinating neurons. Therefore single coordinating neurons were filled with fluorescent dye and the synapses of the coordinating neurons on ComInt1 were marked immunohistochemically with Anti-Synapsin. Dorsally at the midline, where ComInt1 has one ascending and descending dendritic branch and the axons of the coordinating neurons pass through the other ganglia, we identified synapses of the coordinating

neurons by colocalized presynaptic boutons with the aborizations of the axon of intracellular stained coordinating axons. We could calculate areas of colocalization which correspond so far to the three distinct sizes of EPSPs in ComInt1. Secondly we investigated how ComInt1 decodes the information of the three coordinating neurons and how it is integrated into the own CPG? Therefore we recorded intracellularly from ComInt1 and changed the excitation level by bath application of different carbachol (CCh; cholinergic agonist) or edrophonium chloride (EdCl; acetylcholine esterase inhibitor) concentrations. To investigate direct and indirect actions of the drugs we measured input resistance ($R_{in}$) in an intact network and in the isolated neuron. $R_{in}$ did not change or increased with higher CCh concentrations, but decreased with increased EdCl concentration. CCh and EdCl did also influence the membrane potential, EPSP amplitude and membrane oscillation of ComInt1, but in an unpredictable way. However we suggest that the decoding of coordinating information is due to the effect of intrinsic modulation and externally applied excitation levels.

**Title:** Command-like modulation of motor neurons and interneurons

**Authors: *F. CLOTTEN**, C. SMARANDACHE-WELLMANN
Zoological Inst., Univ. of Cologne, Koeln, Germany

**Abstract:** Locomotion is utilized in a wide range of behavioral contexts. Thus, the evoked motor output needs to be adapted to specific requirements, i.e. initiated or terminated, or modulated in timing or strength. The swimmeret system of the crayfish is an easily accessible model for studying locomotion and both excitatory and inhibitory ‘command neurons’ modulating the swimmeret output were described. However, so far no information is available about the input these neurons receive or their neural targets within the swimmeret system.
In this study separated axon bundles in the connectives of the abdominal nerve cord were stimulated electrically. Histological identification of the stimulation sides revealed that the locations of the stimulated axon bundles were consistent with previously described locations of excitatory and inhibitory ‘command neurons’. Stimulations induced, terminated, and enhanced

rhythmic activity, indicating stimulation of these command-like neurons.
To understand where the descending command-like input arises and where it is propagated within the ventral nerve cord (VNC) electrical stimulations at the level of the commissural connectives were performed. Comparable stimulation effects were observed and stimulus-evoked activity was recorded extracellularly at the most posterior portion of the VNC. These results give evidence that command-like input acting on the swimmeret system originates from high-order neural centers and is propagated throughout the entire VNC.
Both the swimmeret motor neurons (MN) and presynaptic interneurons of the pattern-generating micro-circuits are possible targets of the command-like neurons within the swimmeret system. Intracellular recordings during sub-threshold stimulations revealed a depolarizing effect on the membrane potential of MNs and activation of the CPGs. In addition, persistent swimmeret activity could be modulated by electrical stimulation, i.e. period decreased and power stroke bursts were strengthened. These results give evidence that both the MNs and CPGs are targeted by the command-like neurons.
The question of neuronal targets of the command-like input is associated with the question of potential neurotransmitters. Proctolin initiates and octopamine terminates rhythmic activity within the swimmeret system and evidence is given that these effects are due to release of these chemicals by command-like neurons. In this study, inhibitory stimulation effects, i.e. termination of rhythmic activity, were abolished by bath application of an octopamine antagonist, suggesting that inhibitory command-like neurons use octopamine as a neurotransmitter.

**Title:** Dynamics of coordinated nerve-muscle-body-environment interaction in crustacean swimming

**Authors: *C. ZHANG**[1], C. R. SMARANDACHE-WELLMANN[2]
[1]Dept. of Mathematics, Univ. of Arizona, Tucson, AZ; [2]Inst. of Zoology, Univ. of Cologne, Cologne, Germany

**Abstract:** Effective locomotion arises from the integration of central neural circuits, muscle dynamics, mechanical interaction with the environment and sensory feedback. In mammals and arthropods that walk and swim using limbs, the movements of different limbs must be synchronized, and the phases and forces of each limb's movements must be adapted to changes in behavioral requirements. How do their nervous systems do it? The complexity of these

elements and their interactions, however, has impeded our understanding of these mechanisms at both cellular and system levels. The crustacean swimmeret system is one of the very few locomotor systems in which both the key neurons in the central pattern generating circuit and the topology of the coordinating synaptic network have been clearly identified. This makes possible a biophysical model of coordinated nerve-muscle-body-environment interaction that includes not only the key neural module and their synaptic connectivity but also a realistic musculoskeletal periphery that interacts with the external 3D fluid environment with sensory pathways returning to the central neural modules. Using mathematical modeling and analysis to guide neurophysiological experiments, and experimental results to constrain development of our model, we aim (1) to exploit features of the coordinating circuit to test predictions of requirements for stable metachronal coordination in the presence of proprioceptive input, (2) to quantify the role of proprioceptive feedback on the oscillations of individual modules, and (3) to construct a biophysically-detailed model of nerve-muscle-body-environment interaction, in which the 3D fluid environment provides feedback to the central neural circuit via proprioceptive pathways to individual neurons.

**Title:** Characterization of postinhibitory rebound in spiking and nonspiking neurons in a chain of coupled oscillators

**Authors: *L. SCHLAEGER**, C. R. SMARANDACHE-WELLMANN
Dept. of Animal Physiol., Univ. of Cologne, Cologne, Germany

**Abstract:** Postinhibitory rebound (PIR) is one of several membrane properties that play an important role in producing rhythmic neuronal activities, by depolarizing following a phase of inhibition. We investigate this property in identified neurons of the swimmeret system. These neurons are characterized by membrane potential oscillations and account for the well coordinated generation of power- and return stroke movements of four pairs of pleopodes (swimmerets) at the abdomen of crayfish. To investigate this we isolated the abdominal nervous system and performed current clamp recordings with sharp electrodes at the dendritic aborizations of the neurons. To induce a PIR, hyperpolarizing current pulses at different holding potentials and with different amplitudes were applied. All neurons that are known to receive

inhibitory synaptic input possessed the ability to produce a PIR, which was accompanied by a small sag potential during the hyperpolarization. These are the neurons of the central pattern generator (CPG), IPS and IRS, the coordinating neurons, $ASC_E$ and DSC and the motor neurons PS and RS. The one neuron in the swimmeret system that is characterized solely by excitatory synaptic input, ComInt1, did not show the ability to produce a PIR, nor a sag potential. I could detect major differences in the PIR responses between the nonspiking CPG neurons and the spiking neurons $ASC_E$, DSC, PS and RS. At more depolarized holding potentials the spiking neurons showed a stronger PIR than at more hyperpolarized holding potentials. Contrary effects to a change in holding potential could be observed when inducing a PIR in one type of the nonspiking CPG neurons.In order to explain these contrasting we investigated the ionic basis of the PIR responses. Different ionic currents can account for the generation of a PIR. In other system the hyperpolarization activated cation current ($I_H$) or the L-type calcium current ($I_{CaL}$) were both shown to be key currents for this property. The L-type calcium channel antagonist nifedipine increased the PIR response in the spiking neurons while there was no effect on PIR in the CPG neurons. In both neuron groups the subsequent application of the H-current blocker ZD7288 almost completely suppressed all PIR responses. These results suggest that PIR is an essential mechanism for most of the neurons in the swimmeret system to generate membrane potential oscillations. Furthermore it seems that $I_{CaL}$ and $I_H$ play different roles for the generation of this response in spiking and nonspiking neurons which could account for the observed differences in the evoked PIR at different holding potentials.

**Title:** Stability of a coordinated circuit during temperature perturbations

**Authors: *C. R. SMARANDACHE-WELLMANN**[1], F. BLUMENTHAL[2]
[1]Univ. of Cologne, Cologne, Germany; [2]Zoological Institute, Animal Physiology, Emmy-Noether Group, Univ. of Cologne, Koeln, Germany

**Abstract:** Temperature is a global perturbation, which influences biophysical parameters within neural circuits of animals. The crayfish's swimmeret system is an excellent model to test if the

coordination of distributed neural oscillators is robust against temperature changes. Swimmerets are four pairs of limbs attached to the abdomen, and are used for forward swimming. They are controlled and innervated by four of six abdominal ganglia. In each hemiganglion a neuronal circuit drives motor neurons which activate the limbs in alternating cycles of power-stroke (PS) and return-stroke movement. An identified coordinating circuit, consisting of two coordinating neurons and one commissural neuron (ComInt1), synchronizes these central pattern generators, so that a metachronal wave is present where the last segment starts with the PS activity and the anterior modules follow with a latency of approximately 20 to 25%.
To answer our question we used crayfish which were acclimated at three different temperatures: cold (4°C), intermediate (14°C) and warm (25°C). All experiments were done on the isolated nervous system with extracellular recordings of all motor nerves responsible for swimmeret movements and the two coordinating neurons. Additionally the activity of ComInt1 was recorded intracellularly. Saline with temperatures between 4°C to 35°C was perfused over the nerve cord. Independent of acclimation condition the period of the rhythm and PS burst duration decreased linearly with increased temperature. Duty-cycle was variable towards temperature changes. However, in all experiments the coordinated pattern of PS bursts from segment to segment remained stable, even if the optimum for a stable rhythm was shifted towards the acclimation temperature. Whereas a parabolic correlation was found for the duty cycle, spikes per burst and the interspike frequency of the coordinating neurons of intermediate acclimated animals towards temperature fluctuations. Additionally, corresponding to a faster rhythm frequency of the system the latency of EPSPs elicited by $ASC_E$ respectively DSC spikes in ComInt1 also decreased with rising temperatures. Independent of the acclimation temperature crayfish responded in a stereotyped fashion and were robust and flexible against a wide range of temperatures.

**Title:** Hysteresis as source of threshold variability in neurons encoding coordinating information

**Authors: *A. C. SCHNEIDER**[1], L. SCHLAEGER[2], C. R. SMARANDACHE-WELLMANN[1]
[1]Univ. of Cologne, Koeln, Germany; [2]Dept. of Animal Physiol., Univ. of Cologne, Cologne, Germany

**Abstract:** Across the animal kingdom neural oscillators are involved in generating rhythmic neuronal activity that underlies basic functions, such as locomotion or respiration, and higher cognitive functions, such as perception and memory. Locomotion is driven by central pattern generators (CPGs) that are responsible for controlling movement of individual body segments, limbs, or joints. To produce goal-directed locomotion, the different CPGs need to be coordinated.
One model system to study the coordination of distributed CPGs is the crayfish swimmeret system which produces the same motor output *in vitro* as *in vivo*. Each of the four pairs of swimmerets on the animal's abdomen moves in alternating power-strokes (PS) and return-strokes (RS). All pairs of swimmerets move in a metachronal wave from posterior to anterior with approximately 20% phase-lag between segments. Each swimmeret is controlled by a CPG located in the corresponding abdominal hemiganglion. The four ipsilateral CPGs are coupled by the coordinating neurons $ASC_E$ and DSC. They encode information about their home module's timing, duration, and strength of PS and RS and send it to the other ganglia. The activity of $ASC_E$ is phase-locked with PS; activity of DSC is phase-locked with RS. This ensures the encoding of timing and duration. Relative burst strength is encoded by the number of coordinating spikes per burst, and the range of spikes is adapted to the average burst strength of the current motor output.
We could show in our experiments that, next to synaptic input from the CPG, the coordinating neurons possess an intrinsic hysteresis mechanism that assists in locking the activity to the motor output. For this, we recorded intracellularly from the coordinating neurons, which were chemically isolated with low $Ca^{2+}$ / high $Mg^{2+}$ saline. Stimulating the isolated neurons with repetitive triangular ramps of varying duration, amplitude, and interval, we could reveal hysteresis on two timescales. For each ramp, the first spike was elicited at a more hyperpolarized membrane potential ($V_m$) than the last spike, and more spikes were generated during the ascending than during the descending stimulus slope. This intraburst hysteresis was caused by an increase in spike threshold throughout the spiking activity. Additionally, experiments revealed interburst hysteresis on a longer timescale. In response to subsequent ramps, fewer spikes with a longer latency and at a more depolarized $V_m$ were generated. These hysteresis effects probably increase the robustness of the coordinating neurons against small fluctuations in synaptic input and allow the adaptation to the strength of the motor output by regulating their excitability.

**Title:** Robustness of central pattern generating circuits to changes in pH

**Authors: *J. HALEY**, D. KUSHINSKY, D. SHIN, E. MARDER
Biol., Brandeis Univ., Waltham, MA

**Abstract:** Most neural circuits found in marine animal species must maintain function despite significant environmental changes such as temperature, dissolved oxygen concentration, and pH fluctuations in sea water. Here, we examine the effects of acute pH changes on two rhythmic motor patterns generated by the stomatogastric and cardiac ganglia of the crab, *Cancer borealis*. The pH of the haemolymph of *C. borealis* is around 7.9 while that of seawater ranges from 7.5 to 8.4 and averages 8.1. This is a 25 percent increase in acidity compared to 200 years ago, a result of ocean acidification. In these experiments, we recorded the pyloric and cardiac rhythms while varying the pH of the bath from 5.9 to 11.0. These experiments reveal animal-to-animal variability in the sensitivity of both the cardiac and stomatogastric ganglia to acute changes in pH with preparations “crashing” at varying pH values. Despite this variability, these neural circuits are extremely robust in response to external perturbations, even in extreme conditions, as preparations exhibit a normal rhythm over a 1000-fold change in proton concentration. Moreover, there appear to be fundamental differences in the pH-sensitivity of these two central pattern generating circuits that exist within the same animal with the cardiac ganglia displaying more sensitivity to basic conditions (pH > 9.5) and the stomatogastric ganglia exhibiting greater sensitivity to acidic conditions (pH < 6.5). We compare this data to the pH-sensitivity of in *vivo* cardiac and pyloric rhythms.

**Title:** Critical slowing down as a predictor of transitions in a neuronal oscillator

**Authors: *J. M. RATLIFF**[1], T. O'LEARY[3], E. E. MARDER[2]
[2]Volen Ctr. and Biol. Dept., [1]Brandeis Univ., Waltham, MA; [3]Univ. of Cambridge, Cambridge, United Kingdom

**Abstract:** The crab Cancer borealis experiences a wide range of environments with temperatures that can vary up to 16°C in a single day as well as shifts in pH and salinity. The animal must maintain robust neural activity through all of these environmental fluctuations. The stomatogastric ganglion (STG) of the crab is able to maintain robust activity through large ranges of temperature and pH although the source of this robustness is not well understood. At more extreme temperatures and acidities, the network makes sharp transitions or bifurcations to different stable activity patterns. Recent work has proposed generic indicators to predict bifurcations under the title of "critical slowing down."
In the present study, we recorded intracellularly from the isolated pacemaker of the STG as it approaches transitions when exposed to increasing temperature (n=10) and acidity (n=10). While the temperatures and acidities at which transitions occur vary between preparations, the activity patterns that we observe are stereotyped. We also examined markers of critical slowing down, including variability and flickering, for their use in predicting transitions, and observed a marginal increase in these markers as a transition is approached.

**Title:** A developmental switch in the organization of the dedicated neural network for swimming in Zebrafish spinal cord

**Authors: *Y. ROUSSEL**, T. V. BUI
Biol., Univ. of Ottawa, Ottawa, ON, Canada

**Abstract:** Locomotion is a fundamental task executed by the nervous system across vertebrates. However, the control of locomotion undergoes a process of maturation that occurs throughout development. This maturation process is accompanied by changes in the nervous system, both on an organizational and an operational level. Describing these changes will allow us to better understand how locomotion is controlled in mature individuals. This stereotypical motor activity can be described as a precise pattern of muscle activation operating at specific rhythms. These rhythms may arise from dedicated spinal networks named central pattern generators (CPGs). Larval zebrafish exhibit two signature rhythms: a 0.5 Hz rhythm driving the occurrence of swimming episodes and a 20 Hz rhythm driving tail beats during a swimming episode.
We focus on the 20 Hz tail beat frequency and test for the potential presence of rhythmogenic

mechanisms via application of various drugs such asstrychnine (a glycine antagonist) or heptanol (a gap junction uncoupler).
Previous studies suggest that at 3 days post fertilization (dpf), glycinergic neurotransmission is not necessary to observe 20 Hz oscillations but is needed for left-right alternation. Therefore reciprocal inhibition, a well-established mechanism for CPG operation, is not involved in rhythm generation at this developmental stage. However, heptanol was found to disturb the swimming rhythm suggesting that the electrical synapse framework is key to support swimming at that stage.
While confirming these observations at 3 dpf, our results show that strychnine completely disrupts the 20 Hz rhythm in 4 to 5 dpf fish whereas the other tested drugs had little to no effects on the rhythm. This suggests that in later developmental stages glycine plays an essential role in rhythm generation.
Furthermore, we developed a model testing the idea the possibility that maturation of swimming arises from a transition from electrical towards chemical network. The results support that even if the electrical framework is still present and required early in development, it is no more sufficient to sustained swimming in 5 dpf larvae.
Therefore, our findings support the idea of an operational shift that coincides with the transition of larval zebrafish from burst swimming to « beat-and-glide » swimming, a more mature form of swimming.

**Title:** Critical role of En1-positive neurons for silencing slow-component neurons during fast swimming in zebrafish

**Authors: *S.-I. HIGASHIJIMA**, Y. KIMURA
Okazaki Inst. for Integrative Biosci., Okazaki-Shi, Japan

**Abstract:** Spinal neuronal circuits can produce different speeds of locomotion. It is known that some of neurons are only active during fast movements, while others are only active during slow movements. However, neuronal mechanisms how this switching is achieved are not well understood. Here, we show that V1 spinal neurons (inhibitory neurons that express En1 transcription factor) play a critical role for this in larval zebrafish. We generated transgenic

zebrafish in which En1 neurons in the spinal cord are genetically-ablated by the expression of diphtheria toxin A (DTA). These fish show defects in recruitment patterns of neurons: not only fast-component of neurons but also slow-component neurons were co-activated under the condition when wild-type fish would exhibit fast swimming. These results indicate V1 spinal neurons play a critical role for silencing slow-component neurons during fast swimming in zebrafish.

**Title:** Combining approaches for mapping connectivity and identifying cell types in the vertebrate spinal cord

**Authors: *A. S. DUMITRESCU**, C. DELEUZE, J. ROUSSEL, M. WU, C. WYART
Inst. Du Cerveau Et De La Moelle Epinière, Paris, France

**Abstract:** In the last decade the genetic identification of classes of spinal interneurons has enabled the investigation of circuits upstream of motor neurons (MNs). Of these, V2a excitatory premotor interneurons are a potential key spinal network nexus, as they span both the hindbrain and spinal cord and make direct connections onto MNs. Interestingly, recruitment of V2a neurons is speed-dependent, suggesting these interneurons could contribute to setting locomotor speed. During fast locomotion the dorsal most V2a neurons are activated, while the ventral cells are actively inhibited similar to what has been reported for motor neurons.
Currently a lot less is known about the connectivity patterns between V2a cells and MNs. Past studies tackled this question by performing challenging electrophysiological recordings from pairs of V2as and MNs, which seem to suggest a one to one mapping in terms of 'speed preference' (i.e. a 'fast' V2a – 'fast' MN etc). However, there are several possible speed-dependent network configurations within the premotor pool in terms of divergence (a single V2a neuron *can* project onto multiple motor neurons), and convergence (multiple V2a neurons *can* project onto single motor neurons). Here, we aim to increase the present V2a-MN connectivity map resolution from pairs of cells to small-scale networks (tens of cells) and eventually the full population. We will take advantage of the transparency of the zebrafish larva to implement a

comprehensive approach combining in vivo electrophysiology, state-of-the-art 3D optical stimulation of genetically targeted cells using holography and functional calcium imaging to resolve the connectivity map of V2a neurons. Our first technical challenge is to find efficient opsin actuators or inhibitors of neuronal activity in an *in vivo* zebrafish spinal cord preparation. We are currently screening the following opsins: ChR2, Chrimson, Chronos, CoChR, Halorhodopsin, ChloC, and Arch, by performing *in vivo* electrophysiological recordings of optogenetically stimulated MNs.
In parallel, we are addressing the question of V2a cell heterogeneity – which has important implications considering the potential functional differences between dorsal and ventral cells in mediating fast vs slow locomotor speeds. To this end we are performing a transcriptome analysis on V2a cell populations from larval zebrafish purified via fluorescence-activated cell sorting. Altogether these complimentary approaches should lead us to discover new ways of targeting V2a sub-populations and decipher their function and connectivity patterns in the motor pool.

**Title:** Neural mechanisms for intra- and intersegmental coupling between CPGs in an insect walking system

**Authors: C. MANTZIARIS**[1], T. BOCKEMUEHL[1], A. BORGMANN[1], S. DAUN[2], *A. BUSCHGES[1]
[1]Biocenter Cologne, Univ. of Cologne, Koeln, Germany; [2]Res. Ctr. Juelich, Inst. of Neurosci. and Med. (INM-3), 52425 Juelich, Germany

**Abstract:** In the stick insect *Carausius morosus*, segmental central pattern generating networks (CPGs) contribute to the motor output of the muscles controlling individual leg joints. Intra- and intersegmental coordination of leg stepping is mediated by both neural (i.e., sensory and central) as well as mechanical influences affecting CPGs. Information about the potential contribution of central neural influences to the intersegmental interaction between segmental CPGs still remains elusive (Borgmann and Bueschges, 2015, COIN).
Here, we investigated central interactions between ipsi- and contralateral segmental CPGs that control motor output of the muscles that move the coxa-trochanter (CTr) leg joint. We recorded

the activity of motor neurons (MNs) innervating the depressor trochanteris muscles in all three isolated or interconnected thoracic ganglia. Rhythmic activity in leg MN pools was induced by application of the muscarinic acetylcholine receptor agonist pilocarpine (Bueschges et al. 1995, J Exp Biol). Potential CPG coupling interactions were determined using either phase analysis of the evoked rhythmicity or correlation of contralateral depressor spike activity.
Our results reveal weak intrasegmental coupling between hemisegmental CTr-CPGs. Contralateral CPGs exhibit specific and variable phase relationships in each isolated thoracic ganglion (i.e., anti-phase in the meta-, in-phase in the meso- and no coupling in the prothoracic ganglion). However, in interconnected ganglia, CPGs show a clear tendency for inter- and intrasegmental in-phase activity. Currently, we are studying the network mechanisms that contribute to CPG coupling. For this, we analyze premotor interneuron and MN activity in hemisegmental CPGs by means of intracellular recordings after lesioning commissural tracts between hemisegments.

**Title:** Heterogeneity of V2b premotor neurons in zebrafish spinal cord

**Authors: *R. CALLAHAN**[1], Y. KIMURA[2], S.-I. HIGASHIJIMA[3], M. BAGNALL[1]
[1]Neurosci., Washington Univ. In St. Louis, Saint Louis, MO; [2]Natl. Inst. Natl. Sci., Okazaki, Japan; [3]Ctr. for Integrative Biosci., Okazaki, Japan

**Abstract:** Precise body movements necessitate the coordination of diverse motor pools, which are governed by premotor circuits consisting of different classes of excitatory and inhibitory spinal cord interneurons. The V2b (GATA3+) premotor population, which provides ipsilateral inhibition to motor neurons, has been implicated in regulating flexor-extensor alternation in mouse, positioning it as a key component in the coordination of motor pools (Britz et al. 2015; Zhang et al. 2014). However, to date no study has comprehensively described the anatomy, physiology, connectivity, or functional activity of V2b neurons. We have leveraged the genetic

tractability, transparent skin, and spinal cord accessibility in zebrafish larvae to study the basic anatomy and diversity of V2b neurons identified in GATA3:Lox-RFP-Lox:GFP or GATA3:Gal4; UAS:GFP transgenic animals. All V2b neurons project their axons exclusively ipsilaterally and caudally, though with few ascending collaterals, in contrast with the V2a population (Menelaou et al. 2014). Axon projections exhibit heterogeneity in their dorsoventral trajectories. In contrast with mouse, where the majority of V2b neurons co-express GABAergic and glycinergic markers, the V2b population in zebrafish expresses the glycinergic marker GlyT2 in cell bodies located in the dorsal portion of the cord, whereas the GABAergic marker Gad1b is expressed in more ventrally located V2b neurons. We employed functional imaging to monitor the activity of V2b neurons during locomotion, pairing light sheet microscope imaging of calcium transients in GATA3:Gal4; UAS:GCaMP6f animals with ventral root physiology. Our findings reveal that while general recruitment of V2b neurons is coincident with a swim event, the timing of calcium peaks in relation to the swim bout varies. The anatomical and functional diversity observed in the V2b population suggests the presence of multiple distinct subpopulations, in keeping with recent lines of evidence that each genetically defined spinal population comprises discrete subpopulations (e.g., Menelaou et al 2014; Bikoff et al. 2016; Dyck et al. 2012). Overall these data indicate a more complex vertebrate premotor circuitry than has been previously appreciated.

**Title:** Establishment of a theory on target neural regeneration guided by dorsal root stumps for repairing complete spinal cord transection in adult animals

**Authors: *S. LIN**, T. ZHAO, T. TANG, J. GAO, S. YANG, X. ZHANG, F. KONG, X. LIN, Z. YONG, J. MA, X. WENG, S. JING, S. LIU

**Abstract:** It is well known that dorsal root nerve fibers enter the posterior horn of spinal cord and innervate interneurons of central pattern generation in grey matter. If intercostal nerves or graft nerves delivering signals from supraspinal structures are anatomized to the proximal stumps of dorsal root, the residual myelin or neurolemma of nerve fibers in dorsal root might guide the

regenerating nerve fibers to grow into lower spinal cord, and form synapses with the interneurons that the dorsal root nerve originally innervate. Thus, a novel hypothesis that target neural regeneration guided by proximal stump of dorsal root nerve for repairing spinal cord injury was put forwarded based on the neural anatomy, the neuropathology and the motor neural circuits.
To verify the hypothesis, TRDA and FDA were microinjected either into L4 dorsal root and corticospinal tract, or rubrospinal tract and L4 dorsal root, or into L3 and L4 dorsal roots. Varicosities of different origins were observed to co-contact with various neurons in the gray matter of L3-L4 segments of spinal cord. Furthermore, six months after T11 intercostal nerve-L3 dorsal root anastomosis, TRDA and FDA were microinjected into the T11 intercostal nerve and L4 dorsal root, and the same triple labeled images in L3- L4 cord levels have been detected. The results showed that T11 intercostal nerve-L3 dorsal root anastomosis could reconstruct the connections of the upper and the lower spinal cords.
T11 intercostal nerves-L3 dorsal root stumps anastomosis were performed immediately or lingeringly for repairing lower thoracic spinal cord complete transection in rats, and the anastomosis sites were treated with neurotrophin/growth
factor cocktail. Following the surgery, partial hind limb locomotion recovered gradually. Six months after target repairing, mean BBB scale of hind limb was 14.75±2.10. Regenerative fibers from T11 intercostal nerves were traced to grow into L3 dorsal root stumps and posterior horn, eventually contact with neurons in the gray matter of the spinal cords between L2 and L4. Electrostimulation of the bridged nerves could trigger evoked potentials in sciatic nerve, bladder and colon, and cause locomotion of hind limbs. When the bridged nerves were transected, the evoked potentials and hind limbs locomotion disappeared. Two months after intercostal nerve-lumber dorsal root anastomosis, the hind limbs of the adult monkeys accepted spinal cord complete transection could also move autonomously.
The evidences indicate that the theory on target neural regeneration guided by dorsal nerve root is potentially applicable for repairing the complete functional loss of spinal cord injury in clinical practice.

**Abstract:** TBI-induced spasticity and chronic pain/headache are major health issues in both military and civilian personnel. The objective of this current work is to test the effectiveness of two individual treatments, Electro-acupuncture (EA) and pregabalin (Lyrica) in TBI-induced spasticity and pain-like behaviors in a clinically relevant rodent model of closed head traumatic brain injury (cTBI). In this model we have shown comprehensive evidence of progressive and enduring spasticity (Bose et al., 2013; Hou et al., 2017), and orofacial and somatic allodynia, a hypersensitive pain response induced by non-painful stimulation (Mustafa et al., 2016, 2017). Pregabalin (225ul orally, twice daily for 4 weeks), and EA stimulations were applied immediately after TBI in two separate cohorts of TBI animals as preemptive acute treatments. Six 30 minute sessions of EA stimulation were performed over 2 weeks at 6 acupuncture points using continuous 10 Hz stimulation at an intensity of 3 mA. The velocity-dependent ankle torques, time-locked triceps surae EMGs, H-Reflex testing, and a reward-conflict operant testing paradigm were applied to test spasticity and orofacial allodynia, respectively. In the later paradigm, the rat may choose to access a sweetened milk reward through facial contact with a mildly nociceptive thermal stimulation. The Orofacial Pain Assessment Device (Stoelting, Co) provides a peltier contact window whose temperature can be heated to mildly aversive temperatures. We used a standard hot plate peltier device to test plantar paw lick latencies at 37 - 46 deg C. The cTBI animals showed significant decreases in reward and also plantar lick latency to thermal heat test stimuli, hallmark behaviors for facial and somatic allodynias. Our data to date indicate that animals receiving either treatment exhibited a significant reduction in orofacial and somatic allodynia. In addition, animal receiving either treatment showed significant improvement in physiological indices of spasticity compared to untreated injured control animals. Studies in progress are assessing therapy-induced changes in a comprehensive array of biomarkers, molecules, and receptors related to spasticity and pain signaling and inflammation in the trigeminal and somatic pain pathways. Progressively, these studies may increase our understanding of the neurobiology of TBI-induced spasticity and pain, and the potential mechanisms of action of experimental therapies utilizing EA and pregabalin. The goal of these studies is to enhance the opportunity for the translation of safe and effective treatments for human TBI injury-induced spasticity and pain/headache conditions.

**Abstract:** Spasticity is a major health problem for patients with moderate to severe TBI. Progressively developing spasticity following TBI often represent one of the most significant barriers for practical re-entry of TBI patients into the community. The objective of this preclinical study was to evaluate the safety and efficacy of acute ITB treatments and treadmill locomotor training (Tm), individually and as combined therapy. We employed a comprehensive series of long-term quantitative outcome measures to compare new versus standard of care with ITB treatment following TBI, where this combination therapy appears to potentially represent a paradigm shift in rehabilitation therapy. In these studies ITB (Lioresal® baclofen injection; 0.8µg/hr) and Tm were initiated at one week after injury in a clinically relevant rodent TBI model where we observed enduring spasticity, balance, anxiety and cognitive deficits (Bose et al. 2013; Hou et al. 2017) (Marmarou model; 450g/1.5 m). Spasticity, anxiety-like behavior, balance, cognitive, and home cage activity performances were measured using velocity-dependent ankle torque, an elevated plus maze (EPM), rotorod, Morris water maze (MWM), and Noldus Phenotyper, respectively. One month of ITB and Tm combined treatment completely blocked early onset spasticity and also positive impacts on cognitive, balance, anxiety and activity recoveries. More importantly, this significant therapeutic benefit persisted even after cessation of ITB therapy. The combined therapy group exhibited significantly reduced MWM latency at the fourth day of testing, and significantly less anxiety-like behavior in the EPM. Twelve hour video-tracked activity monitoring data (recorded 6pm - 6am) revealed that compared with non-treated TBI animals, the ITB+Tm group exhibited home caged behavioral

patterns that were most similar to normal animals. These observations indicated that initiating ITB in combination with a Tm produced a robust rehabilitation that was more effective than either therapy implemented individually. This improved spasticity outcome was accompanied by marked up-regulation of GABA/$GABA_b$, norepinephrine and BDNF expression in the spinal cord tissue. These data will be compared and discussed with a data set derived from another study where ITB treatment alone initiated at a chronic time point (post-TBI 1 month) showed less attenuation of spasticity, and it adversely affected balance performance. These broad spectrum of comprehensive data may reinforce confidence in the safety, feasibility, and efficacy of early intervention ITB treatments for TBI using with locomotor and ITB therapy for TBI-spasticity.

**Title:** Simultaneous application of treadmill locomotor exercise and magnetic stimulation improved cervical spinal cord injury (C-SCI)-induced spasticity and gait disabilities in acute and chronic setting

**Authors: *J. HOU**[1,2], R. NELSON[1], N. MOHAMMAD[1], J. WATTS[1], G. MUSTAFA[1,2], S. TSUDA[1,2], F. J. THOMPSON[1,2,3], P. BOSE[1,2,4]
[1]Brain Rehabil. Res. Ctr. of Excellence, North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Neurosci., [4]Neurol., Univ. of Florida, Gainesville, FL

**Abstract:** Cervical spinal cord injury (C-SCI) is a common and frequently devastating injury that can result in a broad range of life-long locomotor impairments, including spasticity and gait disabilities. We recently reported that a serial combination of treadmill locomotor exercise (Tm) with SCI-site magnetic stimulation yielded significant improvement in spasticity and gait (Hou et al., 2014). In order to potentially improve the efficacy of the therapy, here, we evaluated the therapeutic effects of simultaneous application of Tm with injury-site magnetic stimulation

initiated at post-injury (pi) acute and chronic time points. Moderate $C_{6/7}$ contusion injuries (200 kdynes, Infinity Horizon Impactor) were produced in 30 anesthetized adult Sprague-Dawley rats (randomly selected; acute group, n=20; chronic group, n=10). In the acute group, Tm was initiated at pi-day 8, for 5 days each week. Beginning at pi day-14, magnetic stimulation was applied at the injury site simultaneously with Tm, every other day, for 6 weeks. We used a single pulse protocol that we have recently reported (Hou et al., 2014). For the chronic simultaneous treatment group, five rats initiated Tm and magnetic stimulation at pi week-8 and continued for six weeks using the above mentioned treatment regimen. As a measure of spasticity, velocity-dependent ankle torques, and time-locked triceps surae EMGs were recorded at pi week-4 and week-8 for the acute group, and at pi week-8 and week-14 for the chronic group. In the acute group, six weeks of treatments completely blocked the development of spasticity when compared to data obtained from untreated injured controls. However, spasticity was significantly reduced but not completely blocked in the chronic treatment group. To potentially probe mechanisms associated with the therapeutic benefits, to date we have performed immunohistochemistry of the lumbar spinal tissue for the acute group. These results showed robust treatment-induced up-regulation of dopamine beta-hydroxylase, gamma-aminobutyric acid receptor and glutamate decarboxylase. To date, our data suggest that simultaneous application of Tm locomotor exercise and magnetic stimulation at the cervical injury site can be an effective treatment for C-SCI induced spasticity, with acute treatment showing greater efficacy than the chronic treatment. Potential mechanisms of the therapeutic benefits point towards enhancing the descending modulation of presynaptic and postsynaptic factors (noradrenergic and the GABAergic) that regulate motoneuron excitability.

**Title:** Effects of locomotor training intensity on sympathetic-somatomotor coupling in spinal cord injury

**Authors: *T. ONUSHKO**[1], G. MAHTANI[2], T. G. HORNBY[3], B. D. SCHMIT[4]
[1]Biomed. Engin., Marquette Univ., Milwaukee, WI; [2]Stanford Univ., Stanford, CA; [3]Dept. of Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL; [4]Dept. of Biomed. Engin., Marquette Univ. Dept. of Biomed. Engin., Milwaukee, WI

**Abstract:** In people with spinal cord injury (SCI), impaired connectivity between supraspinal and spinal segments below the injury impairs the sympathetic and somatomotor nervous system below the level of the injury. Proper coupling between the systems allows normal physiologic responses during exercise, in which sympathetic and somatomotor systems work together to regulate cardiovascular responses. However, after SCI, improper sympathetic-somatomotor coupling can have deleterious effects during exercise and limit rehabilitation outcomes. The purpose of this study was to understand how locomotor treadmill training affects sympathetic-somatomotor coupling in people with incomplete SCI. Thirteen people (49.8 ± 7.2 years) with motor incomplete spinal cord injuries (ASIA C or D; injury level > T6) participated in a locomotor treadmill training program. Patients were randomized into either a high-intensity (HT; 70-85% of maximum predicted heart rate) group or a low-intensity (LT; 50-65% of maximum predicted heart rate) group, and completed locomotor training over 4-6 weeks, 3-5 days/week. Prior to and following training, we tested sympathetic-somatomotor coupling by eliciting reflexive sympathetic activity via a cold stimulation, noxious stimulation and a mental math task while we measured tendon reflexes, blood pressure and heart rate. We found that patients with incomplete spinal injuries who completed the high-intensity locomotor training protocol exhibited reduced stretch reflex excitability during elevated sympathetic activity. We also observed a trend of increased mean arterial pressure in the HT group compared to the LT group. These results suggest that high-intensity locomotor training may be advantageous to low-intensity training to improve sympathetic-somatomotor coupling in people with incomplete SCI.

**Title:** Epidural stimulation and pharmacological blockade of fast inhibition improve respiratory pacing following complete spinal cord injury

**Authors: *V. MARCHENKO**, T. BEZDUDNAYA, M. A. LANE
Dept Neurobiology/Anatomy, Drexel Univ. Col. of Med., Philadelphia, PA

**Abstract:** The use of epidural stimulation (ES) in patients with spinal cord injury (SCI) has gained increased media attention in the past decade with significant success demonstrated in human studies, including improvement of lower limb motor function in paraplegic patients.

DiMarco, Kowalski and colleagues were first to investigate ES applied to T1-T2 ventral surfaces to restore respiratory function following high cervical spinal cord transection. In the current study we combine ES (at C3-C5 segments corresponding to area of phrenic motor pool) and pharmacological strategies (blocking of GABAa and Glycine inhibitory receptors) for more specific activation of spinal interneurons and motoneurons involved in the shaping of respiratory motor output following C1 transection (C1Tx). All experiments were performed in decerebrate, unanesthetized adult Sprague-Dawley rats, 5-6 h post C1Tx. ES was applied to ventrolateral surface of C3-C5 cervical segments bilaterally via teflon-coated silver (0.01'' bare and 0.013'' coated, AM-Systems) stimulating electrodes (0.2 ms biphasic stimulation, 100-200 Hz during 0.3 s, one train per sec). Prior to pacing procedure, the minimal thresholds (Tr) of current (87.4±10.3 for C3, 73.6±8.2 for C4 and 84.7±8.2 mkA for C5 segments) affecting tracheal flow and end-tidal CO2 level were detected. ES applied to the C4 level (~ 5 Tr, 350.7±41.2 mkA) produced non-fatigue contraction of chest and diaphragm muscles with stable tracheal flow (2.3±0.21 ml of tidal volume) and end-tidal CO2 (4.5±0.3 %) during 1 h. In contrast, ES applied to C3 or C5 segments required much higher current (~ 7 Tr, 633.8±84.5 mkA) with development of muscle fatigue in 5 out of 8 rats. Ten minutes after intrathecal administration of 30 mkl (25 mkMol) of GABAzine and strychnine (blockers of GABAa and glycine inhibitory receptors, respectively) the minimal thresholds were significantly decreased for all segments (62±7.9 for C3, 41.1±6.4 for C4 and 67.9±7.3 mkA for C5). The tidal volume was increased by 43% (3.3±0.27 ml) during C4 pacing and fatigue of respiratory muscles was observed in 2 out of 8 rats during ES of C3 or C4 segments. Based on our results, we conclude that spinal respiratory circuits are tonically inhibited after C1Tx and their pharmacological modulation has the potential to improve ES in patients with SCI.

**Title:** Development of a novel automated device for the assessment and training of skilled locomotion in spinal cord injured rats

**Authors: *T. RICHARDS**[1], P. SHARMA[2], A. KUANG[3], P. K. SHAH[1,2]
[1]Neurobio. and Behavior, [2]Dept. of Physical Therapy, [3]Undergraduate Biol., Stony Brook Univ., Stony Brook, NY

**Abstract:** Although cervical spinal cord injuries (cSCI) account for more than 62% of all SCIs, much less is known about the skilled locomotor recovery of the forelimb and hindlimb following a cSCI. Skilled locomotion is commonly assessed using the horizontal ladder task. However, the non-uniform speed of rats on the horizontal ladder introduces a great source of variability in speed and completion time of the task. Moreover, fine impairments in motor function are compensated by variable walking speeds across the ladder as most rats are unable to complete the task uninterrupted, especially after CNS damage. To overcome limitations posed by the horizontal ladder, in the present work, we have developed a novel Automated Device for the Assessment and Training of Skilled locomotion (ADATS) for adult rats. ADATS is a custom-built device consisting of two circular shaped Plexiglas walls joined together by metal rungs unevenly spaced around the edges. Powered by an integrated step motor, the ADATS rotates in the clockwise or anticlockwise directions at a predetermined tester defined speed, thereby forcing the rats to step at a constant speed. Our rationale is that since motor compensation by speed is eliminated, motor impairments, if any, can be easily discerned. ADATS is also equipped with cables that can facilitate the recording of EMG data to visually display the functional state of the spinal cord. Herein, we validate ADATS as a tool for assessing functional motor recovery of the forelimbs and hindlimbs in ten adult rats subjected to a cervical dorsal crush injury at C4. Skilled locomotor behavior was assessed both on the ADATS as well as on the horizontal ladder using a standard 7-point skilled locomotor scale at multiple time points for ten weeks. We used high resolution video (60 fps) for frame by frame qualitative and quantitative analysis of step placement on the rungs. Our findings demonstrate that there is wide speed variability between and within trials when rats are tested on the horizontal ladder. In contrast, rats tested on ADATS display uniform walking speeds on ADATS as predetermined by the tester. Furthermore, after a cSCI, limb placement errors on ADATS are highly comparable with that of the horizontal ladder at lower speeds. Additionally, at higher speeds on ADATS, the extent of limb placement errors significantly increases. Importantly, ADATS also reveals gross and subtle motor deficits that are undetected by the horizontal ladder. These data are unique and validate the use of ADATS as a sensitive skilled locomotor assessment tool for pre-clinical experimentation.

**Title:** ADATS (automated device for the assessment and training of skilled locomotion) in action: Assessment and training of inter-limb coordination after a cervical spinal cord injury in rodents

**Authors: *P. D. SHARMA**[1], T. RICHARDS[2], A. KUANG[3], P. SHAH[1,2]
[1]Hlth. technology and management, [2]Neurobio. and Behaviour, [3]Stony Brook Univ., Stony Brook, NY

**Abstract:** The horizontal ladder has been used for decades to assess the skilled locomotor recovery following a spinal cord injury (SCI). One aspect that poses a threat to the validity of findings in which the horizontal ladder is used is the lack of speed control during task performance. Differences in walking speeds in rats between experimental trials result in different profiles of coordination. Rats with slower speeds can mask the true coordination deficits as they get more time to compensate for their motor deficits, and many of the subtle coordination deficits go unnoticed. This makes the quantitative interpretation of forelimb-hindlimb (FL-HL) recovery and inter-limb coordination (ILC) difficult. One potential approach of overcoming this confounding factor is to develop an assessment device that controls for the pace at which the rats walk during skilled locomotion. A novel device, ADATS (Automated Device for the Assessment and Training of Skilled locomotion) developed in our laboratory, adds varying degrees of complexities to skilled walking due to its speed control mechanism and ensures uniform speed during locomotion. The main objective of this study is to validate the use of ADATS in assessing ILC coordination following a SCI, and to explore the capacity of ADATS as a motor rehabilitative training tool. Adult rats received a dorsal crush injury at C4. ILC was assessed using seven end points of limb coordination. Training capabilities of ADATS were investigated using stepping patterns and limb engagement during task execution. Our preliminary data show that ADATS is able to capture coordination deficits in all seven end points of ILC to a greater extent than the horizontal ladder. Also, with the use of ADAPTS, rats exhibit an increased proportion of quadrupedal stepping pattern and engagement of forelimbs during skilled locomotion. Our findings also reveal, for the first time, that skilled locomotor deficits are chronically persistent even after mild cervical SCIs. Collectively, these findings suggest that use of currently available tools such as the horizontal ladder alone may not be sufficient if fine motor skills or subtle effects of interventions are to be assessed accurately after SCIs. The sensitivity, accuracy, and consistency with which data are obtained using ADATS provides a strong rationale for using it as a standardized assessment system to assess ILC deficits after a SCI. In addition, ADATS can also function as a forced therapeutic tool because rats are compelled to engage their forelimbs and hindlimbs during walking to keep up with the demanding speeds of ADATS.

**Title:** Consistencies and disparities in supraspinal and spinal neuronal mechanisms dictate the extent of commonalities in forelimb locomotion behaviors

**Authors: *M. ISLAM**[1], T. PENG[1], P. SHAH[2]
[2]Physical Therapy, [1]Stony Brook Univ., Stony Brook, NY

**Abstract:** Treadmill and ladder walking tasks have been used routinely to assess functional motor recovery after neurological dysfunction in rodents. Our preliminary data presented earlier showed that common neuronal drive regulates rhythmic treadmill (TM), overground (OG) and ladder (LAD) walking behaviors in awake adult rats. In this work we expand on those findings and ask to what extent OG, TM, and LAD walking tasks share commonalities of neuronal input. Specifically, our aims are: i) to determine commonalities in EMG activation patterns, motor unit (MU) recruitment and firing rate of treadmill slow (TMS: 13cm/s), fast (TMF: 21cm/s), LAD and OG walking tasks ii) to determine commonalities of neural input in TM and LAD walking tasks in relationship to OG walking. 8 adult rats were implanted with EMG electrodes in 4 muscles: deltoid (DEL), bicep (BB), flexor digitorum superficialis (FDS), and extensor digitorum (ED). Raw EMG bursts of each muscle (> 50 bursts) were filtered, rectified, and normalized to step cycle durations to obtain EMG activation patterns. Also, a 2s processed-EMG signal from each forelimb muscle for each task was extracted to quantify the mean rectified value (MRV: the extent of MU recruitment) and mean power frequency (MPF: rate of MU firing) for categorical cluster analysis. These EMG segments were also used for coherence analysis to determine sources of common neural input between tasks. Our results demonstrate that EMG activation patterns are similar for both proximal (DEL and BB) and distal (FDS and ED) muscles between tasks, except for LAD where FDS muscle has distinct timing of activity. Cluster analysis grouped MRV into 2 clusters: C1 and C2, consisting of OG, TMS, and TMF, and LAD walking, reflecting commonality in recruitment of MU between tasks, except for the LAD. MPF features were grouped into 3 clusters: C1 for OG and TMS, C2 for TMF, and C3 for LAD walking. MPF clusters demonstrated a sizable overlap that suggests commonality in firing of MU between three tasks. Coherence analysis showed significant peaks in almost all cases suggesting the presence of common neural input (supraspinal & spinal) between tasks. The number of these significant peaks were 3-8 in the entire frequency range (1-100 Hz), which suggests diverse sources of neural input between behaviors. Notably, the dominant frequency at

which peak coherence occurs ranged from 11.6-29 Hz across the tasks and muscles used, which indicated that these tasks are dominated by various cortical structures including motor cortical inputs that range from 10-30 Hz. Our results are novel and suggest the presence of common spinal and supraspinal inputs in the rhythmic forelimb locomotor tasks in adult rats.

**Title:** Selective excitation of large diameter sensory afferents with DREADDs enhances functional recovery post-spinal cord injury

**Authors: *B. D. ROBERTSON**[1], G. M. SMITH[2], M. A. LEMAY[4], A. SPENCE[3]

**Abstract:** *Motivation*: It has been demonstrated that sub-threshold epidural stimulation of the lumbar spine can allow voluntary body-weight support, stepping, and leg movement in cases of chronic spinal cord injury (SCI). These studies used electrical stimulation thought to only excite large diameter sensory afferent (LDSA) neurons, but may have had off-target effects (e.g. excitation of pain pathways, known to inhibit motor learning). We sought to develop an alternative approach to excitation of LDSA using designer receptors exclusively activated by designer drugs (DREADDs). DREADDs facilitate genetically targeted neuromodulation, and do not require implantation of stimulating hardware or tethering. They also allow mapping of cells affected by DREADDs and their second order connections.
*Background:* DREADDs are a modified human muscarinic receptors that respond to the drug clozapine-N oxide (CNO) and that can excite or inhibit neurons via G-protein pathways on the hour time-scale. We have previously modulated H-reflex excitability using virally expressed DREADDs in intact rats, and here extend this approach for SCI rehabilitation. We hypothesized that use of DREADDs throughout SCI recovery would result in fewer incidences of foot drag and a more extended limb posture post-SCI during over-ground gait.
*Methods:* One month prior to SCI, five female Sprague-Dawley rats were exposed to a viral vector designed to express the excitatory DREADD hM3Dq (AAV2-hSyn-hM3Dq-mCherry). DREADDs were confined to LDSA of dorsal root ganglia (DRG) L2-L4 through a combination of surgical (direct DRG injection) and viral (2-4µl of AAV2 at 5 X $10^{12}$ MOI) approaches. Two

weeks after viral infusion, animals were trained to walk on a treadmill in 5 minute bouts at 5 fixed speeds (16-32 cm/s in 4cm/s increments) interleaved with a 1 minute rest period. This was done three times a week for 2 weeks, after which we performed a T9-T10 hemisection. Following a one week recovery period, animals received 6 additional weeks of training at the same speeds and duration used pre-SCI, with CNO administration (2mg/kg) 30 minutes prior to the start of training. SCI control subjects (n=5) received the same treadmill training pre-SCI and post-SCI without virus exposure or CNO administration. We collected kinematic data pre-SCI, during initial training post-SCI, and every two weeks post-SCI at all 5 speeds.
*Results:* Preliminary analysis of these data show a significant reduction in rate of foot-drags by 48% for DREADDs animals compared to SCI controls, at six weeks post injury, at a walking speed of 20 cm/s (linear mixed effects model; p=0.043, n=5 rats). Further analysis of kinematic and foot drag data is ongoing.

**Title:** Inflammatory nociception attenuates training induced locomotor recovery after spinal cord injury by altering KCC2 expression

**Authors: *R. JEFFREY-GAUTHIER**[1], M.-P. COTE[2], M. PICHE[3], H. LEBLOND[4]
[1]Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada; [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [3]Dept. de Chiropratique, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada; [4]Anatomie, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

**Abstract:** Following spinal cord injury (SCI), neuroplasticity in spinal network contributes to motor recovery but also to hyperreflexia, spasticity and neuropathic pain development. Activity-dependent therapies such as locomotor training foster functional recovery. However, its extent can be critically limited by the presence of acute and chronic pain. It was recently shown that training positively influences recovery by increasing the expression of the chloride cotransporter KCC2 in lumbar motoneurons suggesting a restoration of inhibitory GABAergic and glycinergic transmission. In complete SCI mice, we showed that inflammatory nociception from complete Freund adjuvant (CFA) injection in sublesional back muscles attenuates training's positive

impact on locomotion without affecting the H-reflex frequency-dependent depression (FDD) recovery. The purpose of this study was to evaluate if CFA injection decreases locomotor recovery by preventing the activity-dependent increase in KCC2 levels associated with training. Four groups of CD1 female mice composed of control spinal mice (n=8), trained spinal mice (n=7), spinal mice with CFA (n=7) and trained spinal mice with CFA (n=6) were completely transected at T7. Hindlimb treadmill locomotion was assessed prior to SCI and on day 7, 14, 21 and 28 post-SCI. In a terminal experiment, the animals were decerebrated and H-reflex, elicited by tibial nerve stimulation, was evaluated at different frequencies (0.2, 5, 10, 0.2 Hz) to assess the FDD. The spinal cord were harvested and lumbar levels of KCC2 measured by Western blotting and compared with immunohistochemistry visualization of KCC2 staining in lumbar spinal cord sections. Additionally, phospho-p38 expression was measured as a marker of neuroinflammation associated with CFA injection. Our results show that CFA injections prevented the restoration of KCC2 expression levels in the lumbar spinal cord. Decreased KCC2 expression was associated with decreased knee angular excursion, increased paw drag and impaired H-reflex depression at 5 Hz and 10 Hz compared to baseline. Similarly, increased levels of phospho-p38 was associated with decreased knee angular excursion, increased paw drag and decreased reflex depression at 5 Hz and 10 Hz. This study suggests a potentially relevant mechanism on the interplay between training and inflammatory nociception and his highly relevant to most SCI individuals that present concurrent musculoskeletal tissue damage.

**Title:** Enhancing chloride extrusion restores reflex modulation after spinal cord injury

**Authors: *J. BILCHAK STROUGHAIR**, M.-P. COTE
Neurobio. and Anat., Drexel Univ., Philadelphia, PA

**Abstract:** Over 75% of spinal cord injured (SCI) individuals experience spasticity with incapacitating symptoms ranging from increased muscle tone to involuntary movements and hyperactive reflexes. We have previously reported that hyperreflexia is attenuated by exercise after SCI through an increase in KCC2 expression in lumbar motoneurons (Côté et al., 2014).

The expression of the chloride cotransporters KCC2 (extruder) and NKCC1 (intruder) largely determine the intracellular concentration of chloride ($[Cl^-]_i$) which in turn significantly affect postsynaptic inhibition through $GABA_A$ and glycine receptors. Consequently, a disruption in chloride homeostasis contributes to several neurological disorders including hyperalgesia, chronic pain, epilepsy and motor spasticity.

Although exercise has the potential to restore chloride homeostasis after SCI, early post-injury implementation of a rehabilitation programs in the clinic is often problematic. Here, we sought to determine if pharmacologically increasing KCC2 expression/activity improves reflex recovery after SCI. We also assess if it has the potential to further enhance activity-dependent recovery. Restoring chloride homeostasis will be achieved using CLP257, a chloride extrusion enhancer, which rescues KCC2 plasma membrane expression and has been shown to successfully alleviate hypersensitivity in models of neuropathic pain (Gagnon et al., 2013).

Adult female Sprague Dawley rats underwent a complete transection (T12) and were assigned to one of 3 groups: 1) untrained, 2) bike-trained or 3) step-trained. During a terminal experiment (4-8 weeks post-SCI), H-reflexes were evoked by the stimulation of the tibial nerve and recorded in the interosseous muscles. Hyperreflexia was estimated by measuring the frequency-dependent depression of the H-reflex (FDD) before and after CLP257 (100uM) was directly applied to the lumbar enlargement of the spinal cord. Spasticity was also assessed using quick stretches of the triceps surae using a dual-mode muscle lever. Our results indicate that CLP257 restores FDD in untrained animals but did not affect trained animals that had already recovered FDD through a rehabilitation program. As expected, the normalization of the FDD response was associated with a decreased $H_{max}/M_{max}$ ratio. Surprisingly, although CLP257 was without effect on the FDD, it significantly increased $H_{max}/M_{max}$ ratio, especially in step-trained animals. Our results suggest that pharmacologically targeting KCC2 activity has the potential to improve reflex recovery after SCI.

**Title:** How timing of rehabilitation after electrical stimulation on rats with chronic corticospinal tract injury effects augmentation of functional recovery

**Authors: *T. T. BETHEA**, J. SANTOS, H. PARK, A. SINDHURAKAR, J. CARMEL
Burke-Cornell Med. Res. Inst., White Plains, NY

**Abstract:** Rehabilitation is standard care after injury to the brain and spinal cord. As we look to incorporate therapies that promote nervous system repair into clinical practice, there is a gap in our understanding of how and when to combine restorative therapies into rehabilitation. Our laboratory has previously shown that electrical stimulation applied to the uninjured corticospinal tract after partial injury improves functional recovery and promotes axonal outgrowth in rats. The goal of our study is to determine the proper timing between electrical stimulation and rehabilitation. We hypothesize that electrical stimulation delivered two weeks before rehabilitation will be more effective than simultaneous application of the two therapies. Adult Sprague-Dawley female rats received a cut lesion of one corticospinal tract (pyramidotomy). Six weeks later, electrodes were implanted over motor cortex, and used to deliver 10 days of electrical stimulation, 6 hours a day, using our previously published protocol. Rats were randomized to receive rehabilitation during the stimulation period (30 minutes after stimulation) or 2 weeks later. To quantify forelimb skill, we used the knob task that measures supination, a critical component of forelimb dexterity that is impaired after corticospinal injury in both rats and humans. To quantify changes in corticospinal axon density, we anterogradely traced axons with biotinylated dextran amine and quantified axon length and distribution within the C6 segment of the spinal cord. Both groups of rats showed a strong and persistent impairment in forelimb supination at 6 weeks after injury. Early result show both groups make a large-scale and sustained recovery of supination with the onset around the time of rehabilitation. Anatomical analyses are ongoing and will be compared with behavioral recovery. Preliminarily, timing does not seem to be a critical variable for combining motor cortex stimulation and rehabilitation.

**Title:** NKCC1 contributes to exercise-dependent recovery of presynaptic inhibition after spinal cord injury

**Authors: *G. CARON**, B. DUFFY, M.-P. COTE
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

**Abstract:** After spinal cord injury (SCI), an initial state of motor depression is often followed by a state of hyper-excitability. The decreased ability to depress spinal reflexes is attributed to increased gain of afferent feedback, loss of descending inhibition and reduced spinal inhibitory mechanisms. Indirect evidence suggests that presynaptic inhibition is decreased in chronic SCI individuals and that it is ameliorated by activity-dependent rehabilitation therapies. However, direct evidence of this phenomenon and the associated mechanisms in chronic SCI animal models remains elusive. Normal CNS inhibition relies on the opening of $GABA_A$ and glycine receptor-gated chloride channels. Chloride homeostasis is largely determined by the relative expression of two chloride transporters: the outward-rectifying KCC2 and the inward-directed NKCC1. Contrary to other neurons, primary afferents lack KCC2 and NKCC1 maintain high $[Cl^-]_i$. Consequently, the opening of $GABA_A$ receptors produces a depolarization that is associated with presynaptic inhibition, a mechanism by which afferents feedback is inhibited in a highly selective manner. After SCI, chloride homeostasis is disrupted in the lumbar spinal cord and leads to increased neuronal excitability associated with spasticity and hyperalgesia. We have previously shown that exercise alters chloride cotransporter expression in lumbar motoneurons which contributes to motor recovery after SCI. However, a disruption in chloride homeostasis also has the potential to impact sensory processing. Here, we explore the role of a change in NKCC1 expression in primary afferents on the level of presynaptic inhibition after SCI and physical activity. Adult Sprague-Dawley females underwent a complete spinal transection and were assigned to a sedentary group or a step-trained group. During a terminal experiment, DRPs and plantar H-reflexes were evoked by stimulating the tibial nerve with or without a conditioning stimulation to PBSt. Our results suggest that step-training increases presynaptic inhibition after chronic SCI as measured by increased DRP amplitude and facilitation. This increase was greatly diminished by blocking NKCC1 with bumetanide. Western Blot analysis revealed a step-training-dependent increase in the expression of NKCC1 in dorsal root ganglion that is correlated

with the increased DRP amplitude and the recovery of presynaptic inhibition. Together, these results provide direct evidence that restoring chloride homeostasis in primary afferents has the potential to restore presynaptic inhibition and improve sensory processing after chronic SCI.

**Abstract:** Spinal cord injury (SCI) is a neurological deficit that impairs both motor and sensory pathways. In a recent work, we have demonstrated that long-term neurorehabilitation, integrating noninvasive brain-machine interfaces, tactile feedback and locomotion training with robotic gait trainer, lead to significant improvements in sensory and motor functions in patient diagnosed with complete paraplegia [1].
We present here a novel non-invasive neurorehabilitation protocol that combines brain-machine interfaces (BMI), functional electrical stimulation (FES) and tactile feedback. The protocol was tested with complete paraplegic patients (ASIA A/B) over a 12-month long training period. In a setup reproducing natural walking using a body weight support system device, the patients imagine moving their own legs to trigger the stimulation of their ipsilateral lower limb to

produce steps. As the sequence initiates, the patients receive tactile feedback on their forearm representing the swinging of the leg and the contact of the foot with the ground. Brain signals are recorded by 16 EEG electrodes centered over the legs sensory-motor area. Legs stimulation is applied through surface electrodes, mimicking synergic contractions of 16 lower limb muscles to reproduce a natural walking pattern. Tactile feedback is displayed on patients' forearm by means of arrays of vibrators.
Patients were able to control the BMI setup after a few training sessions. Using the BMI-FES setup they performed in average 70 steps per session; and a cumulated walking of up to 3000 steps per patient. We observed an increase in the travelled distance per session (from 25 to 55 m), as well as an important decrease in spasticity and muscle fatigue. As a result of the training, we observed neurological improvements below the SCI, and a significant increase in their functional walking (speed and cardiovascular conditioning).
Our work demonstrated the viability of a BMI-FES setup as rehabilitation tool for chronic complete paraplegics.

**Title:** Timing-dependent conditioning of deep dorsal horn neural circuits: Methodology for closed-loop control and implications for spinal cord injury-related neuropathic pain

**Authors: *J. G. MCPHERSON**
Biomed. Engin., Florida Intl. Univ., Miami, FL

**Abstract:** Spinal cord injury (SCI) results in altered neural activity in spinal sensory and motor circuits. Whereas activity-dependent reinforcement of inappropriate neural activity can lead to debilitating motor impairments and neuropathic pain, therapies that restore and reinforce natural, appropriate patterns of neural activity can significantly enhance recovery. Previous work has demonstrated that spinal motor circuits can undergo a type of activity-dependent plasticity that

resembles biphasic spike-timing-dependent plasticity (STDP). In STDP, the order and latency of firing between pre- and post-synaptic neurons determines whether synaptic output is potentiated or depressed. We have recently developed a pre-clinical intervention inspired by this phenomenon that uses intraspinal microstimulation (ISMS) to strengthen descending motor pathways that were spared by the SCI. We have shown that this approach can lead to substantial gains in motor rehabilitation that persist for weeks following discontinuation of stimulation. Because activity-dependent neural plasticity is also an integral component of pain processing, STDP-inspired approaches have a high potential to form the basis of neuromodulatory therapies for pain. In contrast to motor rehabilitation paradigms, we hypothesize that STDP-inspired depressive conditioning will be important for restoring and reinforcing natural neural activity in spinal sensory circuits. However, it remains unknown whether spinal sensory circuits can undergo timing-dependent changes in excitability.
Here, we present a closed-loop neural computer interface that can be used either to characterize basic timing-dependent properties of dorsal horn circuits or as the basis of a novel pre-clinical intervention for SCI-related neuropathic pain. All experiments were conducted in urethane anesthetized adult female Sprague-Dawley rats. We first show that salient non-noxious afferent activity can be discriminated in real-time from intramuscular EMG and used to trigger ISMS in deep dorsal horn circuits. We then show that noxious afferent activity can be discriminated in real-time from peripheral nerves and used as the ISMS trigger. Both triggers are important because the deep dorsal horn contains wide dynamic range neurons that process noxious and non-noxious inputs and are integral to the development and persistence of SCI-related neuropathic pain. By altering the latency and order in which ISMS is delivered relative to the arrival of the peripheral afferent volley, we use intraspinal recordings and spinal reflexes to systematically quantify conditioning mediated changes in neural excitability.

**Abstract:** In our previous studies in anesthetized rats, motor cortex and cervical spinal cord paired electrical stimulation augmented motor function through converging descending motor and sensory afferent inputs into the spinal cord. Cervical spinal stimulation is challenging in awake animals due to narrow epidural space and large neck movement. We developed softening polymer-based electrode arrays (Fig. B), which are thin, flexible, and durable. These electrodes are stiff at room temperature and become supple after implantation into epidural space. We hypothesized that these spinal electrodes would be safe and effective for paired electrical stimulation in awake rats over months. Three sets of electrodes were implanted (Fig. A): spinal array electrodes over dorsal C5-C6, screw electrodes over motor cortex, and EMG electrodes in biceps muscle. We tested electrode impedance and spinal cord stimulation intensity required to provoke a motor evoked potential (MEP) over 6 months or until electrode failure. The effects of paired stimulation were tested in two ways. First, to test immediate effects of paired stimulation, we compared motor cortex evoked MEPs with and without subthreshold spinal stimulation delivered 10ms later. Second, to assess lasting effects of paired stimulation, we paired repetitively for 5minutes and measured cortical MEPs and spinal excitability (spinal MEPs and H-reflex) before and after pairing. The spinal arrays take the shape of underlying spinal cord, as shown by MRI. Electrode impedance was stable up to 6 months, with small increases in spinal cord MEPs. Subthreshold spinal stimulation caused more than threefold increase in cortical MEPs compared to only motor cortex stimulation. Repetitive pairing caused strong augmentation of cortical responses and spinal excitability that lasted for more than an hour after 5 minutes of pairing. Both immediate and lasting effects of paired stimulation were observed to the 6 months. Thus, we conclude that paired stimulation is safe and effective for chronic stimulation and suitable for testing in motor recovery after CNS injury.

**Abstract: Background and aims:** Neuropathic pain after spinal cord injury (SCI) is a complex condition which responds poorly to usual medications. Cell transplantation represents a promising treatment for it; nevertheless, the ideal cell type in terms of neurogenic potential and effectiveness against pain remains largely controversial. Here, we evaluated the ability of fetal neural stem cells (fNSC) to relieve chronic pain, as well as to promote motor recovery in the SCI impactor model. **Methods:** Adult Wistar rats were submitted to traumatic SCI using the NYU Impactor (drop height 25mm) at 9-10$^{th}$ thoracic level after laminectomy. After 10 days, the spinal cord was re-exposed and the animals received four intra-spinal injections of culture medium (sham group) or fNSC extracted from telencephalic vesicle (TV group, GABAergic precursors) or ventral medulla (VM group, serotonergic/ noradrenergic precursors). Cells were extracted from E/14 embryos. Behavioral assessment was performed weekly during 8 weeks. All animals were immunosuppressed by daily intraperitoneal injections of cyclosporine (10mg/kg) and received prophylactic oral administration of antibiotics (Sulfadoxin and Trimethoprin). **Results:** Hot plate test showed improvement in thermal pain sensitivity of ≈47.5% in the TV group in relation to sham group ($p<0.05$) at the 7th and 8th week after transplantation and an improvement of 45.9% ($p<0.05$) and 59.3% ($p<0,01$) at the 7$^{th}$ and 8$^{th}$ week, respectively, of the VM group in relation to the sham group. Mechanical allodynia, as assessed by von Frey filaments, improved 52.1% in the TV group ($p<0.05$) and 49.8% in the VM group ($p<0.01$) at the

8th week. BBB test failed to show a significant motor improvement in either VM group (19% of improvement, p=0.27) and TV group (8.5% of improvement, p=0.69) comparing to sham. In the inclined plane test also no difference across groups was noticed (VM group p=0.25; TV group p=0.88). **Conclusions:** Neuronal precursors from the TV and VM, once implanted into the injured spinal cord, are both able to alleviate pain, but fail to induce any significant motor recovery.

**Title:** Upregulation of spinal 5HT1A receptor and its roles in bladder dysfunction after spinal cord injury

**Authors: *C.-Y. LIN**, K. LI, R. THALLURI, Y.-S. LEE
Neurosci, Cleveland Clin., Cleveland, OH

**Abstract:** Normal lower urinary tract function requires the coordination of detrusor and external urethral sphincter activity during bladder filling and micturition. Experimental studies in animals have demonstrated a dense innervation of serotonergic fibers and the involvement of multiple serotonergic receptors in the spinal reflex circuit for voiding function. Spinal cord injury (SCI) above the lumbosacral level often leads to dysfunction of the lower urinary tract, including detrusor hyperreflexia, wherein bladder compliance is low, high baseline pressures are increased, and filling is accompanied by numerous non-voiding contractions (NVCs) referred to as neurogenic detrusor overactivity. Here, we investigate the expression level of the 5HT1A receptor in the L6-S1 segment of spinal cord as well as the role of 5HT1A receptor in regulating micturition using pharmacological interventions after T8 complete SCI in rats. Adult female rats were divided into two groups: (1) Sham control (T8 laminectomy only) and (2) T8 complete spinal cord transection. The observation period was two months after the original SCI. In anatomical analyses, we identified significant up-regulation of 5HT1A receptor expression in both gray and white matter of the L6-S1 segment after complete SCI. These animals with higher intensity of 5HT1A receptor also showed a higher number of NVC activities. In pharmacological studies, application of a selective 5HT1A receptor agonist (8-OH-DPAT) caused a reduction of NVCs and these effects could be reversed by subsequent application of a selective 5HT1A receptor antagonist (WAY100635). Interestingly, application of WAY100635 alone also resulted in inhibitory effects on NVCs with a reduced number and decreased amplitude, but increased the interval of NVC. These inhibitory effects on NVCs can be reversed by subsequent application of a beta-adrenergic blocker (propranolol). In addition, WAY100365 treatment decreased the coordination of activities between external urethral sphincter and detrusor, but increased the bursting duration and interval of sphincter bursting activity during the voiding period. These data suggest that 8-OH-DPAT may activate certain 5HT1A receptors that are silent following a SCI. On the other hand, WAY 100635 may block the constitutive activities of 5HT1A receptors but activate the beta-adrenergic sympathetic pathway, which in turn relaxes bladder activity. Together, the neuroplasticity of 5HT1A receptors can be a potential therapeutic target for treatment of bladder dysfunction after SCI.

**Abstract:** Metabolic syndrome is a well-recognized risk factor for the development of cardiovascular disease, type 2 diabetes, and neurodegenerative conditions, but there is little information regarding its impact on recovery of function after spinal cord injury (SCI). This lack of knowledge exists despite the concern that cardinal features of Metabolic syndrome, including obesity, insulin resistance, hypertension, and a pro-inflammatory state could negatively impact the response of the spinal cord to injury and its capacity for regenerative repair. To address this gap in knowledge, we investigated the impact of systemic insulin resistance generated in adult mice by diet-induced obesity (DIO) on neurobehavioral outcomes in an experimental compression model of incomplete SCI. Ten-week-old female C57BL6/J mice were provided a regular diet, or one high in fat and sucrose (also referred to as a Western diet), for 7 weeks prior to experimental SCI. Mice continued on the same diets after SCI and were monitored weekly for locomotor recovery. Compared to mice consuming a regular diet, those with DIO demonstrated significant delays in locomotor recovery determined by the Basso Mouse Scale score and subscore, and the Inclined Plane test ($P < 0.05$, Two Way Repeated Measures ANOVA, Newman Keuls post-hoc test). Mice consuming a high fat diet also continued to lag behind their regular diet counterparts in these key motor outcomes 30 days post injury (dpi). To address potential mechanisms, we investigated changes in key markers of inflammation, astrogliosis and neural injury in the spinal cord after 7 weeks of consumption of a regular or high fat diet prior to SCI, and at 14 and 30 dpi, using immunochemical markers. Mice consuming high fat showed higher levels of glial fibrillary acidic protein (GFAP) in the spinal cord prior to SCI and in spinal segments above the injury epicenter at 14 dpi. Levels of Isolectin B immunoreactivity, a marker of microglial cells and monocytes were also higher in the spinal cord of mice consuming high fat prior to SCI. The spinal cord white matter of mice with DIO also showed reductions in the number of immature (Olig2+) and mature (CC-1+) oligodendrocytes prior to SCI, and these reductions in myelinating cells persisted at 14 and 30 dpi. Together, findings in this study identify DIO as a risk factor for impaired neurobehavioral recovery after experimental SCI and suggest the need to identify the mechanisms involved as potential new targets for therapy designed to improve outcomes in individuals with SCI.

**Abstract:** The spinal cord motoneuron (MN) is a unique element of the motor pathway, connecting the central nervous system (CNS) to the target muscle via the peripheral nervous system (PNS). MN cell body and axon's initial portion are located within the spinal cord, and most of the axon is present in the PNS. Due to such topography, lesions to the interface of CNS/PNS are especially severe since they represent a proximal axotomy, leading to 80% neuronal degeneration, within a couple of weeks. In patients, high energy trauma, such as motorbike accidents, can result in brachial plexus root avulsion or crush. Research on cellular and molecular changes in MNs and glial cells following proximal lesions has been carried out in cats and rats, mostly due to technical matters. However, proximal lesions to mice have not been performed in a standardized way. The present work, by the refinement of surgical technique and the use of appropriate surgical instruments, demonstrates the viability of crushing mouse ventral roots in a reproducible manner. Thus, we show herein the time course of neuronal degeneration, synapse retraction and glial reaction after ventral root crushing in C57BL/6J mice. For this purpose, 6-8 week old C57BL/6J mice were submitted to hemilaminectomy to expose the spinal cord lumbar segments (L4, L5 and L6). Once identified, ventral roots were crushed using a nº 5

forceps, for three times of 10 seconds. Operated mice were allowed to recover and were maintained for 7, 14 or 28 days after lesion. Following euthanasia, the spinal cords were collected to assess motoneuron survival by counting of Nissl stained sections, synapse loss (anti-synaptophysin) and glial reactivity (anti-GFAP and anti-Iba-1) via immunohistochemistry. Neuronal survival revealed 30% motoneuron loss seven days after lesion, which increased to 40 and 50% fourteen and twenty-eight days after lesion, respectively. Astrogliosis increased in a time-dependent manner, reaching six-fold upregulation by 28 days after injury. On the contrary, the microglial reaction was more intense in the acute phase after lesion (7 days), becoming reduced by 35% at day 28. The synaptic inputs were reduced by 35% nearby axotomized motoneurons already at day 7 after lesion, and such covering remained until 28 days post-injury. Taking together, the results herein demonstrate that ventral root crushing in mice provides robust data regarding neuronal loss and glial reaction, allowing future studies with transgenic strains that may, in turn, unveil strategies to improve motor recovery after proximal lesions.

**Abstract:** Among patients with spinal cord injury (SCI), >50% involve the cervical spinal cord, with many cases resulting in paralysis of the diaphragm muscle and impaired ventilation. Importantly, most SCIs are incomplete with sparing of descending excitatory inputs to motor neurons. Animal models of incomplete SCI to the upper cervical spinal cord such as unilateral C2 hemisection (C2SH) are widely used to examine neuromotor control of breathing following injury. Excitatory premotor drive to phrenic motor neurons, emanating predominantly from the ipsilateral medulla, is primarily glutamatergic in nature and is mediated by various receptor subtypes, including ionotropic NMDA receptors. There is gradual recovery of rhythmic diaphragm muscle activity ipsilateral to injury over time, consistent with neuroplasticity and

strengthening of spared synaptic inputs to phrenic motor neurons. Following C2SH, the amplitude of respiratory-related diaphragm activity (generally recruiting smaller motor units) is reduced but diaphragm EMG activity during higher force, non-ventilatory behaviors (generally recruiting larger motor units) is only minimally impaired. Thus, there may be differences in cellular mechanisms of neuroplasticity at phrenic motor neurons that may depend on motor unit type. We hypothesized that NMDA mediated neurotransmission plays a role in spontaneous recovery of ipsilateral diaphragm muscle activity post-C2SH. We observe a progressive increase in overall NMDA receptor expression, as measured by mRNA expression of the obligatory NMDA NR1 subunit, in retrogradely labeled phrenic motor neurons post-C2SH. The time course of recovery correlates with changes in phrenic motor neuron NMDA receptor expression, and phrenic motor neuron NMDA receptor mRNA expression is greater in animals displaying recovery vs. those not recovered at 14 days post-C2SH. We further characterized the differences in expression of NMDA receptor mRNA in large vs. small phrenic motor neurons using fluorescent in-situ hybridization techniques. These studies directly address mechanisms underlying postsynaptic neuroplasticity at phrenic motor neurons and recovery after C2SH and support the role of glutamatergic NMDA signaling in recovery of diaphragm activity after cervical SCI.

**Abstract:** Conus medullaris (CM) and cauda equina (CE) forms of spinal cord injury commonly result in paralysis, sensory impairments, and loss of bladder, bowel, and sexual functions. There are presently no treatments to reverse these neurological deficits. The present study investigated a new approach to promote axonal regeneration to reconnect spinal cord neurons with peripheral nervous tissues in a non-human primate model of CM/CE injury. For this purpose, biodegradable and trophic factor-releasing nerve guidance channels (NGCs) were used to bridge tissue gaps. The NGCs were comprised of electrospun polycaprolactone (PCL) tubes with an inner layer of aligned PCL nanofibers for topographical guidance and a PVA-collagen gel for controlled GDNF release (300ng/tube). Adult rhesus macaques underwent a unilateral L6-S3 ventral root avulsion (VRA) injury followed by repair of the L6 and L7 ventral roots. A glial cell derived neurotrophic factor (GDNF)-releasing NGC was placed as a bridge between the spinal cord and the avulsed L6 and L7 ventral roots (n=4). NGCs without trophic factor release were used as controls (n=4). Spinal cord and nerve root tissues were collected for morphological studies at 18 months post-operatively. Morphometric analysis of plastic embedded NGCs and nerve roots was performed using the free AxonSeg software. At 18 months post-operatively, both groups showed good integration between the bridging NGCs and the spinal cord as well as with the attached ventral roots. No graft rejections were detected. Cross-sections of GDNF-releasing NGCs showed a significantly higher percentage of overall tissue occupation (91.7±2.2%) compared to control NGCs (46.5±6.3%; $p<0.01$). Both groups showed a large number of myelinated axons in addition to fibrous tissues, Schwann cells, and blood vessels within the NGCs. The GDNF-releasing NGCs showed 3,230±669 myelinated axons, whereas the control NGCs showed 2,033±906 axons. There was no difference in axon numbers between the groups. There was no difference in fiber size or g-ratio between the groups. Electron microscopy of NGCs from both groups confirmed myelination of axons by Schwann cells as well as the presence of several unmyelinated axons with the NGCs. We conclude that the use of GDNF-releasing NGCs was well tolerated in non-human primates and promoted axonal regeneration in long-term studies. Trophic factor-releasing NGCs may be considered as a new repair strategy for bridging tissue gaps between the spinal cord and ventral roots after CM/CE injuries.

**Abstract:** Traumatic spinal cord injury (SCI) is a devastating neurological condition that occurs primarily at the cervical (cSCI, > 65%) and thoracic (tSCI) levels. Despite the marked neurovascular distinctions of the two levels and strikingly positive response of cSCI to trial drugs such as cethrin compared to tSCI, the mechanisms driving level-specific heterogeneity between their respective milieu remains elusive. We posit that the increased vascularity and grey-white ratio of the cervical cord—relative to the thoracic—results in greater susceptibility to neurovascular disruption, ultimately manifesting a secondary injury of earlier onset, severity, and chronicity. A rat model of moderate clip compression injury was used to induce SCI at the C6-7 and T6-7 levels, with laminectomy-only animals serving as surgical controls. Following sacrifices at 3, 7, 14, and 56 days, samples were subject to RNA-seq, protein work, imaging, and immunohistochemistry. Results of RNA-sequencing revealed striking differences in the onset and temporal profile of astrocytic and pericytic neurovascular processes with canonic stat3-depen-dent gliotic markers—lcn2, gfap and serpina3n—being upregulated in the cervical cord across time. Further, 3D ultrasound and immunostaining revealed rapid tissue loss and hemorrhage starting as early as 3 days post-cSCI with increased gfap and cspg4 staining in the cord. Finally, Western blotting confirmed an increase in stat3-dependent gliotic markers accompanied by a loss of key blood-brain-barrier proteins tjp1 and ocln in cSCI across time. Taken together, this data demonstrates—for the first time—the level-specific heterogeneity of SCI, with cSCI having a quicker onset and chronicity compared to tSCI. Further, these results reconcile the potential reasons behind why preliminary tSCI-derived trial paradigms may not be suited--in both strategy and timing—to cSCI, and hopes to engage clinicians and scientists in the design and study of level-specific therapeutics.

**Abstract:** Human inducible pluripotent stem cells (hiPSC) offer tremendous potential for individualized patient- and diseased-specific therapy. Transplantation of hiPSC-derived neural stem cells (NSCs) could be one of the most promising novel reparative strategies to promote functional recovery after spinal cord injury (SCI). One of the major challenges to realize the full therapeutic potential of hiPSC for SCI and other neurological diseases is to direct hiPSC differentiation into desired neural stem or precursor cells in vitro and then purify these cells before transplantation. In this study, the recombined nestin-EGFP hiPSCs, in which EGFP cassette has been inserted to the nestin locus of hiPSC via homologous recombination, are induced for neural differentiation and GFP expressing NSCs are purified by FACS. The in vitro proliferation and differentiation of purified NSCs is examined using immunohistochemistry. The nude rats received unilateral C5 contusion injuries and grafts of hiPSC-derived NSCs, human fibroblasts or control medium at 2 weeks after SCI. The survival, differentiation and functional outcomes were analyzed by histology and behavioral tests. The purified NSCs expressed nestin, sox2 and sox1 but not iPSC markers, klf4, SSEA3, TR-1-60. The purified NSCs continued to proliferate in the presence of mitogen, FGF2 for a long time? and differentiated into neurons, astrocytes and oligodendrocytes in the respective specific differentiation conditions. Notably, robust survival of grafted NSCs was observed in all animals receiving grafts of purified hiPSC-NSCs at 2 months after transplantation. The majority of grafted NSCs localized in the spared spinal cord around the injured epicenter. Some grafted NSCs differentiated into NeuN+ mature neurons and more into doublecortin+ immature neurons. Some grafted NSCs, especially ones in

spared white matter, differentiated into GFAP+ astrocytes or APC+ oligodendrocytes. The volumes of spared white and gray matter are significantly increased in animals receiving NSC graft. More importantly, recovery of hindlimb locomotor function is significantly enhanced in animals receiving grafted hiPSC-derived NSCs. No teratoma formation was observed in any animals receiving hiPSC-derived NSCs. Our results suggest that hiPSC-derived NSCs have great therapeutic potential for SCI and other neurological diseases.

**Title:** Local BDNF and minocycline delivery to the injured cervical spinal cord using an engineered hydrogel preserves diaphragmatic respiratory function

**Authors: B. GHOSH**[1], Z. WANG[2], J. NONG[2], M. W. URBAN[1], V. A. TROVILLI[1], M. C. WRIGHT[3], *Y. ZHONG[2], A. C. LEPORE[1]
[1]Dept. of Neuroscience, Vickie and Jack Farber Inst. for Neurosci., Sidney Kimmel Med. Col. at Thomas Jefferson Univ., Philadelphia, PA; [2]Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA; [3]Dept. of Biol., Arcadia Univ., Glenside, PA

**Abstract:** We tested a novel biomaterial-based approach to promote repair and protection of neural circuitry that controls diaphragm activation by locally delivering brain derived neurotropic factor (BDNF) or minocycline hydrochloride (MH) to the injured spinal cord in a rat model of cervical contusion spinal cord injury (SCI). BDNF can be used to restore respiratory function via a number of potential repair mechanisms, including phrenic motor neuron (PhMN) protection, regrowth of descending respiratory-associated axons that are interrupted by cervical SCI, enhanced PhMN excitability, and preserved innervation at diaphragm neuromuscular junction (NMJ). However, widespread BDNF distribution resulting from conventional delivery methods such as systemic injection or intrathecal infusion can lead to inefficient drug delivery and adverse side effects. MH is a clinically-available drug that targets multiple secondary injury mechanisms via its anti-inflammatory, anti-oxidant and anti-apoptotic properties. However, MH is only neuroprotective at high local concentrations, which cannot be safely achieved by systemic injection. We developed a clinically viable approach for locally delivering MH and BDNF with controlled dose and duration: a hydrogel-based drug delivery system loaded with either polysaccharide-BDNF or polysaccharide-MH particles self-assembled by physical interactions. Intrathecal implantation of BDNF or MH gel after unilateral C4/5 contusion both robustly

preserved diaphragm function, as assessed by *in vivo* recordings of compound muscle action potential and electromyography amplitudes. However, BDNF did not decrease lesion size or degeneration of cervical motor neuron cell bodies, suggesting that its mechanism of action was not neuroprotection within spinal cord. Instead, BDNF gel significantly preserved diaphragm innervation by PhMN axons, as assessed by detailed NMJ morphological analysis and retrograde PhMN labeling from diaphragm using cholera toxin B. Furthermore, BDNF gel enhanced the serotonergic axon innervation of PhMNs that plays an important role in modulating PhMN excitability; this effect on 5-HT axon growth was not observed with MH. Unlike BDNF, MH gel decreased lesion size and cervical motor neuron loss, suggesting neuroprotection within cervical spinal cord. Our findings demonstrate that local BDNF and MH delivery via hydrogel represent effective and safe strategies to restore diaphragm function after SCI, though they exert therapeutic effects on respiratory neural circuitry via different mechanisms. Thus, co-delivery of both therapeutics can potentially be more effective than individual treatment.

**Title:** Neurotrophin-3 mediates descending afferents to lumbar motoneurons after an above-level spinal cord injury

**Authors: *Q. HAN**[1], B. P. MAUREY[1], W. WU[1], J. D. ORDAZ[1], G. M. SMITH[2], X. M. XU[1]
[1]Stark Neurosciences Res. Inst., Indianapolis, IN; [2]Dept of Neurosci., Temple Univ., Philadelphia, PA

**Abstract:** After spinal cord injury (SCI), the surviving motoneurons, as the final common pathway for motor output, undergo profound dendritic atrophy and synaptic stripping from denervated supraspinal and propriospinal axons. In the present study, we investigated which specific descending pathways innervated the lumbar spinal cord after a T9 contusive SCI (Infinite Horizon with 0.4 mm displacement), and determined whether they contribute to neural synaptic reorganization and functional improvement after adeno-associated virus (AAV)-mediated neurotrophin-3 (NT-3) treatment for lumbar motoneurons. We demonstrated that, among various descending pathways, both the corticospinal tract and rubrospinal tract were almost completely disrupted at the lesion epicenter in both NT-3 treated and non-treated groups after SCI. Although no direct synaptic connections were found between these two pathways and lumbar motoneurons, the indirect cortico-motoneuronal and rubro-motoneuronal connections were still present via pseudorabies virus (PRV)-labeled propriospinal neurons, which were confirmed by electrophysiological recording. The spared proprio-motoneuronal connections were significantly enhanced, as evidenced by the observation of increased anterograde BDA-labeled propriospinal fibers and retrograde PRV-labeled propriospinal neurons after the NT-3 treatment. Using a propriospinal pathway-selective and reversible technique for blocking neuronal transmission, the beneficial effects of NT-3 treatment were significantly reversed in grid walking and rotarod behavior tests, revealing a critical role for the propriospinal-mediated motor control in response to NT-3 treatment. In addition, SCI with NT-3 treatment induced plastic changes of monoaminergic innervation of lumbar motoneurons, which may also contribute to functional recovery. These observations demonstrate that NT-3 treatment can modulate multiple spared descending pathways to maintain dendritic networks and synaptic plasticity of motoneurons after SCI, which could further benefit functional recovery.

**Abstract:** Lower urinary tract dysfunctions arise in a majority of people with spinal cord injuries. Interestingly, the phenotype develops slowly over the first 2-4 months after the injury. The most frequent manifestation is detrusor sphincter dyssynergia (DSD), defined as bladder detrusor contraction with concomitant contraction of the urethral and/or periurethral striated sphincter muscle. DSD can result in high intravesical pressure and reflux of urine to the kidneys. Anti-cholineric drugs in combination with several rounds of daily self-catheterizations are the only treatment options today. The aim of this project was to investigate a potential therapeutic effect on the lower urinary tract of antibodies against the nerve growth inhibitor protein Nogo-A in spinal cord injured rats. Twenty Lewis rats were implanted with a port and tubing system to fill the bladder and monitor bladder pressure, as well as external urethral sphincter (EUS) electromyography electrodes, allowing for repetitive, simultaneous urodynamic measurement and recording of EUS activity in awake animals. A large, incomplete spinal cord injury was induced in all animals at the thoracic level 8. Afterwards, either control IgG antibodies (n= 9) or anti-Nogo-A antibodies (3 mg/week; n= 11) were infused intrathecally for 14 days. From 4 weeks after injury on, when DSD was fully developed in the rats, both bladder and EUS function were investigated. At 5 weeks after lesion, all animals were retrogradely traced from the EUS with Fast-Blue, followed by perfusion a few days later. Immunohistological analyses were performed at the lumbosacral spinal level. Four weeks after a severe but incomplete spinal cord injury, control antibody treated animals showed high intravesical pressures upon bladder filling and a micturition insmall droplets over a long time period, features that are typical of DSD. EUS EMGs showed high frequency activity during that period. In contrast, rats treated with anti-Nogo-A antibodies showed reduced maximal intravesical pressures during micturition by 50% compared to rats treated with IgG antibodies. EMG high-frequency activity of the external urethral sphincter during micturition was significantly lower in the anti-Nogo-A treated spinal cord injured animals, which is close to the level of intact rats. Immunohistological analyses are currently on-going to study the synaptic inputs of the sacral spinal cord sphincter motoneurons and the plastic reactions of spared descending fibers after the lesion and the two kinds of antibody treatments.

**Abstract:** The brainstem often has been thought to be specifically hardwired and bulbospinal fiber growth and plasticity after spinal cord injury have not been studied in great detail so far. Recent data suggest that following axotomy by spinal cord lateral hemisection in adult rats, the *gigantocellular reticular nucleus* (NRG), one of the main nuclei of origin of the descending reticulospinal tract, can sprout vigorously rostral to the lesion site (regenerative sprouting). Some of these severed fibers connect to propriospinal neurons, which run down the intact hemicord, thereby potentially relaying bulbospinal commands to denervated target areas [Filli et al. 2014]. In parallel, spared NRG axons on the contralesional side show sprouting in the lumbar spinal cord, projecting branches directly across the midline into the denervated hemicord (compensatory sprouting; [Zorner et al. 2014]). Animals and humans with this type of incomplete spinal cord injury have been described to show pronounced recovery of hind limb function.
This study aims at investigating the functional relevance of regenerative *vs.* compensatory NRG sprouting for behavioral recovery of locomoter performance, using intersectional viral genetics for introducing chemogenetic silencing tools. Detailed functional assessment of joint movements and limb kinetics during overground walking, wading and swimming under conditions, where one or the other of the plastic NRG projections were inactivated, revealed defined patterns of deficits in chronically recovered animals.
We here present causative data for the functional relevance of observed plastic adaptations of bulbospinal projections in the injured spinal cord for behavioral recovery. Moving from a purely correlative to a more causal understanding of the neuroanatomical processes contributing to functional recovery after spinal cord injury will be fundamental for a successful translation of novel treatment approaches from experimental studies to the clinics.

**Abstract:** A significant number of FDA approved drugs have demonstrated efficacy in preclinical spinal cord injury (SCI). These studies predominantly used thoracic models and treated within one hour after injury. However, most human injuries occur at cervical levels (>65%), and such short windows of intervention used in animal studies are difficult to translate in human trials. We therefore created a team of research staff to assess the effects on functional recovery of the most promising FDA approved drugs when these are administered 3 hours after a cervical spinal cord hemi-contusion injury with the goal of finding robust treatments that could be taken forward into clinical trials.
In 5 experiments, we tested 9 different FDA approved drugs (riluzole, valproic acid, fluoxetine, metformin, inosine, rosuvastatin, acetyl-l-carnitine, glibenclamide, tamoxifen) that had been previously reported to improve functional recovery in SCI lab models.
None of the 9 treatments improved recovery compared to control groups in either a distal limb fine motor task (Montoya staircase: retrieval of food pellets from a staircase, or fruit-loop eating score), nor a proximal limb motor task (cylinder rearing task). We also did not observe any sparing of residual spinal cord tissue for the 6 treatments so far analyzed. However, mRNA expression changes in injured spinal cord tissue indicate appropriate changes in gene expression early after injury indicating the drugs are biologically active at the injury site.
In the light of this series of failures in our paradigm, we decided to reduce our injury force by 20% to 120 kdyn and to start treatment at 1 hour (n=19) and 3 hours (n=19) after cervical hemi-contusion injury (control n = 19). In the primary outcome of distal forelimb use there were no difference in the Montoya staircase task at any of the time points. Similarly, in the cylinder rearing task we did not observe robust differences among the groups at 3, 5 or 7 weeks after injury, however there was a trend for improvement in both the 1 and 3 hour glibenclamide treated groups.

As in previous replication studies, establishing robustness in preclinical models is challenging and possible reasons will be discussed.

**Title:** Sensorimotor activity during attempted finger tapping in late-stage ALS

**Authors: *E. G. PELS**, L. C. M. BRUURMIJN, E. J. AARNOUTSE, M. J. VANSTEENSEL, N. F. RAMSEY
Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

**Abstract:** Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease. It is characterized by a progressive degeneration of both upper and lower motor neurons resulting in paralyzed limbs, loss of speech and eventually locked-in syndrome. The median survival is 2-4 years from onset of symptoms, but can be prolonged with tracheostomy with invasive ventilation (TIV). Incremental evidence suggests that ALS is a multi-system disorder affecting also extra-motor areas, resulting in functional brain changes and behavioral changes (Shen *et al 2015*). A widely used technique to study functional changes within the brain is functional MRI (fMRI). So far, fMRI studies on the representation of limb movement in ALS patients have shown inconsistent results, although increased bi-hemispheric activation in pre- and primary motor cortex, more activation in motor learning related regions (cerebellum, basal ganglia) and recruitment of extra-motor areas such as primary sensory cortex and temporal and parietal regions were generally found. These findings indicate that the loss of motor neurons is compensated by the recruitment of other brain areas or reduced local inhibitory interneuron functioning. Importantly, these studies have been performed with relatively early-stage ALS patients who were still able to move their hand, and little is known about functional changes in the later stages of the disease. Here we report on functional activity in the sensorimotor cortex (M1/S1) of two people with late-stage ALS (revised ALS-FRS score: <5), who both received TIV and were unable to move their hands. M1/S1 activity was investigated using a block-design fMRI task in which the participants alternated attempted finger-tapping and rest. Participants

were scanned on 3T Philips MRI systems using PRESTO scans (TR/TE 22.5/31 ms; voxels 4mm isotropic). Data were compared with that of a group of healthy controls (execution of finger-tapping task). To allow easy visualization and to overcome individual anatomical variation, we used a novel method for normalizing M1/S1, based on anatomical landmarks (Bruurmijn *et al.* submitted). The results of both ALS patients showed significant activation in the hand region of M1/S1, in the same location as healthy controls executing the same movement. Additional activity was observed in face and foot regions, suggesting either additional engagement of these body parts during the attempt, or a reduced ability to activate the hand region selectively. In conclusion, we found relevant cortical activity in M1/S1 of people with late-stage ALS not able to move their hands, despite the significant loss of motor neurons as is known in ALS (Grolez *et al* 2016).

**Title:** Size-dependent axon loss in the corticospinal tract in sporadic ALS patients with predominant upper motor neuron symptoms

**Authors: *F. SONG**[1], J. LIU[1], J. RAVITS[2], J. A. LOEB[1]
[1]Dept. of Neurol. and Rehabil., Univ. of Illinois at Chicago, Chicago, IL; [2]Neurosciences, Univ. of California San Diego Dept. of Neurosciences, La Jolla, CA

**Abstract: Background:** Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that selectively involves both upper and lower motor neurons (MN). The mechanism by which both systems are involved is unknown. However, a common pathological finding in the spinal cord is corticospinal tract (CST) degeneration. We recently found a combination of myelin loss together with axonal loss in the CST tract where axons of different diameters are also

affected in patients with predominant upper MN signs. **Objectives:** In order to better understand the pathology, we compared the degree of axonal degeneration in the CSTs in ALS patients with predominant upper MN symptoms to patients with predominant lower MN symptoms in well-characterized postmortem cervical, thoracic, and lumbar spinal cord regions to determine the anatomical relationships of the connection between upper and lower MN systems in ALS patients. **Methods:** We developed quantitative methods to measure myelin and axon loss in three levels of the spinal cord. The degree of loss of axons of different diameters was measured and quantified in the CSTs as well as dorsal column regions as control in the different levels of spinal cords. **Results:** Patients with clinically predominant upper MN symptoms showed lateral and ventral CSTs degeneration. We found that all three spinal cord regions were affected in the CSTs but not the dorsal column. Quantification of axon density showed a loss of axons of both small and large diameter in the CSTs in ALS patients with predominant upper MN symptoms. Compared to ALS patients with predominant lower MN symptoms, we see a unique gradient of smaller diameter axon loss from lumbar to cervical segments in ALS patients with predominant upper MN symptoms. In ALS patients with predominant lower MN signs, we only see some loss of larger diameter axons. Moreover, significantly more microglial activation is associated with the severity of axon loss in the CST. **Discussion and Conclusions:** Our current findings show an 'All or None' effect of axon loss at all spinal cord levels of the lateral CST that is strongly associated with microglial activation. A 'Dying Back' of only small but not large diameter axons in patients with predominant upper MN symptoms. Our results suggest a selective vulnerability of axonal loss dependent on fiber size in ALS patients with predominant upper MN symptoms and that aberrant glioaxonal interactions in the spinal cord could contribute to axonal degeneration.

**Title:** The impact of imperceivable vibration stimuli on the central nervous system

**Authors: A. D. PASSARO**[1], M. S. TENAN[1], C. A. HAYNES[1], *P. J. FRANASZCZUK[1,2]
[1]Human Res. & Engin. Directorate, US Army Res. Lab., Aberdeen Proving Ground, MD;
[2]Neurol., Johns Hopkins Univ. Med. Sch., Baltimore, MD

**Abstract:** Gaussian noise vibration stimuli has been shown to produce activation in specific contralateral and ipsilateral brain regions as well as decrease physiologic tremor. The present study used electroencephalography (EEG) to evaluate the neurological impact of an

imperceivable vibration stimuli on 4th finger tremor in 17 right-handed participants. Each participant applied force to a stimulated weapon with a trigger-like handle according to a visually-presented force-trace to guide them to a specific force level (20% of MVC) for a 30 second period. The force tremor was used to assess the behavioral effects of the perturbation. The vibration stimuli (Gaussian white noise) was applied during the middle ten second period only (10-20 s). The subsequent EEG analysis focused on the spectral components associated with the sensory perturbation by contrasting that condition with the identical sham condition in which no stimuli was applied.
A spectral decomposition of the 10 second sensory perturbation period as compared to the control condition yielded alpha power (8-13Hz) decreases in several channels over the posterior right of the scalp. Interestingly, the last 10 second period (20-30s) exhibited the most statistically significant differences between conditions with lower power in a narrow low gamma band (30-35 Hz) over the posterior right areas as well as an increase in power over the left lateral and left frontal brain regions (commonly associated with the contralateral primary somatomotor area) observed during the vibration stimuli condition. Behaviorally, the tremor associated with the trigger-pull trended lower during the vibration stimulation (repeated measures t-test p=0.067) but was not different from sham upon removal of the stimuli (repeated measures t-test p=0.649) . Previous studies have suggested that external noise elicits a stochastic resonance-like effect in the human tactile and visual sensory systems as well as decreases physiological tremor. The present study suggests that imperceivable vibration noise stimuli may increase force steadiness and has a definitive central nervous system response; however, these two phenomena may not be time-locked and the effects on the nervous system are longer lasting than the behavioral effects. Further study is required to understand how imperceivable sensory stimuli alters the time-course of motor adaptation and the creation of steady movement.

**Title:** Altered motor axon excitability properties of the flexor carpi radialis following stroke

**Authors: *C. S. KLEIN**[1], C. ZHAO[1], W. HUANG[1], P. ZHOU[1,2]
[1]Guangdong Work Injury Rehabil. Ctr., Guangdong, China; [2]Dept. of Physical Med. and Rehabil., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

**Abstract:** Spasticity and muscle hypertonia commonly develop following stroke, and may be related to motoneuron hyperexcitability. Neuronal plasticity associated with disease can be studied by examining biophysical properties of peripheral axons. Nerve excitability testing by threshold tracking provides an indirect assessment of axonal biophysical properties including ion channel conductance and the resting membrane potential in-vivo. In the present study, nerve excitability testing was completed in 6 men (30-65 y) who had a hemiparetic stroke 1-43 months earlier (mean 13.8 ± 6.9 months). Bilateral recordings of multiple motor axon excitability properties (strength-duration properties, threshold electrotonus, current-threshold relationship, and the recovery cycle) were made by stimulating the median nerve at the elbow and recording the compound muscle action potential over the flexor carpi radialis (FCR) muscle. Upper limb Fugl-Meyer scores ranged from 4-53 and wrist flexor Modified ashworth scores ranged from 0 to 1+. Mean (± SE) hand grip strength was reduced in the paretic compared to the non-paretic limb (4.5 ± 2.6 kg vs. 31.1 ± 4.7 kg, P = 0.001). There was no strong evidence for a change in the resting membrane potential in the paretic side axons. Threshold responses elicited by subthreshold polarizing currents (threshold electrotonus and current-threshold properties) were not different between limbs (P > 0.05), suggesting that internodal properties were unaffected following stroke. However, the mean strength-duration time constant, which reflects nodal persistent sodium conductance, was larger in the paretic compared to the non-paretic limb (0.438 ± 0.015 ms vs. 0.389 ± 0.016 ms (P = 0.05). In the recovery cycle, the relative refractory period and refractoriness at the 2.5 ms delay were also larger in the paretic limb; 4.06 ± 0.218 ms vs. 3.67 ± 0.198 ms (P = 0.003) and 52.2 ± 11 % vs. 30.3 ± 3.4 % (P = 0.09), respectively. There was a trend for the strength-duration time constant to be larger in persons with lower Fugl-Meyer scores (R = -0.7, P = 0.1).The results demonstrate limb differences in nodal properties, possibly reflecting increased persistent sodium currents in the paretic side axons. These preliminary findings suggest altered properties of the nodal membrane in FCR motor axons that may related to the development of spasticity and muscle hypertonia.

**Title:** The effect of lower limb ischaemia on evoked potentials

**Authors: *J. M. BRADSHAW**, J. F. S. MILLWOOD HARGRAVE, P. S. SARAI, P. H. STRUTTON

Nick Davey Laboratory, Dept. of Surgery and Cancer, Imperial Col. London, London, United Kingdom

**Abstract:** Ischaemic nerve block (INB) of the limbs causes motor and sensory evoked potentials loss distal to the block site. Increases in motor evoked potential (MEP) amplitudes in muscles proximal to the ischaemia have been reported and it has been suggested that these are due to increased cortical excitability as a result of deafferentation of the limbs. Small increases in MEPs from contralateral muscles have also been noted. In order to further investigate the effect of ischaemia on cortical excitability and possible mechanisms, we performed an INB on the right calf. Nineteen healthy subjects received transcranial magnetic stimulation of the motor cortex and electromyographic activity of abductor hallucis brevis (AHB) and vastus lateralis (VL) muscles was recorded bilaterally. Somatosensory evoked potentials (SSEPs) were measured following electrical stimulation of the tibial nerve at the medial malleolus, distal to the INB. Near-infrared spectroscopy was used to measure regional tissue oxygen saturation ($rO_2$) at the calf and sole distal to the occlusion as a measure of the progression of peripheral ischaemia. We observed a significant increase ($p=0.008$ for VL, $p=0.007$ for AHB) in the amplitudes of MEPs in the contralateral muscles during ischaemia, in addition to expected decreases in MEPs of the ipsilateral distal AHB ($p<0.001$). However, there was no significant increase ($p = 0.076$) in the MEPs of the ipsilateral VL. SSEPs fell to an average of 41.29% of their baseline vs. 6.50% for MEPs at 30mins of ischaemia ($p<0.05$). These results suggest that increases in cortical excitability occur without loss of sensory input, indicating that complete deafferentation may not be the cause. It is possible that partial deafferentation may be sufficient to augment cortical excitability, or that an alternative mechanism may underlie these changes. Measures of $rO_2$ may provide a potential indicator of ongoing ischaemia and may be used as an adjunct to neurophysiological measurements. Further research is required to better understand the mechanisms underlying alterations in cortical excitability seen in ischaemic models of deafferentation.

**Title:** Vastus medialis oblique activity is positively correlated with functional ability in patients with patellofemoral pain syndrome

**Authors: *R. T. PHAM**, Y.-L. PENG, D. GUPTA, L. GRIFFIN
Kinesiology and Hlth. Educ., Univ. of Texas, Austin, TX

**Abstract:** Patellofemoral pain syndrome (PFPS) is the most common diagnosis of knee joint pathology. It diminishes a patient's capacity and desire to ambulate and limits ability to perform activities of daily life. It has been theorized that a weak vastus medialis oblique (VMO) causes the vastus lateralis (VL) to pull the patella laterally, causing friction and subsequent pain. The Anterior Knee Pain Scale (AKPS) is used widely to quantify physical ability and pain severity. The AKPS surveys the extent of discomfort during everyday activities (prolonged sitting, walking, general pain, stairs, limp, and support), more intense activities (running, jumping, and squatting), and the physiological effects of pain (flexion deficiency, abnormal patellar movement, swelling, and atrophy of thigh). The higher the score, the more able the subject is, with a maximum score of 100. Although the AKPS is commonly used, no studies have been done to evaluate the relationship between the AKPS score and the activation of the medial and lateral vastus muscles. The purpose of this study was to demonstrate the correlation between the total score of the AKPS and the activation amplitude of the VMO and VL during different tasks and force levels. Eight females with PFPS were recruited. The AKPS was administered and maximum voluntary contraction (MVC) force was determined by the average of the three MVCs. Participants then performed a ramp-up to three different target forces (25% MVC, 50% MVC, and 75% MVC) in two different tasks (isometric straight leg raise and isometric knee extension). The holding times were 10 sec for the 25% and 50% MVC, and 5 sec for 75% MVC. Surface electromyography (EMG) was used to measure muscle activation of the VMO and VL during the holding phase. Pearson correlation was used to determine the relationship between the total AKPS score and the normalized EMG activity of the VMO and VL, respectively. The EMG amplitude of the VMO had a relatively low, yet significant, positive correlation with the AKPS score during the 25% MVC straight leg raise task (25 ± 19% MVC, $p=0.03$, $r^2=0.3$) and the 50% MVC straight leg raise task (51 ± 30% MVC, $p=0.03$, $r^2=0.3$). However, there was no correlation between VL EMG amplitude to the AKPS score in all forces and tasks. The total score of the AKPS was positively correlated only with the VMO EMG during straight leg raise tasks at lower force levels which indicates that the more physically able the participants are, the stronger the VMO activation they have.

**Title:** Cross-inhibition sharpens fast motor output in *C. elegans* locomotion

**Authors: L. DENG**[1], C. DOYLE[2], V. MARFIL[1], *G. HASPEL[1]
[1]Biol. Sci., New Jersey Inst. of Technol., Newark, NJ; [2]Bergen County Tech. High Sch., Teterboro, NJ

**Abstract:** To achieve translocation, many locomotor systems produce alternation of antagonist muscle, including axial bending and limb alternation. Cross-inhibition is believed to be key to antagonistic alternation so that when a muscle is activated by the neural circuit, cross-inhibitory elements inhibit a counteracting muscle. Nineteen inhibitory GABAergic motoneurons (D-MNs) in *C. elegans* have been suggested to provide cross inhibition, based on their morphology and inhibitory effect on muscles. They each receive synaptic input from excitatory MNs and provide inhibition to opposing MNs and muscles. The activity of D-MNs during locomotion has not been reported but it is believed that cross-inhibition is key to undulatory dorsoventral muscle alternation in *C. elegans* during backward locomotion. However, we found that cross-inhibition is not necessary for slow antagonistic alternation, but it plays a crucial role in fast alternation. We use a combination of behavior analysis, optogenetics, and calcium imaging to clarify the role of the inhibitory D-MNs. We found that mutants that are deficient in GABA transmission so that cross-inhibition is missing, moved at lower frequency and slower translocation speed in both forward and backward directions. They can perform slow dorsoventral undulation as well as wild type. In contrast, they cannot move rapidly, for example to escape from noxious stimuli, neither backward nor forward. Moreover, we found that both forward and backward undulation frequencies of wild type animals each fall into slow and fast distributions, and that the frequencies of mutants overlap with the low frequency distribution of wild type. When mutant animals were exposed to noxious stimuli that would have induced fast forward or backward undulation in wild type animals, they contracted their posterior or anterior sections, respectively, exhibiting co-contraction of antagonistic muscle. Similar changes in locomotion behavior occurred when D-MNs were acutely inactivated with optogenetics. We recorded the neuronal activity of D-MNs, as well as the activity of excitatory MNs and muscle cells, during restricted locomotion using microfluidic channels that mimic natural shape of undulation so that all elements can be correlated in the same framework of undulatory phase.
Together, these finding support our hypothesis that cross inhibition sharpens the coordination of fast antagonistic alternation. The simple mode of locomotion and small neuronal network that can be comprehensively described and modeled, together with the availability of genetic and transgenic tools make *C. elegans* an exquisite model to further our understanding of motor networks.

**Title:** Motor cortical activities in the animal model of Parkinson's disease

**Authors: *Y. LI**, C. LI, Y. GU, W.-H. YUNG, Y. KE
The Chinese Univ. of Hong Kong, Hong Kong, China

**Abstract:** The primary motor cortex (M1) is responsible for motor execution and contributes to acquisition of new motor skills. Previous studies show that M1 layer V pyramidal neurons have increased burst firing and increased beta power in Parkinson's disease (PD) model. However, most studies have focused on recording extracellular activity *in vivo* or intracellular properties *in vitro* in M1. Properties of these neurons in intact subjects, like the *in vivo* intrinsic membrane excitability and synaptic inputs, which are important in understanding neuronal integration leading to their outputs, are less well addressed. We therefore applied *in vivo* whole-cell patch-clamp technique to record from neurons in M1, focusing on layer V. As a first step, we characterized the electrophysiological properties of these neurons in normal mature mice and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated mice under anesthesia. Neurons were approached, patched blindly and recorded for at least 20 mins. The depth of the neurons was recorded and confirmed by post-mortem biocytin avidin-biotinylated complex method that also revealed the neuronal morphology. Our data show that the intrinsic properties of the neurons, including the resting membrane potential, input resistance and membrane time constant, remain largely unchanged in MPTP-treated mice. Also, the averaged firing rates were unaffected. However, there is an increase in the number of spikes per burst and also a decrease in inter-burst intervals. The proportion of bursty neurons is also increased in MPTP mice. Subthreshold excitatory postsynaptic current (EPSC) and inhibitory postsynaptic current (IPSC) could also be recorded, which could provide insight into the mechanisms underlying changes in the firing patterns in M1 neurons observed in PD subjects.

**Abstract:** Peripheral nerve injuries affect over 90,000 people worldwide every year. During several decades, due to the rapid development of electronics, implantable neural prostheses system is gaining a great attentions. Even though the electronic system has become highly functional and miniaturized, the interface between electrodes and nerve system is still a big limitation. It is mostly because the damaged nerves cannot maintain a stable connection with the electronics. For example, in order to control the artificial hand or leg with a person's intention, encoding the neural signal from the recovered motor neurons should be obtained for long time. In this study, we designed a cell culture platform to investigate how to regenerate motor neurons for a stable connection with electrodes. SU-8, a photoresistor, was used to make a mold (master) with positive relief patterns using soft lithography. Structure made by molded PDMS (polydimethylsiloxane) covers a commercial planar type microelectrode array to utilize electrical recording and stimulation functions. Primary motor neurons from embryonic 14-day gestation ICR mouse spinal cord was dissociated and seeded in the platform. Microchannels between the chambers provide high fluidic resistance that leads to directional neuron growth. In order to confirm successful neuronal growth and regeneration, we attempted to detect the activity of neurotransmitter simultaneously. When neurons grow along the microchannels, we detected acetylcholine from the terminal of the motor neuron using electrochemical method. This study indicates that the microfluidic platform can be an in-vitro neural recovery model.

**Abstract:** Proximal muscles in the arm have a broader cortical representation compared to forearm and hand musculature. They are characterized by higher threshold to TMS motor evoked potentials even in healthy individuals. As a consequence, few studies have evaluated the excitability of corticospinal projections to muscles of the arm and the shoulder. However, muscles such as biceps, triceps, deltoid and trapezius are of particular interest after cervical SCI, both for evaluating the level of the lesion and the efficacy of therapeutic interventions.
In this work we propose to use TMS in combination with high-density surface EMG (HD-sEMG) to obtain a more detailed picture of the evoked activity in the proximal muscles of the upper limb. Our hypothesis is that, not only would HD-sEMG provide a spatial map of TMS-evoked activity in the muscle, but it would also detect MEPs with higher sensitivity compared to standard bipolar surface EMG recording. To the best of our knowledge, only one group has previously adopted HD-sEMG with the aim of studying spatial selectivity of TMS in the forearm musculature.
Here, we compared MEPs obtained with bipolar recording and recording from grids of electrodes when evaluating recruitment curves (RC) and cortical mapping of proximal arm muscles. Single-pulse TMS was delivered to the contralateral motor cortex using a neuro-navigated Nexstim eXimia NBS stimulator via a 70 mm figure-of-eight coil while the subject was at rest. Upon identification of the hotspot and resting motor threshold (RMT) via bipolar recordings, we varied the intensity of the stimulation in percentage of 10% RMT above and below the RMT for obtaining the RC. Subsequently, we moved the coil along a grid of 5x5 $mm^2$ projected virtually

onto the cortical surface in order to record MEPs to 120% RMT across different stimulation sites. We repeated the procedure using an 8x8 grid of electrodes interspaced by 8.5 mm. The protocol was repeated in separate days to verify the stability of measures extracted by the grid. We were able to elicit MEPs in all the tested muscles. We evaluated the peak-to-peak amplitude of the response and the MEP onset latency across the grid of electrodes. Our results suggest that HD-sEMG allows detecting MEPs at lower stimulation intensities, and with a more consistent sigmoid RC shape, compared to bipolar electrodes. Indeed, we could exploit the spatial resolution of the grid to achieve a topographical picture of MEPs propagation in the muscle and for identifying more excitable regions. Given the promising results, we will take the next steps towards evaluating the reliability of this technique for studying proximal muscles both in uninjured and SCI individuals.

**Abstract:** Botulinum toxin is widely prescribed by physicians for managing spasticity post stroke. In an ongoing study, we examine the spatial pattern of muscle activity in muscles of stroke survivors before and after receiving botulinum toxin over the course of several weeks. We hypothesize that botulinum toxin alters muscle electrophysiology by disrupting fiber neuromuscular transmission in an inhomogeneous manner and we seek to detect these changes using grid surface electromyography (sEMG). We recorded sEMG signals from Biceps Brachii (BB) in two chronic stroke survivors using 16x8 surface EMG grid with 8.5mm inter-electrode distance. The grid covered the short and long head of BB. We recorded from both impaired and contralateral sides of our stroke survivors during sustained, non-fatiguing, voluntary contraction at maximum voluntary contraction (MVC) and at 50%MVC. All recorded signals were preprocessed (power line attenuation, 10-500Hz bandpass filtering). We calculated the root mean

squared (RMS) value of each channel for a 5s constant force and presented it as 16x8 RMS map. We compared the RMS maps of pre and post-botulinum toxin sessions. We observed discernible changes in the RMS pattern of BB muscle after receiving botulinum toxin. A significant decrease in sEMG amplitude (RMS) was observed for all 128 channels during MVC contractions. We also found significant differences between the spatial pattern of pre and post botulinum toxin RMS maps at 50%MVC. Botox chemically denervates the muscle fibers around the injection site(s). A reduction in the number of muscle fibers contributing to the force generation results in a significant force reduction at the elbow joint of the botulinum toxin recipients. We further postulate that dysfunctional muscle fibers that are not generating action potentials alter the distribution of sEMG in a non-uniform manner over the skin surface. In conclusion, we have observed the evidence of alteration of the amplitude and pattern of muscle activity after botulinum toxin injection. Further analysis and study will also include motor unit analysis and mapping.

**Title:** Effect of botulinum-toxin on motor unit activity in stroke survivors

**Authors: *S. CHANDRA**, B. AFSHARIPOUR, N. SURESH, W. Z. RYMER
Rehabil. Inst. of Chicago, Chicago, IL

**Abstract:** Use of Botulinum-toxin is often utilized by physicians to reduce muscle spasticity in stroke survivors. This toxin is locally administered to the affected muscle site as an intramuscular injection to inhibit hyperactivation of the spastic muscle. The reduction of muscle spasticity is achieved by blocking neuromuscular transmission, thereby also affecting voluntary muscle activation and in turn, muscle control. We hypothesize that Botulinum-toxin also affects motor unit (MU) functional properties such as motor unit recruitment threshold and motor unit firing rate. By decomposing surface electromyogram signals (sEMG) from Biceps Brachii, we address the effect of Botulinum-toxin on MU activity of the muscle.
Experimental surface electromyogram recordings were performed on three stroke survivors after a thorough clinical assessment. The force and sEMG signals were recorded during an isometric, non-fatiguing elbow flexion under kinematic constraints. Visual feedback of a trapezoidal force

trajectory was provided to the subjects. EMG data were recorded using Delsys Sensor Arrays, which are equipped with special 5 electrode pins. We also recorded surface EMG with 4 bipolar sEMG electrodes. The 4 bipolar sEMG electrodes recorded signals from long and short heads of the distal portion of Biceps Brachii, Brachioradialis and Triceps Brachii. All the data were normalized with a Maximal Voluntary Contraction (MVC) before they were decomposed to individual motor unit action potentials. Multiple experimental trials were performed at different contraction level varying from 30% to 60% of the MVC.
We found variation in motor unit recruitment patterns and the firing rates for the post Botulinum-toxin sessions comparing to baseline recordings (before Botulinum-toxin injection). Along with MVC, the peak to peak amplitude of sEMG of the affected muscle in the impaired side also showed significant decrease in value. Recruitment thresholds also decreased for the higher threshold motor units in the post injection sessions. A compression in the initial recruitment range was observed for the post Botulinum-toxin sessions even though in both the cases the "onion skin" pattern was preserved. A greater variation of firing rates was evident in post Botulinum-toxin sessions. Compared to the pre-injection sessions, the post injection sessions show decreasing trend in the firing rates across all forces. In summary, motor unit control is potentially altered following botulinum toxin injections in muscles that exhibit spasticity.

**Abstract:** Spinal cord injuries (SCI) disrupt the pathways between brain and spinal cord, resulting in impairment of motor control and loss of independent mobility. Most SCIs are

incomplete, however spontaneous plasticity, mediated via the spared spinal pathways is often insufficient to restore normal function. One unique approach to induce plasticity in spared spinal networks is via brief exposures to reduced oxygen levels, also known as acute intermittent hypoxia or AIH. This protocol has been demonstrated to increase voluntary force generation at the ankle joint as well as improve locomotor function in persons with SCI. Whether AIH induced neuroplasticity is equally prevalent in spinal motor pathways regulating upper limb musculature is not known. Accordingly, we tested the hypothesis that AIH will augment upper limb neuromotor function in individuals with incomplete SCI. A randomized, blinded, placebo-controlled and crossover study design was used. We measured isometric elbow flexion and extension strength during maximal voluntary contraction (MVC) in 8 individuals with chronic, incomplete cervical SCI before and 60 minutes after a single session of AIH (15, 90-second episodes of 10% oxygen). Results were compared with trials when subjects received sham hypoxia (15, 90-second episodes of 21% oxygen). Electromyographic activity was also recorded from the biceps brachii and triceps brachii muscles using a 128 channel high density grid. We found that force output during isometric MVC at the elbow flexion and extension changed by 43 ± 13% and 51 ± 22%, respectively, following AIH. In contrast, force output during flexion and extension changed by 13 ± 8% and -4 ± 7%, respectively. The change in flexion and extension strength correlated with increased activation of biceps brachii and triceps brachii. These results demonstrate the potential of AIH to enhance volitional upper limb strength in persons with incomplete SCI. This modality could eventually be developed to induce spinal plasticity as an adjunct to bolster the effectiveness of superimposed rehabilitative training in SCI patients.

**Authors: *N. L. SURESH**[1], X. HU[3], B. JEON[4], W. Z. RYMER[2]
[1]Sensory Motor Perf Prgm, [2]Shirley Ryan Ability Lab., Chicago, IL; [3]BME, UNC Chapel Hill, Chapel Hill, NC; [4]Carnegie Mellon Univ., Pittsburgh, PA

**Abstract:** Muscular weakness is a major impairment limiting motor function following a hemispheric stroke. The objective of this preliminary study was to examine potential motor unit (MU) structural change in paretic muscle of stroke survivors as a measure by which to assess neural and/or biomechanical mechanisms of paresis. A surface electromyogram (sEMG) recording and decomposition system was used to record sEMG signals and extract single MU activities from the first dorsal interosseous muscle (FDI) of two hemiparetic stroke survivors. To characterize MU structural change, an estimate of the motor unit action potential (MUAP) amplitude and duration was derived using spike triggered averaging of the sEMG signal. We also derived parameters from EMG power spectral analysis, such as frequency range and median frequency and made comparisons between data obtained from the affected and contralateral sides of stroke subjects. Our preliminary results reveal MUAPs with systematically smaller amplitude and longer duration in the paretic muscle compared with the contralateral muscle of two tested stroke subjects with moderate and severe impairment. Preliminary results also show significant differences in the median frequency values between the stroke and contralateral side of our three tested stroke subjects. These preliminary results suggest reduced MU size and a reduction in the conduction velocity in post-stroke paretic muscle which could be contributing factors to existing muscle weakness. The sEMG recording and decomposition system combined with our spike triggered averaging technique has the potential to provide an assessment tool for muscular weakness post-stroke.

**Title:** Designer ubiquitinase targeting botulinum neurotoxin a is transgenically expressed and forestalls paralysis

**Authors: *T. RUSSO**[1], P. M. MCNUTT[1], A. B. BRADFORD[2], J. MACHAMER[3]
[1]USAMRICD, Gunpowder, MD; [2]US Army Med. Res. Inst. of Chem. Def, Gunpowder, MD; [3]US Army Med. Res. Inst. of Chem. Def., Gunpowder, MD

**Abstract:** Botulinum neurotoxin serotype A (BoNT/A) is an extremely potent toxin that specifically cleaves the presynaptic protein SNAP-25, blocking cholinergic neurotransmission. The resulting flaccid muscle paralysis becomes fatal once respiratory muscles are intoxicated. Currently, the only FDA-approved treatment for botulism is passive immunization with antitoxin, which removes the neurotoxin from circulation. However, antitoxin is ineffective once toxin translocates to the presynaptic compartment. Our goal is to design a novel treatment that blocks or reverses the catalytic activity of the botulinum neurotoxin light chain (LC) of serotype A within the presynaptic terminal, thereby providing a countermeasure that can be utilized following symptomatic onset. Here we describe the initial validation of a bifunctional designer ubiquitinase (DesUbA), designed to that both block LC catalytic activity and to ubiquitinate LC, accelerating its proteolysis. DesUbA is composed of the single-chain antibody B8 VHH and the ubiquitin ligase domain, TrCP. In preliminary studies conducted in neuroblastoma cells, DesUbA has been shown to both ubiquitinate LC/A as well as block the catalytic activity of LC/A. To test DesUbA performance in a physiological model, C57BL/6J mice were genetically modified to express YFP-DesUbA using a pan-neuronal Thy1.1 promoter. Stable breeding lines were established and TFP-DesUbA expression was confirmed in the brain and peripheral nervous system, including motor neurons and neuromuscular junctions. To functionally validate the acute effects of DesUbA on LC/A activity, isometric contractions were measured *ex vivo* in phrenic nerve-hemidiaphragm (PNDs) intoxicated by BoNT/A. Transgenic PNDs showed greater than 50% delay in times to median paralysis and full paralysis as compared to preparations from wild-type mice, suggesting that DesUbA decreases LC/A activity. The effects of DesUbA expression on LC/A persistence *in vivo* are currently under investigation using novel behavioral models of systemic botulism and local paralysis.

**Title:** The effects of altered stretch reflex sensitivity on motor unit recruitment

**Authors: A. BARRERA-CURIEL**, *Z. K. POPE, R. J. COLQUHOUN, J. A. HERNANDEZ-SARABIA, J. M. DEFREITAS
Oklahoma State Univ. Stillwater, Stillwater, OK

**Abstract: INTRODUCTION:** Motor unit activation is controlled through the integration of descending command and afferent feedback. It is well-established that vibration applied to the muscle manipulates the excitatory synaptic input to muscle spindles by either facilitation (acute vibration for less than 30 seconds) or depression (prolonged vibration for > 10 minutes) of spindle function. Despite evidence that muscle spindles alters motor unit behavior, the direct influence of muscle spindles on motor unit recruitment thresholds (RT) during maximal efforts remains untested. **PURPOSE:** To examine the effects of altering stretch reflex sensitivity on maximal motor unit properties. **METHODS:** 5 healthy men (23 ± 4yrs) and 8 healthy women (23 ± 11) were included in this study. A crossover design was utilized, where each participant performed 1 maximal knee extension under 3 separate conditions: 1) control; 2) acute vibration, applied during the contraction; and 3) prolonged vibration, applied for ~20 min prior to the contraction. Multi-channel EMG was recorded from the vastus lateralis during each contraction and decomposed into the constituent motor unit action potential trains. RT was characterized as the force level (Nm) at which each motor unit started firing. **RESULTS**: 1,120 motor units were detected overall. No significant differences in maximal RT were found from the control to either the acute conditions (p = 0.186) or prolonged conditions (p = 0.089). However, when expressing each motor unit's RT as a function of its action potential size, prolonged vibration significantly altered the slope (p = 0.032, Figure B), but acute vibration had no effect (p = 0.608, Figure A). **CONCLUSION**: Motor unit recruitment threshold decreases when muscle spindle function is depressed, suggesting that higher-threshold motor units are recruited earlier during maximal contractions when muscle spindle sensitivity is altered.

**Title:** Recurrent laryngeal nerve regrowth post-injury: A temporal study of neurotrophic factor expression

**Authors: S. DODHIA**[1], *I. HERNANDEZ-MORATO[2], M. MONTALBANO[2], J. MARTINEZ[3], M. PITMAN[2]
[1]Dept. of Otolaryngology – Head and Neck Surgery, [2]Otolaryngology-Head & Neck Surgery, [3]Med. Scientist Training Program, Columbia Univ., New York, NY

**Abstract:** The recurrent laryngeal nerve (RLN) innervates the intrinsic laryngeal muscles. The exquisite coordination between abductor and adductor muscles of the vocal folds is controlled by two pools of motoneurons. They are located in the nucleus ambiguus within the brainstem that supplies the larynx through the RLN. Injury of the RLN may occur during cervical or cardiothoracic surgery, and leads to vocal fold paralysis affecting vital functions like respiration, deglutition and voice production. Regenerating axons grow toward the laryngeal muscles, but due to non-selective reinnervation, the recovery of the vocal fold movement is typically absent. In previous works, we identified different neurotrophic factors whose expression is coordinated with the timing of axonal reinnervation of the larynx. Two such factors were Glial Derived Neurotrophic Factor (GDNF) and Netrin-1 (NTN-1). In this study the expression of GDNF and NTN-1 in denervated abductor and adductor muscles was analyzed with the mRNA translation of their receptors in the RLN and the brainstem. As laminin α1 (LAMA1) has been shown to change NTN-1 mediated growth cone attraction to repulsion, the expression of this protein in the laryngeal muscles was also studied.
Eighty-four female Sprague-Dawley rats underwent transection of the right RLN and were sacrificed at 1, 3, 7, 21, 28 and 56 days post injury. Ipsilateral posterior cricoarytenoid, lateral and medial thyroarytenoid muscles were collected and the total mRNA and protein were isolated for the determination of GDNF, NTN-1 and LAMA1 expression. Motor axons and motor end plates were immunostained to determine the timing of laryngeal reinnervation. GDNF and NTN-1 receptor expression was also studied in the brainstem and the axonal growth cones by immunohistochemistry and in situ hybridization.
The overexpression of GDNF and NTN-1 in the abductor and adductor laryngeal muscles correlated with the expression of their receptors within the nucleus ambiguus at different time points. LAMA-1 overexpression in the laryngeal muscles was also identified. This is a novel finding not previously described in any model of nerve injury.
Our findings suggest that expression of GDNF, NTN-1 and their receptors are chronologically

correlated with the laryngeal reinnervation. LAMA-1 overexpression may be a RLN axon guidance factor as it is known to induce repulsion of regenerating growth cones when associated with NTN-1 expression. Future study of the specific role of GNDF, NTN-1, and LAMA-1 may be helpful to better understand their function, with the goal of manipulating these neurotrophic factors to promote selective reinnervation with return of vocal fold function.

**Title:** Does follistatin augment skeletal muscle fiber recovery following moderate periods of denervation?

**Authors: *M. S. SHALL**[1], J. E. ISAACS[2], S. MALLU[3], G. PATEL[4], M. A. FEGER[4]
[1]Physical Therapy, MCV/VCU, Richmond, VA; [2]Orthopedic surgery, [3]Orthopaedic Surgery, [4]Orthopedic Surgery, Virginia Commonwealth Univ., Richmond, VA

**Abstract:** Every year there are many nerve injuries that result in significant disability. The surviving motoneuron axons that do regrow to the muscle target are often re-innervating small, weakened, and compromised muscle fibers. The rapid degeneration of denervated muscle fibers following nerve injury seems to be related both to disuse and to a loss of trophic support and feedback normally provided by the intact axons. One approach to prevent atrophy is to facilitate the normal physiologic anabolic shift that occurs in the muscle fibers with re-innervation.
Some research on muscle mass regulation has focused on myostatin, a member of the TGF-β superfamily of signal transduction proteins that regulate muscle mass by inhibiting muscle regeneration. Elevated myostatin serum levels (acting as muscle inhibitors) have been linked to muscle wasting conditions such as AIDS or prolonged bed rest. Additionally, myostatin's protein reducing effects, though seen in all muscle fibers, is most prevalent in type IIb muscle fibers.
In light of the obvious therapeutic potential of manipulating myostatin related pathways for muscle regeneration, an intensive search has been underway for effective myostain antagonists. Follistatin has emerged as one of the most promising. Follistatin influences muscle regeneration at several levels including directly inhibiting myostain, stimulating muscle fiber hypertrophy and hyperplasia, and increasing both muscle fiber protein and myonuclei. Transgenic mice over-expressing follistatin exhibit faster muscle healing following muscle injury as demonstrated by

greater myofiber regeneration, less intra muscular fibrosis, and “superior” muscle progenitor cell formation.
The objective of the study is to determine potential augmenting effects of follistatin on strength, mass, and muscle fiber composition recovery of re-innervated muscle following moderate and long periods of denervation. Preliminary data shows that FS Protein is observed to induce muscle hypertrophy as seen by the increase in animal weight, muscle weight and the twitch force when compared to sham group. Muscle fibers expressing myosin heavy chain type II isoforms tended to be larger in the FS protein treated muscles compared to control animals.

**Title:** Optogenetic muscle activation to restore whisker movement after facial nerve lesion in mice

**Authors: A. BANDI**[1], A. UPADHYAY[1], H. CHANG[1], R. SAKHUJA[1], S. YIANTSOS[1], T. J. VAJTAY[1], C. R. LEE[1], *D. J. MARGOLIS[3,2]
[2]Cell Biol. and Neurosci., [1]Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [3]Cell Biol. & Neurosci., Rutgers Univ., Piscataway, NJ

**Abstract:** Motor nerve damage can lead to complex functional changes in the denervated muscle, including atrophy and hypersensitivity, that can severely impact the restoration of movement. The temporal progression of denervation-induced changes in nerve and muscle function have been challenging to investigate experimentally. We used non-invasive peripheral optogenetic stimulation (Park et al., 2016, Peripheral optogenetic stimulation induces whisker movement and sensory perception in head-fixed mice, eLife, e14140; experiments performed under isoflurane anesthesia) in four transgenic mouse lines expressing channelrhodopsin-2 (ChR2) in either facial nerve or mystacial pad muscles to track changes in light-evoked whisker movements before and after facial nerve transection. Before nerve transection, graded whisker protractions were evoked by increasing light (460 nm) intensity or duration in muscle-expressing mice (Emx1-ChR2, PV-ChR2, and ACTA1-ChR2). By contrast, optogenetic activation of the

facial nerve (Chat-ChR2 mice) resulted in stereotyped, all-or-none, strongly adapting whisker protractions. After nerve transection, longitudinal probing of the distal cut end of the nerve in Chat-ChR2 mice revealed loss of movement within approximately 24 hours, defining a time window of functional denervation. Longitudinal probing of optogenetic muscle activation over 14 days revealed functional changes beginning after the functional denervation, including a reduction of retractions (Emx1-ChR2 mice), an increase in large-amplitude, non-adapting protractions, and increased sensitivity to low intensity stimuli (Emx1-ChR2, PV-ChR2, and ACTA1-ChR2 mice). In additional experiments, we used timed stimulation of retraction and protraction in attempt to reproduce aspects of natural whisking kinematics. After nerve transection, optogenetically induced naturalistic whisker movements were paradoxically improved, largely because of the denervation-induced reduction of adaptation. Our results indicate that peripheral optogenetic stimulation can be used to probe the time course and functional changes of nerve and muscle function after denervation that influence the ability to restore naturalistic whisker movements of denervated muscle. Our results have implications for the potential use of optogenetics for restoring movement in a therapeutic context after nerve damage.

**Title:** Manipulation of the social environment alters activity and body morphology of Dugesia dorotocephala

**Authors: L. GOODRIDGE**, A. STILLAR, A. WEEKS, *M. J. SAARI
Nipissing Univ., North Bay, ON, Canada

**Abstract:** Planaria, *Dugesia Dorocephala,* appear to be behaviourally sensitive to their social environment. Singly housed planaria show reduced activity and increased environmental “scanning” in comparison to group housed planaria. The purpose of this study was to explore activity and body morphology of planaria exposed to four different social environments: singly housed, groups of five, and a group of ten in 5 ml of modified Montjuic salt solution. The fourth group consisted of ten planaria housed in 50 ml of the salt solution. *WormLab* (MBF Bioscience) was used to analyze video files of ten planaria from each of the environments. All groups were

videotaped at day 1 of the experiment and left undisturbed except for water changes which took place every 2nd day. The planaria were individually videotaped once more on day 7. Activity and body morphology measures were collated for the first and the second minute of the videotape. This yielded a mixed $SPF_{4.2}$ design with ten planaria per housing environment. ANOVA indicated a significant effect of Social Environment on speed of swimming and a significant Social Environment by Minute interaction on path length. Surprisingly, body morphology (length, width, and area) varied significantly as a function of Minute. The results confirm the behavioural sensitivity of planaria to their social environment and suggest that body morphology may provide a novel measure of adaptation. **Title:** The effects of social status on dopaminergic regulation of neural circuit activation and behavior

**Authors: *K. CLEMENTS**[1], T. MILLER[1], E. JI[2], F. ISSA[1]
[1]Biol., East Carolina Univ., Greenville, NC; [2]UCLA, Los Angeles, CA

**Abstract:** Social hierarchies permeate the animal kingdom and are crucial for maintaining social communities through proper allocation of resources. Our aim is to address the neural bases of social regulation using zebrafish (*Danio rerio*). Zebrafish form hierarchies of socially dominant and subordinate fish. They produce a well-characterized escape behavior that is mediated by the activation of Mauthner neurons. We used a non-invasive technique of recording field potentials that enable the monitoring of the escape and swim circuits to determine if there were differences between fish of different social status. Our results showed that there was a social status-dependent effect in the activation of the two competing neural circuits and their behaviors. We found that subordinates favored escape over swim while dominants favored swim over escape. We hypothesized that differential activation of these two behaviors and their underlying circuits are affected by social experience through mediation of the dopaminergic system. To test our hypothesis we first augmented dopamine (DA) through injection of L-DOPA. We observed that the significant difference in escape behavior between the two social phenotypes was diminished, suggesting a social status-dependent regulation of dopamine on the escape circuit. Second, whole brain gene expression analysis showed significant upregulation of the dopamine transporter (dat)

in dominants and downregulation of the dopamine receptor 1b (drd1b) in subordinates. There were no significant differences in gene expression of drd2a, drd2b or drd3. We investigated the status-dependent differences in DA receptor expression by pharmacologically injecting DA receptor agonists and antagonists. We found that blocking the drd1b shifted dominant behavior to favor escape over swim, resembling the subordinate behavior pattern. In addition, we observed that antagonizing drd3 lowered subordinates' probability of escape with no effect on dominants. Finally, neither application of drd2 agonist nor antagonist yielded significant effects. Taken together, these results suggest that social status can shift the activation of competing neural circuits mediated, in part, through the balance of DA supply regulated by dat and interpretation of DA by differences in drd1 and drd3 expression and signaling, respectively.

**Title:** Social regulation of the endocannabinoid system and modulation of the escape and swim circuits in zebrafish (Danio rerio)

**Authors: *S. A. ORR**, T. H. MILLER, F. A. ISSA
Biol., East Carolina Univ., Greenville, NC

**Abstract:** Social status-dependent modulation of neural circuits has been investigated extensively in vertebrate and invertebrate systems. However, the effect of social status on shifting the activation between competing neural circuits is poorly understood. Zebrafish (*Danio rerio*) form stable social relationships that consist of socially dominant and subordinate animals. Once the social hierarchy is formed, social status-dependent differences in behavior patterns emerge. Here, we investigated the role of the endocannabinoid system (ECS) in regulating the activation of the swim and escape circuits. Our aim was to investigate how the ECS facilitates the transition between swim and escape circuits in socially dominant and subordinate animals. Endocannabinoids act as retrograde signaling molecules between neurons, and are implicated in inhibition of both excitatory and inhibitory neurotransmission via retrograde binding of the cannabinoid 1 receptor (CB1R). A previous study revealed a novel role for the endocannabinoid 2-Arachidonoylglycerol (2-AG) in modulating the switch in activation between the swim and startle circuits in zebrafish. The ECS displays remarkable plasticity and can be easily up- or down-regulated by targeting CB1R function. To better understand how social status regulates the ECS and its effects on circuit activation, we studied the effects of AM-251, a CB1R reverse agonist, in regulating the status-dependent differences in swim and escape behavior. First, we

show that dominant and subordinate animals display significant differences in locomotor behavior as dominance is established. Subordinate animals startle more readily in response to auditory stimuli, while dominants swim at a higher frequency than subordinates. Secondly, pharmacological blockage of the CB1R via injection of AM-251 suggests that locomotor behavior in subordinate fish is more susceptible to ECS modulation, and that behavior in dominants is relatively more resistant to modulation. Finally, hindbrain gene expression results suggest that ECS genes are differentially expressed according to social status in that DAGL, the enzyme responsible for synthesizing 2-AG, is downregulated in subordinate zebrafish compared to dominants and social isolates (control). However, no differences in CB1R or MGL expression were observed between dominants and subordinates. Our results support the notion that the ECS is socially regulated and involved in mediated changes in relevant social behaviors.

**Abstract:** Social affiliation with conspecifics is a behavior shared by many vertebrates. Zebrafish show robust shoaling behavior in adults that emerges gradually during development. We found that adult zebrafish approach movies of conspecifics but that this behavior attenuates rapidly during repeated movie presentations. Zebrafish carrying mutations in shank3B and fish expressing a dominant-negative shank3B construct, however, exhibit a sustained behavioral response to repeated movie presentations. To investigate the neuronal correlates of these behaviors we established a closed-loop, 3D virtual-reality (VR) approach where adult zebrafish are head-fixed and navigate in a virtual environment that includes movies of conspecifics. Activity patterns in the dorsal forebrain were imaged during behavior by two-photon calcium imaging at single-cell resolution. A subset of neurons showed activity that was correlated to the onset and offset of swimming events. Other neurons responded to perturbations of the VR such as interruptions or reversals of the coupling between motor behavior and the VR. Interestingly, a specific subset of neurons in forebrain regions Dc (possibly homologous to mammalian

isocortex) and Dm (presumably homologous to parts of the amygdala) increased their activity when the animal approached movies of conspecifics. These results are beginning to elucidate neuronal representations of social information and behavior in wild-type zebrafish and in genetic disease models.

**Title:** Sexually-relevant visual and chemosensory signals induce distinct behaviors and brain activation patterns in the social African cichlid, Astatotilapia burtoni

**Authors: *K. FIELD**, C. T. MCVICKER, K. K. JOHNSON, K. P. MARUSKA
Biol. Sci., Louisiana State Univ., Baton Rouge, LA

**Abstract:** Across vertebrates, females are often senders of potent chemical signals that provide information important for coordinating reproductive events. In several fish species, these chemical signals can induce robust reproductive behavioral responses in male receivers. How the brain processes these sexually-relevant signals to elicit these behaviors, however, remains poorly understood. Here, we used the highly social African cichlid fish, *Astatotilapia burtoni*, to investigate how sexually-relevant chemical and visual signals from gravid (full of eggs) females influence behavior and brain activation patterns in dominant males. We presented both chemical (control water or gravid female-conditioned water) and visual (no fish control or gravid female) signals either alone or together and found that males need sexually-relevant visual signals to engage in stereotypical courtship behaviors such as body quivers, waggles, and leads into the spawning territory. However, the number of courtship behaviors was greater when males were dually exposed to visual and chemical signals from females, compared to either sensory signal alone. When a female visual signal was absent, males showed increased swimming and overall activity in response to female-conditioned water compared to control water, suggesting that female-released chemosensory signals may stimulate male searching behavior and motivation. Importantly, we also tested anosmic (olfactory ablated) males to demonstrate that this behavior is primarily mediated by the olfactory system rather than gustation. Using the immediate early gene

*cfos* as a proxy for neural activation, we also found that brain regions of the social decision making network show differential activation when dominant males are exposed to chemical and visual signals together compared to exposure of either sensory signal alone. For example, the ventral part of the ventral telencephalon (homologous in part to mammalian lateral septum) shows more activation in response to sexually-relevant visual signals regardless of whether chemical signals are present or not. In contrast, the dorsal part of the ventral telencephalon (homologous in part to mammalian nucleus accumbens) shows greater activation to sexually-relevant chemical signals regardless of whether visual signals are present or not, and the preoptic area has the greatest activation when chemical and visual signals are presented together. These data provide insight on distinctions between brain regions involved in olfactory processing itself from those involved in integrating multiple sensory modalities to elicit appropriate social behaviors.

**Title:** The behavioral effects of taurine in aggression of female crayfish, Procambarus clarkii

**Authors: *C. M. MECCA**, B. N. THOMAS, R. F. WALDECK
Biology/ Neurosci. Program, Univ. of Scranton, Scranton, PA

**Abstract:** Crayfish will engage in aggressive behavior when confronted by a competing species. Once finished, these confrontations leave crayfish behaviorally effected, referred to as the loser effect (Moore, 2007). When a crayfish repeatedly wins its confrontations, its chances for winning increase, while a loser will continue to lose (Moore, 2007). Although the social behaviors of crayfish have been studied, it is unclear as to not only, what mechanisms are active in determining a confrontation, but also, what mechanisms are controlling the effects after confrontation. Taurine, an amino acid, may be beneficial in understanding aggressive behavior in crayfish (Galler et al., 1990). It is also understood that taurine is essential for the function and development of skeletal muscle and the central nervous system (Picones et al., 1992). In this experiment, the influence of taurine on the losing crayfish in fights between two female crayfish, *Procambarus clarkii*, was studied. Female crayfish were paired by size and then fought twice without drugs to determine the loser. After losers were given taurine, crayfish were fought twice again. All losing crayfish remained losers after administration of taurine. It was observed that there are additional characteristics in female confrontations that are not reported in male crayfish.

The aggression of crayfish given taurine was suppressed after drug administration. Losing female crayfish which had received taurine also had an increase in tail-flip frequency after being drugged with taurine. This might suggest that taurine acts on the regulatory loop in the tail that normally inhibits the tail-flip behavior (Wine and Krasne, 1972).

**Title:** Socially induced sensorimotor filtering plasticity in female African cichlid fish Astatotilapia burtoni

**Authors: M. ADELMAN**, A. CHEN, H. NEUMEISTER, *T. PREUSS
Psychology, City Univ. of New York, Hunter Col., New York, NY

**Abstract:** African cichlid fish *Astatotilapia burton*i have long been used as a model system for investigation of socially induced neuroplasticity. *A. burtoni* males alternate between dominant (DOMm) and territorial, and subordinate (SUBm) and non-territorial social status. We recently showed that male startle escape behavior and sensorimotor filtering abilities (pre-pulse inhibition, PPI) depend on social status. Specifically, SUBm show reduced PPI as compared to DOMm, suggesting that social defeat drives PPI plasticity. Interestingly, when housed without the males, female *A. burtoni* establish a male-like social hierarchy, with DOM females (DOMf) demonstrating territorial and aggressive behaviors towards SUB females (SUBf). However, the effect of social status on startle behavior and PPI in females is not known. Here we asked if DOMf and SUBf housed in female-only communities will demonstrate socially induced differential PPI comparable to their male DOM and SUB counterparts. In addition, since females in gender-mixed communities (COMf) are not frequently subjected to DOMm aggression, we also hypothesized they will not show PPI deficits. To test for PPI, COMf (N=10), DOMf (N=9) and SUBf (N=13) were exposed to a startling (pulse), preceded by a non-startling acoustic stimulus (prepulse), and responses were scored based on the presence of a startle response. Trials were conducted with the prepulse/pulse interstimulus interval (ISI 50ms). Preliminary results showed a trend toward reduced PPI effect in SUBf (51.9% +/- 6.8 SEM) as compared to DOMf (71.9 % +/- 7.0 SEM) which approached significance (p=0.072; independent samples t-test). The baseline startle rates were similar in the two groups. In addition, we found similar PPI effect in COMf (68.8% +/- 8.4 SEM) and DOMm (70.7% +/- 11.8 SEM) with no differences in baseline

startle rates. Taken together, these results suggest that social defeat may indeed drive PPI plasticity independent of gender, and that higher PPI observed in DOMm, COMf and DOMf might represent the default in this species.

**Title:** Interneurons in the primary auditory center of the honeybee brain responsive to air vibration pulses as elicited during waggle dance communication

**Authors:** ***T. WACHTLER**[1], A. KUMARASWAMY[1], K. KAI[2], H. IKENO[3], H. AI[2]
[1]G-Node, Dept. Biol. II, Ludwig-Maximilians-Universität München, Planegg, Germany; [2]Dept. of Earth Syst. Sci., Fukuoka Univ., Fukuoka, Japan; [3]Sch. Hum. Env. Sci., Univ. Hyogo, Himeji, Japan

**Abstract:** Honeybees use the 'waggle dance' to communicate the location of nectar sources to their hive mates (von Frisch, 1967). During the waggle dance, the dancer produces trains of vibration pulses, which are detected by the follower bees via Johnston’s organ on the antennae. To uncover the neural mechanisms underlying the encoding of distance information in the waggle dance follower, we investigated morphology, physiology, and immunohistochemistry of interneurons arborizing in the primary auditory center of the honeybee (Apis mellifera). We

identified and categorized 119 vibration-sensitive interneurons based on morphology and responses to vibration stimuli. Three major interneuron types - the local interneuron DL-Int-1, the output neuron DL-Int-2, and Bilateral DL-dSEG-LP - showed specific GABA immunoreactivity and responded with different spiking patterns to trains of waggle dance-like vibration pulses applied to the antennae. We developed new methods for reconstruction and comparison of morphologies, and investigated the GABAergic local interneuron DL-Int-1 further, specifically its age-related adaptations of physiology and morphology. DL-Int-1 neurons from mature honeybees were morphologically different from those from young honeybees, showing region specific changes to dendritic density. DL-Int-1 also showed significantly stronger inhibition and post inhibitory rebound in mature foragers, further supporting the important role of inhibition in processing waggle dance signals. Our results suggest a disinhibitory network for encoding and processing the duration of vibration pulse trains in the primary auditory center of the honeybee.

**Title:** Modeling visual perception, learning, and memory of wood ants navigating in naturalistic environments

**Authors: *A. J. MENDOZA**[1], D. D. LENT[2]
[1]Biol., California State Univ. Fresno, Fresno, CA; [2]Biol., CSU Fresno, Fresno, CA

**Abstract:** A number of experiments have revealed how different visual features are used to guide familiar foraging routes in wood ants. Using these data, we have developed algorithms to extract visual features that ants use for guidance from panoramic scenes. Through simulation we have characterized how visual cues that ants use are extracted, prioritized and stored during navigation. A foraging model was created in MATLAB to simulate navigation in a procedurally generated environment where the visual cues could be precisely characterized. In these environments, our algorithms extracted and stored the visual cues that were available during a single Levy walk foraging event. Following a random foraging event, the success on subsequent foraging bouts using the stored information was examined. When we examined subsequent foraging walks we found the success of the simulated ant in finding the goal location using only

a particular cue or a combination of cues depended on two factors - the length of the route and decay rate of information in a memory network. To further explore this we simulated the Levy walk foraging event over various sampling points (100-10000) and implemented linear or exponential decay in the networks storing the information. Our data suggests that the optimal strategy is to sample and store between 1000 and 2000 points along the foraging route, independent of scale, with a network subjected to exponential decay. These parameters resulted in a stored representation that allowed the simulated ant to best find the goal on subsequent foraging bouts. We then produced several novel random foraging walks with the same goal location. The subsequent walks for these foraging events had similar success demonstrating sufficient information was stored and resulted idiosyncratic foraging routes due to the varied information encountered during the random walk. Additionally, we explored how multiple subsequent walks updated and modified memory to produce more robust walks over time. Lastly, we compared the success of subsequent of the model when foraging in sparse and cluttered environments. The results of these simulations have provided insight into the mechanisms involved in prioritization and perception of visual information, it supports that ants need only processes relevant cues intermittently and they do not continually process visual information. Additionally, it has let us investigate how learning and storage of spatial information can be optimized in simple networks and nervous systems.

**Title:** Behavioral and neuronal responses in male-exposed female cricket Acheta domesticus

**Authors: *B. A. NAVIA**, C. R. KENT
Dept. of Biol., Andrews Univ., Berrien Springs, MI

**Abstract:** Syllable period-selective phonotaxis in female cricket *Acheta domesticus* as well as the corresponding response of neural elements (such as the L1, L3 and ON1 neurons which influence phonotaxis) have been the focus of multiple studies. Such previous studies, have reported a degree of individual variability in phonotactic behavior..However, obvious differences in their responses based on age are typical for this species. The described behavioral and neuronal responses were correlated, and ranged from selective to unselective in both young and old females respectively. All of these studies have used virgin females raised in isolation. The

current project investigates the possible influence in the phonotactic and neuronal responses of male-exposed females of different ages. We hypothesized that the presence of males would significantly reduce phonotaxis by females to model calls. However, preliminary results reveal an increase in behavioral response and a reduction in syllable period-selective phonotaxis. Furthermore, in contrast with previous studies, we did not observe any correlation between female age and phonotactic responsiveness. Regardless of age, male-exposed females seemed not to discriminate between attractive and unattractive model calls. Additionally, call intensity may also affect syllable-period selective phonotaxis in these females. The potential effects of male exposure on the response of prothoracic auditory interneurons such as L3 are unknown. It had been reported that the L3 auditory interneuron in young virgin females exhibited decrementing response (reduction in the number of action potentials to consecutive sound pulses within a chirp) which has been interpreted as the major driver of syllable-period selective phonotaxis. L3s in old virgin females exhibit significant reduction in their decrementing response. Preliminary results suggest that regardless of age and in contrast to previous finding, L3s of male-exposed females fail to decrement in response to auditory stimuli, irrespective of syllable period. The implications of these results are discussed.

**Title:** Sex differences in sensorimotor coding for the production of duets in plain-tailed wrens

**Authors: *M. J. COLEMAN**[1], N. F. DAY[2], P. RIVERA-PARRA[3], E. S. FORTUNE[4]
[1]Keck Sci. Dept., Claremont McKenna, Pitzer and Scripps Colleges, Claremont, CA; [2]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA; [3]Dept. de Física-Instituto de Ciencias Biológicas, Escuela Politécnica Nacional, Quito, Ecuador; [4]New Jersey Inst. of Technol., Newark, NJ

**Abstract:** Males and females routinely coordinate behaviors, especially in the context of mate selection and reproduction. This coordination requires that each individual integrate sensory cues from its partner to modulate its own motor programs. Plain-tailed wrens (Pheugopedius euophrys) produce a cooperative duet in which male and female birds rapidly alternate syllable production. This duet, which is used in territorial defence and pair bonding, can be coordinated using acoustic cues alone. We investigated the role of acoustic cues in the modulation of brain

activity in male and female wrens. We focused on the brain area called HVC as it is a premotor area necessary for song production that also receives acoustic information. In chronic neurophysiological recordings made in awake, behaving birds, there is little evidence of sensory responses in HVC activity in both males and females. Rather, activity appears to be pre-motor, with bursts of firing starting prior and continuing through the production of autogenous syllables. Nevertheless, there is evidence for sensory modulation of the motor program, as changes in the behavior of one bird are reflected in changes in HVC activity in the other bird during the duet. Interestingly, we observed 'motor replay' in awake birds of both sexes in the absence of syllable production. To further characterize the acoustic inputs to HVC, we replayed duet songs that were produced by the pairs during during these chronic neurophysiological experiments in subsequent acute experiments in which the birds were anesthetized with urethane. In the acute experiments, therefore, HVC activity is 'sensory-only' -- the animal hears its own vocal output and the vocal output of its partner. In this way, we were able to compare the activity in HVC in the context of singing (chronic experiment) and in relation to sensory coding (acute experiment). We found that changes in the activity in male HVC between chronic and acute recordings were more dramatic than in females. In females, we saw an expected shift in the timing of activity between chronic and acute recordings. Surprisingly, neural activity in males shifted dramatically between awake and anesthetized states. In awake birds, activity was characteristically premotor, occurring prior to and during male syllables. However, in anesthetized males, neurons responded strongly to female syllables and had very little response to male syllables. These data likely reflect distinct sex differences in the roles of each bird in the coordination and control of this cooperative behavior.

**Title:** State-dependency of viscerosensory input to the song motor system of passerine songbirds

**Authors: *J. BURKE**[1], J. MCLEAN[1], A. PERKES[2], M. F. SCHMIDT[1]
[2]Biol., [1]Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Motor performance is evaluated continuously by specialized brain circuits and used adaptively to modify behavior moment-to-moment as well as over longer time periods. During vocal behaviors, motor performance is evaluated by auditory feedback and likely also by sensory feedback from the vocal-respiratory periphery (defined henceforth as viscerosensory). Although much work has been performed on auditory feedback, little is known about how and where viscerosensory feedback is evaluated. In the avian song circuit, premotor nucleus HVC responds robustly to auditory stimuli but it is not known whether it also responds to viscerosensory stimulation. Sensory information from stretch receptors in the respiratory apparatus project through the vagus nerve to the nucleus of the tractus solitarius (nTS) up to PAm and eventually to HVC via intermediary thalamic nucleus Uva. Response in HVC to viserosensory stimulation would strengthen the hypothesis that viscerosensory feedback can have a direct influence on forebrain song control circuits.
Our preliminary findings investigating viscerosensory responses in HVC have been inconsistent. Delivery of brief air puffs through a cannula in the posterior air sac of anesthetized (Ketamine/Xylazine) adult male zebra finches elicited responses in less than 20% of recorded sites. We hypothesized that this inconsistency was caused, in part, by anesthesia-dependent suppression of sensory responses in the respiratory brainstem. We therefore performed new experiments in head-restrained awake birds. Under these conditions, we observed sensory responses in HVC but only when birds were quiet; brief arousal, often occurring upon delivery of multiple air puffs, caused suppression of responses. To prevent such arousal, we modified our experimental paradigm to record from HVC in head-restrained birds that were lightly sedated with diazepam. Under these conditions, our preliminary data suggest that neurons in HVC consistently show responses to brief air puffs delivered to the air sacs. We recorded extracellularly from 11 sites in 3 birds and found significant responses at each site with response latencies that ranged from 30 to 50 ms. To make sure that responses were specific to activation of receptors in the air sacs and not caused by click sounds associated with puff delivery, we placed the picospritzer in a sound-proof chamber and interleaved each experiment with controls to ensure that responses were not caused by auditory artifact. These preliminary results provide evidence for state-dependent viscerosensory responses in HVC. Future experiments will probe for response properties in PAm and Uva as well as in HVC of singing birds.

**Title:** Combining auditory and viscerosensory feedback perturbations in adult male zebra finches causes rapid song destabilization without recovery

**Authors: *K. M. MILLER**[1], C. S. LY[1], M. F. SCHMIDT[2]
[1]Biol., [2]Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** The avian song system is an established model for studying learned vocal behavior. Juvenile songbirds crystallize their song using auditory feedback, which remains necessary for maintenance of adult stereotyped song. Disruption of auditory feedback by deafening causes song to deteriorate over a time period that varies across age and species. Because changes in song pattern are not evident until after the bird has produced many hundreds or thousands of songs, deafening-induced song degradation likely is caused by a slow accumulation of error. Viscerosensory feedback includes feedback from vocal musculature, air sacs, and lungs, and it is hypothesized to also play an important role in song maintenance. Song degradation caused by unilateral transections of the vagus nerve, which carries sensory information from the vocal-respiratory periphery, has been surprisingly modest. Typically, unilateral vagotomy causes immediate, but rather subtle, acoustic and temporal degradations of song which often show partial or full recovery within three days. This short time scale can be contrasted with the slower cummulative effect of deafening.
We hypothesized that if both types of feedback are necessary for song maintenance in a basal ganglia-dependent manner, then combining deafening with unilateral vagotomy should result in an increase in error accumulation and, as a consequence, a more profound and rapid degradation of song. Preliminary findings show effects not seen in deafening or vagotomy alone. We observe immediate acoustic deficits similar to previous studies following unilateral vagotomy, however, birds also show rapid acoustic and temporal song degradation that does not recover. Most significantly, we observe syllable omissions and significant variability in syllable duration within 1-2 weeks after nerve transection in deafened birds. Our findings suggest that perturbing both sensory feedback systems causes an accumulation of error that is greater than for each perturbation alone. Future experiments will investigate the role of the basal ganglia circuit in the context of this dual feedback perturbation paradigm.

**Abstract:** C-fos studies indicate that the medial preoptic nucleus of the hypothalamus (MPOA) is activated during male sexual behavior and maternal care. However, to date little is known about the real-time dynamics of MPOA neural activities during behavior. In this study, we used fiber photometry to record MPOA calcium signal in freely moving male and female mice. We found that MPOA was strongly activated by socially relevant cues in both sexes. These results provide new insight into the neural mechanism through which MPOA regulates sexually dimorphic display of male sexual behavior.

**Title:** Acute and long-term biobehavioral outcomes following reduced maternal care and neonatal pain

**Authors: *S. M. MOONEY-LEBER**[1], J. YOUNG[1], S. BRUMMELTE[2]
[2]Dept. of Psychology, [1]Wayne State Univ., Detroit, MI

**Abstract:** Preterm infants are exposed to a multitude of painful procedures while in the neonatal intensive care unit. Although these procedures are in place to promote the survival of the infants, recent research suggests that exposure to many painful procedures may result in impaired brain development. In addition to pain, preterm infants also experience reduced maternal care with traditional incubator care. Preclinical models have indicated that reduced maternal care during the neonatal period results in impaired biobehavioral development. Thus, the current study sought to investigate the biological and behavioral consequences of neonatal pain in combination with reduced maternal care using a rodent model. Rat pups within a litter were assigned to one of 5 groups: unhandled control, tactile control, pain, reduced maternal care, and pain and reduced maternal care. Painful procedures consisted of needle insertion into alternating paws several times a day. Pups in the reduced maternal care groups were placed in a tea-ball infuser for 30 minutes immediately following administration of painful procedures or tactile stimulation. Two cohorts were used to analyzed the acute biological outcomes and the long-term behavioral

outcomes. The first cohort was sacrificed on postnatal day (PD) 4 and serum and brains were collected for enzyme-linked immunosorbent corticosterone assay and magnetic resonance spectroscopy. The second cohort was allowed to mature to adulthood and underwent cognitive and stress reactivity testing (starting on PD 79). Pups that experienced pain and/or reduced maternal care had significantly lower body weights on PD4. Further, exposure to reduced maternal care produced an increase in serum corticosterone and a reduction hippocampal glutamate/creatine ratio, whereas exposure to pain produced a reduction glutamate/creatine ratio in the frontal cortex. From these results, it is hypothesized that exposure to reduced maternal care and/or neonatal pain will produce impaired cognitive functioning and altered stress reactivity in adulthood. Our data suggests that neonatal pain exposure and/or reduced maternal care influence the hypothalamic-pituitary-adrenal axis and the glutamate/creatine ratio in regionally specific fashion, which in turn may influence biobehavioral outcomes later in life.

**Abstract:** In developed countries, childhood abuse and neglect are the most common and preventable causes of abnormal brain development. Often, the result is altered brain function and connectivity that persists into adulthood and is associated with a wide range of psychiatric and medical conditions. Among the most robust findings associated with early life stress (ELS) is abnormal amygdala size, hyperactivation in response to threats, and abnormal connectivity to other brain regions including the hippocampus and the prefrontal cortex. In this study we investigated the effects of ELS on amygdala connectivity and anxiety-like behaviors in a novel rodent model of early life stress called Unpredictable Postnatal Stress (UPS). Here we show that

UPS causes increased anxiety-like behavior in male but not female mice. This increase in anxiety is present in juvenile males and persists into adulthood. Using resting state fMRI (rsfMRI) we found hyperconnectivity between the amygdala and the prefrontal cortex and the amygdala and the hippocampus (both dorsal and ventral regions). Moreover, increased connectivity between the amygdala and these brain regions correlated with increased anxiety-like behavior. This study is the first to use rsfMRI to characterize amygdala connectivity in a mouse model of ELS and its findings are consistent with similar studies in maltreated children.

**Abstract:** Overwhelming evidence suggests that adversity during early life markedly increases vulnerability to a myriad of neuropsychiatric disorders including depression, anxiety, and schizophrenia. Importantly, stress during this time modifies circulating levels of stress hormones, which in turn has downstream effects on neuroimmune function. We hypothesize that these changes likely negatively impact overall neural development via neuroimmune signaling - particularly within the prefrontal cortex (PFC) - thereby leading to altered pathology associated with neuropsychiatric dysfunction. While the etiological mechanisms are not fully understood, resident microglia are thought to be a common source of increased neuroimmune activity through production of inflammatory molecules (e.g. cytokines, chemokines) in response to disruption in homeostasis. Microglia are capable of provoking long-term changes in brain structure and function, particularly within local microcircuitry. Importantly, they have the ability to become chronically sensitized, or ‘primed.’ to over-activation following insult. Early life stress (ELS) via maternal separation (MS) is thought to alter microglial reactivity to subsequent immune activation across development. In order to better understand the impact of MS on microglial priming in the developing immune system, rat pups were separated from their dams

for 4 hours per day from P2-20. In order to stress immune reactivity following MS, rats were exposed to the endotoxin lipopolysaccharide (LPS) at distinct developmental time points (P9, P20, or P40), and the concentrations of ramified and amoeboid PFC microglia were quantified to gain insight to activity states. Additionally, in order to assess the level of release of pro-inflammatory cytokines, quantitative RT-PCR was conducted on isolated microglia, allowing for the analysis of transcripts encoding only microglia-associated molecules, such as TNF-α and IL-10 throughout development. With this method, we are able to directly analyze the variations in neuroinflammatory changes at these distinct time points with ELS and LPS induced stress, providing compelling evidence for a role of early life adversity in altering microglia function in later life.

**Abstract:** Early life stress (ELS) is associated with an increased risk for later development of emotional pathology such as depression and anxiety. The origins of pathology are thought to be rooted in atypical development of circuits regulating emotional responding, including the amygdala. Here we used a mouse model of ELS, in the form of maternal bedding restriction, and tested the effect on amygdala development, and the development of freezing behavior in a tone-associated fear conditioning paradigm. Previous work has established that tone-associated freezing develops as early 15 days of age and stays relatively stable across early development. Here, we found that mice reared under ELS conditions show an unexpected and significant dip in freezing behavior at 21 days of age. This dip in freezing behavior was associated with a precocious maturation and spike in the density and activity of Parvalbumin (PV)-positive cells in the basal amygdala (BA) . To test if the spike in PV-cells was related to suppressed freezing behavior, we took advantage of optogenetic techniques to silence this population of cells in the BA during acquisition and testing phase in the conditioning paradigm. We found that silencing BA PV cell restored normal levels of freezing behavior in ELS reared mice. These results have

implications for understanding the effects of ELS on the ontogeny of circuit development and its impact on the development and expression of fear associated responding.

**Abstract:** Early life adversity increases the lifetime risk for pathology and profoundly impacts neural development. Multiple mouse models of early life stress (ELS) have been developed to aid in understanding the mechanisms underlying risk for pathology development. In recent years, a limited bedding (LB) paradigm has been developed, in which early life stress is induced by limiting dams' access to bedding and nesting resources during defined periods of pup development (Rice et al., 2008). In the current study, we use 24/7 video monitoring to more thoroughly characterization LB manipulation effects on maternal behavior over the circadian cycle, as well as the evolution of changes in maternal behavior across the duration of the ELS paradigm. We also assess maternal behavior prior to and following the completion of the ELS manipulation. Maternal behaviors, including nesting, eating, drinking, and walking, were characterized using a combination of Ethovision automated tracking and hand scoring of videos over the circadian cycle. We have previously characterized the effects of LB manipulations on measures of cognitive, affective, and neural development. As an initial pilot study, we will also provide data related the impact of LB manipulations on development and ELS-associated effects on immune activation in peripheral blood mononuclear cells and neural tissue.

**Abstract:** In humans, childhood exposure to abuse leads to an elevated risk for the development of psychopathology in adulthood. Although much research has investigated the long-term implications of early-life stress (ELS) in adults, its effects on development and the mechanisms it employs remain largely unknown. Here we used a form of ELS to study the underlying mechanisms through which ELS alters neuronal development impacting contextual fear memory expression. Our ELS paradigm restricted maternal access to bedding and nesting materials from postnatal days (P) 4 to 11. Previous data from our lab demonstrates that this form of ELS accelerates the emergence of adolescence-associated fear suppression from P28 to P21. To uncover the underlying mechanism, we obtained hippocampal samples of control and ELS animals at multiple developmental time points (P4 through adulthood). mRNA quantification of brain-derived neurotrophic factor (BDNF) and truncated track b receptor (TrkB.T1; an endogenous dominant negative receptor for BDNF) mRNA revealed a significant increase in BDNF mRNA at P12 accompanied by a decrease in TrkB.T1 mRNA. These results suggest that ELS may lead to a robust increase in BDNF availability at P12. Furthermore, the proliferation of

parvalbumin positive neurons (PV+), known to be a BDNF-initiated process, was revealed by immunohistochemical analysis to be increased in ELS animals at P21 when compared to controls. This acceleration of generation PV+ neurons led us to hypothesize that ELS serves to elevate BDNF and drives the acceleration seen in limbic system development. To test this hypothesis, we employed a genetic approach in which we attempt to both negate the effects of ELS by reducing the amount of functional BDNF via both a Val66Met mutation and BDNF knockout, and to phenocopy the behavioral effects of ELS by genetically eliminating the TrkB.T1 receptor. Our preliminary results suggest that animals which have undergone ELS but have decreased secretion of mature BDNF lack the suppression of fear expression normally observed in wild-type ELS mice at P21.

**Title:** Sex-selective effects of early life stress on the development of attentional deficits

**Authors: *H. GOODWILL**, S. LIN, E. OYERINDE, K. BATH
Brown Univ., Providence, RI

**Abstract:** Stress incurred early in life influences emotional development and increases the lifetime risk for and severity of affective pathology. Women have a heightened susceptibility to the effects of early life stress (ELS) and are twice as likely than men to develop stress-associated pathology, such as depression. Depressive pathology is highly co-morbid with cognitive impairments and inflexibility, resulting predominantly from frontal lobe dysfunction. The prefrontal cortex (PFC), which orchestrates the integration of cognition and emotion through cortical and subcortical pathways, is especially sensitive to chronic and early life stress. We recently demonstrated that female mice exposed to ELS, in the form of maternal bedding restriction, show a sex-selective development of depressive-like behavior and are more severely impaired than male and control mice in rule-reversal learning ($p<0.01$) during an attentional set shifting task. Using optogenetic inhibition of fast spiking (FS) GABAergic interneurons containing the calcium binding protein parvalbumin (PV) in the orbitofrontal cortex (OFC)

of control animals, we can phenocopy the deficits observed in ELS-exposed females. In the OFC, ELS was also associated with a decrease in PV mRNA levels ($p<0.05$), and a female specific decrease in GAD67 ($P<0.01$), a GABA synthesizing enzyme. Here we investigate the developmental time-course of these impairments and the potential underlying mechanisms by which ELS alters PV interneuron development in this region. This work addresses the mechanisms supporting sex differences in risk for the development of affective pathology, which is a relevant and largely overlooked public health concern. It lays the foundation for predictions regarding risk factors and biomarkers that underlie sex differences in vulnerability to stress and associated cognitive impairments linked with depression.

**Abstract:** Previous studies in rodents have reported that prenatal stress can result in adult progeny that show decreased neuronal volume and glutamate receptor expression in the hippocampus, as well as decreased spatial memory performance, and increased anxiety- and depression-like behaviors in open field or forced swim tasks. Studies have also reported that maternal stress during pregnancy can lead to increased expression of specific DNA methyl transferases suggesting epigenetic alterations in gene expression in offspring. In *Caenorhabditis elegans*, extreme heat stress has been shown to decrease adult fecundity while exposure to less severe stressors during worm development increases resistance to oxidative stress in later generations via epigenetic mechanisms. To examine the potential transgenerational effects of in utero stress in *C. elegans*, adult worms were exposed to a mild stressor for ~4 hours; a duration that corresponds to egg formation. Worms were then either bleached for egg collection or were observed for spontaneous behaviors by measuring frequency of reversals and behavioral variability. Spontaneous behaviors were also then measured for subsequent F1 and F2 generations. Preliminary results indicate a decrease in spontaneous reversals in adult progeny of stressed animals compared to progeny of worms exposed to sham or control conditions. Research

in rodents suggests that prenatal stress modulates glutamate signaling in offspring, typically via downregulation of glutamate receptors. To study this possibility in *C. elegans* across generations, expression of *glr-1* (non-NMDA type glutamate receptor) was measured using qRT-PCR. As well, patterns of expression and regulation of GLR-1 receptors were assessed in vivo with confocal imaging of GLR-1::GFP. Taken together, this work could help elucidate the broad effects of in utero stress and provides additional support for the use of the *C. elegans* model system to investigate transgenerational effects of parental experience.

**Title:** Rescue of sex-specific phenotypic outcomes of exposure to early-life stress using pharmacological interventions

**Authors: *S. M. KELLER**, T. S. DOHERTY, A. NOWAK, T. L. ROTH
Univ. of Delaware, Newark, DE

**Abstract:** Experiencing maltreatment by the caregiver can have lifelong consequences for the brain and behavioral trajectories. Epigenetic mechanisms are one potential way via which early-life experiences are capable of inducing long-term effects. In the current study, rodents were exposed to brief bouts (i.e. 30 minutes per day) of caregiver maltreatment for the first seven days of life. Previous work employing this model has shown that adult females exposed to this perturbation during infancy maltreat their own offspring, show altered behavior in the forced swim test, and exhibit alterations in epigenetic marks such as DNA methylation throughout the brain. Because changes in phenotypic outcomes associated with experiencing maltreatment are sex-specific, we conducted one study to examine sex differences in infant caregiving during our maltreatment paradigm. Data indicate that more adverse maternal behaviors are performed toward female, as compared to male, pups in our model of caregiver maltreatment. As the role of epigenetic alterations in causing phenotypic outcomes resulting from caregiver maltreatment is unclear, we conducted a second study where we administered zebularine, a drug which inhibits DNA methylation, to adult female rats. Maternal behavior and behavior in the forced swim test

were measured after a week of zebularine administration. Data indicate zebularine administration normalizes behavior and DNA methylation aberrations associated with maltreatment. Changes in gene expression following our pharmacological intervention will also be presented.

**Title:** An investigation into pharmacological prevention of epigenetic traces left by early-life stress

**Authors: *T. S. DOHERTY**, J. R. CHAJES, T. L. ROTH
Univ. of Delaware, Newark, DE

**Abstract:** Early life stress, particularly within the caregiving relationship, is a major precipitating factor for psychiatric and cognitive disorder. While the mechanisms underlying this connection have yet to be elucidated, epigenetic alterations are leading candidates. We have previously reported altered patterns of methylation associated with exon IX of the brain derived neurotrophic factor (*Bdnf*) gene in the prefrontal cortex of rats following exposure to caregiver maltreatment. Given that *Bdnf* is critical to developmental processes and that its dysregulation is heavily implicated in altered cognitive function and in several psychiatric disorders, aberrant methylation of this gene may underlie altered behavioral trajectories associated with early-life stress. Thus, the aim of this work was to assess the ability of epigenetic drugs (i.e. those that inhibit critical epigenetic enzymes) to prevent altered patterns of methylation at *Bdnf* exon IX previously discovered in our maltreated rats. Infant male and female Long Evans rats were subjected to either nurturing care (from their biological mother or a foster dam) or maltreatment from a foster dam for 30 minutes daily from postnatal days (PN) 1 to 7. One of three drugs (inhibiting either HDACs or DNMTs) or an appropriate vehicle was administered daily to each group prior to caregiving manipulations. Brains and plasma were extracted 24 hours after the last manipulation (on PN8) for methylation analysis. Data demonstrate that both HDAC and DNMT inhibition prevent methylation alterations associated with caregiver maltreatment. Results will be discussed in the framework of epigenetic mechanisms and interventions in early-life stress.

Future work will focus on the utility of epigenome modifiers to prevent aberrant behavioral outcomes associated with maltreatment.

**Abstract:** Early life stress (ELS) is a known risk factor for psychopathology, including anxiety and depressive disorders, substance abuse, as well as cognitive and behavioral deficits. The mechanisms underlying this association, however, remain poorly understood. A likely biological link between ELS and many psychopathologies is its impact on typical development of the hypothalamic-pituitary-adrenal (HPA) axis. Studying this relationship in humans can be challenging due to limitations in prospective studies, as well as confounding factors, such as co-morbid conditions and genetics. To circumvent these difficulties, our group used a translational and well-established ELS model of infant maltreatment by the mother in rhesus macaques. This ELS model consists of comorbid infant abuse and rejection by the mother during the first months of life. To disentangle the effects of the adverse experience from those due heritable factors, infant macaques (n=43) were cross-fostered at birth and randomly assigned to either control (n=21) or maltreating (MALT; n=22) foster mothers. We assessed the developmental impact of adverse care on HPA axis function longitudinally since birth through the juvenile period using (1) measures of hair cortisol (CORT) accumulation, (2) diurnal CORT rhythm, and (3)

glucocorticoid negative feedback via dexamethasone (DEX) suppression tests. Our findings indicate that, although hair CORT levels were not different at birth, MALT infants showed significantly higher CORT accumulation than controls from birth through 6 months, with a parallel trend towards elevated plasma CORT levels. Long-term impact of adverse caregiving was detected at 12 months, with a significant interaction effect between MALT and sex on diurnal CORT rhythm, with MALT females exhibiting higher CORT levels at both the morning and afternoon time points than control females. This effect was not observed in the males. MALT subjects of both sexes showed super-suppression of CORT secretion in response to DEX challenge at 12 months. Neither of the diurnal or DEX suppression effects observed at 12 months were present at 18 months. These data suggest that alterations in HPA function due to maternal maltreatment persist past the early infant period of ELS exposure into the early juvenile period, but are ultimately temporary. Additionally, females are more sensitive to maltreatment-related HPA dysregulation than males. Although HPA axis activity seems to start to recover later in the juvenile period, chronic exposure to high levels of CORT during the first 12 months of life are expected to have long-term consequences for brain, physiological and behavioral development.

**Abstract:** Increased attention has been directed towards determining how environment interacts with genetics on the manifestation of stress-related disorders. This study investigates the differential effects of an enriched versus impoverished environment on behavioral and biochemical endpoints of depression between stress-vulnerable and stress-resilient strains in the chick anxiety-depression model. Black Australorp and Production Red strains were housed in either enriched or impoverished conditions for 4 days followed by a 90 min social isolation test. Rate of distress vocalizations (DVocs) were recorded throughout the isolation period and latency to behavioral despair was calculated. Immediately following testing, bilateral hippocampal tissue

was harvested and brain-derived neurotrophic factor (BDNF) levels were analyzed via an ELISA assay. Regardless of housing conditions, stress-vulnerable Black Australorps entered behavioral despair more quickly than the Production Reds. Significant decreases in BDNF were seen as a result of an isolation stressor, but were dependent on the complex interaction of genetic line and housing stress conditions. Decreases in BDNF were only detected in Black Australorps housed in impoverished conditions and the Production Red housed in enriched conditions. These findings may be relevant to understanding the importance of an individual's environment when treating anxiety and depression in stress-vulnerable populations.

**Title:** Limited bedding conditions during a first lactation episode induces morphological plasticity in the prefrontal cortex and increases attentional flexibility in early lactating multiparous female rats

**Authors: *C.-D. WALKER**[1,3], E. A. OPALA[3], S. VERLEZZA[3], H. LONG[3], D. RUSU[2], B. WOODSIDE, H4A 2Z7[4]
[1]Dept Psychiat, [2]Anat. Dept, McGill Univ., Montreal, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [4]Ctr. for Studies in Behavioral Neurosci., Concordia Univ., Montreal, QC, Canada

**Abstract:** Multiparous (M) females are known to display a significant increase in dendritic spines in the amygdala, septum and hippocampal CA1 compared to primiparous (P) and virgin (V) females, but regions important for cognitive processing, attention and modulation of sequential behaviors such as the medial prefrontal cortex (mPFC) have not been thoroughly investigated. Because of the critical role of the mPFC in "gating" stress and emotional responses, and in modulating some aspects of maternal behavior, a history of stress during a first lactation episode might significantly alter morphological and functional plasticity in this structure in subsequent lactation periods. We compared neuron morphology in mPFC between primiparous and multiparous lactating female rats on postpartum day, PPD5 that had been exposed to the chronic stress of limited bedding and nesting material (LB) during PPD1-10 of a first lactation or that had normal bedding (NB). Golgi-Cox stained neurons in layer II/II of prelimbic (PL) or

infralimbic (IL) mPFC were analyzed. We also examined whether enduring effects of the LB could be observed on attention capabilities in multiparous females, using the attention set shifting task (AST) in PPD5 females. Compared to virgins, all parous female groups exhibited increased spines and dendritic length in the IL, but not the PL mPFC. In the PL, dendritic length was reduced in multiparous females compared to P or V rats. Sholl analysis of the IL neurons revealed that total spines were higher in LB groups than control NB groups, whether they were multiparous and nursing (M) or parous and 2 weeks post weaning (NL). In contrast, P females exposed to adverse LB conditions exhibited a significant reduction in total spines, dendritic length and spine density compared to controls, demonstrating an acute negative effect of LB on IL mPFC morphological plasticity. When tested for attentional capabilities, LB multiparous females on PPD3 showed the lowest number of trials to completion and total errors in the extradimensional shift, a measure of attention mostly linked to mPFC activity. Overall these results suggest that exposure to adverse environmental conditions while nursing significantly affects neuronal morphology in the IL mPFC of mothers and causes both an acute reduction and long-term compensatory increase in spines in this region that persists in multiparous females. These morphological changes associate with greater attentional flexibility, a behavioral change that might be adaptive to the care of the young under adverse conditions.

Psychiatry, Ctr. of Mental Hlth., Univ. of Wuerzburg, Germany, Wuerzburg, Germany; [5]Mol. Psychiatry, Ctr. of Mental Hlth., Univ. of Wuerzburg, Germany, Wuerzburg, Germany, Germany

**Abstract:** Brain serotonergic systems have been implicated in cognitive control and emotion regulation. The rate-limiting enzyme for synthesis of serotonin in the brain is tryptophan hydroxylase 2 (Tph2). There is accumulating evidence that Tph2-deficient mice display disruptions in behavioral phenotypes relevant to stress-related psychiatric disorders, including trauma-, anxiety-, and affective disorders. Furthermore, early life stress, such as maternal separation, can influence *tph2* mRNA expression, as well as *tph2* mRNA expression responses to stress exposure, in adulthood. The aim of this study was to determine how maternal separation affects mRNA expression of serotonin-related genes in the doral raphe nucleus (DR), including *tph2*, the high affinity, low capacity, sodium-dependent serotonin transporter (*slc6a4*), the serotonin type 1a receptor (*htr1a*), the low affinity, high capacity sodium-independent serotonin transporter, organic cation transporter 3 (*slc22a3*), corticotropin-releasing hormone receptor 1 (*Crhr1*), and corticotropin-releasing hormone receptor 2 (*Crhr2*). Male wild type, homozygous and heterozygous *Tph2* knockout mice were exposed to either animal facility rearing control conditions or maternal separation, consisting of daily separation (3 h) of mixed sex litters from the dam from postnatal day 2 (P2) until P15. During separation, pups were maintained under red-light at 29 °C and humidity of 65-70%. On P25, pups were weaned and males were group housed in groups of 3-6. Mice were euthanized as adults on day P100-110. Maternal separation differentially altered serotonergic gene expression in wild type, homozygous and heterozygous Tph2 knockout mice in a topographically specific manner within the DR. The patterns of changes in gene expression were consistent with a previously described anxiety and panic-prone phenotype of homozygous and heterozygous *tph2* knockout mice. Overall, these data are consistent with the hypothesis that gene x environment (G x E) interactions, including serotonergic genes and adverse early life experience, play an important role in vulnerability to trauma-, anxiety-, and affective disorders during adulthood.

**Title:** Effects of delaying parturition on patterns of cell death in the perinatal mouse brain

**Authors: *A. CASTILLO-RUIZ**, M. MOSLEY, N. G. FORGER
Neurosci. Inst., Georgia State Univ., Atlanta, GA

**Abstract:** Post-mitotic cell death is a key event in the development of the nervous system. Despite the established importance of this process, little is known about what initiates or terminates the cell death period. We previously reported striking changes in cell death across multiple regions in the mouse brain following birth, with some regions showing abrupt decreases (e.g., paraventricular nucleus of the hypothalamus (PVN)) and others increases (e.g., CA1 oriens layer of the hippocampus). These results suggest that birth (parturition) may trigger changes in cell death. Alternatively, the timing of cell death may be developmentally programmed and independent of birth. To distinguish between these competing hypotheses, we manipulated gestation length in C57BL/6 mice, a strain in which birth occurs on average at 19.3 days post-coitum (dpc). We established timed-pregnancies and injected dams subcutaneously with oil or with progesterone on 17 and 18 dpc. This progesterone treatment extends pregnancy by one day and mimics the hormonal profiles seen in dams that give birth "late." All animals were vaginally delivered at 19 dpc (controls) or 20 dpc (progesterone-treated). Male and female pups were weighed and euthanized on postnatal day (P) 0, 1 and 2, and their brains were collected for immunohistochemical detection of activated caspase 3, a marker of cell death. For both groups, increases in body weight were associated with birth (days *ex utero*) and not with dpc. In contrast, cell death patterns in the PVN and CA1 oriens layer were associated with dpc irrespective of *ex utero* age. This suggests that perinatal cell death patterns are developmentally programmed, whereas body growth depends on birth. Interestingly, our previous results in the PVN and CA1 oriens layer also show that birth mode (C-section vs vaginal) can alter perinatal cell death patterns, which hints that even though these patterns may be developmentally programmed under normal circumstances (vaginal birth), they can be influenced by experience/environment. Together our results contribute to the understanding of how developmental neuronal cell death is regulated.

**Title:** Neural activation triggered by birth in the neonatal mouse brain

**Authors: *Y. C. DAVILA-VAZQUEZ**[1], A. CASTILLO-RUIZ[1], C. CHEVER[2], N. G. FORGER[1]
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Eddie White Acad., Hampton, GA

**Abstract:** Birth is a dramatic event in the life of placental organisms, involving hormonal surges, uterine contractions and modifications in key peripheral organs. Parturition has been described as an "adaptive stressor" that prepares the fetus for life outside the womb, but how or if birth affects brain development is not well understood. We recently found marked changes in cell death shortly after birth in several brain regions. Furthermore, the pattern of cell death differed significantly between vaginally- and cesarean-delivered pups across multiple brain areas, suggesting an important role of birth mode in the patterning of cell death. The paraventricular nucleus of the hypothalamus (PVN) showed the largest effect of birth mode on cell death, with a transient ~3-fold increase ($P<0.01$) in the density of dying neurons in cesarean sectioned mice on the day of birth. These results suggest that the PVN is particularly sensitive to stimuli at birth. To test the hypothesis that birth triggers neural activation in the PVN, we established timed-pregnancies and collected the brains of male and female offspring *in-utero* at embryonic day (E) 18 (one day before expected delivery), and *ex-utero* at postnatal day (P) 0 (1h and 3h after birth) and P1. Brains were immunohistochemically stained for the expression of the immediate early gene, c-Fos, as a marker of neural activation. We find that the density of c-Fos immunoreactive (Fos-ir) cells in the PVN is about 300% higher on P0 (3h after birth) than on E18 ($p<0.0001$). Fos-ir cell density returned to baseline 24 hours later ($p<0.0001$ for P0 vs P1). A similar pattern was seen in the supraoptic nucleus of the hypothalamus, suprachiasmatic nucleus of the hypothalamus, paraventricular nucleus of the thalamus, subfornical organ, caudate putamen and the lateral habenula. Most brain regions that show Fos-ir cells contain vasopressin and/or oxytocin neurons or receive input from vasopressin and/or oxytocin neurons. We are currently performing fluorescent double-labeling to test the hypothesis that neural populations activated at birth co-localize oxytocin or vasopressin with c-Fos.

**Title:** Transgenerational effects of parental dim light at night on offspring immunity and behavior

**Authors: *Y. M. CISSE**[1], K. L. RUSSART[2], R. J. NELSON[2]
[1]Neurosci., [2]Neurosci. and Behavioral Neuroendocrinology Group, The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

**Abstract:** Environmental light is the most potent signal for synchronizing the circadian system. Disruption of natural light/dark cycles by light at night (LAN) dampens endogenous biological rhythms that maintain optimal function of various systems, including the endocrine, affective, and immune systems. Indeed, exposure to Dim LAN (dLAN) exposure (5 lux) impairs innate and cell mediated immune responses, and increases depressive-like behavior in a TNF-alpha dependent manner in Siberian hamsters (*Phodopus sungorus*). Because of potential transgenerational effects of dLAN, we hypothesized that parental exposure to dLAN *prior* to mating impairs offspring physiological and behavioral immune responses. Adult male and female Siberian hamsters were exposed to either dark nights (DARK) or dLAN for 8 weeks, then paired, mated, and thereafter housed in dark nights. Pairings resulted in four groups: DARK-DARK (Male-Female), DARK-dLAN, dLAN-DARK, and dLAN-dLAN. Separate subsets of adult offspring were tested for adaptive immune, innate immune, and affective responses. Maternal exposure to dLAN dampened cell-mediated immune responses in male and female offspring, increased IgG antibodies to a novel antigen, and decreased sucrose preference. Paternal exposure to dLAN reduced cell-mediated immune responses in female offspring and increased time spent floating in the Porsolt swim test. Melatonin and glucocorticoid receptor expression were altered in the spleen and hippocampus of offspring in a parental sex-specific manner. Global methylation in the spleen decreased in response to parental dLAN. Data will also be presented for febrile, anhedonic, locomotor, and cytokine responses to an endotoxin challenge. Altered immune and affective responses in offspring that have experienced dLAN in the germline indicates that seemingly innocuous nighttime lighting may have transgenerational health consequences.

**Title:** Early life stress reduces neuropathic pain in adulthood - is alteration of spinal microglial reactivity critically involved?

**Authors: J. GENTY**[1], M. TETSI NOMIGNI[1], *P. J. HEUSCHLING[2], F. ANTON[1], U. HANESCH[1]
[1]Univ. of Luxembourg, Luxembourg, Luxembourg; [2]Univ. Luxenbourg, Luxembourg, Luxembourg

**Abstract:** Growing evidence underlines the association between early life adversity and persistent alterations of neural, endocrine and immune functions that may be accompanied by a host of disease patterns such as chronic pain in later life. Neuropathy is a debilitating condition presenting a substantial co-occurrence with stress-related disorders. Despite the established overlapping of biochemical pathways involved in the etiology of these disorders, the intricacy of their mutual interdependence remains. In this context, immunocompetent cells are largely affected during chronic stress and are a key factor in the sensitization of nociceptive dorsal horn neurons. The goal of the present study was to investigate the impact of maternal separation (MS), a well-established model of early life stress in rodents, on chronic constriction injury (CCI)-induced neuropathic pain and to reveal the relevance of spinal microglia activation and pro-inflammatory cytokine regulation.
For this purpose 12 groups of rats were exposed to different combinations of stress condition, CCI-injury and pharmacological treatment. Noxious sensitivity was tested during baseline conditions as well as during subsequent neuropathic and pharmacological treatment conditions. Von Frey hair and the cold plate tests were used for the assessment of mechanical and cold hyperalgesia/allodynia. Amphotericin B, a substance known to activate monocytes and macrophages in the periphery and microglial cells in the CNS was administered to subgroups of animals. At the end of the protocol, rats were sacrificed to assess microglial activation using qPCR and immunohistochemistry.
Our main finding was that maternal separation led to a reduction of CCI-related pain hypersensitivity (thermal and mechanical hyperalgesia/allodynia). We concomitantly observed a downregulation of Iba 1, mRNA a marker of microglial cells, and of IL-1β mRNA, a pro-inflammatory cytokine that may be released by microglia. According to preliminary results, Amphotericin B in turn seemed to enhance CCI-related pain sensitivity, possibly via an activation of microglia.
Our results show that MS may lead to a reduction of neuropathy-related pain in adult age. Stress-related dampening of spinal microglial reactivity may play a critical role in this context.

**Title:** The excitation-inhibition balance in prefrontal cortex neurons during development after early life stress: Influence of the mineralocorticoid receptor

**Authors: *H. KARST**[1], R. A. SARABDJITSINGH[1], M. JOELS[2]
[1]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Univ. Med. Ctr. Groningen, Groningen, Netherlands

**Abstract:** The excitation-inhibition (EI) balance plays an important role during maturation of the brain. A disturbance of the balance may lead to the development of psychiatric disorders. Early life stress (ELS) can cause impairments in cognitive and a variety of behavioral functions later in life. It is hypothesized that a disturbance of the EI balance may underlie these abnormalities. In this study we followed the EI balance during maturation by recording the glutamatergic and GABAergic transmission from neurons in the infralimbic medial prefrontal cortex (imPFC). Mice were stressed from postnatal day (PND) 2 until PND9 using the limited nesting and bedding model. At PND9, PND21 (weaning), at 6 weeks (adolescent) and at 10-12 weeks (adult) male mice were used for ex vivo electrophysiology. In slices of the imPFC we recorded the evoked glutamate (AMPA) current in layer 2/3 cells at a holding potential of -65 mV. In the same neuron evoked GABA currents at +10mV and evoked NMDA currents at +50 mV were recorded. Beside the evoked currents, we also recorded the spontaneous miniature excitatory (mEPSCs) and inhibitory currents (mIPSCs). The mEPSCs were recorded at -65 mV and in the same neuron the mIPSCs were recorded at +10mV. To study the morphology of the neurons during maturation, we filled the neurons with biocytin, which was added to the pipette solution. After recoding, the slices were fixated in paraformaldehyde and later stained with an antibody for biocytin in combination with DAB. From previous studies we know that a high expression of the mineralocorticoid receptor (MR) alleviates the effects of ELS in mice or rats. In this study we investigated the effect of ELS in mice with a lower MR expression (heterozygous MRKO) compared to wildtypes. As was expected, we observed a tremendously high EI ratio at PND9. This, however, was not seen in ELS mice of that age. From adolescence onwards, ELS and control mice were comparable. Yet, the AMPA/NMDA ratio in the adult mice was lower in ELS compared to wildtype mice. In heterozygous MRKO mice the effect of ELS on the AMPA/NMDA ratio seems to appear at an earlier age. ELS furthermore decreased dendritic complexity and the length of apical and basal dendrites of pyramidal neurons in the imPFC in adult male mice, while no effects were seen in adolescent mice. MRKO amplified the effects of ELS on these neurons. We conclude that the EI balance in ELS mice is changed early in life,

followed by a change in the AMPA/NMDA ratio later in life and that a lower MR expression seems to accelerate the effect on the AMPA/NMDA ratio. The morphological changes appear to go hand in hand with the affected AMPA/NMDA ratio.

**Title:** Shaping genetic resilience to early life stress: Sex-specific modulation of mineralocorticoid receptor function on neuroendocrine stress reactivity and behavior in mice

**Authors: *R. A. SARABDJITSINGH**[1], V. BONAPERSONA[1], H. MEEUSEN[1], R. DAMSTEEGT[1], K. SPARNAAIJ[1], R. DE KLOET[2], M. JOËLS[1,3]
[1]Dept. Translational Neurosci., Brain Ctr. Rudolf Magnus, UMC Utrecht, Utrecht, Netherlands; [2]Dept Intrnl. Med., Div. Endocrinology, Leiden Univ. Med. Ctr., Leiden, Netherlands; [3]Univ. of Groningen, Univ. Med. Ctr. Groningen, Groningen, Netherlands

**Abstract:** Adverse environmental factors (such as early life stress (ELS)), in interaction with genetic predisposition, are considered major risk factors for the development and precipitation of psychopathology. Prevailing clinical and rodent studies have shown that the brain mineralocorticoid receptor (MR) may play a key role in shaping resilience to early life stress effects, especially in females. Yet, the mechanism explaining how MR can moderate the effects of ELS on brain function is still poorly understood.
Here we investigated whether i) chronic early life stress (limited nesting/bedding model postnatal day 2-9) affects acute stress reactivity, physiological and behavioral parameters relevant for mood disorders; ii) whether this is exacerbated in the forebrain-specific MR knockout (MRKO; Cre-LoxP system) mouse and iii) if these effects are sex-dependent.
We used a test battery that screens various behavioral domains across development from 4 weeks onwards. Experimental groups consisted of male and female MRKO or wildtype littermate control (flox) mice subjected to either control or ELS condition. For instance, in males, from 4 weeks onwards ELS increased anxiety-related behavior which persisted into adulthood. Anxiety was not affected in females. Results in other behavioral domains (i.e. social behavior and

memory) are currently being analyzed. Preliminary analyses suggest that the effects of ELS and/or MRKO are highly domain- and sex-specific suggesting that ELS affects the brain in a highly complex manner yet differently for specific functional circuits. Interestingly, acute stress reactivity was also sex-dependently regulated. In all experimental groups, restraint stress (10 min) effectively evoked a transient and acute stress response with peak corticosterone levels at approximately 20 min after onset. This stress response did not differ between the male groups (ELS, MRKO). In the females however, compared to controls, both ELS and MRKO resulted in blunted stress peak levels and a smaller area under the curve. This was further exacerbated in the MRKO ELS group. This reduced corticosterone release was associated with reduced pituitary POMC mRNA content and increased adrenal weight. These data suggests that ELS deregulates HPA axis (re)activity specifically in females which is further exacerbated by low function of the MR. Presently, stress indices in limbic brain regions are studied in more detail by Western Blotting of MR, GR, and their target genes.
Altogether, our findings support a sex-specific dissociation between early life stress effects on behavior and the stress system and that MR may be an important moderator in shaping stress resilience.

**Authors: *J. A. HONEYCUTT**, *J. A. HONEYCUTT, C. DEMAESTRI, S. PETERZELL, H. C. BRENHOUSE
Psychology, Northeastern Univ., Boston, MA

**Abstract:** Early life experiences significantly shape the behavioral and neural trajectory of an organism across development. Therefore, disruptions during early developmental periods likely set the course for aberrant brain maturation. Indeed, children who have experienced early adversity often exhibit deleterious effects that manifest as maladaptive behaviors, cognitive impairment, and/or increased susceptibility to mental illness. Increasing evidence in humans with a history of adversity points to a role of atypical corticolimbic circuit development, leading to

changes in functional connectivity between the basolateral amygdala (BLA) and prefrontal cortex (PFC). In rodent models of early adversity via maternal separation (MS) during the postnatal period, comparable neural and behavioral phenotypes are observed, including loss of PFC inhibitory tone and increased anxiety-like behaviors. The neural mechanisms underlying these findings following MS remain unknown, though it is likely that dysfunction is in part driven by precocial BLA innervation of the PFC. To determine the impact of sex and MS on this circuitry, targeted anterograde tracer microinjections into the BLA were performed at key developmental milestones spanning juvenility and adulthood. Labeled axonal fibers from BLA-PFC projecting neurons were quantified within the PFC. We present novel data indicating that MS drives increased BLA innervation of the PFC in a sex- and age-dependent manner, such that juvenile MS female innervation patterns resemble that of their adult control counterparts. This suggests a critical role for early experiences on corticolimbic development and provides putative mechanistic insight into the underlying etiology of adversity-induced vulnerability and resilience.

**Abstract:** Research has shown that early-life stress at key neurodevelopmental time points has many long-term behavioral implications facilitated by neurochemical and neurostructural alterations. Previous studies from our laboratory implicate maternal separation stress (MS) as an underlying risk factor for anxiogenic, depressive, impulsive, and alcohol-drinking behaviors in rats. However, the conditions, mechanisms, and metabolic activity underlying such changes have yet to be elucidated. Alterations to endogenous oxidant protection system, and unbalancing of excitatory tone in mesocorticolimbic regions have been observed in rat models subjected to early life stress. As such, using this MS rat model we investigated changes of neurometabolite

concentrations in the medial prefrontal cortex (mPFC), amygdala, and hippocampus, which are regions that have been implicated in behavioral deficits observed in MD animals. We assessed micromolar concentrations of 21 metabolites using NMR spectroscopy and a secondary quantitation program called Tarquin. This method allowed us to non-invasively take a wholistic snapshot of the neurometabolic profile of our subjects. Using the raw data and ratios of TNAA(N-acetylaspartate), total choline (TCho), and total creatine (TCr) as internal standards, the concentrations of individual metabolites across animals and treatment groups were compared. In the hippocampus, alanine was found to be increased with exposure to MS, whereas glutathione, aspartate, and total glutamate/glutamine were found to be down regulated in MD animals in a sex specific manner. In the mPFC TCr was upregulated in MS animals when compared to controls. Furthermore, in the mPFC GABA and phosphocholine (PCh) were only upregulated in MD females as compared to Cntl females. The amygdala was the most susceptible to the effects of early life stress, with 12 metabolites being altered by MS stress: creatine, GABA, glutamine, glutamate, NAA, phosphocholine, TNAA, phosphocreatine, total glutamate, and glutamine, total creatine, total choline, and taurine. Changes in the amygdala may be the key metabolic driver for previously observed behavioral deficits associated with defective learning and memory, as well as aberrant affect following MS. Furthermore, alterations in GABA, glutamate/glutamine, glutathione, taurine, and alanine support the assertion that excitatory tone as well as the endogenous oxidant protection systems are targets of MS-induced abnormal metabolism in the hippocampus, mPFC, and amygdala.

**Abstract:** It is difficult to overestimate the importance of maternal care in the development of the altricial mammalian offspring. For this reason, disturbances in the mother-infant relationship lead to profound short- and long-term negative neurobehavioral effects in both humans and

rodents. Maternal separation (MS) model is one of the most commonly used rodent models of early-life adverse experiences.
To date surprisingly little is known about the effects of MS early in life on maternal behavior in adulthood. Furthermore, the studies with MS shorter than 3 hours are rather scarce, despite the fact that carrying out manipulations with pups during the investigation of the developmental processes (various tests, pharmacological injections, surgical procedures, etc.) always requires MS for the period starting from 30-60 minutes.
The aim of our work was to study the effects of early-life stress, particularly brief repeated MS procedure (MS-only group, 45 min daily on postnatal days (PND) 3-6) and early pain exposure (MS-saline group, saline injections in combination with MS on PND 3-6) on the subsequent maternal behavior of adult females of 129Sv mice. As potential factors involved in effects of MS, we investigated the changes in the behavior of their mothers on the last day of MS and histone acetylation level in the pups' brain after MS. For the prevention of possible occurrence of the negative influences of MS we proposed the use of pharmacological agent, modulating epigenetic mechanisms underlie the long-term effects of early-life experience, i.e. histone deacetylase inhibitor sodium valproate (50 mg/kg s.c. on PND 3-6).
We revealed that even brief periods of MS during the first postnatal week are sufficient to produce alterations in the behavior of adult females. These changes were manifested in a reduction of exploratory behavior (both pup-directed and non-pup-directed) in comparison with intact dams. Analysis of the behavior of their mothers demonstrated the same reduction of exploratory behavior. We also showed that females from the MS-saline group displayed decreased level of maternal grooming and nursing behavior in comparison with intact dams, an effect which was not revealed in the MS-only females. Administration of sodium valproate prevented the occurrence of these negative effects in the MS-saline group.
Considering human data on the impact of child maltreatment on the development of maternal behavior, our models of brief maternal separation and early pain exposure seem to be novel and promising tools for investigation of the mechanisms underlying the effects of early-life adverse experiences. Sodium valproate could be a candidate agent for their prevention.

**Abstract:** Schizophrenia is a psychotic disorder shown to be more prevalent in low socioeconomic groups with research in human populations implicating stress response dysregulation and, separately, endocannabinoid dysregulation (via cannabis use) in disease onset and exacerbation. Using an animal model, this study explored interactions between the stress response and endocannabinoid systems within the cerebellum, a region dense with the $CB_1$ endocannabinoid receptor and shown to be impaired in schizophrenia.
This study explored behavioral and neural impacts of early life stress in Long-Evans rats reared with or without limited access to bedding during postnatal day (PND) 2-9. Corticosterone (CORT) levels were measured at PND 8 and 70. Rats were assessed on Novel Object Recognition to test memory and Rotarod to evaluate cerebellar integrity at PND 40 and 50, respectively. Lipid analysis was performed on tissue samples of cerebellar interpositus (IP) nucleus via high-performance liquid chromatography and tandem mass spectrometry.
Male rats experiencing early life stress exhibited significantly impaired recognition memory. There were no group differences in Rotarod task performance or CORT levels at PND 8 or 70 across rearing groups, though rats generally exhibited higher CORT levels at PND 70 and females had higher levels overall. At PND 70, male rats experiencing early life stress exhibited a significant decrease in 2-arachidonoyl glycerol (2-AG) and arachidonic acid levels in the IP nucleus compared to normally reared males. Compared to normally reared females, those experiencing early life stress exhibited a significant increase in prostaglandin E2 levels. 2-AG levels were positively correlated with object recognition in males (collapsed across rearing group) and also positively correlated with CORT levels in normal rearing females.
Early life stress, induced by limited bedding, differentially impacted memory in male versus female rats, with males being more impaired. Results suggest that although stress does not alter gross cerebellar function (i.e. motor function via Rotarod task), it appears to alter endocannabinoid dynamics in males in the cerebellar IP nucleus. Further analysis will quantify mRNA for cannabinoid receptors to better characterize aberrations to this system. This work provides a basis for understanding stress impacts on the development of cognitive deficits observed in disorders such as schizophrenia. In the future, we plan to relate these deficits to

impairments in cerebellar-dependent delayed eye-blink conditioning, a robust endophenotype of schizophrenia.

**Abstract:** Early-life stress (ELS) exposure has life-long consequences for both brain structure and function, and can ultimately impact cognitive and emotional behavior, increasing vulnerability to mental disorders. The basolateral amygdala (BLA) plays an important role in anxiety and fear conditioning and through its wide connections to the prefrontal cortex (PFC) and hippocampus (HIP) in particular, can affect stress reactivity and emotional behavior. However, how ELS affects amygdala function and connectivity in developing rats is unknown. We used the naturalistic limited bedding/nesting (LBN) paradigm to induce chronic stress in the pups between postnatal day (PND) 1-9. Normal bedding (NB) conditions were used as control. Sprague Dawley male NB or LBN rats received structural (FLASH, Resolution 0.1x0.1x0.1mm, TA 23 min) and resting-state functional MRI (rs-fMRI, RAREst, Resolution 0.25x0.25x0.8mm, TR/TE 3000/28 ms, TA 5 min) under <2% isoflurane anesthesia on PND18. All scans were obtained on a Bruker 7T MRI (650 mT/m in 150μs) 24 hrs after treatment with Manganese Chloride ($MnCl_2$, 32 mg/kg, sc), an MRI contrast agent. Three rs-fMRI acquisitions for each animal were preprocessed and registered to a group average anatomical image (FLASH). Each run then generated connectivity maps based on four BLA seeds (left, right, anterior and posterior) using FMRISTATS. The individual connectivity maps were transformed into the template space. All three runs were combined to build a subject level connectivity map. The final results were corrected for multiple comparison using Random Field Theory, $p = 0.05$.

Significantly enhanced contralateral PFC connectivity was found in LBN compared to NB pups from both Left BLA seeds, but only from the Right Posterior BLA. Animals subjected to LBN rearing also exhibited increased connectivity from both Posterior BLA seeds to the contralateral HIP. The ipsilateral connectivity to the HIP was only increased in the Right Posterior BLA, while the Anterior BLA networks tended to show reduced connectivity to the HIP. LBN pups showed greater Left BLA connectivity to the paraventricular nucleus and to the insular cortex. In summary, ELS enhanced BLA-PFC/Hip and insula connectivity in immature preweaning pups with a strong contralateral component. Increased connectivity in these critical nodes of the emotion processing network in developing rats might underlie enhanced fear conditioning and anxiety observed in ELS-exposed adults. Furthermore, most structures displaying enhanced connectivity after ELS are also part of the extended stress circuitry that is recruited under chronic stress in adult animals.

**Title:** Sex differences in early postnatal ultrasonic vocalizations and adult hippocampal microglial morphology in California mice (Peromyscus californicus) exposed to paternal deprivation

**Authors: *F. N. MADISON**, A. R. WHITAKER, S. KHANTSIS, E. R. GLASPER
Dept. of Psychology, Univ. of Maryland, College Park, MD

**Abstract:** Early life stressors, such as childhood neglect and abuse, can increase vulnerability to affective disorders in adult life. It has been well established that variations in rodent maternal care mediates development of affective disorders, therefore early maternal separation has been used as a model to examine the enduring consequences of early adverse life events. Maternal separation has also been shown to induce hippocampal neuroinflammation and long-lasting emotional alterations in rodents. Moreover, auditory communication, such as ultrasonic vocalizations (USVs) emitted by pups over the postnatal period, has been shown to direct maternal responsiveness and increase pup survivability. In biparental species, such as the California mouse (*Peromyscus californicus*), where maternal *and* paternal care is necessary for offspring survival, little is known about the effects of paternal deprivation on pup USVs and adult offspring hippocampal structure. The purpose of this study was to determine to what extent sex differences in USV-directed maternal care across the postpartum period exist in the

biparental California mouse. Additionally, we investigated the relationship among sex, paternal deprivation, and activation of microglia in the adult hippocampus. Offspring were either reared by both parents (controls) or the father was removed on postnatal day (PND) 1 and offspring were reared by the mother alone (paternally-deprived) until weaning. USVs were recorded on PND2, 6, 8, 14, 24, and 30. On PND35, male and female offspring from both groups were weaned and paired housed with same sex conspecifics. On PND60, brains were perfused with 4% paraformaldehyde, sectioned, and immunohistochemically processed for the microglial maker Iba1. A sex difference in USVs during the mid-postpartum period (i.e., PND14) may be present, as paternally-deprived females, on average, emit more vocalizations than control and paternally-deprived males. To what extent sex-dependent differences in USVs, as a result of early life experience, underlies microglial activation remains to be determined. However, irrespective of sex, control mice exhibit more ramified than unramified microglia in the subgranular zone of the dentate gyrus – an effect not observed in PD mice. Taken together, these data suggest that USVs may function to elicit parental care in paternally-deprived females. More so, PD may influence stress-related microglial activation.

**Abstract:** Obesity is a national problem, with nearly 40% of American adults and 17% of children and adolescents characterized as obese. Sex differences also exist, with women having higher rates of obesity than men, but the reasons for this are not fully understood. One factor may be stress, as higher stress levels have been reported in women. The subsequent release of cortisol could affect energy balance and play a role in the development of obesity. Alternatively,

the ghrelin hormone stimulates hunger and increased ghrelin levels have been reported during stress. The ghrelin receptor (GhrR) is expressed in regions of the brain that mediate reward and food intake, but few studies have examined the effects of stress on GhrR expression. The purpose of our study, therefore, was to evaluate the effects of early life stress on hypothalamic GhrR expression in males and females. We also employed environmental enrichment as a countermeasure to protect against the effects of stress. We hypothesized that stress in the neonatal period would persistently increase hypothalamic GhrR expression and that environmental enrichment would prevent this increase. Wistar rat pups were exposed to early life stress in the form of maternal separation (MatSep) for 3h/d on postnatal days (PND) 2-14. Control rats were reared normally. All pups were weaned at PND 21, and allowed to grow to adolescence (PND ~49) or adulthood (PND ~70) before testing. Some groups were weaned into standard living conditions, while others were housed with enrichment bedding, plastic tunnels, and 24h access to a running wheel. The hypothalamic region was dissected from fresh-frozen brain tissue and analyzed for GhrR expression by Western blot, quantified by densitometry normalized to actin. Contrary to our hypothesis, our results indicate a trend toward decreased GhrR expression in the hypothalamus of MatSep rats, but that enriched environmental conditions may in fact be able to reverse this effect. The ability of early life stress to cause long-term modifications to ghrelin action in the brain may be an important factor in stress-induced obesity. On the other hand, our findings confirm and extend our understanding of the role of stress reduction in obesity prevention.

**Title:** Vulnerability to addiction is increased by early life stress: Dopaminergic effects and synaptic plasticity

**Authors: *J. N. HAMDAN**[1], S. SAUCEDO, Jr.[3], G. A. LODOZA[4], J. A. SIERRA FONSECA[2], L. E. O'DELL[4], K. L. GOSSELINK[4]
[2]Biol. Sci., [1]Univ. of Texas At El Paso, El Paso, TX; [3]Biol. Sci., [4]Univ. of Texas at El Paso, El Paso, TX

**Abstract:** Stress has been shown to play a role in increasing the incidence and progression of addictive behaviors, making it a concern for the roughly 1.2 million people nationwide who suffer from methamphetamine (Meth) addiction. When stress is experienced during early life, it can persistently alter brain function and increase drug-taking behaviors and risk for addiction in adults. It is not fully understood how stress can mediate changes in drug taking behavior, or how early life stress impacts drug taking behavior in adulthood. The goal of this project, therefore, was to examine molecular changes in the brain that are induced by early life stress and may enhance vulnerability to Meth addiction. Our hypothesis was that stress in the postnatal period would increase the expression of proteins involved in dopaminergic signaling in the reward circuitry. We further hypothesized that stress would decrease the expression of proteins associated with synaptic function and plasticity in brain regions involved in memory and executive function. Male Wistar rats were maternally separated (MS) from their dams for 3h/d on postnatal days 2-14 and assessed as adults. Brain tissues were harvested and the prefrontal cortex (PFC), hippocampus, caudate-putamen (CPu), and nucleus accumbens (NAcc) dissected and evaluated for protein expression by Western blot. The markers examined were: dopamine transporter (DAT), dopamine receptor-1 ($D_1$), dopamine receptor-2 ($D_2$), tyrosine hydroxylase (TH), post-synaptic density 95 (PSD95), NMDA receptor-1 (NMDAR1), and α-synuclein. A significant increase was seen in the expression of $D_2$ in the NAcc of MS rats, while there was a trend toward increased expression of TH and $D_2$ in CPu ($p=0.10$ and $p=0.13$ respectively) and decreased expression of NMDAR1 in PFC ($p=0.07$) and α-synuclein in hippocampus ($p=0.08$). Separate groups of MS animals were behaviorally tested for conditioned place preference (CPP) with 1 mg/kg Meth to identify changes in drug sensitivity caused by MS. Stressed animals did show CPP, but did not demonstrate a difference in preference for Meth compared to controls. Future studies will test responses to different doses of Meth in the CPP paradigm, but our current findings partially support our hypothesis in that long-term changes in dopaminergic and synaptic function were seen or suggested following early life stress.

**Title:** The proinflammatory cytokine TNFa alters neural network activity by injuring GABAergic interneurons

**Authors: *E. TRIPLET**, R. LAFRANCE-COREY, K. MIRCHIA, H.-L. WANG, G. WORRELL, C. HOWE
Neurol., Mayo Clin., Rochester, MN

**Abstract:** Neuroinflammation plays a critical pathogenic role in numerous diseases of the CNS, ranging from traumatic brain injury and multiple sclerosis to epilepsy and Alzheimer disease. Neuroinflammation is associated with local activation of microglia and astrocytes and with infiltration of immune effectors such as monocytes and neutrophils. A common mechanism-of-action shared by these effectors is release of proinflammatory cytokines such as TNFα, IL6, IL1β. Using a murine model of acute CNS viral infection, we have shown that the infiltration of inflammatory monocytes triggers severe injury to CA1 pyramidal neurons in the hippocampus. This injury is associated with seizures and with permanent cognitive impairment. However, despite our understanding of the kinetics of inflammatory monocyte infiltration, CA1 pyramidal neuron injury, seizure evolution, and behavioral sequelae, and despite reports from others showing that IL6 and other cytokines are involved in hippocampal injury in this model system, we do not know the underlying pathogenic mechanisms responsible for disruption of the hippocampal neural circuit.
Preliminary experiments in mice infected with the Daniel's strain of Theiler's murine encephalomyelitis virus indicate that hippocampal parvalbumin-positive GABAergic interneurons are preferentially lost during acute infection. Electrophysiological analysis of long term potentiation in hippocampal slices from infected mice reveals a reduction in GABAergic tone at the Schaffer collateral inputs into CA1. These outcomes are associated with the production of TNFα by inflammatory monocytes, as assessed by flow cytometry, multiplexed cytokine analysis, ELISA, and analysis of hippocampal interstitial fluid sampled by microdialysis. In vitro stimulation of murine hippocampal neural networks with TNFα induces profound changes in spontaneous and evoked calcium transients, as assessed by imaging of neurons transduced with an AAV9 vector driving synapsin promoter-dependent expression of the GCaMP6f calcium reporter. Finally, high-density, high-frequency measurement of field potentials in hippocampal neural networks via multielectrode array analysis indicates that GABAergic tone is rapidly modulated by TNFα and other inflammatory cytokines, suggesting that such factors play a fundamental role in the induction of seizures and disruption of cognition in CNS diseases associated with neuroinflammation.

**Title:** Pubertal stress programs a long-term, sex-specific disruption of the HPA axis

**Authors: *K. E. MORRISON**, T. L. BALE
Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Adverse childhood experiences are one of the greatest predictors for affective disorder presentation for women. As the puberty transition is marked by hormonal changes and ensuing reorganization of the brain and periphery, it may represent a window of vulnerability for adversity to result in long-term programming. Periods of hormonal flux in the female lifespan, including pregnancy, exacerbate the risk for affective disturbances and promote hypothalamic-pituitary-adrenal (HPA) axis dysregulation, a key feature of affective disorders. However, little is understood as to how stress experienced during the pubertal transition alters ongoing brain maturation and its interaction with later-life events, such as pregnancy. We have established a translationally relevant mouse model in which peripubertal stress results in a blunted corticosterone response to acute restraint stress only during pregnancy in females, but produces no effect in males. This suggests that HPA programming by peripubertal stress in females intersects with the state of pregnancy to expose dysregulation. RNA-Seq analysis of the paraventricular nucleus of the hypothalamus (PVN) during pregnancy revealed a reprogramming of gene expression by peripubertal stress, including changes in the GABA system. As the GABA system is critical in regulating PVN responsiveness and is modulated by allopregnanolone, we hypothesized that the rise in allopregnanolone during pregnancy is responsible for eliciting the HPA axis dysregulation. Female mice were exposed to chronic variable stress (CVS) from postnatal days 21-34, and we examined the corticosterone response to acute restraint stress during late pregnancy. Pharmacological reduction of allopregnanolone by systemic injection of indomethacin resulted in the recovery of a normal corticosterone response in CVS females. Importantly, the blunted corticosterone response was recapitulated in CVS adult males treated with allopregnanolone, further supporting a role for this neurosteroid. Preliminary data suggests that disrupting allopregnanolone binding at the GABA-A receptor in the PVN leads to similar recovery of a normal HPA axis response in CVS females. Previous RNA-Seq findings suggest

that the changes in the GABA system are maintained by epigenetic modifications induced by CVS. To address this possibility more directly, effects of peripubertal stress on histone marks in the PVN in both virgin and pregnant adults were examined. Together, these studies provide novel insight into the mechanisms underlying female-relevant risk factors for stress dysregulation, a central endophenotype of affective disorders.

**Title:** Mechanisms of paternal stress programming of neurodevelopment via dad's epididymis

**Authors: *J. CHAN**, N. V. BHANU, B. A. GARCIA, T. L. BALE
Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Paternal exposures to environmental insults such as stress, diet, drugs or toxins have been linked with increased risk of neuropsychiatric disease in subsequent generations. Recent studies using rodent models have shown that paternal exposure to a variety of perturbations can impact offspring behavior and physiology, and have identified changes in histone modifications, DNA methylation, and/or small non-coding RNAs in sperm as potential mechanisms of transmission. However, the mechanism by which paternal environmental exposures reprogram sperm epigenetic marks to subsequently influence offspring development is not known. We have developed a paternal stress model in which chronically stressed males sire offspring with a significantly blunted stress response as adults. Sperm analyses identified a significant increase in 9 microRNA (miRs) following paternal stress exposure. Zygote microinjection of these miRs recapitulated the offspring stress phenotype, providing a functional role for sperm miRs. Our current studies examine the mechanism and timing by which chronic stress alters sperm miRs. Remarkably, studies in our mouse model reveal that males bred 3 months following stress exposure continue to produce offspring with altered stress reactivity, suggesting lasting effects of experience on intergenerational transmission. To determine where in the sperm development or maturation process stress-mediated changes occur, we compared reproductive tissue miR expression where transcriptional assessment revealed upregulation of the same stress-sensitive

miRs found in sperm in the caput epididymis, suggesting that the caput is involved in programming of sperm miRs. Moreover, levels of glucocorticoid receptor (GR) were specifically increased in the caput months after stress end, suggesting GR may play a role in long-term programming. Interestingly, extracellular vesicles (EV) from the caput have been suggested to fuse and alter RNA expression in maturing sperm. To determine if stress alters caput EV miR expression, we developed an *in vitro* model of chronic corticosterone treatment using caput epithelial cells. We show that our model mimics aspects of chronic stress programming *in vivo*, including increases in GR levels long-term. Remarkably, we show that chronic corticosterone treatment alters caput EV miR expression, suggesting a mechanism by which the caput may communicate stress programming to sperm. These studies suggest that paternal experiences can have lasting changes on the germline and future offspring brain development, and offer an exciting novel mechanism by which the environment can dynamically regulate sperm epigenetic marks.

**Abstract:** Prenatal stress is a risk factor for male-biased neurodevelopmental disorders, including early onset schizophrenia and autism. In our mouse model of early prenatal stress (EPS), stress exposure during the first week of gestation imparts long-term HPA stress axis, metabolic and cognitive deficits to male offspring. The placenta, a fetally-derived tissue reflecting fetal sex chromosome complement, provides necessary factors for early brain

development. Thus, sex differences in placental function might radically influence sex biases in neurodevelopmental vulnerability to prenatal insults. We previously identified the X-linked, stress sensitive, nutrient sensor O-linked-N-acetylglucosamine (OGT) as a critical mediator of the sex-specific effects of prenatal stress on offspring brain development. OGT modifies several epigenetic regulators including the H3K27me2/3 methyltransferase, EZH2. In mouse placentas with trophoblast-specific OGT reduction, we found that OGT determines higher protein levels of H3K27me3 in females and genome-wide sex differences in H3K27me3 patterns. We hypothesized that female-biased epigenetic repression (i.e. H3K27me3) protects females from prenatal insults such as EPS. To test this hypothesis, we reduced H3K27me3 in female placentas using trophoblast-specific manipulations of EZH2 and exposed these females to EPS. Decreasing placental EZH2, and H3K27me3, created female vulnerability to the effects of EPS, sensitizing their HPA axis reactivity and causing long-term changes in body weight. To evaluate the role of the X and Y -linked H3K27 demethylases in establishing sex differences in H3K27me3 and confirm the role of H3K27me3 in male risk and female resilience to the neurodevelopmental deficits associated with EPS exposure, we generated trophoblast-specific mouse lines with reducible UTX and inducible UTY. We predict that reducing UTX in male trophoblasts will augment placental H3K27me3 and protect males from sensitivity to prenatal insults. In addition, we predict that reducing UTX while inducing UTY expression in female trophoblasts will masculinize genome-wide H3K27me3 patterns and masculinize placental responses to environmental perturbations. These studies, aimed at elucidating the basic biological differences between male and female developmental programs, bring us closer to fully understanding the etiology of sex-biased neurodevelopmental disorders.

**Abstract:** Understanding how prenatal stress alters the fetal milieu in a sex-specific manner is important for identifying mechanisms involved in perturbations of brain programming, which are often associated with sex-biased neurodevelopmental disorders. In our well-established mouse model, male offspring exposed to early prenatal stress (EPS) have altered hypothalamic pituitary axis (HPA) programming, resulting in increased stress sensitivity and dysregulation in hypothalamic metabolism, endophenotypes identified in boys with autism and men with early-onset schizophrenia. Importantly, our EPS protocol occurs during the first week of gestation, prior to brain development and thus likely alters programming of peripheral tissues in addition to altering neurodevelopmental processes. Previously, our lab found that gene sets important for endo- and exosomal cellular processes were down regulated in the male placenta in response to EPS, suggesting that EPS alters fetal extracellular vesicle (EV) signaling. EVs are small vesicles secreted locally and into the bloodstream by most tissues. EVs transfer proteins, microRNAs, and other signaling factors between cells and tissues as a means of short- and long-distance communication. Using proteomics and small RNA-Seq, we found that EPS exposure altered the miRNA and protein content of EVs in fetal and neonatal circulation. We predict that these alterations in EV cargo contribute to sex differences in programmatic events in the developing brain. Using near infrared *in vivo* and confocal imaging of labeled EVs, we identified sex differences in the accumulation and cellular localization of peripheral exosomes in the developing brain, which are altered by EPS exposure. To assess the direct mechanistic effects of EPS-altered peripheral EVs on brain development, we isolated EVs from control and EPS-exposed neonates and injected these vesicles into age and sex-matched naïve neonates. We found that EVs derived from EPS-exposed males promoted long-term changes in male body weight, HPA stress axis sensitivity and behavior, although female EPS EVs had no long-term programmatic effects. Further, we analyzed RNA-Seq from hypothalamic punches from naïve neonates injected with EVs derived from control and EPS-exposed neonates. This allowed us to link individual EV miRNAs with changes in mRNA expression in the developing brain, and to identify specific vesicular miRNAs important for brain development. Overall, our findings demonstrate that circulating extracellular vesicles contribute to sex-specific neurodevelopmental programming. *Supported by MH091258, MH087597, MH099910, MH104184 and MH108286.*

**Title:** The maternal microbiome plays a causal role in programming offspring gut-brain development

**Authors: *E. JAŠAREVIC**[1], C. HOWARD[1], K. E. MORRISON[1], A. MISIC[1], T. WEINKOPFF[1], P. SCOTT[1], C. HUNTER[1], D. BEITING[1], T. L. BALE[2]

**Abstract:** Prenatal stress is associated with an increased risk for neurodevelopmental disorders. In our established mouse model of early prenatal stress (EPS), lasting reprogramming on offspring development have been demonstrated, including reprogramming of the hypothalamic-pituitary-adrenal (HPA) axis, dysregulation of HPA stress axis responsivity, and post-pubertal growth. Mounting evidence points to an influence of maternal stress experience on reprogramming of the gut-brain axis via the maternal vaginal microbiome. To provide a causal link of the stress-altered vaginal microbiota with reprogramming of the developing gut-brain axis, we used cesarean delivery and oral gavage of neonate mice colonized with vaginal microbiota from either control or EPS dams, and assessed for recapitulation of the EPS phenotype. By manipulating microbial colonization of the neonate gut, we reveal an exciting causal role of the maternal vaginal microbiome in promoting sex-specific recapitulation of neuroendocrine dysfunction observed in our EPS model, including HPA stress axis dysregulation and metabolic alterations. Surprisingly, colonization with a normal microbiome at birth failed to rescue EPS phenotypes, suggesting critical reprogramming of the fetal intestinal niche preceding colonization. Gene set enrichment analysis revealed robust sex-specific differences in gene sets

involved in normal immune function, whereby the expression of genes within these gene sets were disrupted in EPS males, but not females. As sex-specific enrichment of genes involved in innate immunity may reflect functional differences in immune cell populations present in the EPS fetal intestine, we used multicolor flow cytometry to demonstrate sex-specific disruption of EPS on the frequency of immune cell populations in the fetal intestine. To examine the hypothesis that maternal stress reprogramming may render male offspring more vulnerable to additional stressors throughout the lifespan, we used a second hit protocol in which offspring were exposed to chronic stress and programmatic effects on the gut-brain axis were assessed. Analysis revealed a robust disruption of the intestinal barrier. In addition, dysregulation of energy metabolism and neurotrophin signaling pathways was detected in the PVN of stress-exposed EPS males, reflecting potential deficits in neuroplasticity that impacts neuroendocrine function and ability to respond and adapt to external stimuli in these males. Taken together, these studies provide a novel mechanism by which maternal stress experience during pregnancy reprograms the gut-brain axis and confers sex-specific disease risk throughout life.

**Title:** Adolescent stress alters fear conditioning and glucocorticoid receptor expression in basolateral amygdala

**Authors: *R. A. SKIPPER**, C. L. WELLMAN
Dept. of Psychological and Brain Sci., Indiana Univ. Bloomington Dept. of Psychological and Brain Sci., Bloomington, IN

**Abstract:** In humans, early life adversity can lead to a host of debilitating outcomes, including anxiety and depression. This has been modeled in rodents: we have previously shown that a single early life stressor permanently alters emotional learning, fear extinction, and dendritic plasticity in the basolateral amygdala (BLA; Quinn et al., 2015; Skipper et al., in prep). These enduring stress effects are correlated with altered neuroendocrine function. Adolescent stress produces extreme fluctuations in stress hormone levels, which could permanently alter the stress response to produce lasting behavioral changes (Romeo et al., 2016). However, little research

has been done to assess the short-term effects of acute early life stress. Additionally, as many stress-related disorders are more prevalent in women than men, an investigation of sex differences in these effects is warranted. The current experiments assess the short-term effects of acute stress on adolescent fear conditioning and glucocorticoid receptor (GR) expression in the BLA. Male and female rats underwent a 30-minute elevated platform stressor on postnatal day 25 (P25); unstressed controls underwent a similar handling procedure, without stress exposure. On P26, all animals received three tone-shock pairings. Fifty minutes later, brains were collected for immunohistochemistry. Sections were incubated in GR antibody (M-20; Santa Cruz Biotechnology), and immunoreactivity was detected using nickel-enhanced DAB. To quantify GR expression, optical density of each labeled cell within nine 2500 $\mu m^2$ sampling regions evenly spaced through the rostral-caudal extent of BLA was measured and expressed relative to background optical density. Though no behavioral differences were observed during tone presentations, an interesting pattern of results emerged during the 30-second period following each tone. Among unstressed animals, males were significantly more active than females, and this sex difference was abolished by prior stress exposure. This was due to behavioral suppression among males; females showed high levels of freezing and low levels of inter-trial activity that were unaffected by prior stress exposure. Preliminary data suggest that GR levels are higher in the BLA in unstressed males compared to females, and that stress suppresses GR expression selectively in males. Thus, stress may induce different patterns of GR expression in males and females that map onto sexually dimorphic behavioral phenotypes during conditioning. These preliminary findings suggest that sex-dependent stress effects on conditioning in adolescents may be mediated by alterations in expression of GR in the BLA.

**Abstract:** Adverse events that occur early in life have been shown to enhance vulnerability to neurodegeneration in later years. Early life stress (ELS) can induce persistent neurochemical changes that ultimately disrupt neuronal circuits and functions. Among these changes are misfolded and aggregated proteins, hallmarks of several neurodegenerative diseases. In the normal brain, proteolysis is critical to maintain proteostasis, which includes the clearance of abnormal proteins by the ubiquitin-proteasome system (UPS) and the autophagy-lysosomal pathway (ALP). Using ubiquitin as signal, the UPS degrades soluble, short-lived proteins through the proteasome. The ALP is a bulk degradative pathway that involves autophagosome fusion with the lysosome for cellular component destruction and recycling. Accumulating evidence suggests that that these two systems become impaired in neurodegeneration, causing abnormal protein aggregation and leading to irreversible neuronal damage and death. It is known that stress can influence the development and progression of neurodegenerative diseases, yet the underlying mechanisms for this remain poorly understood. We therefore hypothesized that ELS reduces proteolysis in the brain, leading to deficient clearance and subsequent accumulation of abnormal proteins. Wistar rats underwent ELS in the form of maternal separation (MS) for 3h/d on postnatal days 2-14. Brain tissues were then harvested from adults, and hippocampal and cortical regions isolated and evaluated for proteins associated with the UPS and ALP pathways by Western blot. ALP markers (LC3 and p62), UPS markers (20S and 26S proteasome and K48 polyubiquitinated proteins), and disease-associated markers (Tau, phospho-Tau, α-synuclein, and Parkin) were examined. In hippocampus, ALP markers significantly increased following MS. UPS marker expression exhibited sex differences, with increased expression of 20S proteasome and K48 polyubiquitinated proteins in females but decreased expression in males. In hippocampus, phospho-Tau (pSer262 and pThr231) was increased significantly after MS in females, α-synuclein decreased in males and increased in females, and Parkin increased significantly in both sexes. Interestingly, none of the markers showed significant changes in cortical homogenates. Taken together, our results indicate that ELS can selectively modify the protein degradation machinery in different brain regions, which could impact abnormal protein accumulation and the development of neurodegenerative disease.

**Title:** Up-regulation of GLT-1, a glutamate transporter, expressed within glutamatergic axon terminals & on the plasma membrane of astrocytic processes abutting excitatory synapses in the hippocampus contributes to resilience of adolescent female C57BL6/J mice to food restriction-evoked hyperactivity in an animal model of anorexia nervosa relapse

**Authors: *C. J. AOKI**, A. D. SHERPA, O. BILASH, A. A. NAIK
Ctr. Neural Sci., New York Univ., New York, NY

**Abstract:** Severe voluntary food restriction (FR) is the defining symptom of anorexia nervosa, but anxiety, excessive exercise, and maladaptive decision-making contribute to its severity and relapse vulnerability. We are able to quantify these behavioral hallmarks in a mouse model, called activity-based anorexia (ABA). When wheel-acclimated adolescent mice have their food access restricted, they greatly augment their wheel running, choosing to run even during the hours of food access, hence displaying voluntary FR. The ABA model can be extended to also capture relapse, by following 3 days of restricted food access ($1^{st}$ ABA) with 7 days of recovery, then of 4 more days of restricted food access ($2^{nd}$ ABA). While the great majority of mice exhibit FR-evoked hyperactivity during the $1^{st}$ ABA, some even to the point of lethality, only about half exhibit FR-evoked hyperactivity during the $2^{nd}$ ABA (relapse). What might be the cellular and molecular bases for the resilience that is acquired by some but not others between the $1^{st}$ and $2^{nd}$ ABA? **We hypothesize** that excessive excitability of pyramidal neurons in the hippocampus underlies severity of ABA, while up-regulation of molecules that suppress excitability underlie resilience. In support of this hypothesis, we have observed that excitatory synapses of rodent hippocampal pyramidal neurons exhibit heightened levels of synaptic NR2B-NMDA receptors (NR2B-NMDARs) following one ABA induction (DOI:10.1007/s00429-016-1341-7) and that the increased *levels* correlate with severity of individual animals' weight loss. Here, we used electron microscopy to show that animals resilient to relapse exhibit up-regulation of GLT-1 in the hippocampus. ABA relapse vulnerability was quantified in 7 animals, based on the extent of increase in voluntary wheel running during the $2^{nd}$ ABA. This value ranged from 0 to 18 km/day among the animals during the $2^{nd}$ ABA. Pearson's analyses revealed a strong correlation ($p<0.05$) between this measure of individuals' ABA relapse vulnerability and GLT-1 immunoreactivity in glutamatergic axon terminals and astrocytic plasma membranes immediately adjacent to axo-spinous synapses. This correlation was negative ($r=-0.8$ for astrocytes and axon terminals), indicating that individuals with the least vulnerability were the ones that expressed the highest levels of GLT-1 at excitatory synapses. Augmentation of GLT-1 can dampen hippocampal excitability by removing extracellular glutamate and minimizing

NR2B-NMDAR currents. These findings suggest that antibiotics, which increase GLT-1 expression, may be helpful for putting a break on the maladaptive behavior of anorexia nervosa.

**Abstract:** As a $Ca^{2+}$ buffer, sensor and transporter, calbindin critically modulates synaptic plasticity. The reduction of calbindin in hippocampal neurons has been implicated in cognitive disorders, including those induced by early-life stress. However, it is unclear how early-life stress modulates calbindin expression in distinct populations of hippocampal neurons and the contribution of each calbindin-expressing neuronal population to memory. Here, we report that hippocampal excitatory and inhibitory calbindin neurons, respectively, modulate the susceptibility and resilience to early postnatal stress-induced spatial memory deficits. The temporal expression profile of hippocampal calbindin coincided with the critical developmental period of the hippocampus. Stress exposure during this stage lastingly reduced calbindin levels in all CA1 and DG neurons. Reduced calbindin levels in CA1 or DG excitatory neurons, but not CA1 interneurons, strongly correlated with spatial memory impairments. Accordingly, selective knockdown of calbindin in CA1 or DG excitatory neurons mimicked postnatal stress-induced memory deficits in adulthood. By contrast, although calbindin knockdown in CA1 interneurons did not disrupt memory under basal conditions, it preserved memory after an acute stress

challenge. Moreover, calbindin expression levels were suppressed by early-life stress through the cell adhesion molecule nectin3, and in turn reduced IMPase levels. Our findings highlight calbindin as a key molecule for the reprogramming effects of early-life stress on cognition, and exemplify how distinct neuronal populations sharing a same molecule confer the susceptibility or resilience to stress.

**Title:** Early-life stress causes a heightened state of trigeminal nociception and gut dysbiosis: Evidence of risk factor for development of chronic orofacial pain conditions

**Authors: *L. CORNELISON**[1], O. PETERSON[1], J. L. HAWKINS[2], P. L. DURHAM[3]
[2]JVIC/CBLS, [3]JVIC-CBLS, [1]Missouri State Univ., Springfield, MO

**Abstract:** Objective: The goal of our study was to examine the effects of secondary traumatic stress on trigeminal nociception and the diversity of the gut microbiota.
Background: Secondary traumatic stress is described as sensitization in a naïve individual elicited through exposure to an individual who directly experienced some trauma. Early-life stress can promote development of a hypervigilant state and increase the risk of developing a chronic orofacial pain such as migraine or temporomandibular disorder (TMD). There is emerging evidence of the importance of the gut-brain axis in health and disease progression. In support of this notion, gut dysbiosis is associated with multiple neurological diseases. Knowledge of the relationship between increased nociceptive signaling in the trigeminal system and the gut microbiota is essential to better understand the gut-brain axis and subsequent negative health outcomes associated with gut dysbiosis.
Methods: Adult Sprague-Dawley male sender rats were subjected to a water immersion apparatus (primary traumatic stress) and returned to their cages, which were placed next to breeding, pregnant, or nursing female rats that served as receiver rats (secondary traumatic stress). Offspring from receiver rats were allowed to develop until young adults at which time the animals were tested for nocifensive response to mechanical stimulation in two facial areas using von Frey filaments and Durham animal holder. In addition, bacterial diversity in fecal and cecal samples collected from naive and stressed F1 generation (>45 days old) animals was determined by next-generation sequencing.
Results: Early-life stress mediated an increase in the average number of nocifensive responses over the eyebrow and masseter muscle when compared to the level of sensitivity in naïve

offspring, and the effect was greater in females. Both male and female offspring of mothers co-housed with stressed males had lower bacterial diversity, as well as reduced percentages of commensal bacteria, in their fecal and cecal samples when compared to offspring of unstressed animals. More specifically, there was a reduction in the amount of Lactobacillus and Bacteroides in the stressed offspring.
Conclusion: Results from our study demonstrate that early-life secondary stress induces an enhanced level of nociception of trigeminal neurons that temporally correlated with pathophysiological changes in the gut microbiota. Furthermore, our findings provide evidence that early-life stress can promote development of a hypervigilant trigeminal system and gut dysbiosis, pathophysiological conditions associated with chronic orofacial pain conditions.

**Title:** Binge-like alcohol produces long-lasting epigenetic marks on the proopiomelanocortin gene and the stress axis only during the prenatal to prepubertal period but not after puberty

**Authors: O. GANGISETTY**[1], S. MURUGAN[2], M. CABRERA[2], L. CHASTAIN[2], *D. K. SARKAR[2]
[1]Endocrine Program, Rutgers Univ., New Brunswick, NJ; [2]Rutgers, SUNJ, New Brunswick, NJ

**Abstract:** Alcohol exposure (either prenatally or in the early postnatal period) can impact developmental pathways resulting in lasting structural and regulatory changes that predispose individuals to adulthood diseases including long-term hyper-responsiveness to stress with exaggerated circulating glucocorticoids and enhanced anxiety and depression like behaviors. Recently, it has been shown that alcohol exposures during the adolescent periods similarly predisposes individuals to adulthood stress abnormalities including long-term hyper-responsiveness to stress with exaggerated circulating glucocorticoids and enhanced anxiety. This raises the question of developmental timing: when does alcohol programming of stress axis to hyper-response cease? To address this issue we fed young rats at various stages of reproductive development (postnatal period 2-7 days of age; juvenile periods, 15-20 days of age; prepubertal period 23-28 days of age; or post-pubertal period 50-55 days age) with a liquid diet containing 11.34% alcohol to raise blood alcohol levels to a range of 150-200mg/dl. Control animals were

pair-fed an isocaloric volume of maltose dextrin. These rats were maintained in the animal house and challenged with restraint stress around 70 days of age. The stress challenge was conducted in both sexes. For females, the stress study was conducted on diestrus. Several days after the stress response, animals were sacrificed and the mediobasal hypothalamic tissue samples were obtained and used for measurements of proopiomelanocortin (Pomc) DNA methylation and Pomc gene expression. Determination of plasma glucocorticoid levels after restraint demonstrated an enhanced response to restraint stress in adult male and female rats who were given alcohol either on postnatal, juvenile or prepubertal period but not after pubertal period. Since Pomc is known to be an inhibitory regulator of the stress axis, we measured the expression of Pomc mRNA and DNA methylation levels and found reduced expression of Pomc but increased methylation of Pomc gene in rats treated with alcohol on postnatal, juvenile or prepubertal period but not after pubertal period. These results identify a critical period for alcohol programming of the stress axis via epigenetic mechanism of Pomc promoter hypermethylation during the developmental period.

**Title:** The impact of a vasopressin model of preeclampsia on neurodevelopment and neuroimmune outcomes in mouse offpsring

**Authors: *S. B. GUMUSOGLU**[1,2], A. CHILUKURI[1], S. HAIDER[1], S. SCROGGINS[1], J. SANDGREN[1], M. SANTILLAN[3], D. SANTILLAN[3], J. GROBE[4], H. E. STEVENS[2]
[2]Psychiatry, [3]Obstetrics & Gynecology, [4]Pharmacol., [1]Univ. of Iowa, Iowa City, IA

**Abstract:** Background:
Preeclampsia is an often severe, gestational hypertensive condition linked to abnormal child neuropsychiatric outcomes (e.g. autism). This connection between preeclampsia and offspring neurodevelopment is poorly understood. One unique animal model of preeclampsia involves continuous maternal administration of arginine vasopressin (AVP) across pregnancy. Here, we examine whether this model results in altered neurodevelopment and neuroinflammation in

prenatally exposed offspring.
Method:
C57Bl/6J mouse dams were implanted with a subcutaneous osmotic minipump, filled with AVP or saline (administration rate: 24 ng/hr), 3 days prior to mating. Offspring brains were collected at embryonic day 14 (E14), E18, day of birth (P0), postnatal day 7 (P7), and in adulthood, sectioned, mounted, stained for microglia (Iba-1, CD68), and counterstained for nuclei (DAPI). Cortical anatomy and neuroimmune changes were examined. Adult offspring were tested for behavioral phenotypes using the Y-Maze, rotarod, social approach, and elevated plus maze assays.
Results:
Preeclampsia exposed adult males exhibited increased anxiety-like behavior and altered social behavior while adult females exhibited impaired procedural learning and working memory. Preeclampsia exposed males exhibited reduced cortical volume, particularly in deep layers, at E18 and P0 despite showing no changes in cortical plate volume at E14. Volume reductions were also seen to persist at P7 and 3 months of age. Lastly, preeclampsia exposed offspring exhibited increased levels of the pro-inflammatory cytokine IL-17 at E18 and altered cortical microglia in pre- and post-natal brain.
Conclusions:
Within an AVP-based model of preeclampsia, we found that exposed offspring exhibited a constellation of sex-specific, aberrant behavior, suggestive of altered corticogenesis. Exposed male offspring demonstrated reduced cerebral cortex volume, beginning in late gestation, which persisted into adulthood. These offspring also exhibited a pro-inflammatory phenotype, indicated by cytokine and microglia changes. We plan to use this preeclampsia model to understand the maternal physiological mechanisms, immune cascades, and sex-differences underlying these altered offspring phenotypes.

**Authors: *B. D. SACHS**[1,2], A. BUNCHER[1], K. DODSON[1]
[2]Dept. of Psychology, [1]Villanova Univ., Villanova, PA

**Abstract:** A history of early life stress (ELS) is a significant risk factor for a number of neuropsychiatric disorders, but the mechanisms through which early life stressors contribute to the development of mental illness remain largely unknown. It has been hypothesized that long-lasting changes in gene expression induced by ELS might underlie this increased vulnerability to psychiatric disorders, but the specific transcriptional alterations that underlie the negative consequences of ELS have not been entirely identified. Aberrant endorphin signaling has been implicated in several long-term responses to ELS, and thus identifying ways to reverse the effects of ELS on the endogenous opioid system may have therapeutic potential in the treatment of several psychiatric conditions. In the current study, we used c57/BL6J mice to examine the effects of maternal separation stress (MSS), a model of ELS, on the expression of five genes involved in endorphin signaling in three brain regions: the hippocampus, hypothalamus and habenula. Our results demonstrate that MSS leads to a significant increase in the mRNA levels of proopiomelanocortin (POMC) and mu opioid receptor - 1 (MOR1) in the hippocampus. In addition, our data reveal that MSS significantly enhances the mRNA levels of kappa opioid receptor - 1 (KOR1) in the hypothalamus. In the habenula, MSS led to a significant reduction in the mRNA levels of proenkephalin (PENK). We simultaneously examined whether the chronic administration of the selective serotonin reuptake inhibitor, fluoxetine, in adulthood was sufficient to reverse any of the effects of MSS on the expression of endorphin system genes. Chronic fluoxetine administration significantly reduced the levels of MOR1 and POMC in the hippocampus, thus essentially reversing the effects of MSS. Fluoxetine also increased the mRNA levels of PENK and reduced the levels of KOR1 in the hippocampus. In the habenula, fluoxetine reduced POMC levels and increased PENK mRNA. In the hypothalamus, fluoxetine administration also significantly increased the mRNA levels of PENK, as it did in the other two brain areas. Prodynorphin (PDYN) mRNA levels were not significantly affected by either MSS or fluoxetine in any of the brain regions examined. Overall, our data reveal new insight into the regulation of the endogenous opioid system by ELS and chronic antidepressant administration in adulthood, which could have important implications for the development and treatment of neuropsychiatric disorders.

**Title:** Isolation of a potential antipsychotic compound from a Peruvian traditional medicine plant

**Authors: *L. F. TUME**[1], C. GALLO[2], G. POLETTI[2], R. ROJAS[3], M. HURTADO[4], A. J. VAISBERG[1]
[1]Lab. of Cell Biol., [2]Lab. of Mol. Neurobio. and Genet., [3]Lab. of Natural Products, Univ. Peruana Cayetano Heredia, Lima, Peru; [4]Lab. of Mol. Neurobio. and Genet., Univ. Peruana Cayetano Heredi, Lima, Peru

**Abstract:** Background: Schizophrenia is a severe mental disorder that affects approximately 1% of the population. The main symptom is psychosis in which thought and emotions are impaired. Current pharmacological treatments for schizophrenia are partially effective and usually produce side-effects, both factors impacting negatively on patient's adherence to the medication. Since ancient times, Peruvian native communities have recognized behavioral disorders treating them by the use of plant preparations. Peruvian traditional medicine is a potential source of new drugs because of their effectiveness and because they could be acting on different molecular mechanisms compared to the current drugs on the market. Aim: To isolate compounds from a raw plant ethanolic extract (EE) which is active on an animal model of antipsychotic action. Methods: We carried out the isolation based on polarity using preparative chromatography. The compounds were tested in mice treated with MK-801 (N-methyl D-aspartate receptor antagonist). We evaluated hyperactivity in the open field test (OFT)and the prepulse inhibition of startle response (PPI). Cytotoxicity assays were performed on a panel of mammalian cells to determine the GI50 using the sulforhodamine B method. In addition, the EE was tested in binding and functional assays on a panel of receptors altered in mental diseases through the National Institute of Mental Health Psychoactive Drug Screening Program. Results: We obtained a unique chromatographic peak that is active on open field ($p<0.01$) and PPI. The GI50 for this peak is less than the extract in where it was originated. Binding assays performed in the EE showed more than 30% binding to glutamate mGlur5, peripheral benzodiazepine receptor (PBR), serotonin 5-HT2B, histamine H1, and beta 3 receptors. Functional assays revealed that the EE has more than 30% of antagonist activity on GPCR65, GPCR68 and A2A. The EE did not show activity on HERG transport activity. Conclusion: A single peak fraction active in animal models for antipsychotic action has been obtained. The EE has effect on receptors reported to be altered in schizophrenia. Therefore, purification and structure elucidation of the active molecule will help us to the better understand the molecular mechanisms by which is exerting its antipsychotic effect.

**Title:** Effect of embryonic stress on zebrafish GnRH neurons

**Authors: *G. N. MCHUGH**, S. RAMAKRISHNAN
Biol., Univ. Of Puget Sound, Tacoma, WA

**Abstract:** The Effect of Embryonic Stress Exposure on the GnRH Neurons of Zebrafish (*Danio rerio*)
Stress exposure in zebrafish (*Danio rerio*) has been shown to cause reproductive and developmental impediments. The effects of stress on the reproductive neuroendocrine system in adults and adolescents have been explored, but not the effects on developing embryos. This study investigates the effects of embryonic cortisol (stress) exposure on GnRH neurons in the hypothalamus and pre-optic area (HYP/POA). GnRH neurons in the HYP/POA control the pituitary-gonadal axis (HPG-axis) through the release of reproductive hormones such as luteinizing hormone and follicle stimulating hormone. Changes to the HPG-axis during development can affect fecundity, and sexual reproduction. We wanted to see if early perturbation of this axis via cortisol exposure would have effects on the GnRH neural system. Embryos were collected from transgenic zebrafish with GnRH neurons tagged with a green fluorescent protein (GFP). This allowed for the observation of the developing GnRH neuroendocrine system. These embryos were exposed to chronic doses of cortisol at 5 μM and 10 μM from fertilization until 72 hours post fertilization (hpf). At 72 hpf, GnRH-GFP embryos were anesthetized, mounted and imaged using an inverted epifluorescent microscope at 488nm excitation / 512nm emission. The area and diameter of the HYP/POA-GnRH neurons were measured. Embryos exposed to 10 μM cortisol showed a significant reduction of area by 20% and diameter by 23% in individual GnRH neurons compared to age-matched controls ($p < 0.005$). The lower stress dose of 5 μM did not show any effect on GnRH neuron sizes. Imunohistochemistry was preformed to examine glucocorticoid receptors on GnRH neurons following 10μM cortisol exposure. The number of receptors on cortisol exposed GnRH neurons reduced by almost 50% compared to vehicle treated controls. This is one of the first studies showing that early embryonic stress exposure has direct effects on the developing HYP/POA GnRH neurons involved in the neuroendocrine system.

**Title:** Early life stress predicts behavioral problem symptoms, cortisol rhythms, and epigenetic profiles in childhood

**Authors: *C. LEWIS**[1,2], R. S. STYLES[1], I. PIRAS[2], L. D. DOANE[1], M. J. HUENTELMAN[2], K. LEMERY-CHALFANT[1]
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]NeuroGenomics, Translational Genomics Res. Inst., Phoenix, AZ

**Abstract:** Childhood social stressors, such as parental loss, neglect, and abuse, have long been associated with pathogenesis of psychiatric and physical health disorders (McEwen, 1998). Early life stress (ELS) is related to long-lasting alterations in typical and stress-responsive hypothalamic-pituitary-adrenal (HPA) functioning, which is related to psychiatric vulnerability (Gunnar & Quevedo, 2007). A recent review of literature suggests that epigenetic alterations likely mediate ELS-induced HPA dysregulation (Turecki & Meany, 2016). However, less severe childhood environments such as parenting practices also shape HPA function and psychopathology (Kuhlman et al, 2013). We examined whether characteristics of the primary caregiver and parenting practices at 2.5 years of age predicted cortisol diurnal rhythms, behavior problem symptoms, DNA methylation, and RNA expression at 8 years of age. Preliminary analysis included 85 out of 250 twin pairs participating in the longitudinal Arizona Twin Project, 52% female, 32% monozygotic (MZ), 50% European American (Am), 31% Latinx, 9.5% Asian Am, 7% African Am, and 2.4% Native Am (Lemery-Chalfant et al, 2013). ELS was assessed at twin age 2.5 years and is the first principal component of Parenting Daily Hassles, low perceived social support, punitive punishment (Parental Responses to Child Misbehavior), home chaos (Confusion, Hubbub, and Order Scale), CES-D maternal depression, and low maternal emotional availability. Salivary cortisol, buccal cells, and parent report of problem behaviors on the Health and Behavior Questionnaire were collected when twins were 8 years old. Saliva samples were collected in-home three times a day for three consecutive days. Gene methylation and RNA expression was assessed using Infinium HumanMethylation450 BeadChip Kit and RNA sequencing. ELS predicted more conduct disorder [$\beta = .348$, $t(76) = 2.49$, $p = .002$] and

oppositional defiant symptoms [β = .276, $t(76) = 2.49$, $p = .015$]. ELS predicted a flatter evening cortisol slope [β = .256, $t(77) = 2.25$, $p = .027$], but was not associated with morning slope or levels. Additional models examined methylation and RNA expression of HPA axis genes (e.g., glucocorticoid receptor). All analyses controlled for ethnicity, sex, and SES. ELS plays an important role in shaping child development and psychiatric and physical health outcomes. Our results extend this knowledge to less severe environments defined by parenting and characteristics of the primary caregiver. Findings highlight the importance of early childhood environments and elucidate the contributions of early environment to mental health and stress physiology in middle childhood.

**Title:** Vagus nerve stimulation directly activates limited myelinated afferents but indirectly increases unsynchronized activity in unmyelinated second and higher order sensory neurons in rat nucleus of the solitary tract

**Authors: *E. BEAUMONT**[1], R. P. CAMPBELL[1], M. C. ANDRESEN[2]
[1]Biomed. Sci., ETSU, Johnson City, TN; [2]Physiol. and Pharmacol., Oregon Hlth. & Sci. Univ., Portland, OR

**Abstract: Background:** Vagus nerve stimulation (VNS) is currently used to treat patients with drug resistant epilepsy, depression and, more recently, heart failure. The mild intensities used in chronic VNS suggest that primary visceral afferents and central nervous system activation are involved. Here we determined the neuronal responses of the first vagal receiving neurons within the nucleus of the solitary tract (NTS). **Methods:** NTS neuronal activity was recorded in chloralose anesthetized rats (n=12). Single tungsten electrodes were stereotaxically placed in the caudal medial NTS. A bipolar coil electrode was implanted around the left cervical vagus nerve. High intensity, single or paired shocks established vagal afferent conduction velocity as well as synaptic order (second vs higher). VNS followed clinically styled guidelines for setting bradycardic intensity (BI) at a current intensity which induced a 5% bradycardia. **Results:** Our

chief findings indicate that VNS at BI increased activity in one third of NTS neurons. VNS directly activated only NTS neurons second order to myelinated vagal afferents. Most VNS-induced activity in NTS, however, was unsynchronized to vagal stimuli (spontaneous activity). BI was subthreshold for all direct, vagal C-fiber inputs and yet VNS increased spontaneous but not synchronized spikes in both second and higher order NTS neurons. Overall, NTS neurons that responded to transient changes in blood pressure were similarly activated by BI VNS as pressure-insensitive neurons: 75% monosynaptic vagal A-fibers, 14% monosynaptic vagal C-fibers and 76% vagally polysynaptic neurons. Provocatively, BI VNS was clearly A-fiber selective and yet activated unsynchronized spikes in C-fiber second order neurons ($p<0.05$). Elevation in spontaneous activity was quantitatively much larger than synchronized activity and extended well into the periods of non-stimulation, particularly for NTS neurons receiving higher order inputs. Surprisingly, 33% of polysynaptic NTS neurons responded to 0.5 BI, indicating that large myelinated vagal afferents underlie VNS indirect activation ($p<0.05$). **Conclusions:** This study indicates that VNS directly activates only myelinated vagal afferents to NTS second order neurons without directly activating C-fibers. Conversely, VNS indirectly activated NTS C-fiber second order neurons as well as higher NTS neurons. This indirect activation is likely induced by the recruitment of intra-NTS and/or supra-NTS networks and raise interesting potential for identifying contributions of vagal afferent brain pathways underpinning of therapeutic benefits.

**Title:** A method for the measurement of autonomic control: Quantitative analysis of the properties of cardiovascular dynamics using the scaling exponent computed by mDFA

**Authors: *T. YAZAWA**
Tokyo Metropolitan Univ., Hachioji, Japan

**Abstract:** The beating heart is dynamically controlled by the autonomic nerves. All the organs including the heart is tightly connected through the brain. Fluctuation/variation of the heartbeat represents momently varying inner emotional tension. This psychological variations of the inner world, anxiety for example, is detectable and even quantifiable. Using a long-time electrocardiogram (EKG), we show that we can quantify the state of heart. We recorded EKGs by our own EKG amplifiers. The amplifier has a newly designed electric circuit, which enabled

us to record a stable EKG, i.e,. the amplifier made it possible to capture a perfect EKG where the EKG trace never jump-out from the PC monitor screen. Using this amplifier, we constructed a perfect time series data of approximately 2000 heartbeats without missing a single beat. For the analysis of the EKGs, we used “modified detrended fluctuation analysis (mDFA)” technique, which we have recently developed by our group. The mDFA calculates the scaling exponent (SI, scaling index) from the time series data, i.e., the R-R interval time series data obtained from EKG. Detecting 2000 consecutive peaks, the mDFA can distinguish between a normal and an abnormal heart: a normal healthy heartbeat exhibits an SI of around 1.0, comparable to the fluctuations exemplified as the 1/f spectrum. The heartbeat recorded from subjects who have stress and anxiety exhibited a lower SI. Arrhythmic heartbeats and extra-systolic heartbeats both also exhibited a low SI ~0.7, for example. We propose that the mDFA technique is a useful computation method for checking the cardiac control condition which reflects the state of mind as well as the state of heart functioning.

**Title:** Development of NO-ergic synaptic transmission in sympathetic ganglia

**Authors: *P. M. MASLIUKOV**, K. MOISEEV
Normal Physiol., Yaroslavl State Med. Univ., Yaroslavl, Russian Federation

**Abstract:** NO is generated by the enzyme nitric oxide synthase (NOS) and acts as a neuromodulator in the sensory and autonomic neurons A large number of adult mammalian sympathetic preganglionic neurons express NOS. However, there are only few works concerning the development of NO-mediated synaptic transmission in the sympathetic ganglia. The aim of this study was to identify expression of NOS in sympathetic preganglionic neurons and effects of NO on synaptic transmission in sympathetic ganglia during the development.
Experiments were performed on rats of different ages (newborn, 10-day-old, 20-day-old, 30-day-old, 180-day-old, 3-year-old) using immunohistochemistry, electrophysiology and western-blotting in accordance with the national and international principles of laboratory animal care. The results showed that in all age groups NOS-immunoreactive (IR) neurons were absent in

sympathetic ganglia. In the spinal cord, the largest number of NOS-IR sympathetic preganglionic neurons was located in the nucleus intermediolateralis thoracolumbalis pars principalis (nucl.ILp). In newborns, a large portion of NOS-IR neurons colocolized calbindin, calretinin and cocaine- amphetamine-regulated transcript (CART). During the first month of life, the proportion of NOS-IR neurons decreased significantly, while the number of neurons containing choline acetyltransferase increased. In newborns, all preganglionic neurons were NOS-IR, while in one-month-old rats 30-35% of preganglionic sympathetic spinal neurons were NOS-immunonegative. Decreasing in the expression of NOS in the spinal cord in the first month of life was further confirmed by western blotting. Evoked synaptic potentials in the superior cervical sympathetic ganglion were inhibited with NO donor sodium nitroprusside and augmented by the NO synthase inhibitor L-NAME from the moment of birth. We did not observe any difference on the morphological and electrophysiological properties of NOS-IR neurons between adult and old rats.
Thus, in early postnatal ontogenesis, there is an age-related change in NO-ergic sympathetic transmission with in a decrease in the number of sympathetic preganglionic neurons expressing NOS in the early development. NO inhibits synaptic transmission in sympathetic ganglia in young and old rats.

**Title:** Y1 and Y5 receptor localization and function in the guinea pig cardiac plexus

**Authors: F. M. TIERNEY**[1], S. E. ALLEN[1], A. M. GINSBURG[1], *J. C. HARDWICK[2]
[1]Biol., [2]Ithaca Col., Ithaca, NY

**Abstract:** Chronic heart disease leads to imbalances within the autonomic nervous system, often resulting in an upregulation of sympathetic output with a corresponding decrease in central parasympathetic activity. In addition to the increased release of norepinephrine from sympathetic fibers, there is also an elevation in the release of the neuropeptide, NPY, from sympathetic fibers. These sympathetic efferents also innervate the intrinsic cardiac nervous system. Parasympathetic neurons of the cardiac plexus respond to NPY with a hyperpolarization and a decrease in the duration of the afterhyperpolarization of the action potential. This study examined the expression of specific NPY receptor subtypes in intracardiac neurons of the guinea

pig intrinsic cardiac plexus. In addition, we characterized the role of receptor subtypes in mediating the changes in action potential properties. Preliminary analysis of mRNA for NPY receptors demonstrated that both Y1 and Y5 receptors are expressed in the cardiac plexus and within atrial muscle tissue. Immunohistochemical studies show significant expression of Y1R in cardiac neurons, although not all neurons express the Y1 receptors. Y5R staining was not as prominent in neurons as the Y1R. Intracellular voltage recordings from cardiac neurons were performed on whole mount preparations superfused with either 100 nM NPY, 100 nM D-Arg-NPY (Y1-specific) agonist, or 100 nM BWX-46 (Y5-specific agonist). A two minute perfusion with NPY resulted in a ~25% reduction in the t1/2 (time to reach 50% of original resting membrane potential) of the afterhyperpolarization. Perfusion with the Y1 agonist produced a similar response. Perfusion with the Y5 agonist was less potent (~15% reduction with a shorter duration of action), suggesting that expression/function of the Y5R is reduced in neurons, relative to the Y1R. Addition of the Y1R-specific antagonist, BVD 10 (1 uM) to the perfusion solutions completely inhibited the response to D-Arg-NPY, without altering the response to the Y5 agonist. The response to NPY in the presence of the Y1 antagonist was smaller with a shorter duration, similar to the Y5 agonist. Taken together, these studies suggest that the Y1R is the predominant NPY receptor on intracardiac neurons, but there is also evidence for Y5R expression. Both of these receptors appear to induce alterations in ionic currents underlying the action potential and future studies will explore the ionic mechanisms of these receptors in more detail and as well as how their expression and function is affected by chronic heart disease.

[5]Martinos Ctr. For Biomed. Imaging, Charlestown, MA; [6]Dept Radiol, Mass Gen. Hosp., Charlestown, MA

**Abstract: Introduction:** The vagus nerve plays an important role in the regulation of cardiovascular function and vagus nerve stimulation (VNS) in patients with cardiovascular disease improves prognosis. VNS has negative chronotropic and dromotropic effects, reduces baroreflex sensitivity, and decreases circulating plasma catecholamine levels. In animal models of myocardial infarction, VNS prevents ventricular fibrillation and sudden cardiac death. Despite these promising findings, morbidity associated with invasive VNS has limited its clinical application. Thus, the mapping of alternative non-invasive pathways for vagal modulation is of critical relevance. An alternative, non-invasive method of VNS is stimulation of the auricular branch of the vagus nerve (ABVN) in the external ear. However, the neural pathway connecting ABVN afference with cardiovascular outcomes is not well understood. In this study, we aim to functionally map the ABVN – brainstem – cardiovagal outflow pathway in rats.
**Methods:** Healthy adult male and female Wistar rats were used. We evaluated cardiovagal efference by recording ECG and cervical vagus nerve activity in response to ABVN stimulation. ECG was used for heart rate variability (HRV) analysis which is the most effective and widely used method to assess autonomic modulation of cardiac reflex function. We calculated power in high frequency band (HF-HRV) that reflects cardiac parasympathetic nerve activity and power in low frequency band (LF-HRV) that has a dominant sympathetic component. To characterize brainstem circuitry activated by ABVN stimulation, we stereotaxically injected lidocaine to inhibit neuronal activity in selective nuclei including nuclei tractus solitarii (NTS). At the end of the stimulation-recording period, brains were obtained for c-Fos immunohistochemistry as a surrogate marker for neuronal activation.
**Results:** We recorded ECG and cervical vagus nerve activity before, during, and after ABVN stimulation in control (n=5) rats and animals that received bilateral lidocaine injection (4%, 0.1 μl per site; n=5) into the NTS. HRV analysis showed that ABVN stimulation significantly increased HF-HRV power and decreased LF-HRV/HF-HRV ratio ($p<0.05$). The effect of ABVN stimulation on these parameters was abolished in rats that underwent NTS blockade. Preliminary analysis of cervical vagus nerve activity suggests that rapid biphasic response to ABVN stimulation was absent in animals with NTS blockade.
**Conclusion:** ABVN stimulation increased cardiovagal outflow via the NTS. Involvement of other nuclei and the contribution of specific neurotransmitter systems will be evaluated further.

**Title:** Breathing and the amygdala: Potential implications for SUDEP

**Authors:** W. P. NOBIS[1], ***C. ZELANO**[2], J. TEMPLER[2], G. LANE[2], G. ZHOU[2], S. SCHUELE[2], *C. ZELANO[2], *C. ZELANO[2]
[1]NEUROLOGY, [2]Northwestern Univ., Chicago, IL

**Abstract:** Sudden unexplained death in epilepsy (SUDEP) is the most frequent cause of death in epilepsy patients. Accumulating evidence indicates that SUDEP may involve impaired breathing and apnea during and after seizures. However there are a number of additional known pathologic features of SUDEP including ictal arrhythmias, ictal or postictal central apnea and autonomic dysregulation. The variety of pathological features combined with the rareness of the disease have left the underlying neural mechanisms of SUDEP poorly understood. Brainstem structures have been implicated in some models of SUDEP, but higher order control of these structures by seizures is unknown. The extended amygdala, comprising chiefly of the central amygdala and the bed nucleus of the stria terminalis, is a part of the central autonomic network that is interconnected between higher order cortical areas, brainstem, and hypothalamic networks raising the possibility that it could be the missing link in the mediation of SUDEP. The central amygdala is activated by seizures, and its activation can have powerful effects on heart rate, blood pressure and respiratory function. Furthermore, extended amygdala projections reach areas that are important for control of cardiorespiratory function including the nucleus of the solitary tract and the ventrolateral medulla. Recent intracranial EEG data from several groups have shown that electrical stimulation of the human amygdala induces apnea, and recent local field potential recordings have demonstrated that neural oscillations in the amygdala become synchronized during natural inhalation. Taken together, these data suggest a role for the amygdala in controlling respiration. In this study, we will show data from five additional epilepsy patients confirming that electrical stimulation of the human amygdala induces apnea. Preliminary data suggest that this stimulation-induced apnea can be prevented in two ways. First, if the patient is instructed to take a breath after the apnea has begun, they are able to do so, suggesting it can be overcome with preserved consciousness. Second, if stimulation is administered during mouth breathing (as opposed to nose breathing), no apnea occurs. Our data support the hypothesis that the amygdala may play a role in SUDEP, and also provide evidence for two techniques that can overcome or prevent amygdala-related apnea.

**Title:** Direct projections from orexin neurons to pre-sympathetic neurons in the paraventricular nucleus of the hypothalamus

**Authors: *O. DERGACHEVA**, D. MENDELOWITZ
Pharmacol. & Physiol., GW Univ., Washington, DC

**Abstract:** Orexin neurons are generally thought to be sympathoexcitatory; however, the functional connectivity between orexin neurons and the bulbospinal pre-sympathetic neurons (PSNs) in the paraventricular nucleus of the hypothalamus (PVN), has not been established. To test the hypothesis that orexin neurons project directly to PSNs in the PVN, channelrhodopsin-2 (ChR2) was selectively expressed in orexin neurons to enable photoactivation of ChR2-expressing fibers while examining evoked postsynaptic currents in PSNs in rat hypothalamic slices. Selective photoactivation of orexin fibers elicited short-latency postsynaptic currents in PSNs. These light-triggered responses were heterogeneous, with a majority being excitatory glutamatergic responses (59%), and a minority of inhibitory GABAergic (35%) and mixed glutamatergic and GABAergic currents (6%). Glutamatergic, but not GABAergic, postsynaptic currents were diminished by application of the orexin receptor antagonist almorexant indicating orexin release facilitates glutamatergic neurotransmission in this pathway. This work identifies a neuronal circuit by which orexin neurons likely exert sympathoexcitatory control of cardiovascular function.

**Abstract:** In recent decades, multiple vole species have provided valuable insights into different social behaviors. Meadow voles exhibit changes in their social behavior across seasons. Female meadow voles are highly territorial and aggressive toward other females in the summer months, but in the short days of winter, they form selective, communal groups. For this study, female meadow voles were pair housed in either short or long photoperiods. Individuals were implanted with cardiac telemetry transmitters and baseline cardiac parameters were measured. Following collection of baseline data, specific autonomic nervous system signaling pathways were suppressed using atenolol, atropine, or a combination of the two, and compared to a saline control injection. All individuals underwent all treatments, which were counterbalanced with 48 hours between treatments. Atenolol is a beta-receptor blocker that has been shown to increase heart rate by antagonizing the cardiac response to circulating epinephrine and norepinephrine. Atropine is a muscarinic acetylcholine receptor blocker that decreases heart rate variability and the phenomena of respiratory sinus arrhythmia. Prior studies have characterized cardiac function in prairie voles—a close relative of the meadow vole; female prairie voles were included in this study to allow direct comparisons. Meadow vole heart rate and heart rate variability were not significantly different from those of prairie voles. Meadow voles responded as expected to pharmacological suppression of the autonomic nervous system, and effects of these drugs did not differ between the species. Additional data will be presented on photoperiodic variation within meadow voles. Characterization of meadow vole cardiac physiology will allow for future studies of the influence the autonomic system has on behavior and vice versa.

**Title:** Role of muscarinic acetylcholine receptor 2 in anti-myocardial ischemia effect by acupuncture

**Authors: *S. CHEN**, C. DUANMU, J. WANG, L. QIAO, J. LIU, J. ZHANG
Inst. of Acupuncture and Moxibustion, CACMS, Beijing, China

**Abstract:** Ischemic heart diseases are common malady leading to serious impacts on people's health in developed as well as developing countries. Previous studies show that acupuncture produces positive therapeutic effects on these diseases. Given the fact that acute myocardial ischemia (AMI) is usually concomitant with the increase of the sympathetic nerve activities but decrease of the vagal nerve activities, we hypothesized that acupuncture reduces MI via enhancement of the vagal tones. This work was carried out on the wild type (WT) and gene knockout (KO) muscarinic acetylcholine receptor M2 (M2AChR) mice. The MI model was developed by isoproterenol administration i.p. Electroacupuncture (EA) stimulation (0.5mA, 2Hz) was applied at "Neiguan" acupoint (PC6) for 20 minutes. Electrocardiogram (ECG) was recorded for the evaluation of the MI condition as well as the analysis of heart rate variability (HRV) via the root mean square of successive differences (RMSSD), high frequency (HF) and the ratio of low frequency (LF) verus HF and so forth. Further, by means of the biochemical, immunohistochemical and molecular biological methods, we evaluated the changes of relevant cardiac enzymes in serum, and the expressions of the M2AChR and the downstream molecules like bcl-2 and caspase3 in the ventricular myocardium. We found that 1. KO mice demonstrated higher heart beats than WT mice particularly in MI-1d period. During MI induction, the ST-segment and the J-point of ECG elevated or lowered notably in both WT and KO mice. Concurrently, the heart rate accelerated, the RMSSD and HF decreased whereas the ratio of LF/HF increased significantly. 2. EA could reverse the abovementioned changes. In comparison with the WT mice, EA led to no much effect on KO mice evaluated with RMSSD. Atropine, the M2 receptor antagonist, blocked the EA effect of elevating RMSSD and reducing the ration of LF/HF. 3. MI resulted in significant increase of serum LDH and CK-MB in both content and activity. After EA treatment, these increases were reduced. 4. EA upregulated the expressions of M2 and its intracellular downstream molecule bcl-2 reduced by MI but downregulated the expressions of caspase3 raised by MI. The evidence indicates that acupuncture achieves the effect of MI reduction through the M2AChR and bcl-2/caspase3 signaling transduction pathway. Our study provides new data for the elucidation of the molecular mechanism of acupuncture on MI and thereby holds promise for the management of cardiovascular diseases in clinic.

**Title:** Exercise training normalizes excitability of presympathetic neurons by increasing GABAergic transmission in heart failure rats

**Authors: Y. SHEN**[1], S. LEE[1], S. HAN[2], *P. RYU[1]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Chonbuk Natl. Univ., Jeonju, Korea, Republic of

**Abstract:** Sympathetic hyper-activation is a hallmark of heart failure (HF). Recent studies showed that exercise training (ExT) decreases peripheral sympathetic nerve activity in HF patients. However, underlying mechanisms of such effects are not well understood. In this study, we examined the changes in the hypothalamic presympathetic neurons in the HF rats after a 3-week period ExT. The rat model of HF was prepared by ligation of left descending coronary artery. At 3-4 weeks after the surgery, the animals were exercised on a motor-driven treadmill for 3 weeks. At 8$^{th}$ week following the surgery, the electrical activity of the paraventricular nucleus neurons projecting to the rostral ventrolateral medulla (PVN-RVLM) was recorded by slice patch clamp technique combined with retrograde tracing. We also collected electrocardiogram data for heart rate variability (HRV) analysis. ExT induced a reduction in the firing rate of PVN-RVLM neurons in HF rats (3.40 vs. 1.98 Hz) with an increase in the frequency of IPSCs (1.13 vs. 3.14 Hz) without affecting EPSC. Replacement of $Ca^{2+}$ with $Mg^{2+}$ in recording solution reduced miniature IPSC frequency more in HF-ExT than in HF group (40.4 vs. 71.4%). GABA-A receptor blocker (bicuculline, 20 μM) increased the firing rate more in HF-ExT than in HF rats (10.3 vs. 93.0%). In addition, the input resistance (752 vs. 1025 Mohm) and the peak of after hyperpolarization (-22 vs. -26 mV) in PVN-RVLM neurons were larger in HF-ExT rats than HF rats. ExT also reversed the reduced circadian fluctuations in heart rate and the sympatho-vagal activity in HF rats. Collectively, the results indicate that ExT normalizes the hypothalamic pre-sympathetic hyper-activation and blunted circadian rhythm in sympatho-vagal balance in HF rats. These are largely due to ExT-induced increase in GABA release. Our findings newly provide a synaptic mechanism of ExT-induced beneficial effect in HF patients.

**Title:** Effect of sodium hydrosulfide on tachycardic responses induced by stimulation of the preganglionic sympathetic outflow in pithed rat

**Authors: *S. HUERTA**, S. V. CASTILLO-SANTIAGO, M. E. CHACON-BECERRIL, J. A. TORRES-PÉREZ, A. SÁNCHEZ-LÓPEZ, D. CENTURION
Pharmacobiology, Cinvestav-Sede Sur, Ciudad de Mexico, Mexico

**Abstract:** Hydrogen sulfide ($H_2S$) is a gasotransmitter that, at physiological concentrations, mediates complex responses in the cardiovascular system. Recently it has been shown that $H_2S$ produces negative chronotropic and inotropic responses in isolated heart. Also, in anesthetized rats, it has been observed that sodium hydrosulfide (NaHS) induces bradycardia although the mechanisms remain elusive. On this basis, the present study was designed to explore the potential capability of NaHS to inhibit the cardiac sympathetic outflow in pithed rat. For this purpose, 72 male Wistar rats (300-350 g) were used. Animals were anesthetized with isoflurane (3%), the trachea was cannulated for artificial ventilation and the rats were pithed by inserting a stainless-steel rod through the orbit and foramen magnum into the vertebral foramen which was later replaced by an electrode enamelled except for 1 cm length 7 cm from the tip to stimulate the cardiac sympathetic outflow (C7-T1). Catheters were placed in: the left and right femoral veins for drugs administration and the left carotid artery to record heart rate and blood pressure. Animals were initially divided into 3 groups: (1) cardiac sympathetic outflow stimulation; (2) i.v. bolus of exogenous noradrenaline; and 3) i.v. bolus of isoproterenol. Those groups were then subdivided into 4 groups that received a continuous infusion of (1) nothing (control group); (2) PBS (vehicle); (3) NaHS 310 μg/kg min; and (4) NaHS 560 μg/kg min. We observed that tachycardic responses induced by cardiac sympathetic outflow stimulation were significantly diminished in a dose-dependent manner by i.v. continuous infusion of NaHS. Nevertheless, continuous infusion of NaHS failed to modify on tachycardic responses induced by i.v. bolus of noradrenaline or isoproterenol. Thus, we concluded that NaHS inhibits the tachycardic responses through a pre-junctional mechanism and did not interact directly with post-junctional receptors.

**Title:** The role of periaqueductal gray (PAG) lesions on pain processing and cardiovascular regulation

**Authors: *S. NAIR**, P. BROWNING, E. A. MURRAY, B. B. AVERBECK
Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract:** The periaqueductal gray (PAG) is located in the midbrain, immediately surrounding the cerebral aqueduct. It plays an important role in mediating defensive behaviors and it influences functions including pain processing, fear and anxiety, cardiovascular control, vocalization, and lordosis. Although there has been considerable work on the PAG in rodents, there is minimal work on this structure in monkeys. Some functions attributed to the PAG, including intra-specific threat processing, may differ among species. Therefore we have examined the effects of ibotenic acid lesions of the PAG in rhesus monkeys (*Macaca mulatta*) on both pain processing and cardiovascular control. We examined both of these functions through four separate assessments each, two pre-operative and two-post-operative. Pain was measured through the use of a von Frey (VF) filament-based nociception assay and vital signs were obtained using standard procedures. Our preliminary results indicate no significant difference between the change in pre-operative and post-operative VF measurements or vital signs when comparing monkeys with PAG lesions (n = 4) and sham-operated controls (n = 4). Ongoing work includes evaluation of social and nonsocial defensive responses.

**Title:** Moderate intensity exercise improves heart rate variability in obese adults with type 2 diabetes

**Authors: *R. K. GOIT**
Nepalgunj Med. Col., Banke, Nepal

**Abstract:** The aim of this study was to determine the effect of moderate aerobic exercise on heart rate variability (HRV) in obese adults with type 2 diabetes. 41 obese adults with type 2 diabetes participated in this study. Anthropometric and metabolic parameters were measured, and resting electrocardiogram (ECG) for the HRV analysis at spontaneous respiration was recorded for 5 min in supine position before and after six months of supervised aerobic training given thrice-a-week. The mean age, body mass index (BMI), and duration of diabetes of the study population were 44.1 ± 4.5 years, 30.94 ± 1.36 kg/$m^2$, and 16.3 ± 2.7 years, respectively. In time domain variables, standard deviation of all RR intervals (SDNN), the square root of the mean of the sum of the squares of differences between adjacent RR intervals (RMSSD) and percentage of consecutive RR intervals that differ by more than 50 ms (pNN50) were significantly increased after exercise. In frequency domain variables, high frequency (HF) ($ms^2$) and HF (nu) were significantly increased while low frequency (LF) ($ms^2$) were significantly decreased after exercise. But LF (nu) and LF/HF ratio were unaffected after exercise. These data suggest that thrice-a-week moderate intensity aerobic exercise for six months improves cardiac rhythm regulation as measured by HRV in obese adults with type 2 diabetes.

**Title:** Inhibition of catalase reduces arterial pressure and renal sympathetic nerve activity in hypertensive rats

**Authors: *M. R. LAUAR**[1], L. T. TOTOLA[2], T. S. MOREIRA[2], D. S. A. COLOMBARI[1], L. A. DE LUCA JR[1], P. M. DE PAULA[1], E. COLOMBARI[1], C. A. F. ANDRADE[1], J. V. MENANI[1]

[1]Dept Physiol. and Pathol., Dent. School, UNESP, Araraquara, Brazil; [2]Dept of Physiol. and Biophysics, Inst. of Biomed. Sci., Univ. of Sao Paulo, USP, Sao Paulo, Brazil

**Abstract:** The 2-kidneys, 1-clip (2K1C) hypertension is characterized by increased renin-angiotensin system (RAS) and sympathetic activity. In rats with 2K1C hypertension, chronic subcutaneous (sc) administration of the catalase inhibitor 3-amino-1,2,4-triazol (ATZ) reduces mean arterial pressure (MAP) and improves autonomic modulation. In the present study, we analyzed the changes in renal and splanchnic sympathetic nerve activity in 2K1C hypertensive rats treated with sc injection of ATZ. Male Holtzman rats (initial weight 150-180 g, n=4-6/group) received a silver clip around the left renal artery to generate 2K1C hypertension. Six weeks after the surgery, MAP and renal (rSNA) and splanchnic (sSNA) sympathetic nerve activity were recorded in urethane-anesthetized and artificially-ventilated rats that received an injection of ATZ (300 mg/kg of body weight) sc. The sc injection of ATZ in 2K1C hypertensive rats reduced MAP (160 ± 13 mmHg 1 h after ATZ, vs. control: 180 ± 13 mmHg pre-ATZ) and rSNA (-52 ± 10% 1 h after ATZ), without significantly changing the sSNA (-8 ± 16%). The present results suggest that increasing the availability of endogenous $H_2O_2$ with the injection of ATZ produces anti-hypertensive effects associated with decrease in renal sympathetic nerve activity.

**Title:** The development of cardiovascular dysfunction in a rat spinal cord crush model and responses to pharmacological interventions of serotonin and dopamine receptors

**Authors: *C. TRUEBLOOD**, I. IREDIA, V. J. TOM, S. HOU
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

**Abstract:** Selection of a proper spinal cord injury (SCI) animal model that is conducive to study therapeutic effects of cell transplantation is imperative for research in cardiovascular functional recovery. We recently found that neural stem cells grafted into the lesion of crushed spinal cord achieved better survival and integration than other dura-opened injuries. However, it is unknown whether cardiovascular dysfunction develops in this model. Disordered hemodynamics following SCI is mainly attributed to the interruption of supraspinal pathways. Given the preservation of neurotransmitter receptors in the lower cord, e.g., those for serotonin (5-HT) or dopamine (DA), they could be potential targets for drug treatment to restore autonomic function. Accordingly, the purpose of this study was to determine hemodynamic consequences of a crushed SCI, and to define the effects of 5-HT or DA receptor agonists on cardiovascular performance. Adult rats underwent complete spinal cord crush at the $4^{th}$ thoracic level. Using a radio-telemetric system, we recorded multiple hemodynamic parameters prior to or 2 and 4 weeks after injury, including resting mean arterial pressure (MAP) and heart rate (HR), as well as spontaneous or colorectal distension (CRD)-induced autonomic dysreflexia (AD), evidenced by simultaneous hypertension and bradycardia. This was followed by drug delivery targeting 5-HT and DA receptors. The results showed that resting HR was dramatically increased whereas MAP did not change compared to pre-injury. Spontaneous AD occurred after injury, without distinction in events at different time points. Yet, developed CRD-induced AD revealed a significant increase in MAP change and decrease in HR change over time. In the chronic stage of SCI, subcutaneous administration of apomorphine (a non-selective DA receptor agonist, 10-300 μg/kg) or 8-OH-DPAT (a 5-$HT_{1A}$ receptor agonist, 5-100 μg/kg) did not affect resting hemodynamics. In contrast, a 5-$HT_{2A}$ receptor agonist DOI (5-100 μg/kg) remarkably increased resting MAP levels with dose-dependent effects. During CRD, administering DOI (20 μg/kg) did not eliminate or alleviate episodic hypertension. Additionally, intrathecal injection of DOI (1-20 μg/kg) in urethane-anesthetized SCI rats elicited a cumulative response of increased resting MAP and decreased HR, indicating the effects at least partially via the central mechanism. Histological analysis confirmed lesion completeness in most cases using serotonergic axons as an indicator. Thus, the crushed SCI is sufficient to induce cardiovascular abnormalities and this model responds sensitively to pharmacological stimulation of 5-$HT_{2A}$ receptors.

**Title:** Monosynaptic excitatory projection from PVN oxytocin neurons to the LC

**Authors: *X. WANG**[1], D. S. MENDELOWITZ[2]
[1]Pharmacol. and Physiol., [2]George Washington Univ., Washington, DC

**Abstract:** The paraventricular nucleus of the hypothalamus (PVN) and the locus coeruleus (LC) are critical in controlling autonomic function under normal conditions and regulating cardiovascular activity in response to stressful challenges. The PVN is a heterogeneous nucleus, including the vasopressin neurons and oxytocin (OXT) neurons. It has been reported that oxytocin released from PVN oxytocin neurons can reduce anxiety and stress. Neurons in the locus coeruleus (LC) innervate extensive areas of the brain and the spinal cord and are most active in wakefulness. Systemic application of oxytocin may increase social interaction and decrease anxiety and stress reactions by decreasing noradrenergic release in the locus coeruleus. This study is to examine whether oxytocin neurons in the PVN directly modulate the LC neuron activity or not. To selectively expression and stimulation of PVN oxytocin neurons we applied viral transfection approach. Two viral vectors in combination with the Cre-Lox recombination system were used. In this system one viral vector expresses Cre recombinase under the specific oxytocin promotor. The second vector expresses ChR2 (H134R). This is a Cre-dependent vector that has silencing double-floxed inverse open reading frames which insures expression is only initiated in oxytocin neurons that selectively express Cre. Whole cell patch clamp technique was used to recording stimulation evoked postsynaptic events in the LC neurons. Biocytin (0.05%) was added in the patch solution to further identify the neurons in the LC using immunohistochemistry staining. Ontogenetic stimulation of ChR2 expressing PVN oxytocin-cre-fibers evoked excitatory inward currents in LC neurons with an average of amplitude of -65.4 ± 4 pA . This evoked excitatory currents was blocked by the glutamatergic receptor antagonists AP-5 (50 μM) and CNQX (μM). Further work will examine the roles, if any, co-release of oxytocin.

**Title:** Analysis of the vasopressor responses induced by sympathetic stimulation or several adrenergic agonists in pithed rats treated with high-fat diet

**Authors: *A. SACHEZ-LOPEZ**, M. E. BECERRIL-CHACON, E. J. GUTIÉRREZ-LARA, D. CENTURIÓN
Farmacobiología, Cinvestav-Coapa, Mexico, Mexico

**Abstract:** Obesity is a risk factor for the development of cardiovascular diseases. The extent to which obesity affect the cardiovascular function in pithed rats remains unknown. Thus, the aim of this study was to determine the effect of high-fat diet on the vasopressor responses induced by sympathetic stimulation. This experimental model allows evaluating the cardiovascular responses without the influence of the central nervous system. For this purpose, 12 animals were divided into two groups. The first group (n=6) was treated with normal diet and the second group (n=12) was treated with high-fat diet with lard 30% during 12 weeks. Next, body weight, blood triglyceride levels as well as blood glucose and plasma insulin were determined before postprandial glucose. In both groups the blood glucose and plasma insulin were determined after administration of glucose (1 g $Kg^{-1}$, p.o.) at 5-120 min. Then, rats were: (1) anaesthetized with isoflurane; (2) pithed with a stainless steel road; (3) assisted with artificial ventilation; and (4) cannulated for i.v. administration of several drugs. The vasopressor effects to sympathetic stimulation or i.v. administration of noradrenaline (1-10 mg $Kg^{-1}$), methoxamine (0.03-10 μg $Kg^{-1}$) and UK 14,304 (0.56-18 μg $Kg^{-1}$) were determined. High-fat diet produced increases in body weight without significant changes in basal blood glucose, basal plasma insulin or HOMA-index or blood triglycerides. However, high-fat diet (HFD) significantly decreased glucose tolerance after administration of 1 g $Kg^{-1}$ glucose (p.o.) while plasma insulin levels remained unchanged. Furthermore, sympathetic stimulation or i.v. administration of noradrenaline, methoxamine or UK 14,304 elicited dose-dependent vasopressor responses in either animals treated with normal diet or HFD. The responses to sympathetic stimulation remained unaffected by HFD. In marked contrast, the vasopressor responses were significantly increased by HFD. The above results suggest that high-fat diet significantly increased the functionality of alpha1 and alpha2 adrenoceptors in systemic.

**Title:** Alpha and beta adrenergic receptors increase the serotonin-induced vascular smooth muscle contraction through $Ca^{2+}$ regulation

**Authors: *D. M. MEJÍA**[1], P. SEGURA MEDINA[2], V. CARBAJAL SALINAS[2], M. VARGAS BECERRA[1], E. TORREJÓN GONZÁLEZ[1], P. CAMPOS BEDOLLA[1]
[1]Inst. Mexicano del Seguro Social, Ciudad de México, Mexico; [2]Inst. Nacional de Enfermedades Respiratorias, Mexico, Mexico

**Abstract: Background**: Role of serotoninergic and adrenergic systems has been widely studied in the vascular smooth muscle (VSM) tone and cardiovascular physiology. Serotonin (5-hydroxytryptamine) is one of the main vasoconstrictors in arteries and veins trough the 5-$HT_{2A}$ receptor. In the same way, alpha- and beta- adrenergic receptors (a- and b-AR) are principal therapeutic targets in a lot of cardiovascular pathologies. Previously, in other studies we have found that 5-$HT_{2A}$ receptor just contribute partially in aorta contraction. For this reason, we proposed that other signaling pathways could be participating. Due to the importance of $Ca^{2+}$ intracellular concentration ($[Ca^{2+}]i$) for an adequate VSM contraction, we evaluated the adrenergic system role in the serotonin-induced aorta contraction and the $[Ca^{2+}]i$ by simultaneous measurements *in vitro* model. **Material and methods**: Thoracic aorta rings were obtained from male Hartley guinea pigs (400-600 g) and stimulated by non-cumulative 5-HT concentrations (0.1 to 100 μM). The role of 5-$HT_{2A}$ receptor was evaluated with the antagonist ketanserin (0.01 μM, KT). In addition, we used α- and β- AR agonist and antagonists on 5-HT-contraction by *in vitro* system. In another set of experiments, we evaluated simultaneous measurements of $[Ca^{2+}]i$ and vascular contraction. Contraction responses were expressed respect to 80 mM KCl maximal contractile activity by mean±SEM. **Results**: All 5-HT concentration produced sustained contraction on aorta rings, and it is concentration-dependent response. The maximal contractile activity by 100 μM of 5-HT (56.68±1.4%) was reduced by KT (33.01±1.27%) in 41.76% of the response. a- and b- AR antagonists reduced significantly 100 μM 5-HT contraction. Prazosin (a-AR antagonist) decreased highly significantly by 50.66% 5-HT contraction ($p<0.0001$). And propranolol, (b-AR antagonist) reduced 54.49% ($p<0.0001$). Consistently with another studies, we found that α-AR agonist, phenylephrine, induced the maximal contraction response (94.09±3.19%) on aorta, while isoproterenol (b-AR agonist) scarcely induced 3.39±0.8% of aorta contraction. $[Ca^{2+}]i$ was 100% decreased in the 5-HT response when a-AR antagonist was preincubated ($p<0.05$). **Conclusions:** a- and b-adrenergic receptors enhance the serotonin-induced contraction in guinea pig aorta. This contractile activity is modulated by mechanism involving the movement of $Ca^{2+}i$ and maybe through 5-HT receptors presynaptic activation.

**Title:** Co-inhibition of neurons in the rostral ventrolateral medulla by GABA and Glycine

**Authors: H. GAO**, *A. DERBENEV
Dept of Physiol., Tulane Univ., New Orleans, LA

**Abstract:** Presympathetic neurons in the rostral ventrolateral medulla (RVLM) are best known for their contribution to the control of sympathetic nervous system and homeostatic functions of the body. Both glycine and GABA were identified as fast inhibitory neurotransmitters in the RVLM. However, the mechanisms of GABA and glycine release and/or co-release in the RVLM remain to be determined. Whole-cell, patch-clamp recordings were conducted from presympathetic neurons identified with PRV-152, to investigate GABAergic and glycinergic inhibitory mechanisms in rat brainstem slices containing RVLM neurons. We tested the hypothesis that the release of glycine is associated with the activity of neuronal network. Our data revealed that inhibitory postsynaptic currents (IPSCs) recorded from RVLM neurons composed from both GABAergic and glycinergic synaptic events. In steady state conditions, GABA is the predominant inhibitory neurotransmitter in the RVLM. Surprisingly, after activation of the inhibitory network, the GABAergic and glycinergic neurotransmission were reversed. Under resting condition, the proportion of glycinergic IPSCs was less than 10% of the total IPSCs. Activation of the inhibitory network produced saturation of inhibitory events mediated by GABA and increased the average frequency of glycine-mediated IPSCs. After network activation, glycinergic IPSCs represent more than half of the total IPSCs in the RVLM. Our data suggest that glycinergic inhibition provides a secondary synaptic inhibition in presympathetic RVLM neurons. This novel mechanism has the potential for fine tuning of the sympathetic output controlling homeostatic functions.

**Title:** Analysis of the vasodepressor responses induced by NaHS, sodium nitroprusside and acetylcholine in rats treated with high fat diet

**Authors: *C. B. GOMEZ**[1], M. BECERRIL-CHACÓN[2], E. GUTIÉRREZ-LARA[1], A. SÁNCHEZ-LÓPEZ[1], D. CENTURION[1]

**Abstract:** Endothelial and vascular dysfunction is reported in isolated arteries from rats treated with high fat diet. However, up to date, it is unknown whether this effect is observed in the complete systemic vasculature in vivo. Thus, the aim of this study was to determine the effect of high fat diet on the vasodepressor responses to NaHS, acetylcholine or sodium nitroprusside in pithed rats infused with methoxamine. This experimental model allows evaluating the cardiovascular responses without the influence of the central nervous system. For this purpose, 12 animals were divided into two groups. The first group (n=6) was treated with normal diet and the second group (n=12) was treated with high-fat diet with lard 30% during 12 weeks. Next, body weight, blood triglyceride levels as well as blood glucose and plasma insulin were determined before postprandial glucose. In both groups the blood glucose and plasma insulin were determined after administration of glucose (1 g Kg-1, p.o.) at 5-120 min. Then, rats were: (1) anaesthetized with isoflurane; (2) pithed with a stainless steel road; (3) assisted with artificial ventilation; (4) cannulated for i.v. administration of several drugs; and (5) infused with methoxamine (20 μg Kg-1 min-1). The vasodepressor effects to i.v. administration of NaHS (1-10 mg Kg-1), acetylcholine (0.03-10 μg Kg-1) and sodium nitroprusside (0.56-18 μg Kg-1) were determined in animals infused with methoxamine. High fat diet produced increases in body weight without significant changes in basal blood glucose, basal plasma insulin or HOMA index or blood triglycerides. However, high fat diet significantly decreased glucose tolerance after administration of 1 g Kg-1 glucose (p.o.) while plasma insulin levels remained unchanged. Furthermore, i.v. administration of NaHS, acetylcholine and sodium nitroprusside elicited dose dependent vasodepressor responses in either animals treated with normal diet or high fat diet. These responses were not significantly different in both groups. The above results suggest that high fat diet induced obesity but not insulin resistance and produced no significant changes in the vasodepressor responses to the above drugs in systemic vasculature.

**Title:** A cholinergic network for coordinating locomotor and sympathetic activities

**Authors: *J.-R. CAZALETS**[1], M. SOURIOUX[2], S. S. BERTRAND[3]
[1]Bordeaux, France; [2]Univ. de Bordeaux, INCIA, France; [3]INCIA CNRS UMR5287, Bordeaux, France

**Abstract:** The onset of locomotion, as any other forms of physical activity, mobilizes the autonomic nervous system to match the increasing physiological demand. These autonomic responses mostly rely on the coupling between sympathetic and somatic motor activity. We know that cholinergic neuromodulation plays an important role in the control of locomotor networks; moreover several lines of evidences also suggest that spinal cholinergic input may activate sympathetic intermediolateral (IML) neurons. Here, using an isolated *in vitro* spinal cord from neonatal rat in which the autonomic and the locomotor networks remain intact, we show that application of a muscarinic receptor agonist (oxotremorine) induces synchronized oscillations of sympathetic intermediolateral neurons and somatic motoneurons. When the cord was partitioned at T13 level and oxotremorine was applied to the thoracic compartment, both thoracic and lumbar segments displayed synchronized oscillations, suggesting a leading role of thoracic neurons over lumbar network. Finally, this coordination between rhythmogenic networks responsible for two different motor functions provide the first evidence for the existence of a cholinergic activated spinal network that specifically synchronizes somatic to sympathetic outflow in the newborn rat spinal cord.

**Title:** Effect of chronic administration of estradiol on the vasopressor responses induced by the sympathetic nervous system in rats with fructose induced insulin resistance

**Authors: *E. J. GUTIÉRREZ**[1], A. SÁNCHEZ-LÓPEZ[1], M. E. BECERRIL-CHACÓN[1], M. B. RAMÍREZ-ROSAS[2], D. CENTURIÓN[1]
[1]Pharmacol., CINVESTAV, Distrito Federal, Mexico; [2]Univ. Autónoma de Tamaulipas, Reynosa Tamaulipas, Mexico

**Abstract:** During aging, women and men experience an increase in cardiovascular risk. In the reproductive period, women have a lower prevalence of hypertension than men, whereas after menopause this relationship is reversed. After age 50, women have a higher prevalence of

hypertension compared to aged-matched men. These evidences suggest that estradiol may be involved in the development of hypertension. Some evidence suggests that diabetes suppresses female advantage and eliminates differences in risk of developing cardiovascular disease in premenopausal women. The objective of this study was to analyse the effect of 17β-estradiol on the cardiovascular responses induced by sympathetic stimulation or by several agonists in rats with fructose-induced insulin resistance. Thus, the vasopressor responses induced by sympathetic stimulation or i.v. bolus injections of the agonists noradrenaline (endogenous ligand), methoxamine ($\alpha_1$) and UK 14,304 ($\alpha_2$) were determined in female rats with fructose-induced insulin resistance or control rats pretreated with: (1) estradiol or (2) its vehicle (oil). For this purpose, animals were treated with fructose or its vehicle (water; control) during 16 weeks. After this time, both groups were divided into two subgroups: (1) sham-operated and (2) ovariectomized (ovx) rats. Next, both subgroups were subcutaneously treated with either: (1) estradiol (10 mg/kg) or (2) its vehicle (oil; 1 ml/kg) daily during 35 days. Then, under anaesthesia with isoflurane, animals were pithed and prepared to measure blood pressure and heart rate. In sham operated rats, insulin resistance diminished the vasopressor responses to sympathetic stimulation, noradrenaline and UK 14,304 while responses to methoxamine remained unchanged. In ovariectomized rats, insulin resistance did not change the vasopressor responses. On the other hand, in control animals, ovariectomy significantly decreased the vasopressor responses to sympathetic stimulation and noradrenaline while in fructose-fed rats ovariectomy did not change the above cardiovascular responses. Interestingly, in ovariectomized rats, 17β-estradiol: (1) increased sympathetic stimulation responses in animals treated with fructose; (2) diminished noradrenaline responses in control animals; (3) did not modify the responses to methoxamine and UK 14,304 in control or fructose-induced insulin resistance. These data suggest that 17β-estradiol is capable to restore the decreases in the vasopressor responses to sympathetic stimulation observed during insulin resistance.

**Title:** Activation of hypothalamic oxytocin neurons restores oxytocin release to parasympathetic cardiac vagal neurons of the brainstem in left ventricular hypertrophy induced heart failure

**Authors: *J. DYAVANAPALLI**[1], D. MENDELOWITZ[2]
[1]George Washington Univ. Dept. of Pharmac, Washington, DC; [2]George Washington Univ., Washington, DC

**Abstract:** Heart failure (HF), is characterised by an autonomic imbalance i.e., high sympathetic and depressed parasympathetic activities to the heart. Oxytocin, traditionally involved in promoting lactation and uterine contractions, has been known to improve stress induced changes in autonomic balance. Parasympathetic activity to the heart originates from cardiac vagal neurons (CVNs) in the brainstem, whose activity has been shown to be controlled, in part, by excitatory synaptic input co-releasing oxytocin from hypothalamic paraventricular nucleus oxytocin neurons (PVN). Activation of PVN oxytocin neurons is crucial for the activation of CVNs that increases parasympathetic activity to the heart. This study tests if activation of oxytocin neurons restores oxytocin release to activate CVNs and hence increases parasympathetic activity to the heart that is diminished in left ventricular hypertrophy induced heart failure (HF). Left ventricular hypertrophy was elicited in rats by aortic pressure overload using a transaortic constriction (TAC) approach. Selective activation of PVN OXT fibers projecting to CVNs was achieved by chemogenetic DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) and optogenetic Channelrhodopsin (ChR2) approach. A cocktail of viral vectors, cre expression under OXT promoter (AAV1-OXT-Cre) +floxed DREADDS (AAV2-DIO-HM3Dq-mcherry) + floxed ChR2 (AAV1-EF1a-DIO-hChR2) were co-injected in to the PVN. 3 groups of animals Sham , TAC and TAC+Treatment (activation of DREADDS by daily injection of CNO) were used to assess oxytocin release upon photoactivation of PVN ChR2 fibers surrounding CVNs at 2,4 and 6 weeks post-surgery using cultured Chinese hamster ovary cells co-expressing OXT receptors and $Ca^{2+}$ indicator, R-GECO. There were no changes in calcium responses in CHO cells trigged by photoactivation of PVN ChR2 fibers neibouring CVNs among 2, 4 and 6 weeks post sham. However, there is a blunted activation of CHO cells at 6 weeks post TAC compared to 2 and 4 wks post Tac groups (% increase in fluorescence: 18.6 ± 2.6 at 2 wks, n=9; 19.2 ± 2.0 at 4 wks, n=16 and 10.5 ± 1.5, n=16 at 6 wks post Tac). Further, the blunted CHO cell responses at 6 wks post Tac were completely restored by activation of PVN OXT neurons at 6 wks post TAC+Treatment (21.6 ± 2.0; n=22 in sham, 10.5 ± 1.5; n=16 in TAC and 25.1 ± 1.6; n=22 in TAC+Treatment). These results indicate reduced PVN release of oxytocin onto CVNs likely contributes to depressed parasympathetic cardiac activity in HF. Hypothalamic oxytocin neuron activation may restore CVN activity and blunt cardiovascular dysfunction in HF.

**Title:** Novel brain microrna therapy treats hypertension

**Authors: J. GORKY**, D. DECICCO, R. VADIGEPALLI, *J. S. SCHWABER
Pathol, Daniel Baugh Inst., Philadelphia, PA

**Abstract:** Decades of research on spontaneously hypertensive rat (SHR) model of hypertension have suggested that essential hypertension occurs as a result of perturbations in the blood pressure control network. Previous work has found perturbations in the kidney, the carotid body, and the nucleus of the solitary tract (NTS) each to be sufficient to control hypertension. Within each organ system too, there are claims that one signaling pathway or another is the primary driver of hypertension. Instead, it may be more useful to consider hypertension as the emergent property of a network that has been pushed out of a normotensive equilibrium into a compensatory, yet ultimately pathological state. The crosstalk between and within organ systems can be largely represented by an interconnected set of gene regulatory networks. In this work, we show that small perturbations in the gene regulatory networks in the NTS by selectively blocking two microRNAs (miR-135a and miR-376a) are sufficient to lower blood pressure in the SHR model. Furthermore, this effect appears driven by only modest changes in putative gene targets of these miRNAs, suggesting that the *combination* of genes that are targeted in the network is responsible for the effect rather than just one gene or another. While the use of anti-sense oligonucleotides to treat hypertension is itself novel, the demonstration that hypertension is the consequence of network emergence suggests new treatment paradigm altogether is needed.

**Title:** Association of depressive symptoms with regional brain tissue integrity in heart failure

**Authors: *B. ROY**[1], M. WOO[1], G. FONAROW[2], R. KUMAR[3]
[1]Sch. of Nursing, [2]Div. of Cardiol., [3]Dept. of Anesthesiol., Univ. of California at Los Angeles, Los Angeles, CA

**Abstract:** Heart failure (HF) patients often feel depressed, which prevent them performing routine activity leading to recurrent hospitalization and increased mortality. Multiple brain regions in HF show tissue damage, but associations between regional brain tissue integrity and depressive symptoms are unclear. T2-relaxometry procedure is known to show brain injuries in patients with HF, and this method may be useful here to examine such relations. Our aim was to assess relationships between brain tissue integrity and depressive symptoms in HF subjects using T2-relaxometry procedures. Proton-density and T2-weighted images were acquired from 12 HF (age, 54.3±8.6 years; 9 male; BMI, 29.3±6.4 kg/$m^2$; LVEF, 26.3±6.4%; NYHA functional class II/III 94/6%), using a 3.0-Tesla MRI scanner, and depressive symptoms were examined with the Zung Self-Rating depression scale (ZSDS) questionnaire. Whole-brain T2-relaxation maps were computed, normalized, and smoothed. The smoothed T2-relaxation maps were used to examine associations between regional brain tissue status (higher T2-relaxation indicates more injury) and individual ZSDS scores (higher scores show severe depression) in HF subjects voxel-by-voxel using partial correlation procedures (SPM12; covariates, age, gender; uncorrected threshold $p<0.005$). Significant positive correlations ($p<0.005$) between regional T2-relaxation values and ZSDS scores appeared in several sites, including inferior and mid temporal gyrus, right cerebellar cortex, cerebellar vermis, basal forebrain, external and internal capsule, pons extending to mid-brain, pre-frontal and frontal cortices, occipital and parietal cortices, amygdala. Negative correlations between T2 values and ZSDS scores emerged only in cerebellum. HF subjects show significant correlations between depressive symptoms and brain tissue integrity in areas that control mood function. The findings suggest that site-specific brain injuries are promoting to depressive symptoms, consequently contributing to increased morbidity and mortality. Therapeutic strategies should be developed to reduce brain injury, which may greatly impact mood function and improve the prevailing condition.

**Abstract:** Anorexia nervosa is associated with cardiovascular dysfunction including ventricular hypertrophy, hypotension and bradycardia due to severe food restriction (**FR**). Two weeks of FR in female Fischer rats models the cardiovascular dysfunction observed in anorexia including increased activity of the peripheral angiotensin type 1 receptor (**$AT_1R$**). The goal of this study was to evaluate the effect of FR on the expression and function of the $AT_1R$ and levels of angiotensin (**Ang**) peptides in brain regions that regulate the sympathetic nervous system (**SNS**) since the brain RAS regulates SNS. Food intake was reduced by 60% for two weeks in Fischer female rats (200g body weight). At day 7, a guide cannula was placed in the lateral ventricle and on day 14, the femoral artery was catheterized to record mean arterial pressure (MAP) and heart rate (HR). A parallel group of animals were used for measuring Ang peptides by LC-MS/MS and $AT_1R$ expression by receptor autoradiography in brain regions involved in SNS control. FR reduced body weight by ~12%, $p<0.05$; MAP by ~8 mm Hg, $p<0.05$; and HR by ~29 bpm, $p<0.05$; compared to control (CT) rats. Intracerebroventricular (icv) injection of Ang-[1-10] caused a higher pressor response ($p<0.005$) in FR compared to CT even though icv Ang-[1-8] reduced MAP in FR rats ($p<0.02$) without altering HR. Similar responses were observed after icv injection of Ang-[1-7] ($p<0.0001$). Losartan administered icv lowered MAP more in FR compared to CT rats ($p<0.03$). FR increased $AT_1R$ binding in the paraventricular nucleus ($p<0.005$) and in the rostral ventrolateral medulla ($p<0.05$). No differences in $AT_1R$ binding were observed in the amygdala, subfornical organ, vascular organ of lamina terminalis, median preoptic nucleus, solitary tract nucleus and caudal ventrolateral medulla. After spiking samples with Ang-[1-8], both Ang-[1-8] ($p<0.05$) and Ang-[3-7] ($p<0.05$) were increased in the brainstem of FR compared to CT rats. We also observed an increase in Ang-[1-8] ($p<0.0005$), Ang-[2-8] ($p<0.05$) and Ang-[3-8] ($p<0.05$) in the hypothalamus in the FR compared to the CT group. When the samples were spiked with Ang-[1-10], there was a decrease in Ang-[1-10] ($p<0.005$) and an increase in Ang-[1-7] ($p<0.05$) in the brainstem, and only Ang-[2-10] ($p<0.05$) was increased in the hypothalamus. These results suggest that increased AT1R activity mediated

by Ang-[1-7] and Ang-[1-8] in the paraventricular nucleus and rostral ventrolateral medulla contribute to the increased SNS activity observed in FR rats and in women with anorexia nervosa.

**Title:** Carotid chemo-and baro-receptor in the ovariectomized and estrogen treated female

**Authors: *J. CIRIELLO**[1], M. MAXIMOS[2], C. V. R. DE OLIVEIRA[3]
[2]Physiol. and Pharmacol., [3]Anat. and Cell Biol., [1]Univ. Western Ontario, London, ON, Canada

**Abstract:** The effects of 17β-estradiol (E) in ovariectomized (OVX) females on the distribution of carotid chemo- and baro-receptor afferent fibers was investigated using the transganglionic transport of a mixture of wheat germ agglutinin- (2%) and cholera toxin B-subunit- (5%) conjugated horseradish peroxidase (HRP). Tract-tracing experiments were done in age matched adult OVX only or OVX + E (30 pg/ml plasma) Wistar rats. The combined HRP solution was applied directly to the carotid sinus nerve (CSN), carotid body (CB) and carotid sinus (CS). After application of HRP to the CSN or CB in both groups of females, the distribution of fiber and presumptive terminal labeling in the ipsilateral nucleus of the solitary tract (NTS) complex was found to be greater in the OVX only female compared to OVX + E treated female for both the CSN and CB. However, the density of the projections was greater after CSN labeling. In both groups of females, dense fiber and presumptive terminal labeling was found within the dorsolateral (Sdl), medial (Sm) and commissural subnuclei, and nucleus gelatinous of the NTS complex. Additionally in the OVX only females, at and just caudal to area postrema (ap), labeled fibers were found to course through and around the ventrolateral NTS subnucleus and between the dorsal motor nucleus of the vagus and hypoglossal nucleus before turning and heading towards the ventrolateral reticular formation. Most of these labeled fibers appeared to terminate within the nucleus ambiguus (Amb) and in a region immediately caudal and ventral to Amb. After application of HRP to the CS in either group of females, afferent labeling was found restricted to the ipsilateral NTS complex only, primarily within the Sdl, Sm and interstitial subnucleus. The CS projections in the OVX + E treated females were overall denser than those

found in OVX only females. Furthermore, CS projections to NTS overall were considerable less than those observed that originated in the CB. Taken together, these data suggest that cardio-respiratory differences observed between pre-and post-menopausal females may be related in-part to medullary afferent connections of chemo- and baro-receptors. Supported in part by a grant from HSFO of Ontario.

**Title:** Behavioral and pharmacological interactions on heart rate and performance on the rotarod endurance and coordination test

**Authors: *A. L. ZMAROWSKI**[1], S. REED[1], B. VISNICK[1], M. A. HAWK[2], R. LORDO[1], T. VINCI[1]
[2]Safety Pharmacol., [1]Battelle, West Jefferson, OH

**Abstract:** The safety pharmacology core battery investigates potential adverse effects of pharmaceuticals on the function of vital organ systems including the cardiovascular and central nervous systems (CNS). However, these systems are rarely examined in parallel. Drugs may have different effects under resting or stimulated conditions, and therefore the simultaneous investigation of cardiovascular and neurobehavioral endpoints provides a more thorough evaluation of drug safety assessment. This study was conducted to evaluate cardiovascular changes during baseline performance in neurobehavioral tests and after treatment with pharmacological agents. Animals were implanted with telemetry units monitoring blood pressure (BP) and heart rate (HR). After surgical recovery, animals were tested for endurance and coordination in the Rotarod test. Animals were tested for 4 trials per day for up to 6 minutes per trial after treatment with vehicle (water for injection), amphetamine (AMPH, 1 and 2 mg/kg), MK-801 (0.1 and 0.15 mg/kg) and Diazepam (DIAZ, 5 and 10 mg/kg). The initial rotational speed was 4 revolutions per minute (RPM) that accelerated to 40 RPM over the test duration. HR and BP increased with placement on the rotarod and was further elevated with acceleration over time. After falling, HR rapidly decreased and remained low during the inter-trial interval (ITI) time. AMPH improved performance with animals maintaining rotarod performance longer than with vehicle. AMPH elevated HR in general, and during rotarod performance, though HR was not increased further with accelerating Rotarod speed and BP was not impacted. HR and BP were highest of all treatments with MK-801 and stayed elevated during the ITIs. However, animals could not maintain performance, falling off almost instantly. DIAZ reduced HR, BP, and

performance during rotarod testing. The combined assessment of physiological and behavioral endpoints provides a more complete evaluation of drug-induced effects under baseline and stimulated conditions and thereby improve overall pharmaceutical safety testing.

**Abstract:** Women are resistant to hypertension and cardiovascular disease prior to menopause due to the protection afforded by ovarian hormones. After menopause, women are not only more susceptible to cardiovascular disease, they are also more susceptible to mild cognitive impairment and conversion to dementias. Accumulating studies indicate the brain angiotensin system (**BAS**) plays a role in cognitive function in addition to its ability to regulate the cardiovascular system. Therefore, the aim of this study was to assess the effect of ovarian hormone loss on the BAS and gene expression in the hippocampus of the hypertensive Dahl salt-sensitive (**DS**) rat, an animal model of salt-sensitive human hypertension. $AT_1R$ binding was determined autoradiographically in selected brain regions of female hypertensive DS and normotensive Dahl salt-resistant (**DR**) rats that were ovariectomized (**OVX**) or sham-operated (**SHAM**) at 13 weeks of age and sacrificed at 33 weeks of age. In addition, DNA methylation was assessed by ELISA in the hippocampus. Mean arterial blood pressure (MAP) and heart rate (HR) were determined telemetrically (DSI technology) at 29 weeks of age. The MAP of DS sham rats was 181±5 mm Hg while the MAP of DR sham rats was 96±4 mm Hg ($p<0.0001$).

Ovariectomy did not significantly increase MAP in either strain. The HR of the DS sham rats was 426±8 bpm, while the MAP of he DR sham rats was 344±3 bpm ($p<0.0001$). Ovariectomy did not significantly alter HR in either strain. $AT_1R$ expression in the solitary tract nucleus of the DS-OVX rats was significantly reduced ($p<0.05$) from that of the DR-OVX and the intact DS-SHAM rats. There were no differences in $AT_1R$ expression in the piriform cortex, organum vasculosum of the lamina terminals, median preoptic nucleus, subfornical organ, paraventricular hypothalamic nucleus, suprachiasmatic nucleus, and lateral hypothalamus as a function of strain or ovarian hormone status. Global DNA methylation was also reduced in the hippocampus of DS-OVX rats relative to DS-SHAM ($p<0.01$) and DR-OVX ($p<0.05$). These results suggest that strain differences and gonadal functionality have a limited effect on brain $AT_1R$ expression and that the change that does occur is a reduction in $AT_1R$ expression in the nucleus tractus solitarius of the OVX hypertensive strain of female rats. The global DNA methylation changes suggest alterations in gene expression in the hippocampus of the DS-OVX rat. Further studies will be directed to determining which genes are affected at the epigenetic and gene expression level in the hippocampus.

**Abstract:** Neurons are highly sensitive to tissue oxygen level and decrease in oxygen (hypoxia or anoxia) produces modifications in neurotransmission as well in the intrinsic excitability of these cells. Moreover, during the hypoxia the peripheral chemoreflex is activated and produces cardiovascular and respiratory changes to keep the oxygen level in the physiological range. In this study we evaluated the effect of short-term sustained hypoxia [SH (24 hours, $FiO_2$ 10%)] on

the alterations induced by anoxia (5 min) on neurotransmission at the NTS, the first synaptic station of peripheral chemoreflex afferents in the brainstem. For this purpose, we used whole-cell patch clamp technique and brainstem slices of Wistar rats (30 days old). During the experiments normoxia condition were obtained by bubbling the bath solution with 95% $O_2$ e 5% $CO_2$ and for the anoxia condition the bath solution was bubbled with 95% $N_2$ e 5% $CO_2$. We observed that anoxia induced a hyperpolarization (-5 ± 0.2 mV in membrane voltage) and blocked the spontaneous fire frequency in NTS neurons from control rats. However, the SH exposure prevented the anoxic effects on the membrane voltage and in the fire frequency; after anoxia NTS neurons from SH rats preserved spontaneous firing (45 ± 8.5 % of firing rate in normoxia). Anoxia reduced the amplitude of evoked glutamatergic current in the NTS neurons from control group [142 ± 25 pA vs 91 ± 27 pA, $p<0.0001$ (n=14)] as well in SH group [319 ± 73 pA vs 232 ± 68 pA, $p<0.001$ (n=12)] and did not change the resting membrane potential in both groups [control group: -63 ± 3 mV vs -64 ± 7 mV (n=5); SH group: -62 ± 4 mV vs -66 ± 3.2 pA, (n=4)]. These data are showing that the short-term SH prevented the reduction in fire frequency and changes in membrane voltage induced by anoxia in NTS neurons.

**Abstract:** The increased sensitivity to hypertension as women enter menopause may involve alterations in estrogen signaling in neural systems regulating the control of sympathetic output, yet the mechanisms mediating these actions are unclear. We report that estrogen receptor ß (ERß) activation in the hypothalamic paraventricular nucleus (PVN), a critical coordinator of sympathetic function, contributes to basal blood pressure and modulates excitatory neuronal signaling. At the functional level, spatial-temporal deletion of ERß in the PVN of female mice (2 months of age) resulted in an increase in blood pressure in the absence of ovariectomy or a hypertensive stimulus. At the cellular level, ERß was strategically localized to dendrites of PVN neurons receiving excitatory inputs that have been shown to be critical in regulating sympathoexcitatory output. Many of these dendrites also contained the NMDA-type glutamate receptor, whose activation is an important modulator of blood pressure. Importantly, in PVN slices of female mice, application of the ERß agonist diarylpropionitrile (DPN) significantly decreased the NMDA-mediated depolarization of PVN neurons. The NMDA-mediated increase in firing rate was also returned to baseline values by DPN. The role of ERß also was evaluated in the 4-vinylcyclohexene diepoxide (VCD) mouse model of accelerated ovarian failure (AOF). In VCD treated mice, 14-day administration of a slow-pressor dose of angiotensin II (AngII) resulted in an increase in blood pressure at a stage of ovarian failure comparable to perimenopause in women. Significantly, the hypertensive response to AngII was blocked in mice given cyclic systemic administration of DPN (1mg/kg, I.P. for 2 days followed by two days off repeated over the 2 week period). These results indicate that ERß in the PVN of female mice is an important regulator of basal blood pressure and a modulator of NMDA receptor-mediated excitatory signaling. In addition, ERß may also be a significant player in the emergence of AngII-dependent hypertension in peri-AOF mice. These results suggest a novel neural mechanism for the actions of estrogen in blood pressure control. They also provide further support that perimenopause is a therapeutic window of opportunity for estrogen-based management of hypertension as women transition through menopause.

**Abstract:** Acute intermittent porphyria (AIP) is one of the main forms of congenital porphyria, an enzyme deficiency disorder in the biochemical pathway of heme formation, which affects individuals causing both peripheral (i.e. autonomic nerve dysfunction) and central (i.e. neuropsychiatric symptoms) nervous system (NS) disabilities such as neuropathic pain and hemodynamic imbalance as well as hallucinations and social behavior problems, respectively. Accumulation of 5-aminolevulinic acid (ALA), an early residue in the biosynthesis of heme, may act as the causal agent for these pathological effects in AIP. Using two rodent models of AIP, our goal was to search for and characterize changes in social behaviors in parallel to determine the disarrangements in hemodynamic response and pain threshold. For the behavioral and pain studies, we used the mouse strain C57BL/6 with both males and females. Male and female Wistar rats were used on experimental trials for accessing the hemodynamic parameters. Upon long-term treatment using intraperitoneally high concentrations of ALA (40 mg/ml) on alternate days, we tested for behavioral paradigms of motor locomotion, exploratory behavior and anxiety level, neuropathic pain and offensive aggressiveness in C57BL/6 mice. The hemodynamic parameters were assessed both non-invasively with ultrasound/color Doppler and invasively with direct recordings of blood pressure, heart rate and cardiovascular autonomic modulation by spectral analysis in Wistar rats. Behavioral paradigms showed that long-term treatment with ALA promoted an important reduction in motor locomotion in both male and female mice and very low propensity for offensive aggression in males relative to controls. In addition, there was a marked increase in the perception of pain. Our method with ultrasound/Doppler accessed the blood flow of mesenteric-portal venous system, which presented lower blood flow in ALA-treated rats. ALA-induced reduction in mean blood pressure was observed in males with no differences in heart rate (HR). In the HR variability analysis, there was a decrease in both pulse interval (PI) variance and PI standard deviation in the ALA group. ALA-induced autonomic changes could be observed with a decrease in high frequency and low frequency bands of PI, but without difference in symopathovagal balance. Systolic arterial pressure variability was also decreased in ALA group. Altogether, our study shows long-term NS changes in porphyria-like conditions, which may aid in the development of specific diagnostic tools and methods to access heme disorders-related clinical signs and to improve medical and rehabilitation care in affected individuals.

**Abstract:** Single ventricle congenital heart disease (SVCHD) patients show white matter injury in neighboring sites that control autonomic, mood, and cognitive functions, issues that are common in the condition. However, it is unclear whether SVCHD subjects have predominantly axonal or myelin injury. Diffusion tensor imaging (DTI)-based axial diffusivity (AD), which measures water diffusion parallel to fibers and shows axonal changes, and radial diffusivity (RD), which measures water diffusion perpendicular to fibers and indicates myelin changes, may be useful to examine such differences in SVCHD subjects. In this study, our aim was to examine regional brain axonal and myelin changes in SVCHD patients compared to healthy controls using DTI-based AD and RD procedures. We collected two separate DTI series from 12 SVCHD (age, 15.7±1.1 years; body mass index, 20.9±3.0 kg/m$^2$; 6 male) and 27 control subjects (age, 15.8±1.1 years; body mass index, 22.3±5.3 kg/m$^2$; 14 male) using a 3.0-Tesla magnetic resonance imaging scanner. Whole-brain AD and RD maps were calculated from each series, realigned and averaged, normalized to a common space, and smoothed. The smoothed AD and RD maps were compared between groups using analysis of covariance, with age and gender included as covariates (uncorrected threshold, $p<0.001$; extended cluster size, 10 voxels). No significant differences in age, body-mass-index, or gender appeared between SVCHD and control subjects. SVCHD subjects showed increased AD and RD values in multiple brain sites, although AD changes were more wide-spread, including the prefrontal and frontal gyrus, precentral and post-central gyrus, anterior, mid, posterior cingulate, corpus callosum, insular sites, hippocampus and parahippocampal gyrus, amygdala, mammillary bodies, pons, cerebellar cortex, occipital and temporal gyri, thalamus, and parietal area, compared to controls. Adolescents with SVCHD show significantly increased AD and RD values, indicating loss of both axonal and myelin integrity in brain areas that regulate autonomic, mood, and cognitive

functions. These findings may result from delayed brain development in early stage of life or hypoxia/ischemia induced processes accompanying the condition.

**Title:** Brain inflammation in streptozotocin-treated diabetic rats contributes to development of cardiovascular complications and is modulated by oral saline intake

**Authors: O. AL ZAHRANI**[1], E. ALAHMADI[2], H. HABEEBALLAH[1], E. BADOER[1], *M. J. STEBBING[1]

**Abstract:** We have previously shown that microglia become activated within cardiovascular control centres in the brains of streptozotocin (STZ) treated diabetic rats and not in surrounding areas. In the paraventricular nucleus (PVN), microglial activation is not seen until 6 weeks after induction of diabetes and is preceded by intense activation of PVN neurons associated with chronic dehydration and electrolyte imbalance (1). Others have shown that giving 1% saline to drink after induction of diabetes increases blood pressure in STZ-treated rats (2). We therefore investigated the relationship between PVN microglial activation, the development of diabetic cardiovascular complications and the effect of saline intake of both of these processes. Male Sprague Dawley rats were made diabetic with a single injection of STZ via the tail vein. Fluid intake and blood parameters were monitored throughout experiments in control rats and diabetic rats given tap water or saline to drink. Blood pressure was measured via tail cuff in conscious rats and cardiac function was studied under anaesthesia via echocardiography and ventricular pressure measurements. Microglial morphology was quantified using immunohistochemistry for cd11b (1). After 2 weeks, diabetic rats drinking 1% saline showed microglial activation in the PVN and elevated blood pressure, but control rats and diabetic rats drinking tap water did not. Inhibition of microglial activation via icv minocycline infusion prevented the increase in blood pressure in diabetic rats given saline. At 6 weeks post-STZ, diabetic rats given tap water showed elevated polydipsia, blood parameters consistent with dehydration, activation of PVN microglia, and functional signs of cardiomyopathy, but diabetic rats given 1% saline for 6 weeks did not, suggesting a delicate balance between electrolyte intake and electrolyte loss in these animals. In a separate set of experiments 0.9% saline intake did not increase blood pressure in STZ diabetic rats at 2 weeks and diabetic rats given low level insulin supplementation to prevent dehydration

showed no sign of cardiomyopathy even after 10 weeks of diabetes. We conclude that neuroinflammation in the PVN and other cardiovascular control centres, secondary to chronic fluid and electrolyte imbalances may contribute to the development of diabetic complications and preventing dehydration may be therapeutic. **Abstract:** The central nervous system, especially the hypothalamus and the ventrolateral medulla, regulates the cardiovascular function. Pathological persistent activation of the central cardiovascular regulatory system has been thought to cause hypertension. Electrophysiological studies have shown that stimulation of the dorsomedial hypothalamus and paraventricular nucleus of the hypothalamus evokes augmentation of sympathetic nervous activity through excitation of the ventrolateral medulla. However, spatiotemporal dynamics of multicellular activities in the ventrolateral medulla in response to hypothalamic activation have not been well analyzed. In this study, we investigated how the ventrolateral medulla responds to electrical stimulation of the hypothalamus, by fluorescent optical imaging using a voltage-sensitive dye (voltage imaging) which allows us to visualize multicellular activities and to analyze their spatiotemporal dynamics. The brain stem spinal cord preparation containing the hypothalamus was isolated en bloc from the neonatal Wistar rat (P0-2) under deep anesthesia with isoflurane. The preparation was dyed with a voltage-sensitive dye (Di-2-ANEPEQ) that was solved in oxygenated artificial cerebrospinal fluid (aCSF). After dyeing, the preparation was fixed with the ventral side up in a recording chamber and continuously superfused with oxygenated aCSF at 26-

28°C. The viability of the preparation was confirmed by recording neural respiratory output from the 4th ventral root of the cervical spinal cord. Using a CMOS sensor array (MiCAM Ultima, BrainVision, Tokyo) connected with an epifluorescence microscope, we conducted voltage imaging of neural activity of the ventral medulla. We observed spread of depolarizing optical signals on the ventrolateral medulla evoked by electrical stimulation of the hypothalamus with 2 different modalities. One was single pulse stimulation which was 3 msec in pulse duration and 0.5 mA in intensity. The other was tetanic stimulation with 10 Hz and 0.4 mA in intensity for 10 sec. Single pulse stimulation evoked only brief excitation in the ventrolateral medulla, but tetanic stimulation induced excitation that persisted nearly 10 sec after the cessation of the stimulation. Observed prolonged excitation of the ventrolateral medulla induced by tetanic stimulation of the hypothalamus may partly explain the pathophysiological mechanism of hypertension. Also, this imaging method would contribute to unraveling the mechanism of cardiovascular regulation by the central nerve system.

**Title:** RVLM C1 neuron ablation normalizes cardiorespiratory control in heart failure

**Authors: *R. DEL RIO**, D. C. ANDRADE, C. TOLEDO, H. S. DIAZ
Lab. of Cardiorespiratory Control, Univ. Autónoma De Chile, Santiago, Chile

**Abstract:** Heart failure (CHF) is characterized by sympathoexcitation and breathing disorders. The rostral ventrolateral medulla (RVLM) is hyperactive in CHF. However, there is no direct evidence between the relationship of RVLM chronic hyperactivation, sympathoexcitation and progression of cardiac deterioration in CHF. We hypothesized that selective elimination of cathecolaminergic neurons from the RVLM delays cardiac deterioration in CHF rats. CHF was induced by volume overload in male Sprague-Dawley rats (250±20g). Ablation of C1 cells was performed by anti-dopamine-beta hydroxylase (DβH)–saporin toxin (DβH+SAP) injected into the RVLM. The degree of HF was estimated by echocardiography. Cardiac function was assessed by intraventricular PV loops. Arrhythmia index and breathing disorders were scored. Central and peripheral chemoreflex and cardiac autonomic control were also study. Partial

elimination of C1 RVLM neurons (≈50%) delay the decrease in fractional shortening in CHF rats (CHF+Veh: 59±5 vs. 45±1 %, $p<0.05$, pre vs. post vehicle, respectively; CHF+DβH-SAP: 57±4 vs. 51±4 %, $p>0.05$, pre vs. post toxin, respectively). In addition, compared to CHF vehicle treated rats, CHF+DβH-SAP rats showed (CHF+Veh vs. CHF+DβH-SAP, respectively): i) a reduced cardiac sympathetic drive (-98±12 vs. -52±7 ΔHR, $p<0.05$), ii) an improvement in both cardiac diastolic (0.009±0.001 vs. 0.004±0.001 mmHg/µl, $p<0.05$) and systolic function (0.2±0.01 vs. 0.5±0.1 mmHg/µl, $p<0.05$), iii) a reduced number of arrhythmias (95±20 vs. 48±14 events/hour, $p<0.05$), and iv) a reduced incidence of breathing disorders (9±1 vs. 6±1 apneas/hour, $p<0.05$). Finally, the detrimental autonomic and cardiovascular effects induced by central chemoreceptors activation were abolished after C1 neurons ablation in CHF rats. Neither hypoxic nor hypercapnic ventilatory chemoreflex responses were affected by DβH-SAP treatment. Our results showed that the RVLM play a pivotal role on the progression of cardiac deterioration and in the maintenance of autonomic imbalance and breathing disorders in CHF. In addition, our results showed that the sympathoexcitation and cardiac function deterioration induced by central chemoreflex activation is related to the activation of RVLM C1 neurons.

**Title:** Thyroid hormones set the beat: Thyroid hormone receptors control the development of hypothalamic parvalbuminergic neurons in charge of cardiovascular function in male mice

**Authors: *L. HARDER**[1], S. DUDAZY-GRALLA[3], H. MÜLLER-FIELITZ[2], J. HJERLING LEFFLER[4], B. VENNSTRÖM[3], H. HEUER[5], J. MITTAG[1]
[1]Mol. Endocrinol., [2]Inst. für Pharmakologie und Toxikologie, Univ. of Luebeck, CBBM, Luebeck, Germany; [3]Dept. of Cell and Mol. Biol., Karolinska Institutet, Stockholm, Sweden; [4]Karolinska Institutet, STOCKHOLM, Sweden; [5]IUF – Leibniz Res. Inst. for Envrn. Med., Duesseldorf, Germany

**Abstract:** It is well established that proper thyroid hormone (TH) signaling is crucial for brain development and function. This becomes most evident in untreated congenital hypothyroidism leading to irreversible mental retardation, as well as in maternal hypothyroxinemia, which is associated with neurological dysfunction in the offspring causing e.g. autism. In the brain, TH actions are mainly mediated by TH receptor alpha 1 (TRα1). Consequently, mice heterozygous for the dominant-negative mutation R384C in TRα1 display extensive neuroanatomical abnormalities, including a deranged development of a parvalbumin (PV) expressing neuronal subpopulation in the anterior hypothalamic area. As these neurons centrally control blood pressure and heart rate, they constitute an important link between developmental hypothyroidism and hypertension. However, the exact orchestration of TH signaling necessary for proper development of hypothalamic PV neurons remains elusive. Using eight different mouse models with altered TH signaling during development, we unraveled the underlying molecular mechanism in great detail. Our immunohistochemical data reveal that PV neurons in the anterior hypothalamic area are GABAergic neurons with short projections remaining within the nucleus. Unlike cortical PV neurons, anterior hypothalamic PV neurons do not originate from the medial ganglionic eminences and are independent of a genetic developmental program involving Nkx2-1. Moreover, we identified a TH signaling pattern, necessary for hypothalamic PV cell development: First unliganded TRβ signaling is required until the cells become postmitotic at E12, followed by a switch to liganded TRα1 signaling until birth. Postnatally, the cells do not longer depend on TH. As previous loss-of-function studies indicated that the neurons control blood pressure and heart rate, we finally tested their involvement in the acute regulation of cardiovascular functions using chemogenic tools. In summary, our findings strengthen the connection between maternal thyroid function and offspring blood pressure control, and reveal the first clear neuroanatomical target of maternal thyroid hormone signaling. With that we add evidence on the impact of maternal thyroid disease on the offspring and the importance of routinely screening of pregnant women.

**Title:** EFFECTS of cisplatin on the gut - brain -axis of the least shrew (Cryptotis Parva): Immunohistochemical studies using orexin R-1 receptor and serotonin

**Authors: *M. S. AL-TIKRITI**
Col. of Osteo. Med. of the Pacific/Anatomy, Western Univ. of Hlth. Sci., Pomona, CA

**Abstract:** The gastrointestinal tract (GIT) receives dual innervation by the autonomic nervous system (ANS); the sympathetic (splanchnic) and parasympathetic (vagus and pelvic spinal nerves) systems. These nerves are either excitatory (para.) or inhibitory (symp.). Vagal afferent neurons reside in nodose ganglia and are the sole primary sensory neurons that receive signals from the gut lumen to the nucleus of the solitary tract (NTS) which is densely innervated by serotonergic terminals. A third division of ANS are intrinsic to the GIT neurons called the enteric nervous system (ENS) which reside in the (Auerbach's) plexus between the inner circular and outer longitudinal muscle layer and in the submucosa (Meissner) plexus. The purpose of this study was to find out the extent of damage on the GIT and its sensory afferents caused by cisplatin. We used immunocytochemistry to detect serotonergic neurons, and orexin-1 receptors. We used nine shrews; three as controls and the remainder were injected with 10 mg/kg cisplatin (i.p.) and sacrificed 24 hours post-injection. The whole heads were demineralized with 2% formic acid for 2 weeks afterwards they were fixed with 10% neutral buffered formalin for 5 days. Samples that contained the nodose ganglia and GIT walls were processed for paraffin embedding, using standard procedure and 10 um thick sections were collected. In our previous studies; we found that cisplatin has significant impact on the GIT function indirectly via the release of several emetogenic neurotransmitters/mediators including 5-HT, substance P (SP) from the GIT enterochromaffin cells. Our current findings shows that the least shrew is similar to rats, cats and humans, by having co-localized serotonergic neurons that express OX-R1 in cells of nodose ganglia. In addition, cisplatin causes severe damage to the ganglia as manifested by shrinkage and pyknotic nuclei of the nodosal neurons. Histological examination of the GIT revealed some damage to the mucosa as shown by cellular vacuolation, exfoliation and cell death that are not only were apparent near the surface epithelium of the stomach and intestine, but also down deep close to the base of the glands. Immunohistochemical studies revealed that no 5-HT labeled cells were observed in the GIT of cisplatin treated animals compared to those of the normal gut. In conclusion, it can be deduced that cisplatin not only damages the GIT cellular elements, but also affects the neurons of the nodose ganglion, and therefore, alters the sensory stimulatory input from the GIT to brain.

**Abstract:** Pelvic floor muscles (PFM) play supporting and functional roles for the physiology of the urogenital apparatus. It is generally assumed that damage to these muscles because the labor trauma leads to the onset of lower urinary tract disorders including urinary incontinence (UI). Scant studies, however, have been focused on the integrity of the nerves controlling PFM. To understand how multiparity affects the propagated electrical activity and morphometry of pelvic floor nerves, we aimed this work to evaluate the compound action potential (CAP) and the histological characteristics of the nerves of pubococcygeus (Pc) and bulbospongiosus (Bs) muscles in rabbits. To this end, the nerves of the Pc and Bs muscles from young nulliparous (YN) and multiparous (YM) rabbits were dissected to analyze the CAP electrophysiological recordings *in vitro*, applying electrical stimuli of variable intensity, frequency, and fixed duration (0.05 ms). Moreover, contralateral nerves were fixed to evaluate their histological characteristics. The results showed that multiparity decreased both the amplitude (3213.00 ± 641.40 vs. 1260.00 ± 127.20 mV; $P<0.05$) and the area under the curve (3001.00 ± 902.10 vs. 785.10 ± 100.90 mV*ms; $P<0.05$) of the Pc nerve CAP. The same was true for the Bs nerve in the amplitude (3193.33 ± 191.95 vs. 1760.00 ± 391.40 mV; $P<0.05$) and the area under the curve (2929.00 ± 217.50 vs. 1319.00 ± 267.70 mV*ms; $P<0.05$). Notably, multiparity did not affect any component of the CAP when measured in the EDL muscle nerve as a control. Morphometry results of the nerves suggest a classical Wallerian degeneration process in multiparas. Our present findings support that multiparity reduced the Compound Action Potential of the Pc and Bs nerves possibly due to the damage of motor axons.

**Title:** Mechanisms for communication between the gut and brain

**Authors: *D. C. PETERSON**[1], M. LYTE[2]
[1]Physical Therapy, High Point Univ., High Point, NC; [2]Vet. Microbiology and Preventive Med., Iowa State Univ., Ames, IA

**Abstract:** Numerous studies have indicated that variations in the intestinal microflora can influence brain activity and may greatly affect various psychosis. Whether this influence is due to direct neuronal circuitry or more global systemic influences is unknown. The current study attempts to identify the mechanism by which the intestine influences brain activity by optogenetically manipulating the activity of the vagal nerve to a subsection of the jejunum. Methods: Normal mouse behavior was recorded during behavioral activities (i.e., elevated plus maze, open-field, and forced swim tests) for a period of two weeks. Mice were then surgically given 3-5 injections (0.01-0.03 µl) of either an optogenetic vector (AAV-CaMKIIa-eNpHR3.0-EYFP) or saline control into the mesenteric wall of the jejunum. During surgery the cervical vagus was identified, and a fiber optic ferrule implanted to allow illumination of the vagus nerve. After surgical recovery, behavioral tests were initiated for 2 weeks to assess variations in behavior from the initial control that may be caused by the surgery. These tests were then utilized as the control behavioral activity for each animal. Four weeks post-surgery, behavioral experiments were initiated in which vagal afferents to the injected regions of the jejunum were either deactivated with light stimulation of the vagus or in the normal (non-deactivated) state. Results were then compared for each animal. Results: Mice activity was consistent across pre-surgical control, post-surgical control, and post-surgical normal state behavioral tests. In the saline condition, animals with light activation of the vagus showed no variation in their behavioral activity from that of the other control states. In the optogenetic light deactivation condition, animal behavior was dramatically different. In each behavioral test, animals showed a freezing behavior for the extent of time that the vagus was deactivated. Within the forced swim experiments, frozen animals did not keep their head above water and tended to sink to the bottom of the tank (requiring multiple rescues during each session). Conclusions: Optogenetic deactivation of the vagal afferents of the jejunum had a dramatic and immediate influence on animal behavior. Therefore, this pathway provides an optimal mechanism by which the enteric system can influence brain activity and thus behavior.

**Title:** External urethral sphincter and voiding function in unanesthetized decerebrate rats

**Authors: *J. S. CARP**, T. F. FULTON
NY State Dept. of Hlth., Natl. Ctr. For Adaptive Neurotechnologies, Albany, NY

**Abstract:** The external urethral sphincter (EUS) muscle is vital for regulating the timely passage of urine through the urethra. Past studies of anesthetized rats with intact neuraxes linked efficient voiding to phasic EUS activation (bursting). We recently published studies of EUS activity during voiding in unanesthetized unrestrained rats showing that EUS bursting was not uniformly evident during spontaneous voiding, but was consistently present four weeks after spinal transection (LaPallo et al. Neurourol Urodyn 35:696-702, 2015; LaPallo et al. J. Neurotrauma, in press). To perform physiological and pharmacological assessment of EUS function under anesthesia-free conditions, we are developing methods to record EUS electromyographic activity (EMG), bladder pressure, and urine output in unanesthetized decerebrate rats before and after intrathecal drug administration.

Female SD rats were each implanted under isoflurane anesthesia with: bilateral fine stainless steel wires in the EUS; a suprapubic catheter (PE90) in the dome of the bladder; an intrathecal catheter (PE10) after L2 laminectomy for drug administration; and a catheter (PE50) in the left carotid artery. A tube was glued to the skin surrounding the meatus to collect urine for weighing. Decerebration was performed based on the method of Dobson and Harris (Exp Physiol 97:693-8, 2012), including temporary occlusion of the right carotid artery and occlusion of the sagittal sinus with suture. After aspirating cortical tissue to expose the colliculi, the brain was transected with a scalpel and the entire forebrain was aspirated. Hemostasis was achieved using compressed sponge (Gelfoam) pieces treated with tissue adhesive (Vetbond). Isoflurane was discontinued gradually after decerebration.

The procedure was performed in rats with intact neuraxes and in rats four weeks after spinal transection. Animals that had mean blood pressures of ≥80 mm Hg after decerebration exhibited normal voiding function. EUS bursting was pronounced in the chronic spinal rats, but was less evident in intact rats. Chronic spinal rats exhibited non-voiding contractions prior to most

voiding episodes. Administration of the 5HT2A/C agonist DOI increased overall EUS EMG activity, but reduced the duration of EUS bursting, reduced voiding efficiency, and increased urine leakage.
These preliminary studies are consistent with results of our previous studies in unanesthetized freely-moving rats that EUS bursting does not always occur in intact rats but is almost always seen in chronic spinal rats. They also show the feasibility of using decerebrate rats for studying EUS function without the influence of anesthesia.

**Title:** Suppression of bladder activity following saphenous nerve stimulation in a continuous urodynamic model: A pre-clinical study

**Authors: *Z. MOAZZAM**, P. B. YOO
Inst. of Biomaterials and Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** Introduction: Chronic symptoms of overactive bladder (OAB) affect nearly 18% of the world's adult population however, the current algorithm of incontinence care is modest in treatment efficacy. Recent work from our lab has shown that short-duration (10 min) electrical stimulation of the saphenous nerve (SAFN) can elicit bladder-inhibitory responses in urethane-anesthetized rats. However, it is unclear whether longer-duration trains of electrical pulses can augment the inhibitory effects of SAFN stimulation. In particular, and if so, how do urodynamic parameters alter during such bladder responses. Methods: Acute experiments were conducted in 10 urethane-anesthetized rats. The bladder dome was catheterized and connected with a pressure transducer and an infusion pump. The bladder was continuously infused with saline (0.08 ml/min) to establish a stable BCR (baseline phase). The SAFN was instrumented with a bipolar

nerve cuff electrode. The stimulation amplitude was set at 25 μA, and 40-minute stimulation trials were applied at frequencies of 10 Hz and 20 Hz. The measured basal pressure (BP), inter-contraction interval (ICI) and contraction amplitude (CA) were analyzed during both the intra-stimulation and post-stimulation periods. Each variable was normalized to the baseline of each experiment.
Results: Compared to baseline, 40 minutes of SAFN stimulation caused notable changes in each of the 3 urodynamic variables. In response to SAFN stimulation at 10 Hz (n=7), a significant increase in BP (116±6.5%) occurred during the intra-stimulation period, followed by changes in CA (70.5±8.0%) and ICI (62.1±7.2%) during the post-stimulation period. In 5 of 7 stimulation trials, we report episodes of bladder atonicity that lasted 33.0±11.3 minutes. In response to 20 Hz SAFN stimulation (n=7), there was a rapid increase in ICI (131.6%) during the initial 10 minutes, that subsequently returned close to baseline by the end of the intra-stimulation period. Significant increases in BP (124.5±10.6%) and decreases in CA (79.3±5.5%) were also observed, but the duration of bladder atonicity were markedly shorter (4.0 ± 1.2 min, 4 of 7 stimulation trials). Conclusion: The results of this study show that the duration of electrical stimulation has a significant effect on the bladder-inhibitory reflex mediated by SAFN afferents. With longer stimulation trials, we were able to observe consistently a notable upshift in the BP, reduction in the CA, and even the complete loss of voiding function for extended periods (10 Hz). Further work is needed to better understand the mechanism(s) that modulate these urodynamic variables.

**Abstract: INTRODUCTION:** Intestinal enterochromaffin (EC) cells are the specialized epithelial mechanosensors of the gastrointestinal (GI) epithelium that are functionally and developmentally similar to Merkel cells in the skin. EC cells release serotonin (5-HT) in response to mechanical stimuli. Recently, we discovered that human and mouse EC cells express the mechanosensitive ion channel Piezo2, but otherwise little is known about primary EC cell mechanosensitivity. **AIMS:** To characterize mouse primary EC cell mechanosensitive currents and the downstream signaling of mechanical stimulation. **METHODS:** NeuroD1 is a transcription factor important for enteroendocrine (EE) cell development. We generated a novel mouse model NeuroD1-cre::GCamP5/tdTomato in order to identify and study EE cell intracellular $Ca^{2+}$ dynamics. Immunohistochemistry was performed in colon tissues for 5-HT (EC cell marker) and chromogranin A (CgA; EE cell marker). Primary colon epithelium cultures were used for whole-cell patch clamp and $Ca^{2+}$ imaging experiments. Mechanical stimulation was performed by membrane displacement with a piezoelectrically-driven glass probe or shear flow. **RESULTS:** Immunostaining showed that 87% of all $CgA^+$ cells were $tdTomato^+$ and 85% of all $5\text{-}HT^+$ cells were $tdTomato^+$. No labeling was found outside GI epithelium. Mechanical stimulation of colon EE cells produced inward mechanosensitive currents (15.9±4.5 pA/pF, $C_m$=3.4 pF, n=4) with fast activation and inactivation kinetics (single exponential fit with $\tau_{inact}$ 11.1±2.8 ms, n=4). Current-distance relationships were fit well by Boltzmann functions, with a mid-point of 4.2±0.3 µm (n=4). The current-voltage relationship was linear crossing near 0 mV, suggesting a voltage-independent behavior (n=4). Both chemical stimulation, with 50 mM KCl ($\Delta F/F_0$ 6.3±1.2, n=6) and mechanical stimulation by shear flow significantly increased intracellular $Ca^{2+}$ ($\Delta F/F_0$ 2.3±0.7, n=3), with fast responses (time to peak 3-5 s) and return to baseline within 60 s. **CONCLUSIONS:** In the mouse colon epithelium, NeuroD1 specifically marked a high percentage of EE and EC cells. Primary colonic $NeuroD1^+$ cells had mechanosensitive currents that were inward and non-rectifying with fast activation and inactivation kinetics. Mechanical stimulation of $NeuroD1^+$ cells in primary cultures produced rapid intracellular $Ca^{2+}$ changes. These results suggest that primary EC cells have mechanosensitive ion channels with biophysical properties of Piezo2 and that mechanical stimulation of these cells elicits intracellular $Ca^{2+}$ changes, which likely precede force-induced 5-HT release. **Title:** Direct mechanism of autonomic influence on intestinal epithelial stem cell proliferation

**Authors: *E. A. DAVIS**[1], W. ZHOU[2], M. E. FELDNER[3], M. J. DAILEY[1,2]
[1]Neurosci., [2]Animal Sci., [3]Sch. of Mol. and Cell. Biol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

**Abstract:** The mammalian intestinal epithelium is critical for nutrient absorption, hormone release and immune function. Stem cells located in the intestinal epithelial crypts proliferate and differentiate to produce mature cells that serve these functions. The autonomic nervous system influences intestinal epithelial stem cell proliferation. However, it is not known whether these mechanisms are direct (influencing the stem cells themselves) or indirect (acting via other cells that affect stem cell proliferation). Thus, we evaluated 1) gene expression of autonomic neurotransmitter receptors in intestinal epithelial stem cells and other crypt cells, and 2) proliferative response of intestinal epithelial organoids to application of the primary autonomic neurotransmitters *in vitro*. Briefly, small intestinal crypts were isolated from adult Lgr5+ (a stem cell marker)-GFP and wild-type mice and sorted into two populations: high GFP expression (stem cells) and low GFP expression (other crypt cells) using fluorescent activated cell sorting. Relative mRNA expression was quantified in each cell population by quantitative real time-PCR. In a separate experiment, small intestinal crypts were isolated from adult wild-type mice and grown into organoids for ten days. Organoids were treated with an autonomic neurotransmitter or a vehicle control. Proliferation was quantified using the CyQUANT NF Cell Proliferation Assay Kit at 0h, 2h, 4h and 6h after neurotransmitter administration. We found that the α2A adrenoreceptor was expressed in the stem cells and other crypt cells, and that subtypes of muscarinic acetylcholine receptors were expressed in the crypt cells. Furthermore, intestinal epithelial organoid proliferation was decreased in response to norepinephrine ($p<0.05$), but not epinephrine. These results suggest a direct mechanism for the autonomic nervous system to influence intestinal epithelial stem cell proliferation.

**Title:** Effects of hypogastric nerve transection on the bladder-inhibitory reflex evoked by saphenous nerve stimulation in anesthetized rats

**Authors: *K. S. FRANZ**[1], P. B. YOO[2]
[1]Inst. of Biomaterials and Biomed. Engin., [2]IBBME, Univ. of Toronto, Toronto, ON, Canada

**Abstract: Background** It is established that reflex inhibition of bladder function can be achieved by electrically stimulating the sacral spinal nerve, pudendal nerve, and the tibial nerve in anesthetized animals. Recent work in our lab has shown that electrical stimulation of the saphenous nerve (SAFN) can also elicit bladder-inhibitory responses; however, the mechanism of this reflex is unknown. Given that the hypogastric nerve (HGN) modulates bladder function and projects to similar lumbar spinal regions as the SAFN in rats, we hypothesized that the bladder-inhibitory effects of SAFN stimulation involve a spinal-mediated mechanism. In this study, we investigated the effects of bilateral HGN transection on the bladder-inhibitory effects of SAFN stimulation.
**Methods** Acute experiments were conducted in 11 urethane-anesthetized rats (250-300g, female), where the effects of bilateral HGN transection on SAFN stimulation were tested in the same (n=4) or in separate (n=7, 3 post-transection rats) animals. Using a surgically implanted suprapubic catheter, the bladder was infused continuously with 0.1% acetic acid (AA). Following 60-minute baseline period, changes in bladder function were measured in response to 40-minute stimulation trials applied at 10 Hz and at amplitudes of 50 µA and 100 µA. Electrical pulses were delivered via a bipolar nerve cuff electrode placed around the SAFN. Bilateral HGN transection was performed caudal to the inferior mesenteric ganglion.
**Results** Bladder atonicity, characterized by loss of bladder activity and urethral sphincter muscle bursting, was observed in response to SAFN stimulation trials applied at 50 µA and 100 µA. In rats where SAFN stimulation was tested in the same animal (n=4), atonic bladder episodes occurred in 1 of 4 rats before HGN transection, but in 3 of 4 rats after HGN transection. These episodes lasted 10.6 minutes and 11.6 ± 4.0 minutes, respectively. In rats where SAFN stimulation was tested in separate animals (n=7), bladder inhibition periods occurred in 1 of 4 rats with HGN intact, but in 2 of 3 rats with HGN transected. The duration of these episodes was 7.0 minutes and 45.2 ± 24.4 minutes, respectively.
**Conclusion** The increased incidence of SAFN-mediated episodes of bladder atonicity following HGN transection (25% pre-transection vs. 71% post-transection) suggest that the absence of the sympathetic pathway enhances the bladder-inhibitory effects of SAFN stimulation in AA-infused rats. Further work is needed to better characterize the precise role of the HGN during SAFN stimulation.

**Title:** Changes in bladder capacity and voiding efficiency estimated during continuous-fill cystometry in anesthetized rats that are provided with tibial nerve stimulation

**Authors: *J. P. PAQUETTE**[1], P. B. YOO[1,2]
[1]Inst. of Biomaterials & Biomed. Engin., [2]Edward S. Rogers Sr. Dept. of Elec. & Comp. Engin., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** Although the precise therapeutic mechanism is unknown, tibial nerve stimulation (TNS) is used clinically to treat symptoms of overactive bladder. Recent preclinical studies show that TNS can evoke significant bladder-inhibitory responses that persist beyond the period of electrical stimulation, by changes in bladder capacity (BC) and the inter-contraction interval (ICI). However, there is limited knowledge of the effects of TNS on urodynamic parameters that characterize voiding function, which include voided volume, post-void residual, and voiding efficiency (VE). The goal of this study was to characterize changes in urodynamic function that result from TNS during continuous-fill cystometry. Non-survival experiments were conducted in urethane-anesthetized Sprague-Dawley rats (280 - 316 g, n = 3, female) instrumented with a suprapubic bladder catheter. A stimulating bipolar nerve cuff electrode was implanted on right tibial nerve, and a pair of wire electrodes were inserted into the right foot. Rats were placed in a prone position, where a force-displacement transducer was positioned to collect fluid excreted from the urethral meatus. The study protocol involved continuous infusion of saline into the bladder (0.05 mL/min). Following an initial baseline period (90 minutes), TNS was applied for 30 minutes (6T, 10 Hz) and post-stimulation effects were measured for 30 minutes. The post-void residual bladder volume was measured at the end of each experimental trial to estimate the BC and VE of every bladder void using the recursive mass balance equation of the bladder. Compared to baseline, TNS resulted in negligible changes in the BC (1.5 ± 5.8%) and ICI (-0.2 ± 0.8%) during the intra-stimulation period. In contrast, notable increases in both variables - 17.1 ± 15.9% and 34.0 ± 4.6%, respectively - were observed during the post-stimulation period. These results are consistent with the bladder-inhibitory effects of TNS. Interestingly, despite the inhibitory effects of TNS, we also observed apparent increases in the VE, particularly during the post-stimulation period (10.8 ± 14.4%). The preliminary results of this study confirm the bladder-inhibitory effects of TNS (i.e., increased BC and ICI), and also show a concomitant

increase in the VE. Further work is needed to understand the potential role of these physiological variables in the therapeutic effects of TNS in patients.

**Title:** Real-time estimation of bladder pressure through dorsal root ganglia recordings in an overactive bladder model

**Authors: *A. OUYANG**, T. M. BRUNS
Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

**Abstract:** Overactive bladder patients often suffer from incontinence and a frequent urge to urinate. Previous studies have established electrical stimulation at various locations in the peripheral nervous system to improve continence. However, continuous stimulation facilitates habituation of neural pathways and consumes battery power. Sensory feedback-based stimulation may offer greater clinical benefit by driving bladder function only when necessary. In this study, we use sacral-level dorsal root ganglia (DRG) as a recording site to monitor the bladder state. We acquired neural recordings from microelectrodes in S1 and S2 DRG during acute alpha-chloralose anesthetized feline procedures and monitored bladder pressure. During each trial, 0.5% acetic acid in saline was infused at 2ml/min until leaking was observed. Overactive bladder was confirmed by observing a lower volume threshold for voiding and increased bladder activity. A Kalman filter was used to establish a training model for estimating bladder pressure from thresholded DRG neural activity (training). This model was then applied to neural data from a bladder fill in real-time to estimate the pressure (testing). The bladder pressure was estimated every 2 seconds, using 9 recording channels and a firing rate normalization method. In a pilot study, we were able to decode bladder pressure with a 10% normalized root mean squared error (NRMSE), and a correlation coefficient (CC) of 0.98 for a 15 minute infusion trial. Subsequent offline analysis using the training model established from a saline-only bladder fill and tested on an overactive-model bladder fill, yielded an accurate estimation (NRMSE of 7% and a CC of 0.96). Reversing the training and testing order yielded similar performance (NRMSE of 14% and CC of 0.96). The relationship between the bladder pressure and the multiunit firing rates from channels used in the estimations changed minimally between the healthy and overactive bladder

models. This result suggests the potential of using decoded sensory feedback to define control signals for a closed-loop bladder neural prosthesis, in a dysfunctional bladder state.

**Title:** Evaluating neurogenic oscillations in vaginal blood perfusion as a genital sexual arousal response to peripheral nerve stimulation in anesthetized female rats

**Authors: *L. L. ZIMMERMAN**[1,2], I. C. RICE[1,2], M. B. BERGER[3], T. M. BRUNS[1,2]
[1]Biomed. Engin., [2]Biointerfaces Inst., Univ. of Michigan, Ann Arbor, MI; [3]Obstetrics and Gynecology, Univ. of Michigan Hlth. Syst., Ann Arbor, MI

**Abstract:** The aim of this research is to determine the effects of pudendal and tibial nerve stimulation on the genital sexual arousal of an anesthetized female rat through analysis of neurogenic oscillations in vaginal blood perfusion. Female sexual dysfunction (FSD) is a condition which can include deficits in desire, arousal, orgasm, and lubrication. FSD affects between 40-45% of sexually active women, yet there are limited treatment options. In clinical studies involving sacral neuromodulation (SNM) and percutaneous tibial nerve stimulation (PTNS) for bladder dysfunction, female patients sometimes note an additional positive impact on sexual function. Few prior studies have examined this effect preclinically, and there is no standard method for evaluation of genital arousal. We have shown the ability to elicit increases in vaginal blood perfusion with peripheral nerve stimulation as shown by changes in laser Doppler flowmetry (LDF) signals from the vaginal wall. Previous studies in unrelated applications have segmented the frequency contributions of LDF signals into different sources, including neurogenic sources. The neurogenic range of tissue perfusion oscillations is from 0.076-0.200 Hz, and any changes in this range suggests modulation by the autonomic nervous system. This frequency range also eliminates the impact of DC drift, respiration artifacts, and bladder contraction artifacts on signal analysis. In this study, we propose to evaluate increases in neurogenic oscillations as an indicator of peripheral nerve stimulation-driven genital sexual arousal. In anesthetized female rats, we isolated and stimulated the pudendal or tibial nerve unilaterally for thirty minutes. The stimulation frequency was between 5-40 Hz with an amplitude that was 2-4 times the threshold for causing a distal muscle response. Vaginal blood perfusion was measured with LDF as the primary proxy for arousal, with changes in the neurogenic frequency range assessed with wavelet analysis. Significant increases in the energy of neurogenic oscillations is a proxy for genital sexual arousal. Across experiments, 6/8 pudendal

nerve and 12/15 tibial nerve procedures had increases in the neurogenic frequency range. This research demonstrates that analysis of the neurogenic power in LDF signals provides a novel approach for assessing genital arousal responses. Furthermore, these results suggest that peripheral nerve stimulation may be utilized as a treatment for FSD.

**Title:** Detecting bladder afferent activity from the surface of sacral dorsal root ganglia with a non-penetrating thin-film electrode array

**Authors: *Z. J. SPERRY**[1,2], K. NA[3], S. S. PARIZI[3], H. J. HILOW[1,2], J. P. SEYMOUR[3], E. YOON[3], T. M. BRUNS[1,2]
[1]Biomed. Engin., [2]Biointerfaces Inst., [3]Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI

**Abstract:** In this work, we demonstrate the ability of a thin-film non-penetrating electrode array to record bladder afferent activity from the surface of sacral dorsal root ganglia (DRG). Sacral DRG contain cell bodies for lower urinary tract afferents from the pelvic and pudendal nerves. Interfacing with the DRG could allow for closed-loop neural control of bladder function. In order to overcome the limitations of penetrating electrode arrays, we have developed a flexible polyimide electrode array with iridium electrode sites. This array interfaces with the DRG surface without penetrating the epineurium. We have previously demonstrated the ability of this array to detect cutaneous afferent neural activity, but this is the first report of recording bladder afferent activity from the surface of DRG. Under isoflurane anesthesia, we exposed the lumbosacral DRG of cats and placed a suprapubic bladder catheter for infusion and pressure monitoring. Under alpha-chloralose anesthesia, we placed the array on the surface of a DRG, noting its relative location, and infused room temperature saline into the bladder in 5 mL boluses to a volume of 30 mL. We recorded electrical signals at the DRG surface at 30 kHz using a Ripple Grapevine system. Electrode potentials were high-pass filtered offline with a cut-off of 250 Hz and noise floor threshold crossings times were determined using Plexon Offline Sorter. Finally, we calculated threshold crossing frequency and correlated this firing rate with bladder pressure. Multiple channels on an S2 placed array had firing rates which were highly correlated

with bladder pressure (max correlation: 0.82). 6-8 channels with bladder afferents were identified in each trial, usually clustered on closely-spaced electrode sites used as tetrodes (25 μm pitch). Activity was also identified in the same and other electrode placements corresponding to pudendal and somatic afferents, with spatial differences suggesting somatotopy. These results support our ultimate goal of interfacing chronically with sacral DRG to study bladder neurophysiology and providing closed-loop control toward a neuroprosthetic system.

**Abstract:** Over 400 million people around the world are affected by diabetes. Many diabetic patients struggle with glycemic control and are in high risk of morbidity and mortality. In recent years, the role of the kidney in glucose homeostasis has gained considerable interest. Kidneys are innervated by renal nerves, and renal denervation animal models have shown improved glucose regulation associated with increased urine glucose excretion. We hypothesize that stimulation of renal nerves at high frequencies (5-50 kHz), which can block propagation of action potentials, will increase urine glucose excretion. In this study, the left kidney of male rats was exposed through a midline abdominal incision. A nerve cuff electrode was placed on the renal artery, encircling renal nerves that run along the artery. Both ureters were cannulated to obtain urine samples from each kidney independently. Renal nerves were electrically stimulated (10-50 kHz, 15 V) for 25 minutes, and two minutes into stimulation, a glucose dose (1 g) was administered through the jugular vein. Urine samples were collected at 5-minute intervals, and colorimetric assays were used to quantify the amount of glucose excreted. In two trials of 33 kHz stimulation, the stimulated kidney showed an increase of 6.2 ± 13.8% in accumulated urine glucose excretion and an average of 11.6 ± 5.6% increase in urine glucose concentration with respect to the non-

stimulated kidney. In a single trial of 50 kHz stimulation, the stimulated kidney showed an increase of 24.6% in accumulated urine glucose excretion and an average of 18.9% increase in urine glucose concentration. In separate experiments, renal artery blood flow (mL/min) and kidney perfusion (laser speckle contrast imaging) were measured during nerve cuff stimulation. Electrical stimulation at 10, 50 and 100 kHz showed a small decrease of 4.6%, 1.3% and 3.2% in renal artery blood flow, respectively. Furthermore, we observed a minimal decrease of 0.9% and 1.9% in kidney perfusion at 33 and 50 kHz, respectively. Stimulation at 10 Hz is known to cause glomerular ischemia with kidney surface whitening. We recorded a decrease of 30.7% in renal artery blood flow and 53.1% in kidney perfusion at 10 Hz stimulation. Overall, our results show that kilohertz frequency electrical stimulation on renal nerves is a possible approach for the modulation of urine glucose excretion, with minimal effect on renal blood flow. This study suggests that electrical stimulation on renal nerves is a potential treatment modality for glycemic control.

**Abstract:** Millions of people in the United States suffer from bladder dysfunction and pain caused by interstitial cystitis/bladder pain syndrome and overactive bladder. The underling pathologies for many of these diseases are poorly understood, however it has been demonstrated that sensory nerve fibers play an integral role in many of these diseases. Our lab has been studying the role of these sensory nerve fibers in bladder physiology and pathophysiology using optogenetics. Optogenetics is a powerful tool that can be used to specifically manipulate

neuronal activity using light activated channels and pumps. To better understand the role of bladder afferents in bladder diseases, we have developed multiple approaches using viruses and mouse genetic lines to express opsins in bladder sensory neurons to modulate neuronal activity. We have demonstrated effective delivery of opsins to bladder afferents using intraganglionic injections of adeno associated viral vectors, which produces prolonged, stable expression. However this approach does not restrict expression of the light-sensitive proteins to the bladder, so focal illumination of the bladder is necessary to achieve bladder-specific optogenetic manipulations. We have also found that bladder wall injections of the retrograde herpes simplex viral vectors can achieve short term, bladder afferent-specific expression of opsins. We demonstrate with both approaches that activation of the excitatory opsin channelrhodopsin-2 (ChR2) leads to the initiation of bladder contraction, whereas activation of the inhibitory opsin archaerhodopsin (Arch) results in the delayed contractions. Using genetically engineered mouse lines, we can restrict the expression of these opsins to specific subtypes of bladder afferents. We did this by crossing mice that express Cre recombinase-dependent ChR2 or Arch with mice that express cre recombinase in Nav1.8-expressing neurons, resulting in Nav1.8-ChR2 and Nav1.8-Arch mice. Optogenetic activation of bladder afferents in Nav1.8-ChR2 mice initiated bladder contractions, while inhibition bladder afferents in Nav1.8-Arch mice prolonged cystometric contractions. Altogether, we show that both virally delivered and genetically expressed opsins can be used to bidirectionally modulate and manipulate bladder function. Restriction of opsin expression to other sub-populations of bladder afferents could lead to a better understanding of the role of various afferent populations in bladder function and disease.

**Abstract:** The impact of autonomic nerve injury on smooth muscle is not well understood. We explored the integrity of bladder innervation and smooth muscle function after lower spinal cord injury. The bladders of female canines were surgically decentralized by bilateral transection of all spinal roots caudal to L7, including the dorsal root of L7. Video surveillance of housing cages allowed measurement of the frequency and duration of urination postures at monthly intervals post operatively (PO). Retrograde labeling of pelvic plexus neuronal cell bodies was quantitated from Fluorogold (FG) injected near the ureterovesical junction 3 weeks before euthanasia. Functional integrity of pelvic plexus-bladder innervation was determined by electrical stimulation of the pelvic plexus immediately prior to euthanasia. Bladder caspase-3 immunostaining for cellular apoptosis was quantified to confirm integrity. Micturition postures were observed in only 2/6 animals by 2 months PO and 3/6 by 4 months PO while postures remained intact in sham animals, confirming that decentralization reduces sensation of bladder fullness. The ability of 3/6 animals to sense bladder fullness at 4 months PO may be from sensory nerve sprouting or variations in the bladder sensory innervation. The pelvic plexus maintained its ability to induce *in vivo* bladder contractions a year after spinal cord injury, although sacral root transection significantly decreased maximal bladder contraction. Abundant FG-labeled neuronal cell bodies were observed in ganglia in the pelvic plexus of both sham and decentralized animals demonstrating that the ganglia remain intact up to 6 months after injury despite sensory losses. Immunohistochemical stain for caspase-3 showed no difference across groups, suggesting no increase in apoptotic cell death. Smooth muscle contractility is preserved across groups after *in vitro* nerve-evoked stimulation, indicating that the intramural nerves and smooth muscle of the bladder are intact up to 12 months after injury and therefore, nerve reinnervation strategies could be successful.

**Abstract:** We sought to develop methods for monitoring nerve activity during bladder filling in normal intact bladders, methods that we would eventually use for monitoring effectiveness of sensory reinnervation of the bladder after decentralization and rerouting nerve transfer. Electrophysiology studies were designed to perform nerve stimulation and recording in rats and canines. Animals were anesthetized using isoflurane (3-5% induction dose inhalation). Electroneurogram (ENG) recordings were performed using a bipolar cuff electrode: 1) in rats, from sciatic nerves (n=7) during hind paw stimulation with Semmes-Weinstein monofilaments of varying forces (10g-300g) and, 2) in rats and canines, from hypogastric nerves (n=7 each) during bladder filling. Recordings included electrical stimulation (0.2-10mA, 20Hz) of the hind paw or hypogastric nerve and were performed using a low noise amplifier at 10k gain, sampled at 20kHz, filtered at 300Hz-10kHz. Data was converted from analog to digital and then captured using LabChart software (ADInstruments, CO). Also, maximum changes in detrusor pressures were determined after electrical stimulation of the hypogastric nerves prior to recording. We found in rats that sciatic nerve recordings consistently showed increased afferent fiber discharge with increased size of the monofilament used to stimulate the hindpaw. In contrast, recording from bladder nerves showed that combined afferent and efferent discharges increased substantially in response to bladder filling in 2 of 7 rats, and increased moderately in 2 rats. However, there was no response in the remaining 3 rats, perhaps due to nerve damage during cuff placement. In canines, we found hypogastric nerve activity decreased substantially in response to bladder filling in 1 of 7 dogs, and increased moderately in one dog, and showed no response in the remaining 5 dogs. While we need to improve our technique in canines, based on results from sciatic nerve and hypogastric nerve recordings in rats, our technique may be appropriate for recording afferent nerve activity during bladder filling in animals with surgically rerouted neural pathways.

**Title:** State-dependent stimulation of the pudendal nerve increases bladder capacity and voiding efficiency

**Authors: *J. A. HOKANSON**[1], C. L. LANGDALE[1], A. SRIDHAR[5], P. H. MILLIKEN[5], W. M. GRILL[1,2,3,4]
[1]Biomed. Engin., [2]Electrical and Computer Engineeering, [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC; [5]Galvani Bioelectronics, Stevenage, United Kingdom

**Abstract:** Overactive bladder (OAB), resulting in urgency, frequency, and incontinence, is a highly prevalent condition that leads to medical complications and decreased quality of life. Many persons fail to find therapeutic relief from currently available treatments.
Pudendal nerve stimulation is a promising alternative therapy that is not currently in clinical use. Pudendal nerve stimulation produces increases in bladder capacity in animal models as well as in limited human testing. As well, activity in pudendal nerve afferents, particularly urethral afferents, promotes bladder emptying. By using different stimulation parameters, stimulation of the pudendal nerve may promote differentially bladder filling and efficient voiding. Strong inhibition of the bladder to promote continence can treat incontinence but may reduce voiding efficiency, and some patients exhibit both poor bladder filling and poor voiding (e.g., detrusor hyperactivity with impaired contractility).
We hypothesized that state-dependent stimulation of the pudendal nerve would increase both bladder capacity and voiding efficiency in rat and cat models.
In urethane-anesthetized female Wistar rats, the sensory branch of the pudendal nerve was stimulated during cystometry. In initial experiments, Prostaglandin E2 was administered intravesically as a model of OAB. In three of four experiments, high amplitude stimulation increased bladder capacity, which when followed by low amplitude stimulation, just prior to and during voiding, improved voiding efficiency (n=2), or rescued a bladder contraction from overflow incontinence (n=1) compared to trials without stimulation and trials with stimulation only during bladder filling.
State-dependent stimulation was also investigated in two alpha-chloralose anesthetized male cats. The compound pudendal or sensory pudendal (i.e. dorsal nerve of the penis or DNP) nerve was stimulated to increase bladder capacity. Upon initiation of micturition, this initial stimulus was terminated and replaced by stimulation of the motor branch in a bursting pattern, or stimulation of the DNP using a different pattern than that used during filling, to promote voiding. In both cat experiments state-dependent stimulation improved both bladder capacity and voiding efficiency.
These findings suggest that state-dependent stimulation of the pudendal nerve may be a promising approach to maximize both bladder capacity and voiding efficiency.

**Abstract:** Overactive bladder (OAB), resulting in urgency, frequency, and incontinence, is a highly prevalent condition that leads to medical complications and decreased quality of life. There are several animal models used to investigate the mechanisms of and treatments for OAB. In particular, the spontaneously hypertensive rat (SHR) is a genetic model of hypertension that also exhibits symptoms of OAB that include detrusor overactivity, increased frequency, and decreased bladder capacity and voided volume. While most prior studies were conducted in awake unrestrained rats, they employed catheters implanted in the bladder and tethered to an infusion pump and artificial bladder filling. The purpose of our study was to 1) monitor voiding behavior in awake unrestrained untethered age-matched SHR and control rats, and 2) successfully record bladder pressure and external urethral sphincter (EUS) function in telemetry (TTY) implanted awake unrestrained untethered SHR and control rats. Food and water consumption, body weight, voiding frequency (VF), and voided volume (VV) were recorded. Each rat was placed in a metabolism cage for 23-24 hours per day, up to twice a week. For telemetry (TTY) implanted animals, a pressure catheter was implanted into the dome of the bladder, and a bipolar paddle electrode was inserted between the urethra and pubic symphysis to record bladder pressure (BP) and external urethral sphincter (EUS) electromyogram (EMG). The SHRs body weight, food, and water consumption were decreased compared to controls. However, after normalizing for body weight, no differences in food or water consumption were observed. Controls exhibited a diurnal pattern in their voiding behavior, consisting of larger VV

with decreased VF during sleep cycles and smaller VV with increased VF during awake cycles. SHRs voided less volume less frequently compared to controls; however, no difference in VF was observed after normalizing for water consumption. Additionally, no diurnal voiding pattern was noted in the SHRs (VV was similar during the awake and sleep cycles). BP and EUS EMG activity were successfully recorded in TTY implanted awake unrestrained untethered rats. High frequency osciilations in BP coincided with EUS EMG bursting during voiding. Our results confirm previously reported decreases in VV. However, the lack of increased VF suggests that artificial filling during awake cystometry may alter normal voiding behavior. Further, TTY implanted rats with BP and EUS EMG is a promising approach to understand voiding behavior in awake unrestrained untethered rats.

**Title:** Nerve stimulation increases voiding efficiency in a novel model of detrusor underactivity

**Authors: *E. J. GONZALEZ**, W. M. GRILL
Biomed. Engin., Duke Univ., Durham, NC

**Abstract:** Detrusor underactivity (DUA) is an understudied health concern that affects up to 45% of men and women. The clinical management of DUA is inadequate and fails to improve the quality of life of these patients. The limited availability of animal models that exhibit the integrated pathophysiology of DUA impedes the development of new therapeutic approaches. The current studies characterized the bladder function of an obesity model of DUA and investigated neuromodulation as a management option to restore efficient bladder emptying.

Eight-week old female obese-prone (OP) and obese-resistant (OR) rats were purchased from Charles River (Boston, MA). Experimental procedures were approved by the Duke University IACUC. OP and OR rats were fed a 45% fat diet (Research Diets, Inc.) from 9-21 weeks and a 60% fat diet (Research Diets, Inc.) from 21-24 weeks. Serum was collected from the tail vein for metabolic analysis at 8 and 24 weeks. At 24 weeks, OP and OR rats were anesthetized with urethane (1.2 g/kg s.c., supplemented as needed). The bladder was exposed and a flared PE-60 catheter was inserted into the bladder dome. The catheter was secured and connected via a 3-way stopcock to a pressure transducer and infusion pump. A paddle with platinum iridium contacts was placed between the pubic symphysis and the EUS to record EMG signals. A bipolar micro-cuff (CorTec, Germany) was also placed around the motor or sensory branch of the pudendal nerve or the pelvic nerve for electrical stimulation. Pressure and EMG signals were amplified, filtered, and sampled. Following diet-induced obesity (DIO), OP rats weighed more than OR rats and had normal blood glucose but developed hyperinsulinemia and hypertriglyceridemia. OP rats exhibit DUA and urinary retention following DIO. Compared to OR rats, OP rats had increased volume threshold, decreased peak micturition pressure ($16.6 \pm 1.2$ vs. $23.9 \pm 1.1$ $cmH_2O$, $p \leq 0.001$), decreased voiding efficiency ($8.4 \pm 2.2$ % vs. $40 \pm 5.2$ %, $p \leq 0.0001$), and decreased EUS EMG activity during voiding. Patterned electrical stimulation of the motor branch of the pudendal nerve increased voiding efficiency two-fold in OP rats ($11 \pm 5.8$ % vs. $22 \pm 6.3$ %, $p \leq 0.05$), whereas, stimulation of the sensory branch of the pudendal nerve did not alter voiding efficiency. OP rats also had no change in voiding efficiency and decreased evoked contraction amplitude with electrical stimulation of the pelvic nerve. This animal model may be used to understand the pathophysiology of DUA and establish the efficacy of neuromodulation to recover efficient bladder emptying with urinary retention.

Philadelphia, PA; [3]Electrical and Computer Engin., Temple Univ., Philadelphia, PA; [4]Anat. and Cell Biol., Temple Univ. Sch. of Med., Philadelphia, PA

**Abstract:** We have previously found that succinylcholine, a depolarizing neuromuscular nicotinic receptor blocker, prevents bladder contraction induced by new neuronal pathways established by nerve transfer in decentralized dogs. Here, we studied detrusor pressure response *in vivo* and contractile response of bladder smooth muscle strips *in vitro* from sham, decentralized and reinnervated animals to localize neuromuscular nicotinic receptors involved. Three groups of female hound dogs (5/group) were used: sham, 12-month decentralized and 6-month reinnervated. Decentralization was performed by bilateral transection of all spinal roots caudal to L7, including dorsal roots of L7 and hypogastric nerves. Reinnervation was created by bilateral transfer of obturator nerves to anterior vesical branches of pelvic nerve. Two-way ANOVAs and Sidak post-hoc tests determined group differences. In reinnervated dogs, neuromuscular nicotinic receptor blockade with intravenous atracurium besylate reduced increased detrusor pressure induced by electrical stimulation of upper lumbar nerve roots. Atracurium did not block sacral nerve root stimulation induced pressure in sham-operated controls. *In vitro*, 5 μM atracurium had no effect on nerve evoked contractions in any experimental group. Neither the competitive neuromuscular nicotinic receptor antagonist d-tubocurarine nor the ganglionic antagonist hexamethonium inhibited electric field stimulation (EFS)-induced contractions of reinnervated or sham-operated control bladder strips. 1 μM tetrodotoxin (TTX) blocked contractile response in all groups. Similarly, EFS-evoked contractions were strongly reduced by 10 μM alpha, beta-methylene ATP (α,β-mATP) and 1 μM atropine in all groups. *In vivo* blockade of nerve-evoked bladder pressure by atracurium in reinnervated, but not sham operated controls, suggests that neuromuscular nicotinic receptors mediate bladder contractions induced by upper lumbar stimulation. Because neither atracurium nor d-tubocurarine blocked in-vitro contractions induced by EFS in reinnervated bladders, the neuromuscular nicotinic receptors involved in the neuronal pathways originating from the upper lumbar spinal cord must not be located in bladder muscle or intramural ganglia; they may be located in pelvic plexus ganglia or in the spinal cord. TTX blockade validates that EFS-induced contractions at all frequencies were nerve-evoked. The response to blockade of nerve evoked muscle strip contractions with a combination of atropine and α,β-mATP, indicates that both muscarinic and purinergic components account for virtually all nerve mediated responses.

**Title:** Spinal dopamine receptors continue regulating the recovered urinary function in rats following complete spinal cord transection

**Authors: *S. HOU**[1], H. SHARIF[1], S. L. DAUGHERTY[2], J. H. DEFINIS[1], W. C. DE GROAT[2]
[1]Spinal Cord Res. Center, Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Pharmacol. and Chem. Biol., Univ. of Pittsburg, Pittsburgh, PA

**Abstract:** Lower urinary tract (LUT) function is controlled by multiple neuronal mechanisms at both supraspinal and spinal levels that synchronize bladder and external urethral sphincter (EUS) activity. Recently, we discovered that dopamine (DA) is synthesized in the rat spinal cord and regulates bladder function after a spinal cord injury (SCI) interrupts spinobulbospinal reflex pathways. To fully understand the spinal endogenous DA-ergic machinery in the recovered micturition, we used metabolic cages to measure spontaneous voiding, and employed bladder cystometry and EUS electromyography (EMG) combined with different DA receptor (DR) agonists or antagonists to examine urodynamic responses in unanesthetized SCI rats. Three weeks after complete SCI at the 10$^{th}$ thoracic level, involuntary micturition was reestablished due to the reorganization of spinal reflex circuitry. Subcutaneous delivery of L-DOPA (30 mg/kg), a DA precursor, together with carbidopa (3 mg/kg) decreased spontaneous voiding frequencies and increased voiding volumes. During cystometry and EMG assay, injection of L-DOPA (1-30 mg/kg) in combination with carbidopa (0.1-3 mg/kg) intravenously (iv) decreased the amplitude of bladder contractions and the frequency of non-voiding contractions, and reduced EUS tonic activity but increased the duration of EUS bursting phase, leading to better coordinated detrusor and EUS activity. Apomorphine (1-300 μg/kg, iv), a non-selective DR agonist, enhanced the amplitude of bladder contractions and EUS bursting duration and suppressed EUS tonic activity. Similarly, quinpirole (10-300 μg/kg, iv), a selective $DR_2$ agonist, also increased bladder activity and EUS bursting but decreased EUS tonic activity. A specific $DR_2$ antagonist remoxipride (0.1-3 mg/kg, iv) reversed the effects of quinpirole but when administered alone, it only had minimal effects on bladder and EUS activity. This indicates that the activation of spinal $DR_2$ facilitates voiding. On the other hand, administration of SKF38393 (0.1-3 mg/kg, iv), a selective $DR_1$ agonist, increased tonic EUS activity; while a $DR_1$ antagonist SCH23390 (0.01-1 mg/kg, iv) also increased EUS tonic activity. However, the latter occurred during a period of large spastic movements of the body and legs which made the effects of the drug difficult to evaluate. Thus, spinal DA modulates bladder and EUS activity via distinct receptors: $DR_1$ are more involved in activation of the EUS and urine storage whereas $DR_2$ are more involved in bladder activation,

EUS bursting and voiding. Pharmacological manipulation of spinal DR or DA levels may become a therapeutic strategy to improve LUT functional recovery following SCI.

**Abstract:** SCI rostral to the lumbosacral spinal cord results in detrusor sphincter dyssynergia and neurogenic detrusor overactivity producing highly inefficient voiding. Impaired bladder emptying, resulting in urinary retention with high bladder pressure, is a major problem for SCI individuals. Effective drug treatments do not exist. NGF/receptor interactions contribute to bladder dysfunction after SCI, in OAB and with IC/PBS. Of the NGF receptors, TrkA and p75, p75 is more relevant under pathological conditions, inducing apoptosis and degeneration upon binding proNGF. We have discovered that proNGF, and not mature NGF, is rapidly released into the urine after SCI both in rodents and in humans. Released proNGF in rodents activates p75 in the urothelium, inducing rapid apoptosis of umbrella cells. When we selectively deleted p75 in urothelial cells using conditional knockout strategy with urothelium-specific cre line ($p75^{\Delta}$-UP3a), umbrella cell apoptosis was completely blocked after SCI. We hypothesized that p75 signaling contributes to bladder function under control (spinal intact) conditions and following SCI (complete transection T12-L1). In spinal intact conditions, we evaluated bladder function in conscious $p75^{\Delta}$-UP3a and control $p75^{c}$-UP3a mice. $P75^{\Delta}$-UP3a mice exhibited increased voiding frequency and smaller void volume compared to control. After SCI, however, $p75^{\Delta}$-UP3a mice exhibited increased bladder capacity and intermicturition interval, but overall lower voiding efficiency compared to control. Thus, p75 signaling in the urothelium contributes to micturition

both in control and SCI conditions. ProNGF is released in the CNS after injuries. We evaluated the effect of systemic blocking of proNGF binding to p75 on bladder function using LM11A-31 (100 mg/kg, p.o.; daily) that crosses the blood-brain/spinal cord barrier efficiently and targets p75. Spinal intact mice treated with LM11A-31 exhibited decreased voiding frequency and smaller void volumes similar to that observed in $p75^{\Delta}$-UP3a mice. After SCI, LM11A-31 significantly improved voiding function with overall voiding efficiency reaching that of spinal intact mice. Bladder capacity, intermicturition interval and bladder mass were reduced compared to wildtype mice. LM11A-31 improves motor coordination following SCI without toxicity or exacerbation of pain. These results suggest p75 signaling plays beneficial roles in micturition reflexes in SCI with greater CNS contributions compared to PNS. Blocking p75 action may be a strategy to treat urinary dysfunction after SCI.

**Title:** Regulation and expression of CXCL chemokines in mouse urinary bladder with inflammation

**Authors: *B. M. GIRARD**, M. GUO, S. MALLEY, M. A. VIZZARD
Anat. and Neurobio., Univ. of Vermont Dept. of Neurolog. Sci., Burlington, VT

**Abstract:** Although the primary insult underlying painful bladder syndrome (PBS)/interstitial cystitis (IC) is not known, it has been suggested that the pathophysiology is a “vicious circle” involving uroepithelial dysfunction, inflammation, afferent nerve hyperexcitability, and visceral hyperalgesia and allodynia. We have hypothesized that pain associated with PBS/IC involves an alteration of visceral sensation/bladder sensory physiology. These changes may be mediated, in part, by inflammatory changes in the urinary bladder. Rodent models suggest potential roles for chemokines in the initiation or maintenance of visceral/pelvic inflammation and pain. Using the cyclophosphamide (CYP)-induced bladder inflammation model, we aimed to characterize further the role of CXCL chemokines (CXCL9, CXCL10 and CXCL11). QRT-PCR and ELISAs were used to determine mRNA and protein expression of CXCL9, CXCL10, and CXCL11 in

urothelium and detrusor. Male and female, wildtype C57BL/6J mice were injected (75 or 150 mg/kg, i.p.) with CYP to induce bladder inflammation (4 hr, 48 hr, chronic). In urothelium of female mice treated with CYP, CXCL10 and CXCL11 mRNA significantly ($p \leq 0.05$) increased with 4 hr and/or 48 hr CYP treatment whereas CXCL10 mRNA increased ($p \leq 0.05$) in the detrusor with 4 hr and chronic CYP treatment and CXCL11 mRNA decreased ($p \leq 0.05$) with 48 hr CYP treatment. In urothelium of male mice treated with CYP, CXCL11 mRNA decreased ($p \leq 0.05$) with 4 hr, 48 hr and chronic CYP treatment. In detrusor of male mice treated with CYP, CXCL9 and CXCL11 mRNA decreased ($p \leq 0.05$) with 4 hr, 48 hr and chronic CYP treatment, whereas CXCL10 mRNA increased ($p \leq 0.05$) with 4 hr and 48 hr CYP treatment. Urinary bladder from control (no CYP) female mice exhibited significantly ($p \leq 0.05$) greater expression of CXCL9 and CXCL10 protein expression compared to bladder from control male mice. In urinary bladder from male mice treated with CYP, CXCL9 and CXCL11 protein expression significantly ($p \leq 0.05$) decreased with chronic CYP treatment and CXCL9, CXCL10 and CXCL11 protein expression was significantly ($p \leq 0.05$) reduced with 48 hr CYP-induced cystitis. CXCL mRNA and protein exhibited differential regulation depending on tissue (urothelium, detrusor), sex and duration of CYP treatment. Ongoing studies are exploring the functional role of these chemokines in micturition reflexes in control conditions and following CYP-induced cystitis. CXCL chemokines may be novel targets for treating urinary bladder dysfunction resulting from urinary bladder inflammation.

**Abstract:** In mammals the pelvic floor components perform sexual functions and micturition, which are regulated by the brain and spinal cord at the lumbosacral level. The rupture or avulsion of the lumbosacral roots, affects the spinal cord, generating disability and severe sensory, motor and autonomic dysfunctions, such as urinary retention. The studies on ventral root avulsion of the lumbosacral plexus (VRA) show changes in the morpho-functional of the spinal cord and its target organ (lower urinary tract and pelvic and perineal muscles) involved in micturition. In models, as the rat, were showed changes in spinal cord after VRA. However, the distribution of the lumbosacral plexus is different in that model and the anatomofunctional changes in response to the VRA are usually different between species. It is of great importance to determine the changes in micturition and perineal muscles after VRA in the rabbit. Twelve virgin female rabbits (8 months old) divided into two groups. In a group (4) the anatomical arrangement of the lumbosacral plexus and its innervation towards the inferior urogenital apparatus were described. In another group (8) the immediate effect of VRA during micturition was evaluated. Three cycles of micturition were registered through cystrometry, urethral pressure and electromyograms of bulbospongiosus and ischiocavernosus muscles. Subsequently, the ventral roots were avulsionated and after of an hour the micturition were recorded again. The VRA produced immediate shows changes in micturition and in the perineal muscles activity. The VRA in the rabbit affected the micturition, decreasing the bladder and urethral function, which causes dripping during filling and produces hypoactive bladder; together with the inhibition of the electrical activity of the perineal muscles, due to damage in the spinal cord and efferent pathways that regulate the micturition.

**Title:** Propriospinal neurons coordinating activity of external urethral sphincter

**Authors: *S. V. KARNUP**, W. C. DE GROAT
Pharmacol. & Chem. Biol., Univ. of Pittsburgh, Pittsburgh, PA

**Abstract:** Coordination between bladder smooth muscle and striated muscle of the external urethral sphincter (EUS) is of pivotal importance for micturition. In rats efficient voiding depends on the ability of the EUS to produce rhythmic bursts of activity at the peak of bladder pressure. In rats with an intact neuraxis EUS bursting which is mediated by supraspinal circuitry is immediately eliminated after transection of the spinal cord segments rostral to L3/L4 level but recovers along with reflex bladder activity several weeks after transection. However after transection of the cord caudal to L4 bladder reflexes and tonic EUS activity recover, but EUS bursting is lost. This observation has led to the proposal (Chang, H. et.al., AJP Renal, 292, F1044, 2007) that propriospinal connections between reflex circuitry in the L3/L4 spinal cord and motoneurons innervating EUS (EUS-MNs) located in L6/S1 spinal segments are necessary for bladder-sphincter coordination and EUS bursting. To examine the properties of propriospinal and interneurons in the putative L3/L4 bursting circuitry we used whole cell patch clamp techniques in spinal slices to study neurons fluorescently labeled by trans-synaptic viral tracer PRV-GFP (3µl) which was injected into EUS of neonatal male rats between postnatal days 16-18. Neurons were studied 2 days post-infection. During recording neurons were filled with biocytin for mapping and morphological characterization. Cell bodies of fluorescent neurons were located in the dorsal commissure and on both sides of the central canal. Dendrites were distributed within lamina X and medial part of lamina VII. In longitudinal sections rostro-caudal dendrites could be identified at distances as great as 700 µm from the cell body. Electrical stimulation revealed profound excitatory connections within lamina X and VII in transverse slices, and up to 400 µm along the central canal in longitudinal slices. In some cells antidromic spikes were elicited by stimulation of the ventromedial funiculus at distances ranging from 200-350µm from the cell. Local feed-forward inhibition was infrequent and in most cases weak. Injections of depolarizing current steps resulted in tonic firing in the majority of recorded cells and only a small fraction of cells exhibited phasic or single-spike discharges. Thus, intrinsic properties of EUS-related neurons in L3/L4 indicate that they themselves cannot produce rhythmic bursts. Therefore it is likely that they serve as an output of a more complex L3/L4 circuit capable of generating rhythmic burst activity that is transmitted by propriospinal pathways to the EUS-MNs in L6/S1.

**Title:** Increasing bladder capacity in a fully-conscious, large animal model: Sacral nerve stimulation targeted to late stages of bladder fill-cycle has efficacy similar to continuous stimulation

**Authors: *L. ZIRPEL**, T. S. BRINK
Res. and Core Technology, Restorative Therapies Group, Medtronic Inc, Minneapolis, MN

**Abstract:** Introduction Sacral nerve stimulation (SNS; InterStim® Therapy, Medtronic, Inc.) for overactive bladder and fecal incontinence is delivered in a continuous mode. Recent clinical evidence and the emergence of intermittent percutaneous tibial neuromodulation suggest that equal therapeutic efficacy can be achieved with non-continuous SNS. Previous studies in anesthetized rodent demonstrated that SNS during latter parts of the bladder fill cycle elicit an increase in bladder capacity equal to that of continuous SNS. The goal of this study was to use the fully conscious sheep model to test the hypothesis that SNS delivered in the latter part of the bladder fill cycle can elicit the same increase in capacity as continuous SNS. Methods Repeat, single fill cystometry was performed on 8 sheep. Bladder pressure was recorded by a pressure sensor fed through the catheter. Saline (34°C) was infused at 15 ml/min until bladder pressure increased > 30 mm Hg and the sheep assumed voiding posture. The primary measure was bladder capacity = volume of saline infused before voiding. Animals were implanted with bilateral sacral stimulation leads (Medtronic, model 3889) attached to an implanted neurostimulator to deliver SNS (0.21ms pulse width, 10Hz, maximum tolerable amplitude). Maximum tolerable amplitude (MTA) was determined by increasing amplitude until the sheep lifted the ipsilateral leg; amplitude was then decremented until the sheep was weight bearing on the ipsilateral leg. Bladder fill cycle time was determined with three baseline fills. During subsequent fill cycles, stimulation was applied either 1) continuously, 2) during the first half, 3) during the second half, 4) during the last quartile, or 5) during the last decile of the fill cycle. Since the application of SNS was randomized, results were averaged and compared to their respective baselines using a two-tailed *t* test with significance at $p \leq 0.05$. Results Continuous stimulation produced a significant 37% increase in bladder capacity [67±8 ml to 92±6 ml (mean±SD)]. SNS delivered during the first half of the bladder fill cycle did not elicit a significant change in capacity (42±11 ml vs 44±9 ml), whereas SNM delivered during the second half of the bladder fill cycle elicited a significant 74% increase in capacity (46±11 ml to 80±2 ml). SNS during the last quartile of the fill cycle produced a significant 32% increase in capacity (57±9 ml to 75±6 ml), and stimulation during the last decile did not produce a significant change in capacity (55±10 ml to 53±4 ml). Average MTA = 0.79 mA±0.15 (SD). Conclusions These results provide insight into more energy efficient delivery of SNS, as well as to physiologically-triggered therapy.

**Title:** Interneurons and propriospinal neurons presynaptic to motoneurons of the external urethral sphincter in rat

**Authors: S. V. KARNUP**, K. KIM, *W. C. DE GROAT
Univ. Pittsburgh Med. Sch., Pittsburgh, PA

**Abstract:** Micturition in rats is dependent on the coordinated activity of parasympathetic and somatic efferent pathways to the bladder and external urethral sphincter (EUS) that originate from the preganglionic neurons (PGN) and motoneurons in L6/S1 segments of the spinal cord. In animals with an intact neuraxis, coordination is mediated by supraspinal circuitry, but after spinal cord injury at the level of the thoracic spinal cord micturition is regulated by spinal reflex circuitry consisting of: (1) a lumbar spinal coordinating center (LSCC) located in the L3/L4 spinal segments and (2) efferent neurons and dorsal commissure interneurons in the L6/S1 cord which receive signals from the LSCC. It is assumed that the LSCC is composed of local interneurons as well as propriospinal neurons (PSN) that project to the L6/S1. To identify the neurons in this putative inter-segmental circuitry in male rats (P30 and P60) we injected pseudorabies virus (3-5 μl) encoding green fluorescent protein (PRV-GFP, courtesy: Dr. L., Enquist) into the EUS and injection of PRV encoding red fluorescent protein (PRV-RFP) into the bladder to trans-synaptically label spinal neurons relevant to lower urinary tract function. Optimal post-infection survival was 3 days for P30 and 4 days for P60. Two populations of neurons presynaptic to EUS-MN were identified: 1) interneurons (INs) in L6/S1 above the central canal (CC) in the dorsal commissure (DCM) and 2) neurons in L3/L4 in the DCM and within 200-300 μm lateral to CC. P30 in comparison to P60 animals exhibited greater numbers of labeled neurons. Neurons presynaptic to bladder PGN were located in similar locations. Small numbers of these neurons were co-labled from bladder and EUS. Injections of a retrograde tracer into the L6/S1 cord co-labeled some PRV labeled neurons in L3/L4 indicating that these neurons belong to a propriospinal (PSN) subpopulation carrying signals from the LSCC to caudal segments. Mapping of labeled cells along the L3/L4 segments revealed clusters of neurons. Grading the intensity of fluorescence among labeled cells allowed for distinguishing brightly stained presumed PSNs from weakly stained local interneurons presynaptic to PSNs. Thus an intraspinal circuit regulating activity of EUS and bladder comprises at least four neuronal subpopulations involved in the control of each organ: (1) efferent neurons in L6/S1, (2) INs in

L6/S1, (3) INs in L3/L4 and (4) PSNs in L3/L4. Co-localization of tracers indicates that some of these neurons are involved in control of both organs.

**Title:** Multiple cortical areas influence the neural regulation of the rat colon

**Authors: *D. J. LEVINTHAL**
Univ. of Pittsburgh, Pittsburgh, PA

**Abstract:** Descending neural commands from the brain influence the peristaltic, secretory, and immunological functions of the colon. Such commands contribute to colonic changes associated with increased stress or intense emotion, the anticipation of unpleasant events, or changes in physical activity. However, the cortical sources of descending commands to the colon remain poorly understood. To address this issue, we injected rabies virus into the rat distal colon and used the retrograde transneuronal transport of the virus, along with careful adjustment of survival times, to define the cortical areas that influence the colon. Transneuronal transport of rabies virus led to infection of layer V neurons located primarily within three cortical areas: primary motor cortex, secondary motor cortex, and the primary somatosensory cortex. The majority of neurons within these cortical regions were clustered within their respective representations of the trunk and hindlimb. An important component of the descending influences on the colon could be mediated by neural circuits involving an additional synaptic relay. Thus, we extended the survival time to allow one additional stage of transneuronal transport. In these animals, labeled cortical neurons were still found predominantly within three cortical areas: primary motor cortex, secondary motor cortex, and primary somatosensory cortex. However, a notable minority of labeled neurons was also found within the medial prefrontal cortex and the insula. Thus, while sensorimotor regions of the cortex have the most substantial and direct influence on the colon, non-motor cortical regions also gain a less substantial and indirect influence. These findings have important implications for understanding the neural basis for cerebral cortical influences on the colon. First, the presence of labeled neurons within the trunk and hindlimb representations of somatosensory cortical areas provides a direct linkage between the neural control of motor

function and the colon. This neural substrate may explain how physical movement (or lack thereof) influences colonic function and suggests that exercise could be a potential therapy for some colonic disorders. Second, the insula and prefrontal cortex are involved in cognitive and affective processing, and our results imply that these areas are involved in the regulation of colon function. Such connections provide a concrete neural substrate for the influence of cognitive and emotional processes on colonic function. The latter may partly account for the clinical benefits of cognitive behavioral therapy in those with functional gastrointestinal disorders such as irritable bowel syndrome.

**Title:** Activation of voltage-gated calcium channels in urinary bladder epithelial cells alters reflex bladder activity

**Authors: *J. M. BECKEL**, S. ALTUNAL, K. A. ROSZKOWSKI, B. Y. TANDOC, C. VENKATRAM, W. C. DE GROAT
Pharmacol. and Chem. Biol., Univ. of Pittsburgh, Pittsburgh, PA

**Abstract:** The release of adenosine triphosphate (ATP) from the epithelial lining of the bladder (urothelium) plays an important role in normal and pathological bladder function. When the bladder stretches during filling, ATP is released from the urothelium and is thought to activate nearby afferent nerves and induce the sensation of bladder fullness. ATP release from the urothelium is increased in patients suffering from overactive bladder, a disorder characterized by an increased desire to void at small bladder volumes. Previous research from our lab indicates that pannexin channels are responsible for urothelial ATP release, although the exact mechanism of channel regulation is unclear. For example, we have demonstrated that urothelial cell membrane depolarization increases ATP release. However this is not thought to be a direct effect of membrane potential on pannexin channels, as the effect was blocked by BAPTA-AM, indicating that intracellular calcium is required. Therefore, our current research examines the possibility that voltage-gated calcium channels exist in the urothelium and that these channels

can modulate urothelial ATP release through pannexin channels. Using RT-PCR and immunofluorescence, we confirmed the presence of several voltage-gated calcium channels in rat ($Ca_V$1.2, 1.4, 2.1, 2.2, 2.3, 3.1, 3.2 and 3.3) and human ($Ca_V$1.3, 2.1, 2.2, 2.3, 3.2 and 3.3) cultured urothelial cells. Moreover, these channels were found to be functional, as stimulation of cultured human urothelial cells with the calcium channel agonist Bay K 8644 (100μM) elicited large intracellular calcium transients, as measured with Fura-2AM. These calcium transients were diminished in the presence of the calcium channel antagonist nifedipine (200μM) and increased in the presence of the calcium-activated potassium channel blocker iberiotoxin (200 nM). Stimulation of cultured human urothelial cells with Bay K 8644 also increased extracellular ATP concentrations by ~25%; and this was blocked by pre-incubation with either nifedipine or the pannexin channel antagonist Brilliant Blue FCF (100μM). Finally, intravesical administration of Bay K 8644 increased reflex bladder activity in the anesthetized rat by almost two-fold, indicating that these channels might play a physiological role in bladder function. These results suggest that urothelial voltage-gated calcium channels participate in the control of micturition and may represent a viable target for the treatment of overactive bladder disorders.

**Title:** Modulation of urothelial pannexin channels by intracellular calcium

**Authors: *L. A. BIRDER**[1], A. M. SILBERFELD[2], W. C. DE GROAT[2], J. M. BECKEL[2]
[1]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [2]Pharmacol. and Chem. Biol., Univ. of Pittsburgh, Pittsburgh, PA

**Abstract:** ATP is an important transmitter in the sensory limb of micturition. Release of ATP from the bladder urothelial cells (UTCs) in response to stretch or chemical stimulation can act on nearby afferent nerves to increase their excitability, leading to increased bladder sensations. As patients that suffer from benign bladder pathology such as overactive bladder (OAB) exhibit increased urinary ATP levels, insight into the mechanisms controlling UTC ATP release is an

important step in understanding the etiology of OAB. We have previously determined that ATP release from UTCs in response to stretch is mediated by pannexin channels, large-pore ion channels, permeable to ATP. However, little is known about the intracellular pathways that modulate pannexin channels in UTCs. In other cell types, pannexin channels can be controlled by membrane depolarization, post-translational modifications and intracellular calcium concentrations $[Ca^{2+}]_i$. Given that many studies have already determined that $[Ca^{2+}]_i$ is an important mediator of UTC ATP release, we first focused on this mechanism. Stimulation of a human urothelial cell line (TRT-HU1) with the α3 nAChR agonist cytisine (200μM), which increases $[Ca^{2+}]_i$, increased extracellular ATP concentrations, as measured by the luciferin/luciferase assay. This release was blocked by the pannexin channel antagonist Brilliant Blue FCF (BB-FCF, 100μM). Increasing intracellular calcium using the ionophore ionomycin (1μM) also increased ATP release, which was also blocked with BB-FCF. Pretreatment of cells with the calcium chelator BAPTA-AM (10μM) also blocked increases in ATP release by cytisine or ionomycin. Conversely, treatment of cells with the α7 nAChR agonist choline (5mM) reduced extracellular ATP concentrations, an effect that was mimicked by application of caffeine (1mM), which releases calcium from intracellular stores. To determine if membrane depolarization modulates pannexin channels, cells were stimulated with high potassium (40mM) or the sodium-potassium pump inhibitor ouabain (1mM). Both agents increased extracellular ATP concentrations and were blocked by BB-FCF. ATP release induced by membrane depolarization was also blocked by BAPTA-AM, indicating that depolarization did not have a direct effect on pannexin channels, but most likely activated a voltage-gated calcium channel present in UTCs. These data suggest that intracellular calcium plays a major role in modulating pannexin channel function in UTCs, with influx of extracellular calcium having an excitatory effect and release of calcium from intracellular stores having an inhibitory effect.

**Title:** Liver-related neurons in the paraventricular nucleus of the hypothalamus are more active in db/db mice

**Authors: *A. ZSOMBOK**, H. GAO, A. J. R. MOLINAS, K. MIYATA, X. QIAO
Dept Physiol, Tulane Univ., New Orleans, LA

**Abstract:** Preautonomic neurons in the paraventricular nucleus (PVN) of the hypothalamus contribute to the regulation of hepatic functions via the autonomic nervous system. Despite the importance of the brain-liver pathway, the cellular properties of liver-related neurons remain to be elucidated. Liver-related PVN neurons were identified with a retrograde trans-neuronal viral tracer. Whole-cell patch-clamp recordings were used to test the hypothesis that liver-related PVN neurons are more excited in the diabetic condition. In db/db mice, the majority of liver-related PVN neurons fired spontaneously; whereas, in lean mice the majority of liver-related PVN neurons were silent. Persistent, tonic inhibition was identified in liver-related PVN neurons. The magnitude of tonic inhibitory control was not different between lean and db/db mice. The transient receptor potential vanilloid type 1 (TRPV1)-dependent regulation of liver-related PVN neurons were also investigated. Capsaicin, a potent TRPV1 agonist increased excitatory neurotransmission in lean mice; whereas, capsaicin did not alter neurotransmission of liver-related PVN neurons in db/db mice. These findings demonstrate plasticity of liver-related PVN neurons in a diabetic mouse model and suggest altered autonomic circuits at the level of the PVN; which can contribute to autonomic dysfunction and dysregulation of neural control of hepatic functions including glucose metabolism.

**Title:** Effect of electroacupuncture at ST36 and CV12 on visceral sensory in gastric nociceptive stimulus

**Authors: *X. WANG**, W. HE, H. SHI, Y. SU, L. HU, X. JING
Inst. of Acupuncture and Moxibustion, CACMS, Beijing, China

**Abstract: Objectives:** The aim of this study was to observe the effect of electroacupuncture (EA) at ST36 and CV12 on c-fos expression and the firing rate of gastric related neurons in the nucleus of solitary tract (NTS) after intragastric administration of acid. **Methods:** 16 rats were randomly divided into four groups: intragastric physiological saline administration group, intragastric acid administration group, EA ST36 and EA CV12 interference groups. C-fos expression was characterized by morphological observation of immunofluorescence and Westen Blot. And 27 rats were randomly divided into three groups: intragastric acid administration

group, EA ST36 group and EA CV12 group. Neuronal spikes of NTS was recorded by electrode before and after intragastric administration of HCl (0.5 mol/L) . **Results:** Intragastric administration of HCl potently induced expression of c-fos in NTS. Electroacupuncture at ST36 and CV12 inhibited this effect, while EA ST36 showed the more obvious inhibitory effect. Intragastric administration of 0.5M/L HCL led to a rapid increase in integral of firing rates of excitatory neurons in the NTS, which was significant at 90 seconds and remained elevated for 45mins. In the time-window from 8 mins to 30 mins after intragastric acid administration, EA at ST36 and CV12 elicited inhibitory effects on excitatory neurons in NTS, and the inhibition rate of EA ST36 was significantly higher than EA CV12. **Discussion/Conclusion:** In conclusion, EA at ST36 and CV12 regulated gastric nociceptive visceral afferent in NTS in gastric nociceptive stimulus. The difference between the two points possibly suggest the different never afferent. The information of EA at ST36 directly contacted with NTS through the vagus visceral afferent, and information of EA at CV12 contacted with NTS through sympathetic splanchnic afferent with spinal dorsal horn.

**Title:** Brain-gut axis: Early-life stress promotes alterations in intestinal permeability and hippocampal 5 HT1A mRNA expression in juvenile rats

**Authors: *J. A. BRAVO**[1], C. ASTUDILLO-GUERRERO[1], J. ESCOBAR-LUNA[1], G. ROSSI-VARGAS[1], C. BARRERA-BUGUEÑO[1], M. GOTTELAND[2], M. JULIO-PIEPER[1]
[1]Pontificia Univ. Catolica de Valparaiso, VALPARAISO, Chile; [2]Dept. de Nutrición, Facultad de Medicina, Univ. de Chile, Santiago, Chile

**Abstract:** Early-life stress, such as maternal separation (MS) in rodents has been used to model stress-related psychiatric disorders and alterations in intestinal function, however most reports focus on the effects seen at adulthood. Here we evaluated the effect of MS (3h/day from post-natal day (PND) 2 to PND12) on colon barrier function in male Sprague-Dawley rats at PND21 and PND35, and compared them to non-separated (NS) controls. Additionally, through in situ hybridization we evaluated topographical changes in hippocampal 5-HT1A mRNA expression, which is as a marker of stress-related psychiatric disorders. Colon permeability to

macromolecules was evaluated through the everted gut sac technique, applying FITC-conjugated 4.4kDa dextran (FD4.4) on the mucosal side, and then measuring fluorescence in the serosal side for up to 3 hours, while transepithelial electrical resistance (TEER) was determined through Ussing chamber studies. There was no difference in permeability to FD4.4 and TEER between MS and NS at PND21. However, at PND35 there was an increase in permeability to FD4.4 in MS rats when compared to NS, while no differences in TEER where found between both groups. Additionally, when MS rats at PND35 were subjected to a 5min swim stress, they showed a blunted corticosterone response in comparison to swim-stressed NS rats. Furthermore, FD4.4 permeability in swim-stressed MS rats was lower than in non-swim stressed MS rats. In addition, hippocampal 5-HT1A mRNA expression was higher in both layers of the dentate gyrus and cornus ammonis 1 of MS rats in comparison to their controls at PND21.
These data show that early-life stress affects gut permeability to macromolecules at PND35, and that this phenomenon is sensitive to corticosterone. Furthermore, and as opposed as what has been reported in adulthood, early-life stress affects hippocampal 5-HT1A mRNA expression in young animals and is observed as early as PND21, suggesting an alteration in the brain-gut axis that might contribute to the development of stress-related psychiatric disorders later in life.

**Title:** State dependent lower urinary tract reflexes

**Authors: *Z. C. DANZIGER**[1], W. M. GRILL[2]
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Duke Univ., Durham, NC

**Abstract:** Fluid flow in the urethra can evoked two opposite reflexes that augment continence and micturition. The guarding reflex generates contraction of the external urethral sphincter (EUS) in response to fluid entering the urethra, while the augmenting reflex mediates contraction of the urinary bladder coupled with the relaxation of the EUS in response to fluid entering the urethra. We quantified how sensory feedback from the bladder and urethra interact to determine which of these two functionally opposite reflexes was activated in response to urethral flow. We

quantified urinary tract reflex responses to controlled urethral flow *in vivo* in urethane anesthetized (1.2 g/kg s.c.) female rats (n=12). We isolated and independently filled the bladder and urethra to test a wide range of combinations of bladder volume (from ~30-~160% of the distention evoked reflex threshold volume) and urethral flow rate (0.1-11ml/min) that represent the typical range of physiological stimuli in rat. We found a distinct bladder volume threshold (approximately 75% of bladder capacity) that determined whether the guarding or augmenting reflex was evoked by urethral flow, suggesting a discrete state-dependent transition between continence and micturition-promoting reflexes. Further, we found that the magnitude of EUS contractions during the guarding reflex was proportional to the urethral flow rate, while the magnitude of the bladder contractions during the augmenting reflex was independent of urethral flow rate. Taken together, this evidence indicates that the urinary tract switches between two separate reflex pathways to support micturition and continence by integration of sensory signals from both the bladder and the urethra. This study provides the first quantitative evaluation of how sensory information generated from flow through the urethra and bladder volume interact to engage the micturition reflex or activate the guarding reflex. Characterization of how interacting sensory signals mediate reflexive bladder control is critical for understanding diseases of the lower urinary tract and to guide the development of new treatments.

**Abstract:** Stress plays a role in exacerbation and possibly development of functional lower urinary tract disorders. Chronic water avoidance stress (WAS) in rats is a model with high construct and face validity to bladder hypersensitive syndromes, such as interstitial cystitis/bladder pain syndrome (IC/BPS), characterized by urinary frequency, bladder hyperalgesia and heightened stress responsiveness. Given the overlap of brain circuits involved

in stress, anxiety, and micturition, we examined the effects chronic stress has on bladder function, as well as its effects on regional brain activation during bladder filling.
Female Wistar-Kyoto rats were exposed to WAS (10 days) or sham paradigms. On day 11, cystometrograms were obtained during titrated bladder dilation, with visceromotor responses (VMR) recorded simultaneously. Cerebral perfusion was assessed during bladder distension (20-cm$H_2O$) following i.v. administration of [$^{14}$C]-iodoantipyrine. Regional cerebral blood flow was quantified by autoradiography and analyzed in 3-D reconstructed brains with statistical parametric mapping.
WAS rats compared to controls showed a decreased pressure threshold and visceromotor threshold triggering the voiding phase. At 20-cm$H_2O$, VMR was significantly greater in WAS animals compared to controls. WAS rats showed greater activation in cortical regions of the central micturition circuit, including the posterior cingulate, anterior retrosplenial, somatosensory, posterior insula, orbital, and anterior secondary (supplementary) motor cortices, as well as in thalamus, hypothalamus, striatum, parabrachial and Barrington nuclei. Seed analysis showed increased functional connectivity of WAS compared to control rats of the posterior cingulate cortex to the pontine parabrachial nucleus; of the Barrington nucleus to anterior dorsal midline and ventrobasilar thalamus and somatosensory and retrosplenial cortices; and of the posterior insula to anterior secondary motor cortex.
Our results show a visceral hypersensitivity during bladder filing in WAS rats, as well as increased engagement of portions of the micturition circuit responsive to urgency, viscerosensory perception and its relay to motor regions coordinating imminent bladder contraction. Results are consistent with findings in humans with IC/BPS, suggesting that WAS may serve as an animal model to elucidate the mechanisms leading to viscerosensitive brain phenotypes in patients. Ongoing work is evaluating the effects of ceftriaxone, a modulator of the glutamate transporter previously reported to diminish hyperalgesia in the WAS model, on functional brain responses of the micturition circuit.

**Title:** Hypothalamic PVN neurons rapidly modify circulating insulin levels

**Authors: *I. PAPAZOGLOU**, Z. CUI, J.-H. LEE, S. G. RANE
NIDDK, Bethesda, MD

**Abstract:** Insulin is secreted from pancreatic ß-cells in response to changes in levels of circulating nutrients and hormones. This process is tightly regulated by the autonomic nervous system that strongly innervates the pancreatic islets. Although the role of intra-islet effects of autonomic nerve terminals is well studied, little is known about the way preautonomic centers in the central nervous system regulate insulin secretion. Retrograde tracing studies using PRV (pseudorabies virus) have shown that the highest density of second order preautonomic neurons for both sympathetic and parasympathetic innervation of pancreas are located within the paraventricular nucleus (PVN) of the hypothalamus. We are using chemogenetics to manipulate the activity of specific neuronal populations in the PVN and monitor changes in circulating insulin levels. We stereotactically inject AAV viruses that induce the expression of DREADDs (Designer Receptor Exclusively Activated by Designer Drugs) in the PVN. These receptors (excitatory or inhibitory) can only be pharmacologically activated by a synthetic ligand injected intraperitoneally. We find that stimulation of Sim1 neurons in the PVN results in a rapid decrease in glucose stimulated insulin secretion (GSIS) which is accompanied by an increase in glucose levels. Notably, stimulation of these neurons also significantly suppresses basal fasting insulin levels. Chemogenetic inhibition of Sim1 neurons, on the other hand, significantly enhances GSIS and reduces glycemia. Further, stimulation of a smaller population of PVN neurons, the oxytocin (OXT) neurons, leads to a rapid improvement of GSIS. To characterize this neuronal network, we are testing the role of autonomic preganglionic neurons downstream of the PVN. To achieve this, we use an AAV-Cre virus than can travel anterogradely from the PVN to the brainstem (parasympathetic neurons) or the spinal cord (sympathetic neurons). A second AAV virus injected locally will induce Cre-dependent expression of DREADDs, so that only neurons that receive projections from the PVN express these receptors. Finally, it is important to know if Sim1 neurons can sense acute changes in blood glucose. To assess that, we are using *in vivo* photometry to monitor the activity of Sim1 neurons in hyper- or hypoglycemic states. Taken together, the findings of this study will lead to a functional characterization of neurocircuits that are implicated in the central regulation of insulin secretion.

**Title:** Comparison of bladder inhibitory effects of patterned spinal nerve stimulation with conventional neuromodulation in the rat

**Authors: *X. SU**, H. A. SIMENSON, K. J. PARALIKAR, H. D. ORSER
Medtronic, Minneapolis, MN

**Abstract:** Electrical stimulation of the sacral spinal nerve has been used in the treatment of patients with increased frequency and urge incontinence. The frequency of continuous, fixed 10 Hz stimulation is optimal in both measures of isovolumetric of “normal” bladder (1) and cystometry of hypersensitive bladder of cystitis (2). The present study compared the effectiveness of patterned frequency of spinal nerve stimulation (SNS) with continuous, fixed-frequency nerve stimulation at motor threshold intensity in an animal model of the bladder reflex contraction (BRC). In anesthetized female rats (urethane, i.p. 1.2g/kg), wire electrodes were placed under each of the L6 spinal nerve to produce bilateral SNS. A cannula was placed into the bladder via the urethra and the urethra was ligated to ensure an isovolumetric bladder. Saline infusion induced BRC. Using motor threshold intensity, continuous stimulation at fixed frequencies of 4 Hz (n=5) and 10 Hz (n=7) decreased the frequency of BRC of 71 ± 24% (mean, SEM) and 85 ± 18% of controls, respectively (v.s. no stimulation, n=10, $p<0.05$, two-way ANOVA). Fixed-frequency stimulation at 0.01, 0.1, 1, 40, and 100 Hz did not demonstrate a trend change on BRC. When stimulation frequency is delivered with a 4-6 pulse/burst pattern in every 1-100 seconds, neuromodulation has demonstrated a trend towards effectiveness, with a four-pulse burst stimulation (interburst 1 Hz and intraburst 40 Hz or 4 pulses of 40 Hz per second) showing the most difference, reducing the BRC frequency of 74 ± 8% of control, n=8, $p<0.05$, two-way ANOVA). However, it is not more effective than continuous neuromodulation at a fixed frequency of 4 Hz or 10 Hz at BRC inhibition. Secondary to efficacy, saving energy is an important factor to increasing a device's lifespan. We report that burst stimulation is not more effective than continuous neuromodulation and does not offer an energy saving benefit. Without further knowledge regarding mechanisms and potential benefit of burst stimulation on bladder control in patients with neuropathological conditions, applications should utilize continuous fixed 10 Hz stimulation for maximal clinical outcomes.

**Title:** Effect on pelvic floor muscles activity, simulating changes during multiparity

**Authors: *R. LOPEZ JUAREZ**[1], R. ZEMPOALTECA[1], D. CORONA[1], F. CASTELAN[1,2], M. MARTINEZ-GOMEZ[2]
[1]Ctr. Tlaxcala Biologia de la Conducta, Univ. Autonoma De Tlaxcala, Tlaxcala, Mexico; [2]Inst. de Investigaciones Biomédicas, Univ. Nacional Autónoma México, México-DF, UNAM, Mexico, Mexico

**Abstract:** In women, pelvic floor dysfunctions are a major public health issue because their high prevalence and negative impact on quality of life. One of the main functions were affected is the urinary. We reported that blocking the activity of perineal muscle bulbospongiosus (Bsm), ischiocavernosus (Iscm) and pelvic muscle as the pubococcygeus (Pcm) causes changes in micturition. In multiparous young rabbits we have shown that the histological arrangement of the genitourinary apparatus is modified. Other changes include urodynamic function, contractile force and morphometry of the pelvic floor muscles and paravaginal pelvic plexus. Possibly, during passage of the fetus by vagina the nerves would suffer damage and cause urinary and sexually dysfunctions. Virgin and multiparous female chinchilla rabbits (10 to 12 months old) were used in the study. Cystometrograms were recorded simultaneously with electromyograms, before and after crushing of Bsm or Pcm nerves were evaluated. After the crushing of the Bsm nerve, the urodynamic parameters showed a decrease in voiding volume, maximum pressure and bladder efficiency ($P<0.001$) and increase in residual volume. When the Pcm nerve was crushing, the voiding volume, interval between contractions, threshold pressure, maximum pressure and bladder efficiency decreased ($P<0.001$) and the residual volume increased ($P<0.001$). In multiparas, voiding volume, interval between contractions, threshold pressure, maximum pressure and bladder efficiency decreased ($P<0.001$) and the threshold volume and residual volume increased ($P<0.001$). Electromyographic records show Bsm activity during the voiding phase and the Pcm during urine storage. The activity of the Pcm and Bsm after crushing the electrical activity were decreased and disorganized. Crushing modify the bladder function by

reducing bladder efficiency due to the increase in residual volume. Crushing to the nerve of the Bsm or Pcm seems to simulate some of the alterations produced in the multiparity model.

**Title:** NPY/PYY receptor activation in the dorsal vagal complex increases food intake and attenuates satiation

**Authors: *R. C. RITTER**, N. HUSTON, L. BRENNER
Dept. of Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

**Abstract:** Although fourth ventricle or parabrachial injections of NPY/PYY receptor agonists are reported to increase food intake, it is not known whether selective activation of NPY/PYY receptors in the dorsal vagal complex (DVC) contributes to control of food intake. To investigate this possibility, we first used fluorescence in situ hybridization to survey the prevalence of NPY/PYY receptor subtypes, Y1R, Y2R and Y5R, in vagal afferent neurons, and in the DVC, including the nucleus tractus solitarius (NTS). Many vagal afferent neurons in the nodose ganglia expressed Y1R and/or Y2R mRNA. Y2R mRNA often was co-expressed with mRNA coding for CCK-A receptor. Y1R, Y2R and Y5R expressing neurons were rare or not detectable in the NTS. These observations confirm the presence of Y1R and Y2R in the DVC, where previous immunohistochemical observations suggested their expression on vagal afferent endings, and also on some NTS neurons. To determine the effects of DVC Y2R activation on food intake and satiation, we implanted rats with cannulas aimed for the left or right DVC, and measured 4h food intake following NTS injection of a selective Y2R agonist, PYY 3-36 (100 ng/100nl), during the morning, beginning 2h after lights-on. In another group of rats we examined the effect of NTS PYY 3-36 (200 ng) injection on reduction of food intake following intraperitoneal (IP) injection of CCK (3 μg/kg) in rats following an overnight 15hr fast. To verify cannula placements and patency, we injected 100 nl biotintylated dextran (BDA) via the DVC cannulas, just before collecting brains for histology. Incubation of brain sections with Alexa 488 IB4 and Alexa 555 avidin revealed NTS vagal afferent terminals and the spread of BDA injections respectively. Only rats with cannula tips located in the DVC, and BDA infiltrating the NTS, as delineated by IB4 labeling, were accepted as valid placements. We found that DVC injection of PYY 3-36

(100 ng) significantly increased food intake over 4h in sated rats with verified NTS placements (N= 9). Rats with placements in which BDA injection did not infiltrate the NTS did not significantly increase their intake. Co-injection of Y2R antagonist into the NTS together with PYY 3-36, attenuated increased food intake (N=6). Finally, NTS injection of PYY 3-36 significantly attenuated or abolished reduction of food intake by IP CCK (N=10). These results indicate that selective activation of YR within the DVC increases food intake and attenuates CCK-induced satiation. Furthermore, our results are consistent with the hypothesis that Y2R located on central vagal afferent endings mediate increased food intake and reduced satiation following hindbrain PYY 3-36 injections.

**Title:** Anorexigenic effect of alpha-melanocyte stimulating hormone in nucleus accumbens is mediated by frontal cortex throtropin-releasing hormone and dopamine pathways in rats

**Authors: *E. ALVAREZ**[1], F. GAMA[2,3], P. DE GORTARI[2]
[1]Neurociencias, Inst. Nacional De Psiquiatria, Mexico City, Mexico; [2]Inst. Nacional de Psiquiatria, Mexico City, Mexico; [3]Escuela de Dietetica y Nutricion del ISSSTE, Mexico City, Mexico

**Abstract:** A wide array of neuropeptides and peripheral molecules act in the central nervous system to control food intake. Apart from the homeostatic aspects of food intake, hedonic regulation is crucial in modern societies where palatable food is readily available. Hypothalamus is considered as the regulator of the homeostatic aspect of feeding, while the mesolimbic system (containing the nucleus accumbens [NAcc]) is involved in the control of the hedonic aspects of this behavior via dopamine (DA)ergic signaling. Neuropeptides from the hypothalamic arcuate nucleus, including α-melanocyte stimulating hormone (α-MSH), are some of the most potent modulators of food intake. α-MSH acting in the paraventricular hypothalamic nucleus (PVN) enhances the expression of another anorexigenic neuropeptide, thyrotropin releasing hormone (TRH). α-MSH administration into the NAcc reduces food intake motivation and induces DA release. NAcc has projections to the prefrontal cortex (PFC) a region which by DA signaling is related to decision-making and food seeking behavior. PFC expresses high densities of DA containing terminals, and DA activity in this region is enhanced during feeding after food

deprivation. Since α-MSH directly modulates TRH expression in the PVN and TRH is also expressed in the Nacc, we were interested in analyzing if α-MSH actions when injected intra-NAcc, are mediated through TRHergic neurotransmission and the role of the PFC DAergic signaling as the possible ultimate target. Male rats were fasted for 48h and injected with α-MSH directly into the Nacc before refeeding. Animals showed a significant decrease in food intake after refeeding and an enhanced expression of TRH in the Nacc. Moreover, DA receptor 2 (D2R) expression was increased in the PFC after α-MSH injection in the NAcc. PFC administration of an antisense oligo directed against TRH-receptor type 2 (TRH-R2), but not to the receptor type 1, was able to reverse both the decrease in food intake and the increase in D2R expression in the PFC induced by α-MSH. In conclusion, α-MSH administration into the NAcc activated TRHergic neurons in this nucleus, which by their afferents to the PFC, and by acting through its TRH-R2 receptors; mediated the anorexigenic effects of α-MSH. Moreover, it is possible that changes in DA signaling in the PFC are also involved in this effects of α-MSH mediated by TRH. This implicates TRH not only as a modulator of energy homeostasis but in regulation of hedonic feeding.

**Title:** Neuropeptide Y modulates discrete elements of prey capture via receptors in the optic tectum

**Authors: *J. A. CARR**[1], R. ISLAM[1], B. N. HARRIS[2]
[2]Biol. Sci., [1]Texas Tech. Univ., Lubbock, TX

**Abstract:** The optic tectum (in non-mammalian vertebrates) and superior colliculus (in mammals) rapidly inhibit food intake when a visual threat is present. Previous anatomical and electrophysiologial evidence in toads (Bufo sp.) suggest that neuropeptide Y (NPY), originating from cells in the thalamus, may play a role in the inhibition of tectally mediated prey capture. Here, we ask the question, do tectal NPY receptors modulate food intake in juvenile *Xenopus laevis*? Specifically, we asked 1) does the anuran tectum possess Y2 receptors? 2) does tectal NPY administration alter prey-capture behavior? 3) does tectal NPY administration decrease food intake? Using immunohistochemical and immunoblotting approaches we found that the tectum of *X. laevis* is richly innervated with Y2 receptor-immunoreactive axons and terminal fields. To determine whether NPY acts on tectal receptors to alter prey capture behavior and food intake, we administered various doses of porcine NPY (0, 1.5, 15, 150 ng) bilaterally into the

tecta of juvenile frogs. Frogs were then subjected to a prey capture behavioral assay and behavior was video recorded and analyzed using JWatcher. NPY injected via the tecta failed to significantly reduce food intake at any dose tested. However, NPY differentially altered discrete components of prey capture behavior. The largest dose of NPY (150 ng) increased the latency to contact food, and reduced the amount of time in contact with food and the number of mouth wipes. NPY did not significantly alter arm sweeps or time spent exploring or moving. We conclude that NPY acts in a dose dependent fashion on receptors in the tectum to slow the approach toward potential prey and accelerate food consumption when food is contacted. Whether these behaviors facilitate predator avoidance while feeding will require further testing. This work was done in partial completion of requirements for the Master's degree at Texas Tech University (R.I.)

**Title:** Requirement of MRAP2 for ghrelin-mediated hunger sensing

**Authors: *T. YIN**[1], D. SRISAI[3], A. LEE[1], A. ROUAULT[1], J. A. SEBAG[2]
[2]Mol. Physiol. and Biophysics, [1]Univ. of Iowa, Iowa City, IA; [3]molecular physiology and biophysics, Univ. of Iowa / F.O.E.D.R.C., Iowa City, IA

**Abstract:** Ghrelin is the only known circulating orexigenic hormone. It is primarily secreted by the stomach and acts at its receptor, GHSR1a, in the hypothalamus to signal hunger and promote food intake. For this reasons, the modulation of ghrelin signaling is a promising strategy for the treatment of obesity, anorexia, cachexia and diabetic gastroparesis. In this study we identify the melanocortin receptor accessory protein 2 (MRAP2) as a critical new partner of GHSR1a. We show that MRAP2 interacts with GHSR1a and strongly potentiates ghrelin-stimulated signaling both *in-vitro* and *in-vivo*. Additionally, we show that the orexigenic effect of ghrelin is lost in *Mrap2* KO mice. Finally, we demonstrate that, in the absence of MRAP2, fasting fails to activate AGRP neurons. Our results suggest that MRAP2 is an important modulator of the energy homeostasis machinery that operates through the regulation of multiple GPCRs throughout the hypothalamus.

**Title:** The effect of methadone in the consumption of a high carbohydrate diet at weaning and its repercussion on the intake of hypercaloric diet in adult male rats

**Authors: *J. A. MATA-LUÉVANOS**[1], J. JUAREZ[2]
[1]Lab. de Farmacología y Conducta, Inst. De Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. Guadalajara, Guadalajara, Jalisco, Mexico

**Abstract:** Overweight and obesity have become a health issue, which, in most cases is due to high intake of palatable food. This palatability is mostly based on the caloric density, making hypercaloric food the most preferred. High consumption of hypercaloric food, often high in carbohydrates (carbs), may produce aberrant patterns of eating, among other problems. There is evidence that infancy may be a critical period for the exposure to food with high content of carbs and fat, which in turn may have an important impact on the choice of food and eating patterns on later life. Maturation of some neurotransmission systems at this age and the implication of opioids in the hedonic salience of stimuli, suggest that alterations of this pathway may play an important role in the salience of alimentary stimuli. On this basis, the effects of methadone (opioide agonist) administration (MA) on the consumption of high-carbs food during pre-adolescence and its repercussion on the consumption of a hypercaloric food in adulthood were studied. Four groups of male Wistar rats were exposed to different pharmacologic treatment on infancy during 18 days, starting at 23 postnatal day (PND), which was associated to the exposure to a food rich in carbs (CHO); at 75 PND, as adults, all groups received a hypercaloric diet (HCD, rich in carbs and fat) during 4 weeks. Food intake and body weight were registered. Groups: METCHO: MA prior CHO presentation. CHOMET: MA after CHO presentation. VEHCHO: Vehicle Administration (VA) prior CHO presentation. CHOVEH: VA after CHO presentation. Base line (BL) of only standard food was measured at 70-75 PND; post-treatment (PT) assessment with only standard food at 103-108, and all animals were re-exposed (RE) to the HCD at 108-113. Group CHOMET showed the highest consumption of CHO diet in preadolescence; however, there were not group differences in the body weight. Higher consumption of HCD diet was observed in CHOMET during adulthood, but interaction (groups X weeks) indicated that differences were significant respect of METCHO and VEHCHO in week 2. After the four weeks under HCD exposure, all groups showed a decrease in standard food

consumption in PT period, which was significantly lower than intake in BL. In the period of HCD exposure, CHOMET gained more weight than VEHCHO and METCHO in week 2 and only than VEHCHO in week 1. Body weight gain was significantly lower in PT than in BL regardless of group. Results support that opioid system plays an important role in the consummatory phase of the alimentary behavior, and that preadolescence is a critical period for feeding behavior.

**Abstract:** The average western diet is too high in calories, leading to obesity, type II diabetes, and other health complications. Behavioral and neurobiological interventions have had some success at reducing food intake, but often have side effects or lack efficacy. One supported approach is modulating plasma tryptophan (trp) levels, which is related to brain serotonin. Many factors influence trp regulation, most importantly diet and exercise, but growing evidence supports a role for the gut microbiome in influencing host metabolism, and even contributing to amino acid homeostasis. Our research seeks to understand whether a prebiotic supplement of resistant starch (RS), which has a demonstrated ability to affect gut bacteria, can alter gut bacterial trp production and ultimately diet.
Healthy men and women were recruited for these studies. Prior to the first visit, subjects provided a fecal sample, 4-day diet log, and were given an acute dose of RS. Hunger and craving were assessed using a visual analog scale. The initial visit was followed by a four week daily RS supplementation and a second visit. We evaluated mRNA expression for one trp producing gene (TrpB of the trp operon) and one trp degrading gene (TnaA, tryptophanase), in a highly abundant species in the human gut, *Bacteroides ovatus*. With a limited sample size (n=5), we observed an inverse relationship between the pre/post supplement changes in TrpB and TnaA. The inverse

relationship between TrpB and TnaA expression supports the hypothesis that these genes are subject to similar regulatory forces influenced by dietary patterns. Following 4-weeks of RS-supplementation, hunger was correlated with decreased TrpB and increased TnaA expression. This is consistent with the hypothesis that aspects of food intake can be influenced by alterations in gut-microbe mediated trp availability to the host. This work begins to address the potential role of the gut microbiome on neurotransmitter substrate availability and host behavior.

**Abstract:** The majority of research investigating the neural control of food intake has focused on homeostatic and hedonic mechanisms, with relatively few studies examining the contributions of brain regions traditionally associated with cognition. Increasing evidence, including our own, strongly indicates that dorsal (dHC) and ventral (vHC) hippocampal neurons, which are critical for memory, also regulate ingestive behavior. Memory can be a powerful mechanism for influencing eating behavior because it provides a record of recent energy intake that can outlast most physiological signals. We demonstrated previously that muscimol-induced inactivation of dHC or vHC neurons after the end of a sucrose meal, when the memory of the meal would be consolidated, accelerates the onset of the next meal and increases intake during the following meal. Centrally infused muscimol, however, inhibits neural activity for several hours and can affect all cells expressing GABAA receptors. If dHC and vHC neurons control intake through a process that involves memory, then optogenetic inhibition of principal dHC or vHC

glutamatergic neurons restricted to the period immediately following a meal should promote meal initiation and increase intake. In the present experiment, male Sprague-Dawley rats were stereotactically injected with AAV-CaMKIIα-eArchT3.0-eYFP or a control vector (AAV-CaMKIIα-GFP) into dHC or vHC and a fiber optic probe was implanted above the AAV infusion site. Our results indicate that optical inhibition of dHC or vHC glutamatergic neurons for 10 min after a sucrose or chow meal decreases the latency to eat again and increases intake during the next meal when the neurons are no longer inhibited. These results support the hypothesis that dHC and vHC glutamatergic neurons, which are essential for memory, are also critical for regulating energy intake during the postprandial period.

**Abstract:** Hunger, driven by negative energy balance, elicits the search for and consumption of food. These effects are elicited through changes in the natural activity patterns of neurons in the hypothalamus and elsewhere. We have recently identified two populations of neurons within the brainstem's dorsal raphe nucleus (DRN), expressing vesicular transporters for either GABA or glutamate (hereafter, DRN Vgat or DRN VGLUT3 neurons, respectively), that are responsive to physiologic stimuli encoding hunger- and satiety-related states. Furthermore, these two populations can potently and reciprocally regulate food intake and related behaviors, over both acute and prolonged timescales. Local and global connectivity mapping suggests multiple

mechanisms through which these neurons may alter feeding and related behaviors. This work demonstrates the cell type-specific mechanism through which the DRN regulates feeding.

**Abstract:** Obesity is a serious illness affecting more than one-third of the adult population, and alarmingly, more than 17% of children in the USA. Obesity is associated with high mortality and increased risk of developing other medical conditions, such as diabetes. To fight obesity, the gain of knowledge on how neural circuits control feeding is vital. There are about two decades of evidence suggesting that the hippocampus, an important brain region associated with episodic memory, may control feeding. However, the mechanism by which hippocampal neurons modulate feeding and its underlying circuit remains unclear. We reasoned that the hippocampus must respond to food in a similar manner as time cells and place cells are activated by temporal or spatial changes respectively. We believe that visual, gustatory or odorant appetitive cues may be able to activate specific hippocampal cells in order to create a food engram and thus, communicate with existing feeding circuits. Thus, the molecular identification of a specific ensemble that fires in response to food or eating would enable us to perform a functional analysis of the high-order circuit that modulates energy intake by the hippocampus. Here, we report the unbiased description of a molecularly defined neuronal population within the hippocampus that expresses dopamine 2 receptor (D2R) and that is activated by appetitive cues and energy states. The selective inhibition or activation of D2R neurons using chemogenetics is sufficient to induce changes in food intake. Moreover, projection-specific manipulations of these neuronal connections using optogenetics reveal a novel extrahippocampal circuitry that project to the

septal and cholinergic basal forebrain and control feeding behavior. These findings describe a previously unidentified role for hilar mossy cells within the hippocampus and shed light on how food cues can suppress feeding through activating a specific hilar mossy cells to septal cells circuitry.

**Title:** Elucidating metabolic and molecular mechanisms by which intermittent fasting enhances endurance and brain function in mice

**Authors: *K. MOEHL**, K. MAROSI, M. P. MATTSON
Natl. Inst. On Aging, Baltimore, MD

**Abstract:** Evolutionary considerations suggest that the brain and body have been optimized to perform well/optimally in the fasted state (*Ageing Res Rev.* 2015; 20:37-45). Sports physiologists and endurance athletes are currently investigating nutritional ketosis as a potential method for attenuating the decrease in physiological performance associated with the decline in endogenous carbohydrate stores. The increase in lipid oxidation associated with the metabolic switch to a ketogenic state has been shown to have beneficial effects on the brain as well as muscles. Because fasting is the most potent physiological stimulus for ketosis, we designed a study to determine the impact of intermittent fasting during endurance training on performance, and to elucidate the underlying cellular and molecular mechanisms. C57BL/6 male mice were randomly assigned to either *ad libitum* feeding or alternate day fasting (ADF) groups, and half of the mice in each diet group were trained daily on a treadmill for 1 month (45 minutes of running with increasing speed or incline each week). A run to exhaustion endurance test performed at the end of the training period revealed superior performance in the mice maintained on ADF during training compared to mice fed *ad libitum* during training. Mice in the ADF-running group displayed a lower respiratory exchange ratio throughout the $VO_2$ max test, improved glucose homeostasis, and elevated ketone levels. These findings, supported by the literature, suggest that the increased contribution of lipid and ketone bodies oxidation to energy provision during exercise may be beneficial for endurance running performance. The potential benefits of exercise in a ketogenic state on a range of brain functions (cognition, anxiety, motor skills) are currently being investigated. Analyses of gene expression in cerebral cortex, hippocampus, liver, and soleus tissues, and metabolomics analysis of blood suggest that the metabolic switch invoked by

intermittent fasting and exercise modulates a wide range of molecular pathways including those regulating mitochondrial biogenesis, autophagy and cellular plasticity. Supported by the NIA Intramural Research Program.

**Title:** Transcriptional profiling of lateral hypothalamic cell types following obesity at cellular resolution

**Authors: *M. L. BASIRI**[1], M. A. ROSSI[1], G. D. STUBER[2]
[2]Psychiatry, [1]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

**Abstract:** The lateral hypothalamic area (LHA) mediates a broad range of motivated behaviors. In particular, historical and contemporary work has described the LHA as an essential substrate in the regulation of feeding behavior and caloric intake. To mediate its diverse functional tasks, the LHA exhibits broad molecular heterogeneity, with intermingled LHA cell types employing distinct neurotransmitter and neuropeptide systems. Although recent work has broadly described the functional involvement of inhibitory and excitatory LHA circuits in feeding behavior, the specific cell types underlying discrete LHA behavioral functions remains relatively unknown, and whether LHA molecular representations are sculpted by chronic caloric excess has not been explored. Here, we perform massively-parallel single-cell RNA sequencing across 20,194 LHA cells to characterize LHA transcriptional diversity following ad libitum access to a high-fat diet versus a taste-matched control. By comparing transcriptional profiles across cells, we identify discrete LHA neuronal and glial cell types, and identify novel potential markers for distinct LHA neurocircuit activities. Furthermore, we describe global diet-induced LHA molecular reprogramming and identify putative molecular pathways underlying behavioral changes during obesity. This work provides a molecular foundation to explore how transcriptional definitions

may inform circuit dynamics and behavioral output in complex neuronal tissue, as well as how these definitions may be altered in response to divergent systemic conditions.

**Title:** Activity of glutamatergic neurons in lateral hypothalamus is suppressed by obesity

**Authors: *M. A. ROSSI**, M. L. BASIRI, J. M. OTIS, H. VAN DEN MUNKHOF, J. A. MCHENRY, O. KOSYK, W. GUO, G. D. STUBER
Univ. of North Carolina-Chapel Hill, Chapel Hill, NC

**Abstract:** The lateral hypothalamic area (LHA) is a molecularly and functionally heterogeneous region that is critical for motivated behaviors. Glutamatergic neurons within the LHA are known to influence feeding and reward phenotypes; acute activation of LHA glutamatergic neurons suppresses feeding, while ablation facilitates intake of calorically dense foods and weight gain. Given the established role of these neurons in feeding, we sought to determine whether the activity profiles of LHA glutamatergic neurons reflect satiety state and how this activity changes during the onset of obesity. Using *in vivo* deep brain two-photon calcium imaging in awake, behaving mice, we found that LHA glutamatergic neurons exhibit relative suppression of activity during consumption of a sucrose solution when mice are fasted compared to when they are fed. We then induced obesity via unrestricted access to a calorically dense high fat diet for 12 weeks in a randomly chosen subset of mice while the remaining mice were maintained on unrestricted access to a taste-matched control diet. We found that glutamatergic activity during sucrose consumption was suppressed following chronic exposure to high fat diet and that the depressed activity preceded dramatic weight gain. Using *ex vivo* electrophysiology, we confirmed that LHA glutamatergic neurons were less excitable following chronic high fat diet exposure. These data support a role for lateral hypothalamic glutamatergic neurons as a negative regulator of feeding.

Elevated activity of lateral hypothalamic glutamate cells is associated with a reduction in food intake, while increased caloric intake is associated with reduced neuronal activity.

**Title:** Transiently opening the blood-brain-barrier in the diagonal band of Broca using MR-guided focused ultrasound results in short-term reductions in weight gain

**Authors: *S. MOONEY**[1], K. HYNYNEN[2]
[1]Sunnybrook Res. Inst., Toronto, ON, Canada; [2]Med. Biophysics, Univ. of Toronto/ Sunnybrook Res. Inst., Toronto, ON, Canada

**Abstract:** The diagonal band of Broca is a promising target for manipulating food intake and weight gain in rodents. Here, we used MR-guided focused ultrasound to manipulate this basal forebrain structure. Rats were treated with ultrasound to either transiently open the blood-brain-barrier or to cause minor edema in the area. Food intake and weight gain were then recorded for 5 weeks following treatment. Blood-brain-barrier disruption resulted in a decrease in weight gain 1 week after the treatment. This was true of young animals that gained large amounts of weight during the beginning of this experiment and of older animals that had reached a lower rate of weight gain. No effects were seen in food intake or activity levels. These results suggest that ultrasound-mediated disruption of the blood-brain-barrier results in a short-term decrease in weight gain persisting up to 1 week.

**Abstract:** Ghrelin is an appetitive hormone mainly produced by endocrine cells in the stomach. Ghrelin has been implicated in appetite, metabolism, stress, and more recently, in drug seeking. The growth hormone secretagogue receptor (GHSR) is the endogenous receptor for ghrelin, and it is expressed widely throughout the central nervous system and the periphery. The development of transgenic models would allow us to study the functional role of ghrelin signaling in physiology and behavior, which includes a role in homeostatic control of energy intake and obesity, and potentially, drug dependence. We sought to generate a novel GHSR knockout (KO) rat line through CRISPR/Cas9 mutation of the GHSR gene in a Wistar background. Using RNAscope, we confirmed the absence of GHSR expression in brain tissue. We also observed that GHSR-KO rats ate and weighed significantly less than wildtype (WT) rats. There were no group differences in locomotion, which suggests that the reduced body weight in GHSR-KO rats was a direct consequence of decreased food intake. Finally, GHSR-KO animals, compared to their WT littermates, were insensitive to food-intake promoting effects of a challenge dose of ghrelin. Together, the data suggest the successful development of a novel GHSR-KO rat that exhibits several features expected to result from GHSR knockout. This novel GHSR-KO rat model constitutes a useful tool for investigating the specific role of ghrelin signaling in physiology and behavior, which will be particularly important for defining the role of ghrelin signaling in addiction.

**Abstract:** *Pleurobranchaea californica* is a powerful neuroethology model allowing us to assess fundamental links between gene expression, network excitability, and behavioral arousal all with single-neuron resolution. We sequenced identifiable single-neurons, whole CNS and 12 peripheral tissues to create an encompassing *Pleurobranchaea* hybrid reference transcriptome. *Pleurobranchaea* has distinctive food-seeking and avoidance behaviors dependent on its hunger state. These behaviors are controlled by the feeding network and partially modulated by a bilateral pair of giant serotoninergic metacerebral interneurons (MCCs). Analysis of indole metabolites in these MCCs has previously shown that satiated animals have reduced levels of serotonin (5-HT) and its metabolite 5-HT-$SO_4$ (but not of its precursor tryptophan or the metabolite 5-hydroxyindole acetic acid) 24 hrs post-feeding, compared to unfed controls. We collected extracellular recordings from the cerebral-buccal-connectives from *Pleurobranchaea* 24 hours post-feeding or unfed (n=6 per group) and found a decrease in spike frequency in satiated animals. Together the data suggest a reduction in synthesis and possibly in release of serotonin in satiated MCCs and also reduced firing activity of the MCCs. We investigated whether changes in RNA expression contribute to this phenotype by comparing single-neuron MCC transcriptomes from hungry and satiated animals (n=6 per group). RNA-seq data were mapped against the hybrid *Pleurobranchaea* transcriptome assembly. Normalized RNA expression levels in transcripts per million (TPM), and differential transcript expression were calculated using RSEM and DESEQ2. Preliminary data showed many differentially expressed genes. Satiated MCCs showed increased expression of the inhibitory neuropeptide PRQFVamide. Though previously implicated in feeding networks of *Aplysia californica*, PRQFVamide has not been shown to be expressed in MCCs before. Expression patterns of PRQFVamide were confirmed via *in situ* hybridization in satiated and hungry *P. californica* CNSs and in satiated *A. californica*. MRNA-binding proteins associated with sequestering and promoting translation of transcripts were upregulated in satiation and hungry animals respectively. These mRNA binding proteins could contribute to the changes in serotonin synthesis and release observed in *P. californica*. These finding suggests a potential new mechanism of post-transcriptional regulation of serotonin expression and a new role for an identified feeding network neuropeptide.Funding: NSF

**Abstract:** Vasoactive intestinal peptide (VIP) acts as an anorectic signal that inhibits food intake. VIP microinfusion in the paraventricular nucleus of the hypothalamus promotes plasma increase on the concentrations of glucose, free fatty acids, and corticosterone. The aim of this study was to evaluate the effects of VIP on the activation of neurons in the paraventricular nucleus of hypothalamus (PVN), and the effects of pretreatment with corticotrophin releasing hormone (CRH) receptor antagonist type 1, antalarmin (ANT), and type 2, antisauvagine (AS30), on food intake in response to intracerebroventricular (ICV) administration of VIP. Male Wistar rats (250-280 g) with 16h fasting received ICV microinjection (lateral ventricle, by stereotaxy, Paxinos and Watson) of AS30 (5 μg in 5 μL), ANT (0.25 μg in 5 μL) or vehicle, and after 15 minutes animals received VIP (40 ng/g in 6 μL) or saline (0.9% in 6 μL). After 15 minutes animals were fed and the amount of food intake was determined for 120 minutes. In another set of experiments, the animals received only VIP or saline ICV microinjection and after 90 minutes were intracardially perfused for Fos-related antigen (FRA) immunolabeling. In both protocols, cannula placement was histologically evaluated (CEUA No. 4929201580). Data were statistically analyzed by ANOVA two-way, followed by Student Newman-Keuls test (SNK) and T-test in results with normal distribution and homogeneity of variance, and significance level of $p<0.05$. VIP microinjection increased ($p<0.05$) the number of FRA-immunoreactive neurons in medial, ventral, and posterior parvocellular subdivisions of the PVN. As expected, VIP microinjection reduced ($p<0.05$) food intake in vehicle pretreated animals, but there was no effect on ANT pretreated group, which showed higher food intake than vehicle-VIP animals. In AS30 pretreated group, VIP microinjection reduced food intake, but this value was also higher than vehicle-VIP animals. These data indicate that central microinjection of VIP is able to activate parvocellular PVN neurons, in subdivisions with high expression of CRH neurons. Moreover, pretreatment with ANT reversed and AS30 partially reversed the reduction of food

intake induced by VIP, suggesting that VIP-induced hypophagia involves the activation of CRH neurons in the PVN, and thus both CRH-1 and CRH-2 receptors act as mediators of the central effects of VIP on energy homeostasis.

**Title:** Divergent effects of high fat diet on intrinsic and synaptic excitability in AgRP neurons

**Authors: *W. WEI**, C. KACZOROWSKI, K. M. S. O'CONNELL
Res., The Jackson Lab., Bar Harbor, ME

**Abstract:** In the arcuate nucleus of the hypothalamus (ARH), neurons co-expressing the neuropeptides agouti-related peptide (AgRP) and neuropeptide Y (NPY) are essential for driving food intake. Consistent with their role in regulating energy balance, their activity is tightly correlated with an animal's nutritional status, as increased activity is associated with food deprivation and decreased activity associated with satiety. AgRP neurons are modulated both by peripheral signals such as leptin and ghrelin as well as by synaptic inputs from glutamatergic and GABAergic circuits originating from other CNS regions. Our lab has recently demonstrated that AgRP neuronal excitability is sensitive to diet and body weight, implicating diet-induced plasticity of AgRP neurons as a causal factor in the development and maintenance of obesity. In this study, we found that the high-fat diet (HFD)-induced increase in AgRP neuronal excitability is persistent and does not reverse, regardless of the duration of HFD feeding, even after returning the mice to a low-fat diet for 2 months, suggesting that HFD induces a persistent remodeling of neuronal excitability, possibly including synaptic inputs. We hypothesized that HFD may induce an increase in excitatory synaptic input, with a concomitant decrease in inhibitory input, contributing to the overall increase in excitability in AgRP neurons following HFD. However, changes in synaptic activity did not mirror the change of the intrinsic firing rate. While fasting was associated with an increase in the frequency of excitatory postsynaptic currents (EPSCs) as expected, to our surprise, chronic HFD feeding had no significant impact on EPSC frequency.

Further, we observed no significant effect of fasting on the inhibitory postsynaptic current (IPSC) frequency, while HFD was associated with a significant increase in the frequency of IPSCs in AgRP neurons. Thus, HFD consumption may result in a failure of postsynaptic AgRP neurons to efficiently integrate incoming synaptic information and/or induce plasticity in the postsynaptic properties that determine excitability.

**Abstract:** Over the decades in the United States, obesity has increased rapidly due to a decrease in nutritional benefits in food replaced by an increase in high fat and artificial glucose content, enabling many individuals to make poor diet choices. Similar to drug addictions, consumption of a high fat diet enables individuals to develop a dependency on the diet and undergo withdrawal effects like anxiety and overeating when a diet replacement occurs. This study focuses on whether change of diet can produce long term alterations to explorative and anxiety-like behaviors in male C57BL/6J mice. Mice were housed in a standard caging in a 12:12 light/dark cycle, with access to either a 60% high fat diet (high fat continuous HFC) or regular chow (RC) ad libitum. After six weeks on the high fat diet, all mice were subjected to the open field for five minutes and the light:dark box assay for ten minutes each to assess explorative and anxiety-like behaviors. Afterwards, one half of the mice fed high fat diet were switched to regular chow (high fat diet replacement HFR) for 3 weeks. After 3 weeks, mice were subjected to the same behavioral tests to assess possible long term changes to behavior - either a recovery of behavior to controls or possible long term withdrawal effects. Prior to the food switch, no differences were found amongst all the groups for the open field, but mice fed high fat diet (HFC and HFR) did exhibit reduced number of transitions within the light:dark box. After the food switch, HFC had reduced velocity, distance and rears than the high fat replacement group and regular chow controls, indicating decreased explorative behaviors in mice continuously fed a high fat diet. Mice continuously consuming high fat diet spent more time within the dark zone compared to mice with high fat diet replaced or regular chow controls, indicating increased anxiety in mice

fed high fat diets. In summary, mice continuously fed high fat diets exhibited increased anxiety and decreased explorative behaviors compared to regular chow controls and mice with high fat diet replaced with healthy chow. These results indicates that replacing a high fat diet with a lower caloric diet can produce a rebound effect which suggests that the behavioral deficits caused by high fat diet can be avoided by switching to a healthy diet.

**Abstract:** Despite obesity have multifactorial causes, recurrent over-consumption of energy-dense foods is a common feature of these patients. Energy-dense diets are usually highly palatable and activate the brain reward circuit, promoting over-consumption of food. It is generally accepted that endocannabinoid system plays a key role in the regulation of energy homeostasis and food intake regulation, and activation of CB1 receptors in the NAcS consistently stimulate food intake. However, recent reports have provided evidence implicating brain CB2 receptors in modulating a CNS functions. For instance, activation of brain CB2 receptors in mice inhibited both the behavioral and neurochemical effects of cocaine, suggesting that CB2 receptors functionally modulate the mesolimbic DA system and DA-related functions. Accordingly, we propose the hypothesis that the activation of cannabinoid CB2 receptors in the in the NAcS affect the processing of hedonic properties of palatable food. Thus, the aim of this study was to evaluate the effect of administration of the selective CB2 receptor agonist, GW-405833, in the NAcS on palatable food intake in pre-satiated rats. Male Wistar rats were anesthetized and were stereotaxically implanted with unilateral guide cannulas for injection into the NAcS and had a 5-day recovery period. Then, during a 7-day period of habituation, rats (220-240g) were deprived of food for 21 hours, and then they had access to the standard food (solid)

during 2 hours, and finally they had access to the experimental food (sweetened condensed milk, 10% sucrose) for 1 hour during the light phase of the light/dark cycle. This procedure was performed in order to guarantee that animals were pre-satiated at the time of access to the palatable food, consuming it by its palatability properties. Body weight was monitored on a daily basis to ensure animals continued growing and were appropriately adapted to the food-restricted paradigm. In the experimental sessions, the animals were injected with vehicle and different doses of GW-405833 (0.25, 0.5 or 1.0 μg, multidose crossover design, where dose was determined by a Latin square with an inter-test interval of 2 days, each rat was registered in 3 independent experimental sessions) before having access to experimental food (rats were in the same feeding paradigm as in the habituation period). According to our results, GW-405833 administration had a dose-dependent stimulatory effect of palatable food ingestion. Our findings provide experimental evidence that cannabinoids and endocannabinoids in the NAcS may stimulate feeding by increasing the hedonically positive sensory properties of food via CB2 receptors.

**Title:** Nucleobindin-2/nesfatin-1 in the hypothalamic paraventricular nucleus is regulated by metabolic factors

**Authors: *D. GANTULGA**[1], Y. MAEJIMA[2], M. NAKATA[2], T. YADA[2]
[1]Dept. of Basic Sci., Sch. of Pharm. and Biomedicine, Natl. Unive, Ulaanbaatar, Mongolia; [2]Physiol., Jichi Med. Univ., Shimotsuke, Japan

**Abstract:** Nesfatin-1, an anorectic peptide processed from nucleobindin-2 (NUCB2), is an emerging new player in regulation of food intake and energy metabolism. NUCB2/nesfatin-1 is localized in the hypothalamus including paraventricular nucleus (PVN), the region serving as an integrative center for energy homeostasis. Extensive studies on the neural pathways downstream of PVN NUCB2/nesfatin-1 have shown a pivotal role of oxytocin and corticotropin-releasing hormone. In contrast, the factors that regulate NUCB2/nesfatin-1 neurons in PVN remain unknown. This study aimed to clarify whether high glucose, insulin and leptin could directly activate NUCB2/nesfatin-1 neurons in the PVN, and whether the NUCB2/nesfatin-1 expressing

in PVN mediates anorectic action of leptin.Glucose (10 mM) and insulin (10-13 M) increased $[Ca^{2+}]_i$ in 55 of 331 (16.6%) and 32 of 249 (12.9%) PVN neurons, respectively. The post $[Ca^{2+}]_i$ measurement immunocytochemistry indicated that 32 of 55 (58%) glucose-responsive neurons and 20 of 32 (63%) insulin-responsive cells were NUCB2/nesfatin-1 neurons. Substantial fraction of glucose-responsive NUCB2/nesfatin-1 neurons in the PVN also responded to insulin and vice versa. In addition, leptin (10-11 M) increased $[Ca^{2+}]_i$ in 44 of 208 (21.2%) PVN neurons, and 30 of 44 (68.2%) the leptin-responsive neurons were identified as nesftin-1 neurons. These results indicate that high glucose, insulin and leptin activate the PVN NUCB2/nesfatin-1 neurons. Furthermore, central injection of leptin significantly increased NUCB2 mRNA expression in vivo, and treatment of isolated PVN slices with leptin in culture increased NUCB2 mRNA expression. In mice injected with AAV-NUCB2-shRNA, both central and peripheral leptin injection failed to inhibit food, indicating that PVN NUCB2 serves as a substantial mediator of leptin action in PVN. In conclusion, high glucose, insulin and leptin are upstream regulators of PVN NUCB2/nesfatin-1 and PVN NUCB2/NUCB2/nesfatin-1 neurons at least partly mediate the leptin signaling for inhibiting feeding. This study contributes to our understanding of regulation of PVN NUCB2/nesfatin-1 and highlights the role of PVN NUCB2 in energy homeostasis.

**Title:** Biogenic amine octopamine attenuates effects of acute starvation and environmental stress in the house cricket (acheta domesticus)

**Authors: *G. M. DOWNING**, B. ARRIAGA, K. A. ALEGRETE, C. A. MOFFATT
Biol., San Francisco State Univ., San Francisco, CA

**Abstract:** Environmental complexity and caloric restriction have been shown to alter neurogenesis in vertebrate species; however, their effects in arthropods remain poorly understood. In our lab, we utilize a novel organism, Acheta domesticus (the house cricket) to study neurogenesis. We have found neurogenesis is increased in adult crickets housed in enriched environments and decreased in those housed impoverished environments. We also found that acute starvation decreases neurogenesis. Interestingly, we also found that neurogenesis persisted at high rates in crickets even when they were housed in impoverished

conditions and starved at the same time, suggesting that crickets maintain a commitment to maintaining neurogenesis even in extremely stressful conditions. Our goal in the current experiments was to determine if the neuromodulatory hormone octopamine (OA) plays a role in mediating the changes in the rate of neurogenesis we see in stressful conditions. OA is critical for lipid synthesis, and stimulates insulin-producing cells in the mushroom bodies, a region of the brain where neurogenesis occurs in adult crickets. We hypothesized that decreases in OA activity contribute to the decrease in neurogenesis in environmentally impoverished and calorically restricted conditions. To test this hypothesis, we housed crickets in an impoverished environment and acutely starved them for 96 hours. All crickets had access to water for the duration of the experiment. Following 96 hours, crickets received a 10µL injection containing 5µL BrdU (20mg/mL), a thymidine analog incorporated into DNA during the S-phase of the cell cycle, and 5µL of a 50 mM, 100mM, or 200mM solution of OA, or with 5µL of saline. Two hours later, the crickets were sacrificed and their brains were processed for detection of BrdU immunoreactivity. Relative to saline-injected controls, the number of BrdU-immunoreactive cells was increased in crickets injected with 50 and 100 mM OA ($p < .01$) but not in crickets injected with 200 mM OA ($p > .05$). These data suggest OA upregulates neurogenesis in crickets housed in impoverished environments. Preliminary data from another study suggests OA has similar effects in enriched environments. Future studies will examine the effects that OA antagonists have on neurogenesis in impoverished and enriched environments.

**Title:** Gastrointestinal vagal afferent signaling promotes hippocampal-dependent memory function in rats

**Authors: *A. N. SUAREZ**[1], T. M. HSU[1], G. DE LARTIGUE[2], S. E. KANOSKI[1]
[1]USC, Los Angeles, CA; [2]John B. Pierce Lab., Yale Univ., New Haven, CT

**Abstract:** The vagus nerve is the primary conduit of communication between feeding-relevant gastrointestinal (GI) signals and the brain. Vagally-mediated GI satiation signals, including gastric distension and intra-gastric nutrient infusion, activate neurons in the hippocampus (HPC) through unidentified polysynaptic pathways. The functional relevance of GI-derived

communication to the HPC is unknown. Here we first explored whether chronic disruption of gut-to-brain vagal tone via subdiaphragmatic vagotomy (SDV) negatively impacts HPC-dependent memory function in rats. While SDV did not impair HPC-dependent appetitive learning based on interoceptive energy status cues or social food-related cues, SDV did impair spatial working memory (Barnes maze) and contextual episodic memory (novel object in context; NOIC), two HPC-dependent tasks that involve processing of visuospatial stimuli. Next, to determine whether vagal sensory/afferent vs. motor/efferent signaling regulates HPC-dependent memory function, we employed a novel approach in which a saporin conjugated to cholecystokinin (CCK-SAP) or an unconjugated control saporin is injected into the nodose ganglia, a strategy that preserves 100% of vagal efferent signaling while eliminating ~80% of GI-derived vagal afferent signaling. Similar to SDV rats, CCK-SAP rats were impaired in both the Barne's maze task and NOIC learning relative to controls. Consistent with the memory deficits, immunoblot protein analyses in hippocampus lysates revealed reduced neurotophic [brain-derived neurotrophic factor (BDNF)], and neurogenesis [doublecortin (DCX)] markers in both SDV and CCK-SAP rats relative to controls. These findings indicate that GI-derived vagal afferent signaling is critical in regulating HPC-dependent mnemonic function. Results have direct clinical relevance, as procedures that chronically disrupt vagus nerve signaling (e.g., vBloc) have recently been FDA-approved for obesity treatment.

**Title:** Ghrelin conditions an avoidance in rodents

**Authors: *S. L. DICKSON**[1], C. COOK[2], S. M. LUCKMAN[2], E. SCHELE[1]
[1]Inst. of Neurosci. and Physiol., The Sahlgrenska Academy, Univ. of Gothenburg, Gothenburg, Sweden; [2]Fac. of Biology, Med. and Hlth., Univ. of Manchester, Manchester, United Kingdom

**Abstract:** Feelings of hunger carry a negative valence (emotion) signal that appears to be conveyed through agouti-related peptide (AgRP) neurons in the hypothalamic arcuate nucleus1. The circulating hunger hormone, ghrelin, activates these neurons although it remains unclear whether it also carries a negative-valence signal. Given that ghrelin also activates pathways in the midbrain that are important for reward, it remains possible that ghrelin could act as a positive reinforcer and hence, carry a positive-valence signal. Here we used condition preference/avoidance tests to explore the reinforcing/aversive properties of ghrelin, delivered by intracerebroventricular (ICV) injection (2 µg/injection once a day for 4 days). We found that ICV ghrelin conditioned avoidance, both in a conditioned place preference/avoidance test (CPP/CPA, in which the animals avoid a chamber previously paired to ghrelin injection) and in a conditioned flavor preference/avoidance test (CFP/CFA, in which the animals consume/avoid a taste previously paired to ghrelin injection). These effects of ghrelin to induce a CPA were observed when conditioning to ghrelin occurred in the absence of food (77% reduction in time spent in ghrelin-paired compartment, $P<0.001$) and presence of food (in this case an 82% reduction; $P<0.001$). We did not find evidence, however, that brain ghrelin delivery to rats induces malaise (in the pica test). After conditioning, the preference for the flavor that had been conditioned to ICV ghrelin injection (31 ± 7 %) was dramatically reduced by over half ($P < 0.001$) compared with the initial preference (71 ± 3 %), which was determined prior to conditioning. Our data indicate that ICV ghrelin carries a negative-valence signal consistent with its role as a circulating hunger hormone and with its effects to activate AgRP neurones.1 Betley JN et al., Nature. 2015 521:180-5.

Sch. of Med., Baltimore, MD

**Abstract:** The cytoarchitecture and synaptic organization of neuronal circuits that control feeding behaviors play fundamental roles in regulating homeostatic control of the body. Beginning with early lesion and electrical stimulation studies, the lateral hypothalamus (LH) has long been considered essential in regulating feeding. In addition, the profusion of genetically distinct cell types in the LH make it an ideal circuit to study the neuronal basis of survival behaviors. However, very little is known about which cell types and relevant projections are important for driving and controlling feeding. In this work, we characterized and determined the role of lateral hypothalamic parvalbumin-expressing neurons ($LH^{PV}$) in regulating feeding behaviors in mice. These neurons (340 ± 10, $n$ = 3 mice; bilateral) are distributed in a compact and small cluster in the LH medial to the optic tract. Using a combination of electrophysiology, optogenetics, and *in situ* hybridization assays, we determined that $LH^{PV}$ neurons are fast-spiking (mean firing frequency 194 ± 10 Hz, $n$ = 34 cells), co-express vesicular glutamate transporter 2 (*Vglut2*) mRNA (95% $LH^{PV+/VGLUT2+}$), and provide excitatory inputs onto neuronal circuits within the LH (mean excitatory postsynaptic current (EPSC) amplitude 69.0 ± 5.0 pA, $n$ = 13 cells). This contrasts with the canonical parvalbumin neuron fast-spiking GABAergic phenotype observed in the neocortex and hippocampus. Furthermore, we manipulated the activity of $LH^{PV}$ neurons using chemogenetic techniques to determine whether these neurons are necessary and sufficient to drive feeding behaviors. We found that chemogenetic inhibition of $LH^{PV}$ neurons evoked food intake in sated mice (60% increase in food consumption in comparison to control; $n$ = 12). In contrast, chemogenetic activation of these neurons did not affect food intake ($n$ = 8). Thus, our results indicate that inhibitory inputs onto $LH^{PV}$ neurons orchestrate feeding behaviors. This study sheds light on the importance of understanding the functional roles of specific cell types within the LH in coordinating complex behaviors such as feeding. Additionally, elucidating the mechanisms regulating food intake will allow the identification of novel targets for therapies of metabolic disorders.

**Title:** Alternate day fasting schedule in rats decreases preference for calorically dense diet by increasing meal size and number of meals of standard chow

**Authors: *M. FRANKOT**, A. CARRILLO, Y. TREESUKOSOL
California State University, Long Beach, Long Beach, CA

**Abstract:** Alternate day fasting (ADF), a paradigm involving free access to food for 24 hours followed by no access to food for 24 hours, leads to weight loss for both humans and rats. When rats receive ad libitum access to both a palatable high-energy (HE) food and standard chow they tend to overeat HE food and gain weight. In order to examine how fasting alters diet preference and intake, meal pattern analysis was conducted across daily 23-h sessions in male and female Sprague Dawley rats. Animals were assigned to one of three diet conditions: AD LIB rats were given access to both chow (3.43 kcal/g) and HE diet (4.73 kcal/g) every day, INT rats were given access to chow every day with the addition of HE diet every other day, and ADF rats were given access to both chow and HE diet every other day; no food was administered on alternate days. Given the 24-h food restriction periods, it was anticipated that ADF rats would show the highest preference for HE food versus chow, yet the ADF group displayed decreased preference for HE compared to INT and AD LIB rats ($p < .001$). This effect was more pronounced in male rats than in female rats. Consistent with findings in the literature, access to a palatable caloric-dense diet in a fed state (INT rats) resulted in hyperphagia driven by increased meal size of the HE diet ($p = 0.008$). This was not observed in ADF rats that were presented HE diet and chow following 24-h food restriction. The decreased preference for HE diet in ADF rats appears to be driven by changes in meal pattern parameters. Specifically compared to the INT group, ADF rats initiated more meals ($p < 0.001$) and displayed larger meal size ($p = .035$) of chow. The direct controls of meal size can be categorized as positive (e.g., oral) and negative (e.g., postoral inhibitory) signals; thus here, the ADF schedule appears to increase orosensory stimulation and/or decrease sensitivity to inhibitory cues towards the less-preferred chow. This shift in diet preference may contribute to the effectiveness of using ADF as a dieting strategy.

**Title:** Reward sensitivity deficits in rats following intermittent access to a palatable diet

**Authors: *C. F. MOORE**, V. SABINO, P. COTTONE
Lab. of Addictive Disorders, Departments of Pharmacol. and Psychiatry, Boston Univ., Boston, MA

**Abstract:** Eating disorders and forms of obesity are associated with brain reward dysfunction. In this study we investigated the sensitivity of the brain reward system of subjects undergoing chronic diet cycling by testing the effects of *d*-Amphetamine, a dopamine releaser. For this purpose, a group of male Wistar rats was provided a regular chow diet 7 days a week (*Chow/Chow*), whereas a second group of rats was provided chow for 5 days a week, followed by a 2-day access to a highly palatable sucrose diet (*Chow/Palatable*). Following 5 weeks of diet alternation, we investigated *d*-Amphetamine sensitivity during access to the palatable diet (*'P Phase'*) as well as during withdrawal from it (*'C Phase'*). We measured the effect of d-Amphetamine on locomotor activity and brain stimulation reward (BSR), home-cage self-administration of amphetamine, and *d*-Amphetamine-induced conditioned place preference. In addition, we used quantitative polymerase chain reaction (qPCR) to investigate diet-induced molecular neuroadaptations. Palatable diet cycling resulted in hypophagia of the standard chow, overeating of palatable food upon renewed access, and compulsive-like eating. During the *P*, but not the *C phase*, diet cycled rats showed decreased sensitivity to both the locomotor stimulating and the threshold-reducing effects of *d*-Amphetamine. The rewarding effects of *d*-Amphetamine were also reduced in *Chow/Palatable* rats during the *P Phase*, shown by blunted place conditioning. In addition, during access to the palatable diet, *Chow/Palatable* rats showed increased self-administration of *d*-Amphetamine in the home cage, as compared to controls. Furthermore, we found that intermittent access to a palatable diet altered expression of dopamine signaling targets. These results indicate that diet cycled rats show a phase-dependent deficit in the brain reward system, as revealed by a decreased sensitivity and reward to *d*-Amphetamine, as well as increased self-administration of *d*-Amphetamine when the highly palatable food access is renewed following withdrawal from the diet. In summary these results suggest that, in pathological eaters, brain reward dysfunction may be dependent upon the feeding state of the individuals.

**Title:** The function of hypothalamic microRNA in regulating energy homeostasis

**Authors: *H. YOON**[1,2], T. WHITE[3], P. ZHANG[3], A. KURTI[2], J. D. FRYER[1,2], N. K. LEBRASSEUR[3], J. KIM[1,2]

**Abstract:** Hypothalamus is a primary regulator of homeostasis in the whole body. It links the nervous system to the endocrine system. In particular, the arcuate nucleus (ARC) in hypothalamus controls energy homeostasis. For example, ARC plays important roles in regulating food intake and energy expenditure in response to hormones such as insulin and leptin, released from peripheral organs. In our study, we focused on the function of microRNAs (miRNAs) in hypothalamus as one of the potential regulators of energy metabolism. miRNAs are small non-coding RNAs that regulate posttranscriptional gene expression. They play critical roles in various biological processes and dysregulations of miRNAs are associated with pathogenesis of multiple human diseases.
We performed miRNA profiling from different mouse brain sub-regions and found that a particular miRNA is significantly enriched in hypothalamus, particularly in ARC. Given its unique expression pattern, we hypothesized that the miRNA may regulate neuronal functions specific in hypothalamus. Microarray analysis indicated that the overexpression of this particular miRNA in neuronal cell dramatically affects metabolic processes and lipid transport processes. We also found that overexpression of this miRNA reduces the level of phosphorylated serine/ threonine-specific protein kinase AKT (AKT) and glycogen synthase kinase 3 β (GSK3β) in hypothalamic cell line. Interestingly, insulin signaling pathway mediated by AKT and GSK3β is one of the main regulators of energy homeostasis in hypothalamus. In this context, we further investigated the function of this miRNA in the hypothalamus of wild-type B6 mice under the normal diet and high fat diet feeding condition. Dysregulation of this miRNA in the brain disturbed the energy balance of the whole body and glucose metabolism. This study may help understand the pathophysiological mechanisms of obesity and diabetes.

**Title:** A Neuronal circuit for the response to hypoglycemia in the insular cortex

**Authors: *I. DE ARAUJO SALGADO**, N. BENFREDJ, C. M. LAMY
Univ. of Fribourg, Fribourg, Switzerland

**Abstract:** Given the importance of glucose for the brain, the glycemic level is highly monitored by the central nervous system. A drop in blood glucose level triggers vital behavioral changes to insure survival. Using whole-cell recording, we have previously identified the existence of glucose-sensing cells in the insular cortex (IC), a region involved in interoception and adaptive behaviors. We are now investigating the neuronal circuit associated with those neurons and their behavioral function. Using a transgenic activity reporter mouse model, we confirmed the presence in IC of hypoglycemia-activated neurons in vivo. We then investigated the role of those neurons in adaptive behaviors by re-activating them in vivo. Our study demonstrates the existence of a neuronal circuit in IC implicated in behavioral adaptation to hypoglycemia.

**Abstract:** Working memory capacity (WMC), also known as memory span, can be defined as the maximum number of items one can hold in working memory. WMC is between 5 and 9 and is assumed to be a system involving both short-term memory and executive functions. WMC declines as a result of aging, neuropsychiatric conditions and may be a marker of early onset of Alzheimer's and Parkinson's disease. The prefrontal cortex (PFC) is implicated in supporting WMC, and its connections to the striatum are considered a major pathway in transforming plans into action. In this context, it has been proposed that WMC in humans can be associated with dopaminergic (DAergic) activity in the PFC either directly, through DAergic mesocortical input, or through striato-thalamocortical innervations modulated by the DAergic nigrostriatal pathway. However, whether and how a selective damage of either the PFC or the dorsal striatum (DS), affects WMC performance in rodents, still requires exploration. Additionally, whether an intact interaction between these two brain structures is necessary for a correct WMC performance, lacks experimental evidence. Therefore, in the current study, CD1 mice received bilateral 6-OHDA lesions either in the medial PFC (mPFC) or DS. A separate group of animals received, instead, crossed lesions of the DS, in one hemisphere, and the mPFC in the other. Two weeks after intra-brain injection, all animals were screened for WMC, using a modified version of both the novel object recognition test (6-DOT, six different object task) and the radial maze test, exposing mice to both low- and high-memory load protocols. Our results demonstrate that when lesions selectively affect the mPFC, a profound deficit in object WMC is observed. However, no impairments in WMC were found in the modified version of the radial maze. On the other hand, DAergic depletion in the DS, although leading to increased time spent in exploring the objects, did not result in object WMC deterioration. In spite of that, an increase in the mean error numbers in the radial maze test was registered when a high-memory load paradigm was applied. Interestingly, mice with crossed lesions showed both a slight reduction in object WMC and an increased mean error numbers in the radial maze test. Thus, these data demonstrate that the mPFC and the DS specialize in different aspects of WMC and suggest that functional connectivity between them is necessary to support diverse representation of WMC. Elucidating the precise neural mechanisms underlying WMC would advance our understanding of WMC-dependent cognitive and behavioral capabilities, as well as provide clues to the pathophysiology and treatment of WMC deficits in pathological states.

**Title:** Disruption of the ability of cues to direct movements following silencing of striatal cholinergic interneurons

**Authors: *C. AVILA**[1], A. J. KUCINSKI[1], M. SARTER[2]
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Psychol, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI

**Abstract:** Falls in patients with Parkinson's disease (PD) are correlated with cholinergic but not with striatal dopaminergic losses. Such falls are thought to reflect in part a loss of attentional compensatory supervision of slow and low-vigor movement. Forebrain cholinergic systems normally mediate the detection and processing of exteroceptive and interoceptive cues, including balancing and movement errors. Such information is forwarded to the striatum to guide and correct forward movements, specifically in unfamiliar contexts and involving dynamic surfaces. Following cholinergic losses, the striatum is deprived of such information which, in interaction with slow and low-vigor movement resulting from striatal dopamine losses, yields balancing and movement errors that precipitate falls. We hypothesize that striatal cholinergic interneurons integrate cortical, cue-related input with information related to ongoing movement in the striatum mediated by dopamine. This hypothesis implies that silencing of interneuron function disrupts the ability of cues to direct movements. Here we tested this hypothesis by activating an inhibitory DREADD, expressed bilaterally by dorsomedial striatal cholinergic interneurons, in animals which had been trained to respond to two cues, a tone or light. The "stop cue" instructs the animals to stop treadmill walking and then continue walking after three seconds in the same direction when the treadmill restarts, whereas with the "turn cue" animals learn to stop, turn around, and walk in the reverse direction. The effects of clozapine N-oxide (CNO; 5 mg/kg; i.p.) or vehicle were tested four weeks after DREADD infusions into the striatum. Preliminary findings indicate that CNO administration disrupts the efficacy of the turn cue response while stop-cue-evoked behavior remained unaffected. Control tests confirmed that administration of CNO neither disrupted the animals' ability to turn *per se* nor induced a preferred turning direction. These results support the hypothesis that striatal cholinergic interneurons mediate the integration of cues into complex movement sequences such as turning. Related research will test the hypothesis that the cortico-striatal, glutamatergic transfer of cue information is disrupted following forebrain cholinergic losses. Collectively, this research suggests that new treatments

aimed at restoring cortico-striatal signaling via striatal cholinergic interneurons may facilitate the integration of afferent information originating in cortical and midbrain regions and thus reduce falls in PD patients.

**Abstract:** It has been shown that animals can learn to generate arbitrary patterns of neural activity in the frontal and motor cortices in the context of abstract skill learning, such as operant neuroprosthetic learning tasks, and that this learning undergoes plastic changes in the dorsal striatum as well as cortico-striatal interactions. However, the role of the ventral striatum (VS) during abstract skill learning remains unclear.
Here we investigated interactions between the VS and primary motor cortex (M1) while rats learned to modulate M1 activity to control a one-dimensional auditory cursor that was linked to a sucrose water reward. Animals learned to perform the task above chance level, and become skilled through training. VS firing rates around the time of target hit increased during this learning process, suggesting that the VS is modulated by reward prediction stimuli. These results are consistent with the actor-critic model of reinforcement learning and suggests an evaluative role of the VS during abstract skill learning.

**Title:** A novel functional role for local striatal inhibitory circuits in goal-directed behavior

**Authors: *E. N. HOLLY**[1], M. F. DAVATOLHAGH[1,2], K. CHOI[1], M. V. FUCCILLO[1]
[1]Dept. of Neurosci., [2]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Deficits in goal-directed behavior are the hallmark of many neuropsychiatric diseases. The dorsomedial striatum (DMS) is a key mediator of goal-directed actions, serving as a critical node for integration of sensorimotor, motivational, and cognitive information. The local striatal low-threshold-spiking (LTSI) interneuron population is sparse, yet exhibits strong synaptic control over spiny projection neurons. Therefore, LTSIs are poised to play a key role in regulating goal-directed behavior. To provide initial evidence for LTSI involvement in operant behavior, we virally overexpressed Kir2.1, an inwardly rectifying potassium channel, to decrease excitability of LTSIs in the DMS. After one week of viral expression, mice were trained in a self-initiated operant task consisting of temporally discrete initiation, choice and outcome valuation periods. The task consisted of three phases: 1) Initiation: sustained entry in a central port initiated a trial, and two retractable levers extended. 2) Choice: mice must respond on one of the levers within 10s, otherwise the trial was considered an omission. 3) Outcome valuation: levers retracted and appropriate outcome was delivered. Responding on the active lever resulted in 4s illumination of the central port and delivery of 10 ul chocolate liquid reward, while responding on the inactive lever resulted in 4s darkness. After 1s time out, mice were allowed to initiate a new trial. To test initial action-contingency acquisition, mice were trained in a two-alternative forced choice task to respond on one lever. After 3 consecutive days >50 rewards, the contingency reversed, thereby rewarding the previously inactive lever. Mice were subsequently run in a dynamic serial reversal task, in which the active lever reversed after 8/10 correct responses. Reduced activity of LTSIs resulted in enhanced acquisition of the initial contingency, decreased the number of trials to reverse in the initial single reversal, and improved performance on the first day of the serial reversal task. To further explore the temporal specificity of LTSI involvement in this task, we used halorhodopsin-mediated optogenetic inhibition specifically during the outcome valuation phase. Similar to Kir2.1 overexpression, optogenetic inhibition of LTSIs exclusively during reward delivery accelerated task acquisition. Together, these data suggest striatal LTSI activity during reward processing may inhibit acquisition of new behavioral

contingencies. Current work is focusing on the striatal circuit mechanisms by which this interneuron population modulates goal-directed choice.

**Title:** Visual function of the putamen tail: Stable choice of valuable objects

**Authors: *O. HIKOSAKA**, J. KUNIMATSU
Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

**Abstract:** The basal ganglia, especially the circuits originating from the putamen, are essential for controlling normal body movements. Notably, the putamen receives inputs not only from motor cortical areas but also from multiple sensory cortices. However, how these sensory signals are processed in the putamen remains unclear. We recorded neuronal activity in the caudal part of the putamen when the monkey viewed many fractal objects. Among 63 neurons, 45 responded to the visual objects. A majority of them (40/45, 89%) had receptive fields in the contralateral hemifield. We hypothesized that these neurons changed their visual responses based on the reward outcome, because the putamen receives heavy dopaminergic inputs, as the other parts of the striatum.
To test this hypothesis, we first used a flexible value procedure in which the object-reward contingency was reversed in a block-wise manner. Among 28 visual neurons tested, only 2 showed differential responses based on the expected values. Next, we used a stable value procedure. In this task, the monkey viewed many fractal objects, each of which was followed by a big or small reward, consistently many times. After learning, the monkey tended to look at high-valued (good) objects and avoided low-valued (bad) objects, and did so with no reward outcome (i.e., free viewing), even a long time later (e.g., >1 month). We found that many of the visual neurons responded stably to these ‘good’ and ‘bad’ objects differentially. Such stable value responses were more common in the caudal-ventral part of the putamen (cvPut,12/24, 50%) than in the caudal-dorsal part (cdPut, 5/25, 20%). On the average, the response was stronger to good objects than bad objects in cvPut neurons ($p < 0.01$), but not cdPut neurons ($p = 0.36$). In addition, object-selective neurons were more common among cvPut neurons (15/24, 63%) than cdPut neurons (5/25, 20%). The magnitude of the object selectivity, on the average,

was stronger in cvPut than cdPut ($p < 0.05$). These results indicate that cvPut and cdPut process visual information differently.
Our recent study revealed that cvPut shares its outputs (Amita et al, SfN abstract 2016) with the tail of the caudate nucleus (CDt). CDt and its downstream circuit to the superior colliculus contribute to the automatic choice and rejection of visual objects based on the long-term memory of the object value (Hikosaka et al. Annu Rev Neurosci 2014). Therefore, cvPut would play the same role (i.e., choice by eye movement) and possibly an additional role (e.g., choice by hand). Anatomically, CDt and cvPut, together, can be called 'striatum tail'. However, the function of cdPut is still unknown.

**Title:** Visual function of the putamen tail: Flexible switching of object choice

**Authors: *J. KUNIMATSU**, O. HIKOSAKA
Lab. Sensorimotor Res., Nati. Eye Inst., Bethesda, MD

**Abstract:** We found that neurons in the caudal-ventral part of the putamen (cvPut) encode values of visual objects stably, similarly to caudate tail (CDt) (Hikosaka and Kunimatsu, SfN abstract 2017). Such stable value coding would be useful for automatically and quickly choosing good objects among many others (Hikosaka et al. Trends Cogn Sci 2013). Our new experiment suggests that such stable value coding may also play a key role in flexible switching of object choice, as shown below.
We devised a new value procedure: scene-based value task. The monkey viewed 8 fractal objects in 2 scenes (A and B), repeatedly across days; 4 of them were good (with large-reward) in scene A and bad (with small-reward) in scene B, while the other 4 were good in scene B and bad in scene A. After experiencing this procedure repeatedly (> 5 days), the monkey became able to choose whichever objects were good. Since scenes A and B were presented in a random sequence, the monkey's choice was switched abruptly depending on the scene-context. Moreover, the flexible switching occurred even in the free viewing condition in which no reward was given after the choice.
We then recorded neuronal activity in cvPut while the monkey passively viewed these objects in different scenes. Most neurons in cvPut were visually sensitive and often encoded object values

stably. We found differences between medium spiny neurons (MSNs) and presumed inhibitory interneurons (INs). Among 33 MSNs, 30 responded to the fractal objects, and 14 (47%) reversed their value biases for the objects between scene A and B. 6 neurons responded to the scenes, but only 1 of them (17%) showed scene-selective response. Among 30 INs, 22 responded to the scenes, and 9 (40%) showed scene-selective responses. 29 neurons responded to the objects, but only 2 of them (7%) reversed their responses to the objects between scene A and B. These results suggest that INs encode the scene-context information, while MSNs encode the value of the objects depending on the scene-context. Importantly, the value-coding of MSNs was stable in each scene, which however was reversed flexibly across the scenes, possibly owing to the inputs from INs. In our daily life, the object values often change in different environments and we can choose different objects accordingly. The mechanisms that we found may support the monkey's flexible switching based on stable long-term experiences of various environments.

**Title:** Post-training intra-dorsolateral striatum infusion of corticosterone enhances consolidation of habit memory

**Authors: *R. RESSLER**, M. G. PACKARD
Psychology, Texas A&M, College Station, TX

**Abstract:** Previous research suggests that stress hormones have a profound influence on several brain structures involved in learning and memory. From a multiple memory systems perspective, exposure to stress has been demonstrated to enhance habit memory mediated by the dorsolateral striatum (DLS) while typically impairing cognitive memory mediated by the hippocampus. One interpretation of stress effects on multiple memory systems is that impairment of hippocampus-dependent memory essentially "unmasks" DLS-dependent memory, leading to a stress-induced bias towards the use of habit memory. Alternatively, recent evidence suggests that the stress hormone corticosterone may act directly within the DLS to enhance consolidation of habit memory. The present experiment further examined the effects of post-training intra-DLS administration of corticosterone on consolidation of habit memory. Adult male Long-Evans rats were trained for five days in a DLS-dependent "response" learning version of a water plus maze task in which they began from different starting positions (North/South) and were required to make a consistently reinforced egocentric body turn response at the maze choice point in order to mount an escape platform. Immediately following maze training on days 1 and 2 animals

received intra-DLS infusion of either corticosterone (10 or 20ng) or vehicle. Post-training administration of corticosterone (20 ng) enhanced memory consolidation and subsequent acquisition of response learning in the plus-maze. The findings are consistent with previous evidence indicating that corticosterone can act directly within the DLS to enhance habit memory consolidation, and suggest that the stress-induced bias towards the use of DLS-dependent habit memory may not only reflect a relative impairment of hippocampus-dependent memory. The results are also consistent with the hypothesis that stress hormones may in part act directly within the DLS to influence the development and expression of maladaptive habitual behaviors observed in various human psychopathologies.

**Abstract:** Chronic low-grade brain inflammation is closely associated with metabolic disorders and cognitive impairments. These impairments have been suggested to be preceded by derangements in neurotransmitter receptor-dependent signaling pathways. The purpose of this work was to explore whether high sucrose diet-treated animals (HSD) undergo changes in central neurotransmitter receptors and disorganized behavioral tasks. By using radiotracers and positron emission tomography we studied the distribution and density of the membrane protein vesicular monoamine transporter 2 (VMAT2) and dopamine type 2 receptors (D2R) in HSD-treated Wistar rats. D2R are mainly expressed in striatum body (SB). This structure plays a major role in processing and integrating motor signals, also acquisition of motor habits and execution of motor programs critically regulated by dopamine. VMAT2 and D2R were quantified by $C^{11}$-

dihydrotetrabenazine ([$^{11}$C]DTBZ) and [$^{11}$C] Raclopride ([$^{11}$C]RAC), respectively. We found a decreased density of membrane D2R at 30 weeks of HSD treatment in SB (n=5), however, no changes were imaging visible at 15 weeks (n=5). Conversely, VMAT2 increased its density in the same structure after 15 weeks of treatment (n=6), suggesting a homeostatic mechanism preventing loses of membrane receptors. Accordingly, the rotarod test, a standardized behavioral task, confirmed altered motor learning. These results support alterations in behavior and cognition associated with metabolic derangements. These alterations are likely mediated by chronic low-grade inflammation that underlies the cognitive regions of the brain.

**Title:** Monitoring of corticostriatal synaptic plasticity with an implantable microbiosensor device to understand cognitive performance in neurodegenerative diseases

**Authors: *N. MOORE**[1], C. A. CORDEIRO[2], L. KUHL[2], J. H. A. FOLGERING[2], T. CREMERS[2]
[1]Brains On-Line Llc, South San Francisco, CA; [2]Brains On-Line, Groningen, Netherlands

**Abstract:** The corticostriatal pathway is characterized by a large convergence of cortical neurons into the striatum, and plays a crucial role in motor-skill learning and cognitive performance. This pathway is thought to be involved to modulate striatal synaptic plasticity. Aberrant corticostriatal plasticity has been related to levodopa-induced dyskinesia, a common pathology amongst Parkinson patients. The long lasting, activity dependent changes induced by synaptic plasticity are thought to mediate the ability of the brain to translate experiences into memories. It has been hypothesized that these events could represent the cellular model underlying learning and memory. Depending on the nature of the synaptic modifications, synaptic plasticity can be classified as long-term potentiation (LTP) and long-term depression (LTD).
Although the cellular mechanisms underlying corticostriatal synaptic plasticity are not fully understood, evidence suggests that glutamate receptors (mGlu) are involved in these processes. Synaptic plasticity can be monitored *in vivo* by tracking changes in field Excitatory Post Synaptic Potential (fEPSP) in response to specific stimuli. Fast changes in extracellular glutamate can be monitored by using new developed biosensors with high temporal and spatial resolution (W-Au needle-type microelectrodes).

Glutamate microbiosensors were combined with a monopolar recording electrode (W, 50 µm Ø) and a microinjector and assembled as an implantable microbiosensor device (*i*MBD). To monitor simultaneously synaptic plasticity and glutamate release *in vivo*, the *i*MBDs were placed in the dorsal striatum of anesthetized rats. Additionally, to induce fEPSPs, bipolar stimulation electrodes were placed in the motor cortex (M1). Synaptic plasticity was evoked by applying a high frequency stimulation (HFS) protocol.
Additionally, due to the unprecedented time resolution of our *i*MBD, we identified, following cortical stimulation, a biphasic change in striatal glutamate levels. After HFS, we observed, an immediate (≤5s) increase in glutamate (up to 200 % of basal levels) followed by a fast, but transient decrease. Moreover, we found a long-lasting increase (≥ 90 min post HFS) in glutamate levels in the striatum.
The results obtained using our novel *i*MBD may be the first step to a better understanding of the role of glutamate in synaptic plasticity. Eventually, it may lead to the development of new therapeutic targets for neurodegenerative diseases characterized by aberrant or abnormal synaptic plasticity.

**Title:** Behavioral states determine the effect of dopamine-receptor modulation on oscillatory activity in the rat ventral striatum

**Authors: *P. SCHOENENBERGER**, M. BAINIER, R. LÜTOLF, P. GARCES, O. FAJARDO, J. F. HIPP, R. L. REDONDO
NORD, F.Hoffmann - La Roche Ltd., Basel, Switzerland

**Abstract:** The ventral striatum (VS) is a key node in the brain circuitry controlling motivation, decision making, sociability, and reward processing. In humans, dysfunction of striatal activity is associated with a variety of diseases, such as depression, addiction, and schizophrenia (SZ). Excitatory input from cortical and limbic structures, as well as prominent dopaminergic signals, converge in the VS. There, medium spiny neurons (MSNs) are inhibitory projection neurons classically divided into D1 receptor (D1R)-expressing- and D2 receptor (D2R)-expressing neurons. Alterations in dopamine (DA)-mediated modulation of VS MSN activity is thought to contribute to disease symptoms such as lack of motivation in SZ, or drug seeking in addiction. Specific D1 vs D2 modulation has been pursued as a therapeutic approach to rebalance basal

ganglia function. To better understand those potential therapies, we studied the effect of systemic application of D1- or D2-specific receptor modulators on striatal local field potentials (LFPs) and EEG in freely moving rats. As reported previously, VS activity spontaneously alternates between 50 Hz- and 80-Hz gamma bursts. Interestingly, both pharmacological activation and blockade of D1Rs with SKF81279 or SCH39166, respectively, led to strong increases in gamma activity, but in non-overlapping frequency bands. In addition, some of these effects were limited to particular behavioral states. Specifically, D1R activation resulted in an increase in 80 Hz-gamma during both exploration and rest, whereas SCH39166 increased 50 Hz-gamma power, but this increase was observed only during rest periods. Activation of D2Rs by quinpirole led to an increase in 50 Hz-gamma power and a concomitant reduction in the mean frequency in several oscillatory bands. This is in stark contrast to the effect of D2R blockade by raclopride, a widely-used antipsychotic, on VS oscillations. Complementary EEG recordings provided a global measure of DA receptor-modulator action and we found consistent modulation of EEG activity under several of the conditions tested. These EEG signals have a high translational potential and the knowledge on EEG signatures of different DA receptor modulators may serve as a reference to develop novel therapeutic agents. In summary, we show that modulation of D1R and D2R activity reveals distinct signatures in VS oscillatory activity, which may provide a framework for the development of novel therapeutics seeking to normalize VS pathways. Importantly, the effect of different modulators is determined by behavioral states. Understanding the mode of action of candidate therapies needs to take this variable into account.

**Abstract:** The basal ganglia and cerebellum contribute to various aspects of motor functions. These motor centers constitute multisynaptic loop circuits with the cerebral cortex. The anterior (ACC), but not posterior (PCC), cingulate cortex is considered to give rise to the limbic loop through the ventral striatum, ventral pallidum, and mediodorsal nucleus of the thalamus. However, it has previously been reported in macaque monkeys that the cingulate cortex, including the ACC, sends fibers directly to the dorsal striatum, as well as to the ventral striatum. In addition, the neuronal connectivity between the cingulate cortex and the cerebellum remains to be clarified. Therefore, the present study was undertaken to investigate how the cingulate cortex connects multisynaptically with the basal ganglia and cerebellum by means of retrograde transneuronal double labeling with fluorescent rabies viral vectors; the ACC and PCC in common marmosets were injected separately with the viral vectors expressing GFP and RFP. After the vector injections, the animals were allowed to survive for about 48 and 65 hours to achieve the second- and third-order neuron labeling, respectively. With the 48-hour survival period, the distribution patterns of labeled neurons in the basal ganglia (i.e., internal segment of the globus pallidus and substantia nigra pars reticulata) varied in the ACC vs. PCC injection cases. In the deep cerebellar nuclei, all of the medial, interposed and lateral nuclei contained neuronal labeling after the ACC injection, while the PCC injection produced neuronal labeling in the interposed and lateral nuclei. Such a discrepancy of labeled neuron distribution also occurred with the 65-hour survival period. In the basal ganglia, the labeled neurons were located not only in the ventral striatum, but also distinctly in the putamen and caudate nucleus after the ACC or PCC injection, respectively. Likewise, Purkinje cell labeling within the cerebellar cortex was distributed in both the vermis and the hemisphere after the ACC injection, but in the hemisphere alone after the PCC injection. The present results indicate that multisynaptic inputs from the basal ganglia and cerebellum to the ACC vs. PCC are organized in a differential fashion.

**Title:** Optogenetic modulation of saccade-controlling circuits in the monkey basal ganglia

**Authors: *H. AMITA**[1], H. F. KIM[2], K.-I. INOUE[3], M. TAKADA[3], O. HIKOSAKA[1,4]
[1]Lab. Sensorimotor Research, NEI, NIH, Bethesda, MD; [2]Dept. of Biomed. engineering, Sungkyunkwan Univ., Suwon / Gyeonggi-Do, Korea, Republic of; [3]Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [4]Intramural Reserach Program, NIDA, NIH, Baltimore, MD

**Abstract:** Optogenetics enables to control a specific neuronal pathway. However, few studies have used this technique to study the neuronal circuits in non-human primates (Inoue et al. Nat Com 2015). We applied pathway-selective optogenetics to investigate the oculomotor mechanism of the basal ganglia circuits.
We injected a viral vector (AAV2-CMV-ChR2-EYFP) into the tail part of the caudate nucleus (CDt) of a macaque monkey to perform optogenetics experiments (see below). Histological examinations (done later) showed that ChR2 was expressed in cell bodies in CDt and axon terminals of CDt neurons in the caudal-dorsal-lateral part of the substantia nigra pars reticulata (cdlSNr) and the caudal-ventral part of the globus pallidus externus (cvGPe).
As the first step of optogenetics experiment, we examined the effect of optical stimulation on single neuron activity in CDt using optrodes. Most GABAergic interneurons (INs) (17/19, 89%) were activated tonically. In contrast, medium spiny neurons (MSNs) were tonically inhibited, some of which (2/19, 11%) showed a brief initial activation. These data suggest that INs, which are tonically active, can continue to suppress the output of CDt. Next, we examined whether the optical stimulation of the CDt axon terminals affected postsynaptic neurons in cdlSNr and cvGPe. Many visual neurons (27/43, 63% in cdlSNr; 30/49, 61% in cvGPe) were inhibited, indicating that they received direct inhibitory inputs from CDt. Some of them (11/27, 41% in cdlSNr; 15/30; 50% in cvGPe) showed stable value coding, suggesting that stable value signals originated from CDt. Interestingly, these inhibitory responses were short (5-20 ms), sometimes followed by excitatory responses. In contrast, few non-visual neurons (5/17, 29% in cdlSNr; 1/23, 4% in cvGPe) were affected by the optical stimulation, suggesting that CDt sends mainly visual information to cdlSNr and cvGPe.
Finally, we examined the behavioral effects while the monkey was freely viewing multiple objects. The optical stimulation in cdlSNr facilitated contralateral saccades and suppressed ipsilateral saccades. This effect provides evidence for the facilitatory effect of the direct pathway. More specifically, optical stimulation in cdlSNr selectively activated the inhibitory input from CDt to cdlSNr neurons (shown above), which led to a disinhibition of SC neurons and the facilitation of contralateral saccades. The present study is an important step for investigating the mechanism and function of neuronal circuits in the primate basal ganglia.

**Title:** The cortico-striatal adenosine $a_{2a}$ receptors control spatial working memory in mice and monkeys

**Authors: *Z. LI**[1], X. CHEN[1], T. WANG[2], F. LI[1], L. CHEN[1], F. YUE[2,3], P. CHAN[2,3], J.-F. CHEN[1,4]
[1]The Eye Hosp. of Wenzhou Med. Univ., Zhejiang, China; [2]Wincon TheraCells, Biotechnologies Co., LTD, Nanning, China; [3]Dept. of Neurobiology, Beijing Inst. of Geriatrics, Beijing, China; [4]Boston University, Sch. of Med., Dept. of Neurol., Boston, MA

**Abstract:** Spatial working memory (SWM) is fundamental to cognition by caching behaviorally relevant cues on a timescale of seconds. The medial prefrontal cortex (mPFC) is specially wired to support WM with its persistent neuronal activity in the absence of stimulation while the striatum is postulated to gate WM representations. The adenosine $A_{2A}$ receptor ($A_{2A}R$) is expressed in the cortico-striatal pathway with highly enrichment in the striatopallidal neurons where it integrates dopamine and glutamate signaling to modulate cognition. Our recent genetic and optogenetic studies have implicated the cortico-striatal $A_{2A}R$ in modulation of WM, but the circuit mechanism underlying the cortico-striatal $A_{2A}R$ control of WM is not clear and the therapeutic potential of $A_{2A}R$ antagonists has not been tested in non-human primates. By coupling Cre-loxP-mediated focal $A_{2A}R$ knockdown (KD) with a delayed non-match-to-place (DNMTP) working memory task, we demonstrated the respective effects of focal knockdown of $A_{2A}Rs$ in the dorsomedial striatum (DMS) and mPFC on SWM and also evaluated the effect of systemic administration of KW6002 on DNMTP performance. $A_{2A}R$ signaling in mPFC and DMS exerted opposite modulations of SWM, with focal KD of DMS $A_{2A}Rs$ apparently enhanced while focal KD of mPFC $A_{2A}Rs$ impaired DNMTP performance. Moreover, the $A_{2A}R$ antagonist

KW6002 produced the similar effect of the DMS $A_{2A}$R KD, indicating that KW6002 mainly and predominately acts at the striatopallidal $A_{2A}$Rs in DMS to control SWM. Lastly, as the $A_{2A}$R antagonist is currently evaluated for its motor benefit in Parkinson's disease (PD) patients, we also evaluated the effect of KW6002 on delayed match-to-sample/place (DMTS/DMTP) task in normal and dopamine-depleted Cynomolgus monkeys to explore the potential pro-cognitive benefit in PD. We demonstrated that KW6002 treatment improved SWM performance in DMTS and DMTP tasks of normal and MPTP-treated Cynomolgus monkeys. Together, these findings suggest that the $A_{2A}$R in striatopallidal and mPFC neurons exert distinctive control of SWM to achieve cognitive stability and flexibility. Furthermore, the pro-cognitive effect of $A_{2A}$R antagonists in non-human primate provides the preclinical data to translate $A_{2A}$R antagonists for improving cognitive impairments in PD.

**Abstract:** Parkinson's disease (PD) non-motor symptoms include elevated anxiety and altered decision-making. Altered activity in striosome neurons might support this non-motor phenotype, given that striosomes are an intersection for prefrontal, limbic, and reward circuitry, and have been recently implicated in cost-benefit decision-making. Moreover, striosomes are enriched in the PD-linked *Lrrk2* gene. Using chemogenetics to modulate striosome activity in male and female mice, we identify striosome-dependent behaviors. In particular, we find that reduced striosome activity reduces risky reward-seeking, and alters performance on the elevated zero maze. No sex difference is detected. *In vivo* calcium imaging will be used to study striosome dynamics accompanying the same behaviors in mice. Preliminary results using this method demonstrate a selection of striosome neurons activated by a cue signaling the start of operant trials. Completed findings in wild type mice will form a basis for future comparison to mice carrying PD-relevant Lrrk2 mutations.

**Title:** Chunk learning from complex sequences by mutually supervising recurrent neural networks

**Authors:** ***T. ASABUKI**, T. FUKAI
RIKEN Brain Sci. Inst., Wako, Japan

**Abstract:** Detecting meaningful clusters (chunks) from sequences is a critical element of high-order brain functions such as language acquisition and motor sequence learning. Moreover, chunk learning enables the brain to construct compact representations of complex sequence information, and hence supports the brain's ability of modeling the external world. Chunking is composed of segmentation and concatenation, and several computational studies have modeled these processes. Yet, unsupervised learning of chunks from complex sequences is a challenge for neural network models. Here, we extend the reservoir computing to a novel framework of chunk learning. The proposed model are composed of two recurrent networks that mutually supervise their chunk learning. While each reservoir undergoes supervised learning, the entire network is trained in an unsupervised manner. We explore the conditions required for successful learning and found that noise plays an active role in the proposed chunk learning. Interestingly, when the chunk learning is successful, readout neurons from the reservoirs display a characteristic activity that piles up during the exposure to a specific chunk and rapidly decays outside of it. Some striatal neurons called "STOP cells" indeed show such an activity pattern when a particular motor sequence is repeatedly learned. Thus, our model gives a novel insight into the biological mechanisms of chunk learning.

**Title:** Selective loss of dopamine D2 receptors in GABAergic interneurons modifies cerebral cortical architecture and motor behaviors

**Authors: *G. S. LEE**[1], D. L. GRAHAM[1], L. R. ANDERSON[1], T. S. TRAMMELL[1], M. RUBINSTEIN[2], G. D. STANWOOD[1]
[1]Dept. Biomed Sci, Florida State Univ. Col. of Med., Tallahassee, FL; [2]Inst. de Investigaciones en Ingeniería Genética y Biología Mol., Consejo Nacional de Investigaciones Científicas y Técnicas and Univ. de Buenos Aires, Buenos Aires, Argentina

**Abstract:** Dopamine D2 receptors (D2Rs) modulate a wide range of behavioral and cognitive functions including movement, cognition, and reward. They also play fundamental roles in neurodevelopment, including effects on forebrain differentiation, cerebral cortical interneuron number, and behavioral function. Moreover, disrupted D2R expression and/or signaling contributes to neuropsychiatric disorders including depression, schizophrenia, and attention deficit disorders. To further understand the role of the D2R in frontal cortical interneuron development, we generated a conditional D2R knockout mouse model. D2R was deleted from frontal cortical GABAergic neurons using Nkx2.1-Cre mice to target GABAergic interneuron progenitors from the medial ganglionic eminence. Conditional Nkx2.1.D2RKO mice exhibited no differences in tests of spontaneous locomotor activity, anxiety, depression-related behaviors or working and spatial memory. Nkx2.1.D2RKO mice exhibited greater latencies to fall during a rotarod task, suggesting enhanced motor coordination. Nkx2.1.D2RKO mice exhibited reduced locomotor activity induced by MK-801, suggesting that NMDA receptor antagonist-induced locomotion requires D2R expression in cortical GABAergic neurons. At the cellular level, no significant changes in the number of GAD67+ or parvalbumin+ neurons were observed in the anterior cingulate cortex in adult mice. However, Nkx2.1.D2RKO mice showed a decrease in numbers of parvalbumin+ neurons surrounded by glycan-binding *Wisteria floribunda agglutinin*. This suggests that loss of D2R leads to decreased perineuronal nets around parvalbumin+

neurons which may, in turn, contribute to reduced synaptic stability. Ongoing studies to examine forebrain circuitry and gene expression patterns are underway to identify the developmental, cellular, and behavioral roles of D2R within GABAergic neurons of the telencephalon, and the mechanisms by which D2R dysfunction contributes to the development and pathophysiology of brain disorders.

**Abstract:** Cognitive flexibility, the ability to rapidly alter behavior in response to changing circumstances, is impaired in many psychiatric and neurological disorders, yet the neural substrates of cognitive flexibility remain understudied. Reversal learning is an assay of cognitive flexibility that measures the ability to suppress a habitual response while updating to altered stimulus-outcome contingencies. Current theories implicate the dorsomedial striatum in goal-directed learning that is quickly acquired and highly sensitive to changes in outcome, while the dorsolateral striatum (DLS) drives the subsequent stimulus-bound or habitual performance of actions. However, recent work provides evidence that the mouse DLS is active from the earliest stages of learning a discrimination touchscreen task. Building on these findings, we examined whether the DLS may also be recruited in tasks demanding choice flexibility. To examine whether one DLS output pathway is preferentially recruited during early reversal, we trained naïve C57BL/6J mice on the discrimination task or a subsequent reversal task – in which the previously rewarded stimulus was now rewarded and the unrewarded stimulus was no longer rewarded. Mice were sacrificed after either early discrimination or early reversal training to determine differential patterns of activation in the DLS, via *in situ* hybridization of the immediate-early gene, Arc. Activation was further parsed out as a function of whether it occurred in direct output or indirect output pathway DLS neurons, via *in situ* hybridization of

*Drd1* or *Drd2*, respectively. Next, to interrogate the causal contribution of the direct and indirect pathways on reversal learning, we optogenetically silenced either the direct or indirect pathway (by targeting an AAV carrying the inhibitory opsin, ArchT, in *Drd1*-Cre or *Adora2a*-Cre mice, respectively) as mice made choices during reversal. Results provide further evidence that the DLS may have a previously underappreciated role in modulating cognitive flexibility, with implications for understanding how DLS dysfunction might contribute to disorders characterized by inflexible behavior.

**Title:** Lumateperone (ITI-007) is a postsynaptic D2 receptor antagonist

**Authors: *J. P. HENDRICK**, L. ZHANG
Intra-Cellular Therapies Inc, New York, NY

**Abstract:** *Rationale* ITI-007 (lumateperone) is a new molecular entity with a first-in-class pharmacological profile. ITI-007 is a high affinity serotonin 5-$HT_{2A}$ receptor antagonist with lower but clinically relevant affinity for other targets, including dopamine $D_1$ and $D_2$ receptors and serotonin transporters. ITI-007 also indirectly modulates both NMDA and AMPA glutamate neurotransmission in the prefrontal cortex via D1 receptor and SERT interactions. ITI-007 lacks significant activity at other receptors (e.g., $H_1$, muscarinic, 5-$HT_{2C}$) that may cause unwanted and deleterious effects. In previous studies in vivo, we have shown that ITI-007 is both a pre-synaptic partial agonist (no effect on dopamine metabolism and protein phosphorylation profile consistent with presynaptic partial agonism in the striatum) and post-synaptic antagonist (protein phosphorylation consistent with postsynaptic antagonist activity) (Li et al., 2014, J Med Chem 27:2670; Snyder et al., 2014, Psychopharm, 232:605). We now have further explored the unique interactions of ITI-007 with dopamine receptors *in vitro* to assess its functional D2 activity in systems mimicking a postsynaptic cell. In similar systems, other antipsychotic drugs with partial D2 agonist activity demonstrate partial agonism presynaptically *in vivo*, and postsynaptically as revealed *in vitro* in cells (Burris et al., 2002, JPET, 302:381; Maeda et al., 2014, JPET, 350:589).
*Objectives*: To characterize the D2 functional activity of lumateperone under conditions sensitive to D2 partial agonists in a system mimicking a postsynaptic cell.
*Results*: In contrast to three known postsynaptic partial agonists, bifeprunox, aripiprazole, and brexpiprazole, lumateperone displayed no demonstrable postsynaptic partial agonist activity,

behaving as a D2 antagonist in this system.
*Conclusion*: As noted previously, lumateperone acts in vivo as a presynaptic partial agonist and a postsynaptic antagonist. Data presented here confirm our previous in vivo findings that lumateperone functions as a postsynaptic antagonist. The ability of ITI-007 to act both as a pre-synaptic partial agonist and post-synaptic antagonist is unique and not shared by other antipsychotic drugs.

**Title:** GluA1 AMPA receptor subunit deletion abolishes reinforcement rate learning in mice

**Authors: *J. M. AUSTEN**[1], R. SPRENGEL[2], D. J. SANDERSON[1]
[1]Psychology Dept., Durham Univ., Durham, United Kingdom; [2]Max Planck Inst. for Med. Res., Heidelberg, Germany

**Abstract:** Conditioning occurs more readily with cues of short duration than of long duration. One possible explanation for this phenomenon is that the long duration cues undergo more short-term habituation than the short cues, and this results in poorer learning when reinforcement occurs. GluA1 AMPA receptor subunit deletion in mice reduces short-term habituation; therefore, if the short-term habituation account of the cue duration effect has merit, mice lacking the GluA1 subunit should show a reduced cue duration effect. Mice received appetitive Pavlovian conditioning with a 10 s cue and a 40 s cue. Control mice showed greater learning with the 10 s cue than the 40 s cue; however, as predicted, GluA1 deletion abolished this cue duration effect. Subsequent experiments demonstrated that, rather than being driven by short-term habituation, the cue duration effect seen in control mice primarily reflected sensitivity to the rate of reinforcement across cumulative exposure to the cues (e.g., a 40 s cue has a lower rate of reinforcement than a 10 s cue). The cue duration effect was not seen in GluA1 knockout mice as they were sensitive only to the number of times that a cue was paired with reinforcement, regardless of the reinforcement rate of that cue. These results suggest that, in addition to its previously demonstrated role in short-term habituation, GluA1 is also responsible for weighting

numeric, trial-based information by temporal information in order for animals to achieve rate-based learning. Associative accounts of learning can explain rate-sensitivity in terms of the balance between increments and decrements in associative strength over cumulative exposure to cues. Learning in GluA1 knockout mice may be explained in terms of a failure to reduce associative strength during periods of nonreinforced exposure. This leads to the hypothesis that GluA1 is necessary for changes in learning that occur due to negative prediction error.

**Title:** GluA1 AMPA receptor subunit deletion impairs blocking of flavour preference learning

**Authors:** ***J. A. STRICKLAND**[1], J. M. AUSTEN[1], R. SPRENGEL[2], D. J. SANDERSON[1]
[1]Durham Univ., Durham, United Kingdom; [2]Max Planck Inst. for Med. Res., Heidelberg, Germany

**Abstract:** The GluA1 AMPA receptor subunit plays an important role in learning and memory, with GluA1 knockout mice showing impaired short-term habituation to recently experienced stimuli. An account of GluA1 proposed by Sanderson et al. (2009) presumes that GluA1 is not necessary for associative retrieval and, by extension, prediction error. As yet, however, there have been no direct tests of this hypothesis. We tested this prediction by assessing blocking of flavour preference learning in GluA1 knockout mice. In stage 1 mice drank flavour A paired with 32% sucrose and flavour B paired with 4% sucrose. In stage 2 mice drank compounds of flavours A and X, and B and Y. Each compound was paired with 32% sucrose. In the test session mice were allowed to drink flavours X and Y. Control mice showed a preference for flavour Y indicating that flavour A had blocked learning of flavour X. Contrary to the original hypothesis, GluA1 knockout mice failed to show blocking of learning. A subsequent test phase demonstrated that the lack of blocking in knockout mice was not due to a failure to learn about the blocking flavour. While these results suggest that the role of GluA1 may extend to cue competition effects, it is not clear to what extent performance in the current experiment is influenced by within-compound associations and to what degree GluA1 deletion affects these associations.

**Title:** The GluA1 subunit of the AMPA receptor is necessary for rate-sensitive learning but not learning that is dependent on the number of reinforcements

**Authors: *D. J. SANDERSON**[1], R. SPRENGEL[2], J. AUSTEN[1]
[1]Durham Univ., Durham, United Kingdom; [2]Max Planck Inst. for Med. Res., Heidelberg, Germany

**Abstract:** We have found that appetitive Pavlovian conditioning in mice is determined by the rate of reinforcement. Mice that lack the GluA1 subunit of the AMPA receptor fail to show rate-sensitive learning. In the previous experiments the rate of reinforcement was manipulated by comparing cues with different durations (10 s versus 40 s) and rate was equated by confounding the variables of cue duration and probability of reinforcement per trial (e.g., a 10 s cue reinforced on 25% of trials compared to a 40 s cue reinforced on 100% of trials). It is possible that GluA1 is necessary for rate learning when cue duration is manipulated because of its role in short-term habituation. Therefore, in order to test whether GluA1 is necessary for rate learning regardless of cue duration, mice were trained with two cues of the same duration that were reinforced at different rates. One cue was reinforced on every trial and the other was reinforced on 25% of trials. The partially reinforced cue was presented four times more often than the continuously reinforced cue such that the number of reinforcements was equated between the cues. Normal mice were sensitive to reinforcement rate and showed better learning with the continuously reinforced cue than the partially reinforced cue. GluA1 knockout mice, however, showed equal learning with the two cues. In a second experiment mice were trained with two cues of the same duration that were reinforced at the same rate, but one cue was presented four times more often than the other such that the cues differed in the number of times that they were paired with reinforcement. Both normal and GluA1 knockout mice showed superior learning with the cue that received a higher number of reinforcements. These results demonstrate that GluA1 is necessary for reinforcement rate learning regardless of whether rate is manipulated by cue duration or probability of reinforcement per trial. The fact that in the absence of GluA1 learning switches to being dependent on the number of reinforcements suggests that GluA1 plays a crucial role in the time-dependent aspects of learning that result in sensitivity to rate information.

**Title:** Encoding of conditioned motivation by midbrain dopamine neurons

**Authors: *B. T. SAUNDERS**[1], J. M. RICHARD[1], P. H. JANAK[2]
[1]Dept. of Psychological and Brain Sci., [2]Johns Hopkins Univ., Baltimore, MD

**Abstract:** Conditioned motivational states evoked by rewards and associated stimuli (conditioned stimuli, CSs) are essential for adaptive reward seeking, but they also contribute to a variety of psychiatric disorders, such as addiction. Despite this, we lack a circuit-level understanding of how the brain creates motivation under normal and pathological conditions. Dopamine neurons originating from the ventral tegmental area (VTA) and substantia nigra (SN) have received considerable attention for their role in reward-related processes, but it remains unclear what information is signaled by CS-evoked neural activity within these systems, and how that maps on to conditioned behaviors. To explore this issue, we used fiber photometry to measure activity of dopamine neurons in TH-cre rats expressing GCaMP6. We found that through Pavlovian conditioning, sensory cues paired with optogenetic activation of VTA dopamine neurons become CSs that evoke dopamine neuron activity in the VTA, and elicit conditioned behavioral responses. Furthermore, the magnitude of the cue-evoked dopamine signal predicted the vigor of cue-evoked conditioned behavior. This suggests that rather than simply signaling the learned predictive value of a Pavlovian CS, VTA dopamine neurons encode its incentive motivational value to actually drive actions. We are currently investigating if cue-evoked dopamine neuron signals vary as a function of the sensory modality of the predicted outcome (i.e., optogenetic brain stimulation versus delivery of an external, consumable reward) and across dopamine neuron subpopulations (e.g., VTA versus SN). The goal of these studies is to better understand how phasic dopamine neuron activity contributes to cue-evoked motivational states that drive reward-specific behaviors.

**Title:** Extended experience does not alter the role of dopamine in the nucleus accumbens core, nor recruit dorsal lateral striatum, to facilitate Pavlovian cue approach

**Authors: *K. M. FRASER**[1], P. H. JANAK[1,2]
[1]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

**Abstract:** The attribution of incentive salience to reward-paired cues is dependent on dopamine release in the nucleus accumbens core. These dopamine signals conform to traditional reward-prediction error signals and have been shown to diminish with time following extended training. Here we examined if the diminishing dopamine signal in the nucleus accumbens core has functional implications for the expression of sign-tracking, a Pavlovian conditioned response indicative of the attribution of incentive salience to reward-paired cues. Food-restricted rats were trained in a Pavlovian paradigm in which an insertion of a lever predicted delivery of food reward in a nearby food cup. After 7 or 14 training sessions, rats received in separate sessions infusions of saline, the dopamine antagonist, flupenthixol, or a mixture of the GABA agonists, baclofen and muscimol, into the nucleus accumbens core or the dorsal lateral striatum. Dopamine antagonism within the nucleus accumbens core attenuated sign-tracking, whereas reversible inactivation did not affect sign-tracking but increased non-specific food cup checking behaviors. Neither drug in the dorsal lateral striatum affected sign-tracking behavior. Critically, extended training did not alter these effects. Though extended experience with a Pavlovian incentive cue is reported to reduce cue-evoked dopamine in the nucleus accumbens core, our results suggest this does not alter the function of dopamine in this region to promote Pavlovian cue approach nor result in the recruitment of dorsal lateral striatal systems for this behavior. These data support the notion that dopamine within the mesoaccumbal system, but not the nigrostriatal system, contributes critically to incentive motivational processes independent of the length of training. Future investigations are exploring ways in which cues can proactively invigorate or dampen future reward-seeking driven by ambiguously predictive stimuli.

**Title:** Lateral hypothalamic GABAergic projections to VTA mediate consummatory responses toward fat-enriched foods

**Authors: *M. F. BARBANO**[1], D. N. ACS[2], P. H. JANAK[2,3]
[2]Dept. of Psychological and Brain Sciences, Krieger Sch. of Arts and Sci., [3]The Solomon H. Snyder Dept. of Neuroscience, Johns Hopkins Sch. of Med., [1]Johns Hopkins Univ., Baltimore, MD

**Abstract:** The lateral hypothalamus (LH) exhibits a vast heterogeneity of cell types and connectivity. Until recently, this complexity prevented the study of specific cell populations and their involvement in motivated behaviors. Novel optogenetic approaches have shown that a GABAergic LH neuronal subpopulation is involved in feeding and reward. Nonetheless, the neurocircuitry involved remains unknown. An interesting downstream candidate is the ventral tegmental area (VTA), a region largely implicated in reward-related behaviors. In the present study, we investigated if the GABAergic LH to VTA circuit was involved in the expression of consummatory behaviors by using a combination of optogenetic and behavioral techniques in male VGaT-Ires-Cre mice. We found that VTA photoinhibition of GABAergic LH terminals decreased the operant responses and amount of fat-enriched pellets earned when applied during the entire experimental session of a fixed ratio 5 (FR5) food-reinforced task, as well as of a progressive ratio 3 (PR3). Interestingly, the same results were observed when the photoinhibition was restricted to the consumption phase of FR5 and PR3. The inhibition was ineffective when administered to control animals. Next, we conducted free-feeding experiments and studied if the inhibition of the GABAergic LH terminals in the VTA modified consummatory responses depending on the type of food presented. We observed a decrease in the amount eaten and an increase in the latency to initiate eating when mice were presented with fat-enriched pellets. On the contrary, the inhibition was ineffective when mice were presented with either standard chow or grain-based pellets. Our results demonstrate that inhibition of GABAergic fibers originating in the LH and projecting to the VTA are preferentially implicated in the encoding of consummatory responses for fat-enriched foods. They are consistent with a model in which the LH, given its unique connectivity and neurochemical expression pattern, may convey pertinent homeostatic information to the VTA, which, in turn, and as a key component of the mesocorticolimbic circuitry, can orchestrate goal-directed consummatory behaviors that are critical for survival.

**Title:** Ventral pallidal encoding of reward seeking depends on the underlying associative structure

**Authors: *J. M. RICHARD**[1], N. STOUT[1], D. ACS[1], P. H. JANAK[2]
[1]Dept. of Psychological and Brain Sci., [2]Dept. of Psychological and Brain Sci. and Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Activity in ventral striatopallidal circuitry is thought to be a critical mechanism by which previously neutral cues are able to elicit reward seeking following learning. Recently we have shown that the activity of ventral pallidum (VP) neurons in response to a cue predicting reward availability encodes both the likelihood and latency of subsequent instrumental reward-seeking actions (Richard et al., 2016). Here, we investigated whether VP cue responses would encode and contribute similarly to the vigor of Pavlovian versus instrumental reward seeking behaviors, when these responses consist of superficially similar locomotor response patterns, and are driven by similar levels of reward expectancy. During Pavlovian conditioning, male and female Long Evans rats were trained to associate one auditory cue (the CS+) with delivery of 10% liquid sucrose reward (not contingent on the animal's behavior) and alternative auditory cue (CS-) with no delivery of reward. In the instrumental task, one auditory cue (the discriminative stimulus; DS) signaled availability of the same sucrose reward, if the animal made an entry into the reward port during the cue period; the alternative cue (NS) signaled no reward availability. Rats were trained in one of these tasks until they entered the reward port on >70% of reward cue trials (CS+ or DS), and <30% of control cue trials (CS- or NS), and then were implanted with drivable microwire arrays aimed at VP. We found that, similarly to our previous report, cue elicited activity in ~25% of VP neurons significantly predicts the latency of instrumental reward seeking, even when it consists of a much simpler behavior: entry to a reward port. In contrast, VP encoding of Pavlovian port entry latency did not exceed chance levels. Further, when we

assessed the impact of either VP inactivation with GABA agonists, or dopamine blockade, with the non-selective antagonist flupenthixol, we found that only the latency of reward seeking driven by the DS, but not by the CS+, was affected by these manipulations. These results suggest that VP encoding of latency, as well as the functional contributions of both VP activity and dopamine inputs, are not related to trial-by-trial variation in the value of the expected reward, or to motor invigoration more generally, but to the ability of incentive cues to invigorate reward seeking behaviors upon which reward delivery is contingent.

**Title:** Nucleus accumbens neural activity reflects reward preference and predicts consumption

**Authors: *D. J. OTTENHEIMER**[1], J. M. RICHARD[2], P. H. JANAK[2]
[1]Solomon H. Snyder Dept. of Neurosci., [2]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** The nucleus accumbens (NAc) has long been implicated in the orchestration of reward seeking and consumption. Despite its demonstrated involvement in the processing of a variety of drug and natural rewards, it is less clear how responses in the NAc differ across these rewards. The study of NAc activity in response to rewards with different properties can help characterize which aspects of reward processing the NAc is involved in. Using in vivo extracellular recording, we measured the responses of NAc single units during the consumption of 10% solutions of sucrose and maltodextrin, two rewards of very similar caloric value and palatability. Male Long Evans rats were trained on a single cue that announced the availability of a reward whose delivery was contingent upon port entry. Sucrose and maltodextrin trials were randomly interspersed throughout the session in order to obscure the identity of the reward until its delivery. Rats' individual licks were recorded using a custom-built lickometer that permitted analysis of consumption behavior and corresponding neural activity. Rats licked a similar amount to both rewards although slightly more during consumption of sucrose. This preference was reflected in NAc neural activity, which was biased toward stronger responses during sucrose consumption than maltodextrin. Analysis of the neural activity in 500ms bins, with a sliding

window of 100ms, revealed the greatest difference in firing across rewards occurred between 0.5s and 2.5s after reward consumption onset, following an initial non-reward-specific spike in activity. Moreover, we found that firing rate during the middle portion of reward consumption predicted the total number of licks on a trial-by-trial basis for a large proportion of the population of neurons. This group of lick-correlated neurons fired more strongly during sucrose consumption than maltodextrin, a potential indication that the difference in firing to the two rewards is in part due to the increased licking for sucrose. These results suggest that NAc neurons may be involved in integrating the palatability of rewards in order to direct reward consumption behavior.

**Abstract:** Dopamine (DA) neurons in the ventral tegmental area (VTA) signal reward prediction errors (RPEs) and their activation constitutes a teaching signal that promotes learning about the events leading up to reward. DA neurons in the Substantia Nigra (SNc) also encode RPEs but their functional role in error-correction learning is unclear. Moreover the learning strategy engaged by RPEs remains largely unknown. RPEs could promote model-free learning in which animals learn the value of cues and actions independently of the representation of their outcomes, resulting in rigid behavior insensitive to postconditioning changes in outcome value. Alternatively, through model-based learning, RPEs could contribute to the construction of internal models of the task by connecting certain events with their respective outcome, allowing animals to rapidly adjust their behavior following changes in outcome value. Therefore, the purpose of this study was twofold: 1) Assess the contribution of VTA- and SNc-DA neuron activation in Pavlovian reward learning, and 2) When learning was observed as a result of our manipulations, determine the model-free or model-based nature of this learning. Rats were trained in a Pavlovian blocking paradigm, in which learning about a target cue paired with

reward is prevented (or blocked) if this cue is presented simultaneously with another cue that already signals reward. In this situation, the absence of RPE, presumably materialized by the absence of phasic DA responses, is thought to prevent learning about the redundant target cue. Consistent with the idea that VTA-DA neurons encode a RPE teaching signal, we show that optogenetic activation of VTA-DA neurons during expected reward unblocks learning about the target cue. In contrast, optogenetic activation of SNc-DA neurons did not promote Pavlovian learning (learning remained blocked). This is despite the fact that activation of both VTA- and SNc- DA neurons serve as potent reinforcers in self-stimulation procedures. To determine the associative content of the learning promoted by VTA-DA neurons activation, we combined the blocking paradigm with postconditioning devaluation of the outcome (via lithium-induced taste aversion). We found that the expression of VTA-DA dependent learning is affected by outcome devaluation which indicates that the learned association integrates a representation of the outcome, a signature of model-based learning. These findings reveal that activation of VTA- or SNc-DA neurons engages largely dissociable learning processes with VTA-DA neurons capable of participating in complex model-based predictive learning, while the role of SNc-DA neurons is more limited.

**Title:** Motivational stake promotes goal-directed behavior

**Authors:** ***Y. VANDAELE**[1], H. PROVINCE[1], A.-C. BERARDI[1], P. JANAK[1,2]
[1]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

**Abstract:** Balance between goal-directed and habitual response strategies is necessary for flexible and efficient decision-making. While goal-directed behavior is considered dependent upon Response-Outcome (R-O) associations, habit instead relies on Stimulus-Response (S-R) associations. However, the stimuli that support the S-R association underlying habitual responding in instrumental procedures are poorly defined. To resolve this issue, we designed a discrete-trials procedure, in which rats must wait for lever insertion and complete a sequence of 5

lever presses to obtain a reward (20% sucrose or grain-based pellets). Lever insertion thus constitutes an audio-visual stimulus signaling the availability of the reward. Using sensory-specific satiety-induced devaluation, we found that food-restricted rats trained with grain-based pellets remained goal-directed over training with this procedure, whereas rats trained with a solution of 20% sucrose rapidly developed habit. The aim of this study was to explain this dissociation. To do so, we compared rewards differing in taste (sweet versus unsweet) and/or in nature (liquid versus solid) in animals food-restricted or water-restricted. We found that motivational stake strongly promotes goal-directed behavior. While responding for liquid rewards is habitual when rats are food-restricted, lever pressing for a sucrose solution is goal-directed under conditions of water-restriction. Switching the motivational state from water- to food-restriction restores the original dissociation with habitual responding for sucrose while lever pressing for food pellet is goal-directed. These results are particularly relevant to understand how homeostatic and nutritional factors can affect the balance between goal-directed and habitual behaviors.

Inst., Ann Arbor, MI; [6]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

**Abstract:** Cues that predict the presence of natural rewards can acquire incentive motivational value in addition to predictive value. Notably, cues that acquire incentive motivational value can gain inordinate control over behavior, often leading to maladaptive tendencies such as drug addiction. During a Pavlovian conditioned approach task, in which the presentation of a lever

precedes delivery of a food reward, some rats, termed sign-trackers (STs), approach the lever; while others, termed goal-trackers (GTs), approach the food cup. For STs, the cue becomes an incentive stimulus; whereas for GTs it is merely a predictor. Recently, we have shown that the paraventricular nucleus of the thalamus (PVT) is involved in the regulation of sign- vs. goal-tracking behavior. Selective lesions of the PVT enhance sign-tracking behavior, but this nucleus appears to serve distinct functions in STs and GTs. Relative to GTs, STs show enhanced c-fos expression in the PVT in response to a discrete cue previously paired with food- or drug-reward. Further, for STs, cue-induced c-fos in the PVT correlates with cue-induced c-fos in subcortical regions; whereas for GTs, cue-induced c-fos in the PVT correlates with that in the prelimbic cortex (PrL). Thus, we postulate that the PVT acts as a central node to regulate the attribution of incentive motivational value to reward cues, and that inputs to the PVT from the PrL may inhibit this process. Here, we interrogated the role of this circuit in sign- and goal-tracking behaviors using a dual vector approach to selectively express Designer Receptors Exclusively Activated by Designer Drugs (DREADD) in PrL projections to the PVT. A Cre-dependent viral vector expressing inhibitory Gi or stimulatory Gq DREADD was infused into the PrL, while a CAV-Cre viral vector was injected into the PVT. This resulted in DREADD expression only in PrL-PVT neurons. In GTs, there was no apparent effect of chemogenetic manipulation of the circuit. In contrast, in STs, CNO stimulation of Gi signaling in PrL-PVT neurons increased goal-tracking behavior, while leaving sign-tracking behavior intact. Interestingly, CNO stimulation of Gq DREADD decreased the conditioned reinforcing properties of lever-cue, but did not affect sign- or goal-tracking behavior. Thus, “turning off” or “turning on” the PrL-PVT circuit has differential effects on cue-motivated behaviors that depend on individual variation in the attribution of incentive motivational value to the cue and the way in which this is assessed. Taken together, these data suggest that top-down processes from the PrL to the PVT may be a critical component of cue-motivated psychopathologies, like addiction.

**Title:** The role of cortico-thalamic circuitry in the reinstatement of drug-seeking behavior

**Authors: *B. N. KUHN**[1], M. S. KLUMPNER[2], P. CAMPUS[2], S. B. FLAGEL[2]
[1]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [2]Psychiatry, Univ. of Michigan Dept. of Psychiatry, Ann Arbor, MI

**Abstract:** One of the biggest challenges for the treatment of addiction is relapse, with rates as high as 90%. Relapse is often triggered by cues in the environment (e.g. people, places and paraphernalia) that were previously associated with the drug-taking experience. Thus, in order to better treat relapse, it is imperative to understand the neurobiological mechanisms by which cues in the environment are able to gain inordinate control and lead to maladaptive behaviors. One brain region that has recently been recognized for its role in cue-induced drug-seeking behaviors is the paraventricular nucleus of the thalamus (PVT). The PVT sits at the interface of cortical, limbic and motor pathways, putting it in an ideal location to regulate motivated behaviors, such as drug-taking and drug-seeking behavior. Recent work from our lab suggests that the PVT plays an important role in mediating individual differences in the propensity for cue-induced relapse. However, the specific PVT circuitry mediating this variation in drug-seeking behavior remains unknown. The prelimbic cortex (PrL) is one region that sends dense projections to the PVT and this brain region has been implicated in addiction-related behaviors in both pre-clinical and clinical neuroscience studies. Data from our lab suggests that the PrL-PVT pathway plays an important role in the motivational properties of reward-associated cues. Thus, the aim of the current study is to determine if the PrL-PVT pathway is important for cue-induced drug-seeking behavior. To assess this, we used a dual-vector DREADD (Designer Receptors Exclusively Activated by Designer Drugs) technique that allowed us to specifically assess the effects of inhibiting (Gi-DREADD) the PrL-PVT pathway on cue-induced and cocaine-induced drug-seeking behavior, or reinstatement. Rats underwent 2 weeks of cocaine self-administration followed by 4 weeks of abstinence and then extinction training. Prior to the test for cue-induced and cocaine-primed reinstatement, rats received an injection of vehicle or clozapine-N-oxide (CNO) to activate the inhibitory $G_i$-DREADD. CNO-induced inhibition of the PrL-PVT pathway decreased cocaine-seeking behavior during cue-induced reinstatement, but had no effect during cocaine-primed reinstatement. Thus, the PrL-PVT pathway appears to play a specific role in cue-mediated drug-seeking behavior. The role of this pathway in mediating individual variation in the motivational value of a drug cue is being assessed in ongoing studies. These findings have the potential to further our understanding of the neurobiological mechanisms mediating relapse, and can lead to novel targets for the treatment of addiction.

**Title:** The encoding of incentive salience in the ventral pallidum

**Authors: *A. M. AHRENS**, T. E. ROBINSON, J. W. ALDRIDGE
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

**Abstract:** Some rats naturally attribute incentive salience to a conditioned stimulus (CS) paired with food reward (sign-trackers, STs), while others respond primarily to the predictive value of a cue (goal-trackers, GTs). Sign-tracking is associated with greater cue-induced activation of mesolimbic structures than goal-tracking; however, it is unclear how features of the CS itself might influence the engagement of incentive-related neural pathways. Our goal was to determine how different cue modalities affected the neural encoding of incentive salience within different subregions of the ventral pallidum. We recorded neural activity as rats performed a two-CS Pavlovian conditioned approach task, in which both a lever CS and a tone CS predicted identical food reward. The lever CS elicited sign-tracking in some rats (STs) and goal-tracking in others (GTs); whereas the tone CS elicited only goal-tracking in all rats. In STs, the lever CS elicited robust changes in neural activity in both anterior and posterior regions of the VP, though the direction of the response varied between regions, with primarily inhibition in the anterior VP and a mix of excitation and inhibition in the posterior VP. These changes were not seen when STs were exposed to the tone CS, and in GTs there were no differences in firing between lever and tone CSs. These results show that the entire VP structure encodes incentive signals, and that neural changes in the VP are only observed when a cue has features that promote the attribution of incentive salience in predisposed individuals.

**Title:** Neural representation of sensory-state value in the stratal striosome compartment

**Authors: *T. YOSHIZAWA**, M. ITO, K. DOYA
Okinawa Inst. of Sci. and Technol., Onna-Son, Okinawa, Japan

**Abstract:** The striatum consists of the striosome (patch) and matrix compartments. It was previously hypothesized that the striosome represents state values, whereas the matrix represents the action values or performs action selection. While previous electrophysiological studies have shown that the striatal neurons represent these variables, it has been difficult to discriminate which striatal compartment each neuron belongs to. In this study, we employ cell-type specific calcium imaging and endoscopic microscopy to test whether striosome neurons represent value information.

We used the transgenic mice expressing Cre recombinase selectively in striosome neurons (Gerfen *et al.*, 2013). To express GCaMP6s selectively in striosome neurons, we injected AAV.Syn.Flex.GCaMP6s to their dorsomedial striatum (DMS). After the expression of GCaMP6s, we implanted a GRIN lens to the DMS for endoscopic *in vivo* calcium imaging (nVistaHD, Inscopix). After recovery from the surgeries, mice were classically conditioned with different odor cues that predicted appetitive or aversive outcomes. The possible outcomes were large reward (water 4 µl), small reward (water 2 µl), nothing, or punishment (a puff of air). Within the first 5 days, mice showed predictive licking behavior during the cue and delay period for the odor stimuli associated with a large reward (Early stage). After subsequent conditioning up to 14 days, mice showed different frequencies of predictive licking for large, small, and no rewards (Late stage).

Daily calcium imaging showed that striosome neurons acquired reward-amount-proportional activities during the cue and delay period. These reward predictive activities encode the value of odor stimulus. In addition, some striosome neurons acquired responses during reward presentation period. Intriguingly, most neurons showed these activities specifically in the Early or Late stage. Compared to the control group neurons recorded non-selectively, the striosome neurons more strongly encoded the reward-related value and reward information in the Late stage ($p<0.05$, $\chi^2$-test). In the striosome, the proportions of reward-predictive and responsive neurons were 19% (23 of 123 neurons) and 23% (28 of 123), respectively. In the control, they were 8% (7 of 83) and 7% (6 of 83).

These findings are consistent with the hypothesis that the striosome takes the role of the critic that evaluates the value of sensory state in reinforcement learning. A novel unexpected finding is that the striosome consists of learning-stage-specific-neural ensembles. The results suggest that the striosome takes a more dominant role in reward prediction than the matrix after sufficient learning.

**Abstract:** A range of neuropsychiatric disorders, including drug addictions, are characterized by poor decision-making, particularly under conditions when actions can have negative or punished outcomes. The neural mechanisms underlying these abnormal processes are, however, still poorly understood. To address this gap in the literature, we first developed a novel assay for risky decision-making in mice, building on task previously described in rats (Orsini et al. *J Neurosci.* 2015). Mice were trained to reliably touch one visual stimulus on a computer monitor to obtain a large liquid reward, in preference over a simultaneously presented stimulus that produced a small reward when touched. Then, during test sessions, each touch at the large-reward stimulus produced footshock at increasingly probabilities across successive trial-blocks: 0, 25, 50, 75 or 100% probability of shock. The small-reward stimulus was never associated with shock. We first established that female and male C57BL/6J mice reduced preference for the large-reward in a shock-probability dependent manner. Next, we examined the potential contribution of serotonergic transmission in the nucleus accumbens core (NAcc) in modulating risky decision-making. We focused on this system given prior data implicating both the NAcc and serotonin in risk-related behaviors, but a lack of clear evidence to date that determines the possible link between the two. In one experiment, we optogenetically silenced serotonin inputs to the NAcc from the dorsal raphe nucleus, by targeting an AAV carrying halorhodopsin in *SERT*-Cre mutant mice and shining yellow light into the NAcc during behavioral testing. In another experiment, we bilaterally microinfused either the selective serotonin 5-HT2A antagonist, MDL100907, or the 5-HT2C antagonist, SB242064, directly into the NAcc during behavioral testing. We then quantified, using fluorescence *in situ* hybridization, co-expression of 5-HT2A and 5-HT2C with either of the major dopamine receptor subtypes on NAcc medium spiny neurons (MSN), D1DR or D2DR. In addition, we optogenetically silenced either of these classes of dopamine MSN, via targeting of an AAV carrying archaerhodopsin in *D1dr*-Cre and *Adora2a*-Cre mutant mice, respectively, and shining green light into the NAcc during behavioral testing. Our findings provide support for an important contribution of serotonin input to the

NAcc, acting at specific 5-HT2 receptors and possibly in interaction with dopaminergic activity, in risk decision-making. Research supported by the NIAAA IRP.

**Title:** Individual differences in risky decision-making predict nicotine sensitivity and other addiction-relevant behaviors

**Authors: *D. B. GABRIEL**[1], T. G. FREELS[1], N. W. SIMON[2]
[1]Psychology, The Univ. of Memphis, Memphis, TN; [2]Psychology, Univ. of Memphis, Memphis, TN

**Abstract:** Addiction is characterized by persistent risky decision-making in the face of negative consequences. The rodent risky decision-making task (RDT) models this behavior by measuring preference between small, safe rewards and larger rewards with an escalating risk of physical punishment (mild footshock). This task reliably reveals a subset of subjects with an enduring preference for risky rewards, which may provide insight into addiction vulnerability. Here, we characterized rats as “risky” or “non-risky” in RDT, then compared risk preference with other behavioral traits that coincide with addiction. These included: 1.) reinforcer devaluation, which measures habit formation, 2.) DRL 20, which measures impulsive action, 3.) delay discounting, which measures impulsive choice, and 4.) nicotine locomotor sensitization, which assesses behavioral sensitivity to repeated experimenter administered nicotine exposure. First, we observed that risky rats demonstrated a trend toward stronger habit formation compared to safe rats. Risky rats also showed greater impulsive action than safe rats, while there was no relationship between risk preference and impulsive choice. Finally, preliminary data indicate that risky rats were resistant to nicotine locomotor sensitization. Collectively, these data indicate that the RDT reveals a subpopulation of rats with multiple cognitive features that predict vulnerability to addiction, as well as reduced behavioral sensitivity to nicotine exposure.

**Title:** The effects of enhanced cannabinergic signaling on risky decision-making in rodents

**Authors: *T. FREELS**[1], D. B. GABRIEL[1], N. W. SIMON[2]
[1]Psychology, The Univ. of Memphis, Memphis, TN; [2]Psychology, Univ. of Memphis, Memphis, TN

**Abstract:** Suboptimal decision-making and aberrant cannabinoid signaling are both prevalent in psychopathology. However, little is known about the cannabinergic mechanisms of decision-making guided by risk of punishment. The Risky Decision-making Task (RDT) measures preference between a small, safe reward and a large reward accompanied by an escalating probability of foot shock. We tested the acute effects of multiple doses of systemic AA-5-HT, a fatty acid amide hydrolase inhibitor that enhances endocannabinoid tone, and the selective CB1 agonist ACEA on RDT performance in male Long-Evans rats. We found that neither AA-5-HT nor ACEA affected overall risk preference or omissions in RDT. Interestingly, we found that both cannabinoid treatments increased decision latency in dose-dependent fashion. This effect does not appear to be related to reduced locomotion, reward motivation, or overall task engagement. In addition, we observed that AA-5-HT increased stereotypy and rearing behavior in the open field without altering overall locomotion or thigmotaxy. Our results suggest that enhancing cannabinergic signaling may engender cognitive inefficiency during decision-making without modulating risk-taking behavior.

**Title:** Eyes on the prize: Risk-promoting sensory reward features result in pupil dynamics consistent with a shift in locus coeruleus-mediated control states

**Authors: *M. V. CHERKASOVA**[1], J. J. S. BARTON[2], L. CLARK[2], A. STOESSL[3], C. A. WINSTANLEY[4]
[1]Neurol., [3]Pacific Parkinson's Res. Ctr., [2]Univ. of British Columbia, Vancouver, BC, Canada; [4]Psychology, Univ. British Columbia, Vancouver, BC, Canada

**Abstract:** The presence of sound stimuli during slot machine play has been found to increase arousal measured by self-report and skin conductance (Dixon et al, 2014). We have recently demonstrated that the presence of reward-paired sensory features (money images and casino-inspired jingles) promotes risk taking on an economic decision making task. Here, we used pupillometry as a proxy of locus coeruleus-mediated arousal to examine whether risk-promoting sensory feedback increases arousal, as well as to explore possible links between arousal and risk. Healthy volunteers were randomly assigned to perform the decision making task either with or without the sensory feedback features, with concurrent pupil tracking. Aside from the feedback, the two task versions were visually identical. We found that baseline pupil sizes at trial onset were larger in the group without sensory features ($p = .008$). This could not be a luminance-driven effect: the baseline displays were identical, and the feedback display had higher luminance without the sensory enhancement (white screen), which should result in smaller, not larger pupil sizes. Conversely, phasic pupil dilation across decision and feedback anticipation phases of the task (measured as area under the curve with respect to trial baseline), was greater in the presence of the sensory features ($p = .01$). Moreover, the magnitude of decision- and anticipation-related phasic pupil responses on a given trial was significantly associated with the likelihood of taking a risk ($ps \leq .0006$). Changes in pupil dynamics in response to sensory task enhancement are consistent with a shift from a more exploration-dominated to a more exploitation-dominated control state, as proposed by the adaptive gain theory of noradrenergic signalling (Aston-Jones and Cohen, 2005). The former is associated with the tonic mode of locus coeruleus activity, characterized by more enduring but less discriminative responsiveness of cortical neurons. The latter is associated with the phasic mode, characterized by more selective increases in neuronal responsiveness to task-relevant stimuli. Reward-paired audio-visual stimuli, which are ubiquitous in electronic gambling, might shift the balance towards a more exploitation-dominated state, where cortical neurons are selectively responsive to game-related stimuli. Heightened phasic responses to task events characteristic of this state appear to be linked to risk taking.

**Title:** The abused inhalant toluene increases risky decision making in a rodent model of probabilistic discounting

**Authors: *K. M. BRAUNSCHEIDEL**[1], S. B. FLORESCO[2], J. J. WOODWARD[3]
[1]Neurosci., Med. Univ. of South Carolina Dept. of Neurosciences, Charleston, SC; [2]Univ. British Columbia, Vancouver, BC, Canada; [3]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

**Abstract:** Volatile organic solvents cause intoxication and neurochemical changes that are similar to classic drugs of abuse. These include transient and persistent changes within several cortical regions including the medial prefrontal cortex (mPFC) that can lead to a loss of "top-down" control of complex behaviors. The mPFC undergoes significant maturation during adolescence and previous studies in our lab have shown that adolescent mPFC neurons are particularly sensitive to toluene. As solvent abusers often show impaired decision making, it is important to understand how toluene affects choice selection, especially when the choice involves uncertainty. To explore this question, we used a well-validated rodent model of risky decision making termed probabilistic discounting (PD) and tested animals on this task after chronic exposure to toluene. To mimic patterns of human toluene intoxication, we treated adolescent male and female Sprague-Dawley rats with twice daily, fifteen minute exposures to toluene vapor (5700 ppm) for five consecutive days (P39-44). After reaching adulthood (P60), rats were trained to lever press for a palatable food reward (20% sweetened condensed milk). One lever delivered a small, certain reward (30 µl, 100% of the time) while a second lever delivered a large, uncertain reward (90 µl, reinforcement probability degrades over 5 successive blocks of 18 trials). Rodents exposed to toluene during adolescence did not show altered risk taking behavior in adulthood, although they did take significantly longer to lever press compared to air treated controls. Interestingly, acute exposure (15 min) of adult animals to toluene (5700 ppm) 45 min prior to PD increased selection of the large/risky lever even when the reinforcement was extremely uncertain. This was due to both increased responsiveness to risky reinforcement and decreased loss aversion. These differences were not observed following exposure to a lower concentration (2850 ppm) of toluene. A previous study in our lab demonstrated that toluene induces an endocannabinoid-mediated long-term depression of glutamatergic synaptic activity in

the mPFC. Ongoing studies are testing the hypothesis that the toluene-induced increase in risky behavior are mediated via endocannabinoid modulation of mPFC activity.

**Title:** vmPFC value signal for high calorie snack foods relates to weight gain in first year students

**Authors: *S. NESELILER**[1], K. LARCHER[2], Y. ZEIGHAMI[2], S. SCALA[2], R. REID[3], R. ANDERSEN[3], A. DAGHER[4]
[1]McConnell Brain Imaging, Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Montreal Neurolog. Inst., Montréal, QC, Canada; [3]McGill Univ., Montréal, QC, Canada; [4]McGill Univ., Montreal, QC, Canada

**Abstract:** Wanting is the psychological process of incentive salience, through which cues predicting reward acquire subjective value. Increased subjective value for high calorie foods might underlie the neurobiological basis of the vulnerability for obesity. Therefore, increased subjective value for food cues should increase the probability of food intake and subsequently lead to weight gain.
We tested this hypothesis using the Becker DeGroot Marschak auction paradigm (BDM) to assess the subjective value for high calorie versus low calorie food items in first year university students[1]. We utilized the first year university students to study the neurobiological basis of the vulnerability for weight gain since students tend to gain more weight in a short period of time during the first year of university compared to age-matched controls[2]. In addition, for most students this is the first time they are making food decisions independently. Therefore, we predicted that increased subjective value for high calorie food cues would result in increased weight gain in this population.
**Methods**
72 first-year students who were living independently for the first time outside of the family home enrolled in the 8-month long study (mean BMI at entry: 22.6±2.5 SD). Participants underwent fMRI during which they completed the BDM auction task at beginning of the school year. In the BDM task, participants bid on high and low calorie snack foods and trinkets. We measured participants' weight at the beginning and at the end of the school year using a medical scale.

The data was pre-processed using FSL (www.fmrib.ox.ac.uk/fsl)[3]. The BOLD activity to high calorie food cue at high bidding versus low bidding was compared to low calorie food cue at high versus low bidding. Using this analysis, we investigated how the caloric content modulated by subjective value (measured by bidding) interacts with weight gain.

**Results**

There was substantial variability in weight change among our participants (mean weight gain in pounds 3.0± 6.3 SD). In the brain, the caloric content modulated by subjective value interacted with weight gain. Participants with higher weight gain showed increased BOLD in left vmPFC (T-value=3.4, MNI: X=-8, Y=38, Z=-10) and left medial OFC (T-value= 3.2, X=-4, Y=48, Z=-10).

**Conclusions**

Increased value-related activation in the vmPFC was correlated with weight gain in first year university students. This result suggests that increased activation in an area that is known to compute subjective value exhibited might underlie the neurobiological basis of the vulnerability to weight gain and obesity.

**Title:** Intranasal oxytocin increases reward circuitry responses to monetary rewards in children with autism

**Authors: *R. K. GREENE**[1], C. ALDERMAN[4], M. SPANOS[4], E. WALSH[2], J. BIZZELL[4], G. D. STUBER[5], L. SIKICH[4], G. S. DICHTER[3]
[2]Dept. of Physical Med. and Rehabil., [3]Psychiatry, [1]The Univ. of North Carolina - Chapel Hill, Chapel Hill, NC; [4]Duke Univ., Durham, NC; [5]Psychiatry, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

**Abstract:** Background: Oxytocin (OT) administration has been shown to improve social symptoms of individuals with autism spectrum disorder (ASD); however, the mechanism of action behind this effect is unclear. Although evidence suggests that these behavioral changes

may be attributed to the effect of OT on the mesolimbic dopamine system, no study to date has examined the effect of OT on this specific neural system. Additionally, whether OT impacts responses to social reward specifically has not been investigated. Therefore, this study examined the effects of a single dose of intranasal OT on neural responses to social and nonsocial rewards in adolescents with ASD.
Methods: In this placebo-controlled double-blind study, twenty-nine adolescents with ASD (age: *M*=13.38 years, *SD*=2.32) completed two fMRI scans, one after OT administration and one after placebo administration. During each scanning session, participants completed social and monetary incentive delay tasks, which required that participants press a button as quickly as possible after seeing a reward availability cue. If a button was pressed quickly enough participants would "win" either a monetary reward (represented by an image of currency) or social reward (represented by an image of a happy, direct-gaze face).
Results: Analysis of the anticipatory phase of the monetary condition revealed greater activation in the right nucleus accumbens (NAcc), the left putamen, and the anterior cingulate gyrus (ACgG) during the OT condition compared to the placebo condition. Alternatively, analyses of the anticipatory phase of the social reward condition showed no significant increase in activation during the OT condition compared to the placebo condition. To investigate the effects of OT on brain activation to social versus nonsocial rewards, we evaluated a drug condition x reward type interaction. The right NAcc and the left putamen showed greater activation during nonsocial relative to social reward anticipation after intranasal OT administration relative to placebo. Additionally, these analyses revealed greater activation during nonsocial relative to social reward outcome phase after OT relative to placebo administration in the right orbital frontal gyrus and the ACgG.
Conclusions: Results suggest that the effects of intranasal OT administration in ASD may not be constrained to social processing systems, but rather may extend more generally to mesocorticolimbic brain systems that control incentive salience processing, reward valuation, and reward-based learning.

**Title:** Reward and selection history shape neural representations of an attentional priority in human visual and parietal cortex

**Authors: *S. ITTHIPURIPAT**[1], V. A. VO[1], T. C. SPRAGUE[3], J. SERENCES[2]
[1]Neurosciences Grad. Program, [2]Psychology, UCSD, La Jolla, CA; [3]Dept. of Psychology, New York Univ., New York, NY

**Abstract:** Many prominent theories of attention highlight a dichotomy between the top-down and bottom-up control of attention. However, this dichotomy fails to account for many situations where goal-directed behaviors are disrupted by attentional capture that is induced by task-irrelevant distractors associated with reward. This observation supports an alternative framework, which posits that reward and selection history can interact with current behavioral goals in an integrative attentional priority map. While there is strong behavioral evidence in support of this view, less is known about how reward and selection history shape priority signals across cortical areas in the visual hierarchy. Here, we measured neural activity in visual and parietal cortex using functional magnetic resonance imaging (fMRI) while human subjects were performing a value-based decision-making task. During the scan, subjects learned values associated with the colors of visual targets presented at two spatial locations, while ignoring a task-irrelevant distractor in the third location. Across trials, the color associated with each visual stimulus was swapped across three different locations so that we could examine behavioral and neural effects of target and distractor values based on their selection history. We found that target selection bias (i.e., the probability of choosing high-valued over low-valued targets) decreased and response times increased as distractor value increased. Using a multivariate image reconstruction analysis of the fMRI data, we found that distractor value and selection history jointly modulate the gain of spatial representations centered at the distractor location, and such modulations occurred across many retinotopically organized regions of visual and parietal cortex. Importantly, these gain modulations also appeared to modulate the degree of representational bias between selected and unselected target locations. Overall, these results suggest that value-based decision-making is supported via the interaction between reward-based gain modulations of neural representations related to both task-relevant and task-irrelevant stimuli.

**Title:** Using expectancy theory to quantitatively dissociate human neural activation for motivation from that of reward-related factors

**Authors: A. KOHLI**, R. W. LEFCO, *C. F. ZINK
Lieber Inst. For Brain Develop., Baltimore, MD

**Abstract:** Much research has been dedicated to deciphering the neural correlates of motivation and reward processes in the human brain. It has been difficult, however, to attribute neural signals precisely to motivation disentangled from experimentally-manipulated factors that influence motivation. We overcome this challenge with the novel application of an operational theory of motivation, namely the Expectancy Theory (ET), to human fMRI data. The use of ET enables the isolation of activity precisely corresponding to motivation distinct from other factors, including reward magnitude, reward probability, task difficulty, and expected value. According to ET, motivational force (MF), a force that energizes behavior and determines the level of effort to put forth on a given task, is the product of three factors: 1) Expectancy (E) - the belief that increasing effort will increase performance (i.e., success probability/task difficulty); 2) Instrumentality (I) - the belief that increased performance leads to a particular outcome (i.e., outcome probability); and 3) Valence (V) - the extent to which the outcome is desired (i.e., reward magnitude/value). Here, during fMRI, two groups of 50 healthy subjects (n = 100) performed a modified version of the Monetary Incentive Delay task that was designed to isolate neural activity corresponding to each ET variable by assigning cue-predicted task difficulty, reward probability, and reward magnitude in particular combinations. Voxels were classified as activating in response to a particular ET variable based on the relative activation pattern exhibited across cue type. Specifically, average beta estimates for each cue type were extracted from each voxel in the group whole-brain mask, statistically compared using two-tailed, paired t-tests between cue types, and mapped to ET variables according to particular patterns. Subsequently, the ET variable associated with any voxel was only reported if it was replicated between the two groups, with the resultant variable cluster extent > 5 voxels. We find significant signals in the midbrain, ventral striatum, motor cortex, and visual cortex that specifically map to motivation (i.e., MF), rather than other reward-related factors that map to other regions in the brain, such as insula, amygdala, cingulate, premotor, parietal, prefrontal, and orbitofrontal areas. This is important because it clarifies the long-standing confounding nature of motivation versus reward in these signals. It also highlights the practicality and effectiveness of the application of ET to neurobiology to more precisely and accurately probe motivation neural correlates than has been achievable previously.

**Title:** Central amygdala model integrates intra-amygdalar inputs during fear conditioning

**Authors: *B. LATIMER**[1], P. SAMARTH[1], F. FENG[1], D. PARE[2], S. S. NAIR[1]
[1]Univ. of Missouri, Columbia, MO; [2]Rutgers Univ. Newark, Newark, NJ

**Abstract:** Classical fear conditioning (FC) leads to potentiation of conditioned stimulus (CS) inputs to lateral amygdala (LA) neurons, and to increases in the firing of central medial amygdala (CeM) cells. In turn, CeM cells drive conditioned fear responses via their projections to fear effector neurons. However, transmission of information from LA to CeM neurons is indirect, involving basal amygdala (BA), the central lateral (CeL) nucleus, and intercalated cells (ITC), all of which project to CeM. Although CeM is thought to be the main fear output station of the amygdala for conditioned fear responses, the details of connectivity within Ce are not well understood. LA axons contact CeL but not CeM cells, and it is not clear how LA influences CeM through CeL. Also, CeL contains two types of CeM-projecting cells, with inhibitory (CeL-Off) and excitatory (CeL-On) responses to the CS. These two cell types inhibit each other and it was hypothesized that the inhibition of -Off cells by -On cells leads to the disinhibition of CeM cells. However, it is not clear whether LA and BA inputs connect differently to the two CeL cell subtypes and whether intrinsic and afferent synapses to Ce can undergo activity-dependent plasticity.
We developed a 500-cell biophysical model of CeL and CeM to investigate how Ce might integrate afferents from LA, BA and ITC during FC. All afferents are modeled as spike trains using experimental tone response data. The network had experimental estimates of regular spiking (RS) and low-threshold bursting (LTB) cell proportions, and of intrinsic connectivity. Starting with 6% unbiased connectivity for all afferents to CeL, we tuned the connection weights to match both habituation and tone-induced *in vivo* responses: 8% (19/240) of the model CeL cells showed CS-evoked increase (-On) and 9% (22/240) showed CS-evoked decrease in firing rates (-Off) during habituation; the numbers after conditioning were 17% and 14%, respectively. Analysis of connectivity for CeL cells revealed that the only significant difference in connectivity for -Off cells compared to -On cells was from ITC afferents. Further investigation of –Off cells showed that although they were not predominantly of the PKCδ+ type, biasing ITC connections to PKCδ+ vs. PKCδ- type (9 and 6 % vs the original unbiased 6 and 6%) resulted in

82% of the –Off cells being from the PKCδ+ group. Another observation was that a larger proportion of LTB cells, compared to RS cells, were of the –Off type after training, although both types are equally probably of being PKCδ+ or PKCδ-. Tone-induced firing of LTB cells was delayed compared to that of RS cells, suggesting that inhibition from RS cells may add to LTB cells becoming –Off cells.

**Title:** Differential recruitment of competing valence-related amygdala networks during anxiety

**Authors: *S.-C. LEE**[1,2], A. AMIR[1], D. HAUFLER[1], D. PARE[1]
[1]Neurosci., Rutgers Univ., Newark, NJ; [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** The basolateral amygdala (BL) is involved in fear and anxiety but it is currently unclear how the same network supports these two states. To address this question, we trained rats on appetitive and aversive conditioning in different contexts. Distinct groups of BL neurons displayed increased activity during appetitive (CS-R) vs. aversive (CS-S) conditioned stimuli (R-cells and S-cells, respectively) and they were typically inhibited by the other CS. When the CS-S was presented in the safe context, rats entered a long-lasting anxiety-like state characterized by increased inter-CS freezing and impaired reward-seeking. During this state, a subset of BL cells ('state-cells') showed sustained shifts in baseline activity whose time course matched that of the behavioral changes. Many state-cells with increased firing rates were S-cells whereas R-cells only included state-cells with reduced firing rates. Thus, anxiety involves persistent activity changes that are differentially expressed by subsets of valence-specific BL neurons.

**Abstract:** The survival of organisms critically depends on avoidance responses to life threating stimuli or situations. Sensory information about the context needs to be remembered to produce defensive behavior in the same situation. To investigate underlying brain regions to encode dangerous contexts, manganese enhanced MRI (MEMRI) was utilized in the contextual fear conditioned rats. MEMRI is widely used to monitor whole brain activities with high resolution images. The paramagnetic manganese ion, as an effective contrast agent, accumulates in neurons via voltage-gated calcium channels and enhances contrast in the activated tissues captured by T1 weighted MRI.
Fear conditioning was conducted in male Sprague-Dawley rats (6-7 weeks old; weighing 160-240g). The animals were exposed to a conditioning box for an hour. Electric foot shock (1mA 0.5sec duration) was delivered to the floor grid every 3 minutes (total 20 shocks). Control animals were exposed to the same context without foot shocks. The animals received nasal injection of manganese chloride (0.2 mM/kg body weight) dissolved in saline to monitor brain areas involved in olfactory cues of the context. Forty-eight hours after the conditioning, rats were exposed to the same conditioning environment for 10 minutes to test contextual fear memory. Under isoflurane anesthesia, their brains were scanned with Bruker 9.4T MRI. Acquired images were processed and statistical analyses were performed using SPM8. Brain activation maps related to fear conditioning between groups were generated by two sample analysis.
MRI signal enhancement in fear conditioned rats was observed in the olfactory tubercle, amygdala, somatosensory cortex, Caudate putamen (Cpu), granular and dysgranular insular cortex. Nasal injection of manganese produced greater signal enhancement in the olfactory tubercle indicating olfactory processing of the context. The activations in the granular insula cortex, dysgranular insular cortex suggest that the insular cortex plays a key role in pain processing. The activation in Cpu was related to the experience of pain, the coordination of context-dependent movement. Activations in the amygdala, olfactory tubercle and sensory cortex indicates MEMRI detects brain activations related to conditioned fear. Specifically, the olfactory

context cue relayed by olfactory tubercle and foot shock information processed by sensory cortex merge and form fear memory in the amygdala. We employed an activity-dependent MEMRI technique to reveal fear circuits related to the odor context cue.

**Abstract:** Although traumatic events are experienced by over 50% of the U.S. population, only a portion of traumatized individuals develop a subsequent stress disorder. Susceptibility to trauma-induced stress disorders may be mediated by variability in human neurobiology. Prior human neuroimaging research has observed alterations in the function, structure, and biochemistry of a prefrontal cortex (PFC) - amygdala network in individuals with chronic Post-Traumatic Stress Disorder (PTSD). However, the relationship between the neurobiology of the PFC - amygdala network and acute post-traumatic stress remains unclear. Understanding the neurobiology of acute post-traumatic stress may elucidate the etiology of PTSD, and provide quantifiable neural markers for the prediction and prevention of PTSD. Twenty-one trauma-exposed (TE) and nineteen non-trauma-exposed (NTE) volunteers participated in a multidimensional neuroimaging study. Data included structural (diffusion weighted scans), biochemical (1H magnetic resonance spectroscopy), and functional (blood-oxygen-level-dependent; BOLD) images acquired during a Pavlovian fear conditioning procedure. Tractography analyses of the diffusion weighted data revealed the white matter microstructure of both the uncinate fasciculus and fornix/stria

terminalis varied with acute post-traumatic stress severity. Biochemical scans assessed neural glutamate (Glx) levels within dorsal anterior cingulate cortex (ACC). Glx concentrations measured acutely varied positively with both acute and 3 month follow-up post-traumatic stress severity. In addition, functional imaging revealed differences in the dorsal ACC response to safety cues such that the TE group exhibited greater activity compared to the NTE group. Further, the TE group demonstrated altered safety-learning compared to the NTE group indexed via UCS expectancy. Taken together, the present findings suggest 1) trauma exposure may be related to acute changes in the neural substrates that support fear learning processes, 2) microstructure of white matter tracts connecting the PFC and amygdala may be related to development of PTSD, and 3) glutamate within dorsomedial PFC may play an important role in post-traumatic stress. The present study extends our understanding of the neurobiology associated with post-traumatic stress in a unique population, and sheds new light on the etiology of PTSD.

**Abstract: Introduction.** Reinforcement learning (RL) theory describes how expectations and their violations (prediction errors, PE) might drive learning. Appetitive learning and PEs have been studied extensively but as of yet we have little information on where and how aversive prediction errors might be computed. Here, we sought to delineate human brain regions that encode different types of aversive PEs and learning-related signals by using functional magnetic resonance imaging (fMRI) and Pavlovian threat learning (fear conditioning) with partial reinforcement.

**Methods.** 22 participants underwent fMRI scanning at 3T. The conditioned stimuli (CSs) in the experiment were triangles with different colours corresponding to different probabilities of receiving an electric shock to the forearm (unconditioned stimulus, US). We used an axiomatic approach to search for brain regions encoding aversive PE signals, separately for positive, negative, and unsigned PEs. We have previously shown that a beta-Bernoulli optimal Bayesian learning model better explains behavioural data than a range of RL models. Hence, we also analysed neural activity relating to trial-by-trial parameters from this model, representing expectation, model update and surprise.
**Results.** In the axiomatic approach, we did not find any brain regions in which BOLD signals unambiguously fulfilled the axioms for representing positive, negative or unsigned aversive prediction errors. In the model-based analysis, we found that expectation of US probability from our learning model was associated with activation in the left anterior insula and opercula of insula. Moreover, prior entropy of shock probability, a measure of uncertainty about US probability that has been previously related to skin conductance responses, was associated with activation in parietal-occipital, superior-medial frontal, and motor regions. Bayesian surprise about the US outcome was encoded in middle dorsal prefrontal cortex. Finally, model update based on the experienced US from the current trial (KL divergence) related to activity in inferior, middle and superior frontal regions as well as in parietal regions during acquisition of the CS-US associations.
**Discussion.** In contrast to previous work on appetitive, and aversive operant, learning, we did not find brain regions axiomatically encoding PE signals during Pavlovian threat conditioning. Instead, we highlight neural activity related to trial-by-trial parameters from an ideal Bayesian observer model that also best explained previous behavioural data.

**Title:** The neuroimaging of human fear conditioning: Quantitative seed-based and linguistic meta-analyses

**Authors: *D. STJEPANOVIC**, K. S. LABAR
Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC

**Abstract:** The application of fear conditioning across organisms and techniques has begun to detail the neurobiological mechanisms through which fears are acquired and extinguished. These efforts are likely to yield greater insight into anxiety and fear disorders for which aberrant threat processing and regulation contributes to their etiology and persistence. Key in advancing our understanding of fear conditioning is the ability to synergize results across studies to test the consistency of findings. To date, work across animal models, human neuroimaging, and patient-based studies has identified the amygdala to be critical to fear learning and a key node in a network of cortical and subcortical regions that together form a fear-learning network. However, the amygdala has not consistently emerged in quantitative meta-analytic reviews of human neuroimaging studies. One explanation for this discrepancy may be the reliance on whole-brain analyses, which may not be sensitive to hemodynamic activation within the amygdala, given its low signal magnitude, susceptibility to magnetic field artifacts, and variability in peak activation location across subjects. Therefore, the aim of the present work was to attempt to resolve this discrepancy by conducting a survey of the human neuroimaging literature from 1998-2017. We focused on meta-analytic methods that can help elucidate the role of the amygdala and other theoretically-implicated regions of interest. Utilizing seed-based *d* mapping (SDM) of peak coordinates from 32 studies using whole-brain analyses, we identified a network of regions frequently implicated across studies of fear conditioning, including the inferior frontal gyrus, cingulate cortex, superior temporal gyrus, insula, and thalamus. Importantly, when we included in the analysis 33 studies that specifically interrogated the amygdala through region-of-interest analyses, we additionally observed consistent activation within right amygdala. Using a complementary linguistic-based meta-analytic approach through term-based mass synthesis of neuroimaging results from the Neurosynth database, we found similar results, including activity in the bilateral amygdala. Our survey illustrates the challenges inherent in aligning results across imaging studies that use different design and analytic strategies and supports the corpus of data from other methods and organisms that reveal a key role for the amygdala in fear learning.

**Title:** Enhancement of auditory processing by classic fear conditioning in humans: Observations from intracranial recordings

**Authors: *E. BARTOLI**[1], A. R. ARON[2], N. TANDON[3]
[1]Neurosurg., Uthealth Sci. Ctr. At Houston, Houston, TX; [2]UC San Diego, La Jolla, CA; [3]Neurolog. Surgery, Univ. of Texas Med. Sch. at Houston, Houston, TX

**Abstract:** During classic conditioning, the unconditioned stimulus (US, e.g. a shock) and conditioned stimulus (CS, e.g. a tone) are relayed from the thalamus to the amygdala, both directly and indirectly (through sensory cortices). Different amygdaloid nuclei encode the pairing between CS and US and mediate the expression of the physiological and behavioral response to the US, through the interaction with a wider cortical network.
Here, we recorded human auditory cortex with finely spaced intracranial electrodes in a cohort of 8 patients during a classic conditioning paradigm, using a tone as a CS and a shock as a US. Two tones were presented to the participants: one was paired to the US (CS+), while the other one was never associated to the US (CS-).
At an individual level, 7 out of 8 patients showed an increased power of local field potentials in auditory cortex for the CS+ (CS+ vs. CS-, $p<0.01$ assessed with parametric permutation testing on the power percent change at each time-frequency point). The timing and frequency band was quite variable across patients. Two main types of responses were observed: an alpha power increase around tone onset or a theta power increase around tone offset.
At a group level (considering all 8 patients), the increased response to the CS+ was still present (CS+ vs CS-, $p<0.05$) notwithstanding the individual variability. This increased 'auditory response' was found at both sound onset (in alpha and gamma bands) and offset (theta and gamma) during conditioning. The response was diminished along with the time-course of extinction.
Anatomically, the auditory cortex locations exhibiting a dissociable response were not constrained to a specific region but rather spanned through different locations along the superior temporal gyrus and sulcus.
We suppose that the increase in the power of low frequency components, could relate to an increased attentional bias toward the sound predicting the shock (CS+), while the increased power in higher frequencies could relate to increased local activity.
This could be explained by a plastic change promoted by the amygdala to encode more robustly the CS+. Indeed, the amygdala is believed to modulate cholinergic projections to increase attention and perception toward incoming (conditioned) stimuli. This effect has been characterized as an increased response to the CS in sensory cortex, which has been consistently reported in many animal and human studies.
Our results add evidence to the plastic changes occurring in sensory cortices during classic conditioning, by defining the frequency components and the timing at which an auditory response is most sensitive to the association between the US and CS.

**Abstract:** Memories are typically encoded so that they are easily accessible for retrieval. However, the retrieval of some memories formed under stress-, drug- or affect-induced states is impaired unless the brain is in a similar state as it was during encoding. This phenomenon, known as state-dependent memory (SDM), has been implicated in the development of traumatic amnesia, dissociative symptoms of psychiatric illnesses, as well as the persistence of drug addiction. SDM can be modelled pharmacologically, with information encoded and retrieved in a drug-dependent manner. However, beyond psychopharmacological observation, the neurobiological mechanisms of SDM are still not well understood. To identify novel molecular and cellular mechanisms of SDM, we utilized a recently developed pharmacological model consisting of activation of extrasynaptic γ-aminobutyric acid type A receptors ($eGABA_AR$) during contextual fear conditioning. Based upon emerging evidence that this receptor population can be modulated by the oxytocin system, including our findings that SDM was completely abolished by Oxtr knockout, we used chemogentic approaches to determine whether Oxtr are required for SDM encoding or retrieval. We also performed morphological and immunohistological studies to characterize the identity of the putative Oxtr-positive neuronal populations involved in SDM. Together, these experiments suggest that Oxtr, by contributing to the cellular and behavioral functions of $eGABA_AR$, modulate inhibitory neurotransmission in the hippocampus. In addition to elucidating fundamental principles of SDM, this study is likely to have broad implications for $eGABA_AR$ and Oxtr function, which show abnormalities in most major psychiatric disorders and are important targets for psychopharmacological interventions.

[1]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL; [2]Northwestern Univ. - Chicago, Chicago, IL; [3]Tohoku Univ., Sendai, Japan

**Abstract:** Memories encoded during certain cognitive, affective, pharmacological, or other brain states can often be retrieved only when the brain is returned to the same state present during encoding. We have recently shown that such state-dependent learning requires the activation of extrasynaptic GABAa receptors (eGABAaR) in the dorsal hippocampus (DH); in wild-type (WT) mice, intra-hippocampal administration of the eGABAaR agonist gaboxadol (GBX) prior to fear conditioning yields a memory that can only be retrieved when mice are tested on GBX. In keeping with the role for inhibitory synaptic neurotransmission in the generation of network oscillatory activity, GBX also induces robust changes to local field potentials (LFPs) in DH. eGABAaR colocalize with oxytocin receptors (OxtR) in the dentate gyrus, and can also be activated by oxytocin, but it is not known whether OxtR signaling alone or interactions between these neurotransmitter systems contribute to hippocampal oscillations. To examine this, we tested WT and OxtR knockout (OxtR venus) mice for differences in baseline and GBX-induced patterns of local field potentials in DH. Close interactions between OxtR and eGABAaR suggest that treatments targeting these systems could have significant potential for ameliorating trauma-related dissociative symptoms.

**Title:** Corticotropin-releasing factor (CRF) neurons in the oval nucleus of the bed nucleus of the stria terminalis ($BNST_{ov}$) modulate fear and anxiety in rats

**Authors: *A. N. ROMAN**[1], D. MARTINON[1], J. A. DABROWSKA[1,2]
[1]Cell. and Mol. Pharmacol., [2]Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

**Abstract:** Corticotropin-releasing factor (CRF) is a neuropeptide responsible for regulating the autonomic, endocrine, and behavioral responses to stress. One significant population of CRF cell bodies is located within the oval nucleus of the bed nucleus of the stria terminalis ($BNST_{ov}$), a region of the brain that mediates adaptive responses to stressors, such as fear and anxiety. This research investigates the role of these CRF neurons in the $BNST_{ov}$ regarding the acquisition of conditioned cued and non-cued fear. We used designer receptors exclusively activated by designer drugs (DREADDs) within adult transgenic CRF-Cre rats (developed by Pomrenze et al., 2015) to modulate this system. In this model, Cre recombinase is exclusively expressed by CRF neurons. We performed bilateral $BNST_{ov}$ injections of viral vectors driving Cre-dependent expression of DREADDs and reporter protein, mCherry, in both Cre+ and Cre- rats. Viruses used encoded either DREADDs-Gi (pAAV-hSyn-DIO-hM4D(Gi)-mCherry(AAV8)) to silence CRF neurons or DREADDs-Gq (pAAV-hSyn-DIO-hM43(Gq)-mCherry(AAV8)) to activate them. Four weeks after stereotaxic AAVs injections, we measured baseline acoustic startle reactivity of all rats. Then, we used a fear-potentiated startle (FPS) paradigm to determine if activation or inhibition of the CRF neurons in the $BNST_{ov}$ affects cued and non-cued fear in the FPS. The DREADDs selective ligand, clozapine-N-oxide (CNO, 1 mg/kg/mL, IP), was administered prior to fear conditioning. Rats were tested for FPS expression 24 hours later. In order to confirm DREADDs expression, we used striatal-enriched protein tyrosine phosphatase (STEP), which selectively colocalizes with $BNST_{ov}$ CRF neurons. We confirmed through fluorescent immunohistochemistry that mCherry was exclusively expressed on CRF neurons in the $BNST_{ov}$. This mCherry expression was found on neuron membranes, dendrites, spines and axons. We also found that activating or inhibiting CRF neurons in the $BNST_{ov}$ modulates cued and non-cued fear measured in FPS in distinct ways. In light of this data, future experiments will aim to further elucidate the functional role of CRF neurons in the $BNST_{ov}$ and confirm the

specificity of DREADDs expression in this promising animal model. This work is supported by a National Institute of Mental Health grant (R00MH096746) and CMS RFUMS start-up funds to JD.

**Abstract:** The basolateral amygdala (BLA) and medial prefrontal cortex (mPFC) have extensive bidirectional connections mediating the bottom-up and top-down processes that regulate affective memory. Dysregulations in these interactions are believed to contribute significantly to the etiology of affective disorders such as depression and anxiety. Previously, we have used NMDA-induced activation of the nucleus accumbens shell (NACshell) to reveal a cholinergic-glutamatergic link that may contribute to top-down regulation of attentional processing. In the current study, after achieving stable baselines we activated the BLA with reverse dialysis perfusion of NMDA (250 uM, 1 hr) and simultaneously measured (20 min collection intervals) changes in the levels of 5 different neurotransmitters in the mPFC and BLA of the same animals. BLA activation resulted in significant increases in extracellular levels (expressed as mean maximum increase above baseline) in DA (97 ± 30%), ACh (55 ± 17%), and glutamate (58 ± 36%) in mPFC. BLA activation did not significantly affect 5-HT (19 ± 15%) or GABA (23 ± 17%) levels. Because our previous experiments with NACshell activation and prefrontal levels revealed that increases in cortical glutamate were secondary to elevations in cortical ACh and stimulation of alpha7 receptors located on glutamatergic terminals, we determined the effects of intra-cortical perfusions of the alpha7 nicotinic antagonist alpha-bungarotoxin (BGT; 1.0 uM) on the intra-BLA-NMDA-induced increases reported above. Administration of BGT effectively blocked the NMDA-induced increases in cortical DA, Glutamate, and ACh. Perfusions of NMDA into the BLA also produced local increases in DA (78 ± 43%) and ACh (103 ± 42%)

within the BLA. Again, these changes were completely blocked by intra-cortical BGT perfusion - suggesting a corticofugal origin for evoked DA and ACh within BLA. To our knowledge, the ability of BLA stimulation to evoke cortical ACh levels, the top down stimulation of local DA and ACh levels in BLA, and the dependence of these bidirectional loops on alpha7 nicotinic receptors are novel observations. These neurochemical results following pharmacological activation of otherwise resting animals will be contrasted with those seen following a more naturalistic behavioral activation of this BLA-PFC circuit during the acquisition and extinction of trace fear conditioning. Collectively, the demonstration of how activity within these bidirectional loops changes as a function of different behavioral states may provide a justification for alpha7 antagonists in the treatment of affective disorders.

**Title:** Brain mechanisms mediating punishment-induced suppression of responding for ethanol

**Authors: *L. R. HALLADAY**, A. KOCHARIAN, A. HOLMES
Lab. of Behavioral and Genomic Neurosci., Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

**Abstract:** Alcohol use disorders (AUDs) are often characterized by persistent alcohol intake despite harmful consequences. The inability of aversive consequences to reduce drinking behaviors in those with AUDs may be due to an impairment in the neural mechanisms regulating punished behaviors. Past studies have shown that areas of the prefrontal cortex, amygdala, and nucleus accumbens are important for aspects of drug seeking and behavioral flexibility. However little is known about the role of these regions in mediating punished alcohol-seeking. To examine this, we implanted chronic microelectrodes in the prelimbic (PL) and infralimbic (IL) subregions of the prefrontal cortex, the basolateral amygdala (BLA) and nucleus accumbens shell (NAc) to record neuronal activity in freely-moving mice performing a punished-suppression of alcohol-seeking task. Mice were first trained to lever press in order to obtain an alcohol reward, and then during subsequent probe-tests, subjected to a mild footshock when the lever was pressed. Neural recording data revealed several populations of cells that significantly changed their firing rate either during drinking or responding on the lever. Notably, during punished probe-tests, a sub-population of cells in IL significantly increased their firing rate when animals approached the reward lever but did *not* press it, suggesting a role for IL in the inhibition

of responding in the face of negative outcomes. Optogenetic silencing of cells in IL confirmed this role. These data demonstrate neuronal encoding of punished alcohol-seeking in distinct neural ensembles and suggest that resistance to the suppression of alcohol-seeking seen in AUDs may be related to aberrant activity in the IL cortex.

**Title:** Conditioned taste aversion learning drives synaptic depression in rat primary gustatory cortex

**Authors: *M. HALEY**, A. FONTANINI, A. MAFFEI
SUNY At Stony Brook, Stony Brook, NY

**Abstract:** Conditioned taste aversion learning (CTA) is a learning paradigm in which an animal learns to dislike an appetitive, novel taste after it has been paired with gastric malaise. This form of learning is hypothesized to depend on plastic changes in the functional connection between the basolateral amygdala (BLA) and the primary gustatory cortex (GC), as well as plasticity within GC. However, to assess the role of plasticity in CTA learning it is first necessary to determine how CTA learning affects GC circuit activity and physiology, and to gain a deeper understanding of the capacity for plasticity at BLA-GC synapses. Here we used CTA training and an optogenetic approach combined with whole-cell patch clamp recordings in acute GC slices to determine the effect of this form of learning on GC neuron excitability and the BLA-GC synapse. Our results indicate that CTA learning shifts the balance of excitatory and inhibitory synaptic inputs onto GC neurons toward excitation, and increases GC neuron intrinsic excitability. In addition, CTA learning weakens BLA-GC synapses, suggesting that CTA learning may depend on Long Term Depression (LTD) of the BLA-GC synapse and increased excitability of the GC circuit. To test this possibility, we first identified patterns of activity for LTD at BLA-GC synapses in slice preparations and tested whether CTA learning altered the capacity for this form of plasticity. In CTA trained animals, induction of LTD with a phasic activity paradigm was impaired and a competing Long Term Potentiation (LTP) was unveiled (% of neurons: Control - LTD, 63.3%; CTA - LTP, 58.8%; $\chi^2$, $p < 10^{-3}$), indicating that CTA learning has altered the state of BLA-GC synapses. This switch in the sign of plasticity was selective for the phasic induction paradigm, as tonic activation of BLA afferents induced

comparable LTD in control and CTA animals (Control - LTD, 91.7%; CTA - LTD, 100%). Finally, we asked whether phasic-LTD was sufficient to induce CTA. To do that, we substituted the gastric malaise typically paired with sucrose during CTA training with the phasic stimulation paradigm for LTD using optogenetic activation of BLA terminal fields in GC, and assessed CTA learning in rats. The pairing of sucrose and phasic-LTD activation of BLA afferents in GC was sufficient to induce a CTA. Our results demonstrate that CTA learning induces pleiotropic effects on GC circuits, and directly link CTA learning with LTD of BLA-GC synapses onto L2/3 EXC neurons.

**Title:** Hubs involved in hipocampal loss compensation in contextual fear learning impair contextual discrimination

**Authors: *T. B. DOS SANTOS**, C. A. COELHO, M. G. M. OLIVEIRA
Univ. Federal De São Paulo, Sao Paulo, Brazil

**Abstract:** Pre-training dorsal hippocampus (dHPC) lesions do not impair contextual fear conditioning (CFC), suggesting that other structures can compensate and promote CFC learning. A previous study from our laboratory pointed to the perirhinal (PER) and retrosplenial cortices (RSC) as hubs in the network engaged in CFC learning in the absence of the dHPC. Current theories propose that the hippocampus forms a configural representation of the context, however, the contribution of these compensating hubs, and their interaction with dHPC, to a configural representation of the context are unknown. Here we employed double lesions to investigate the effect of pre-training double NMDA-induced lesion in dHPC and PER or dHPC and RSC on the performance of a contextual discrimination task. Male *Wistar* rats underwent neurotoxic lesions

in the dHPC, PER, dHPC+PER or were SHAM animals in experiment 1 (n = 11-12) or in the dHPC, RSC, dHPC+RSC or were SHAM animals in experiment 2 (n = 4-5). Contextual discrimination task consisted of 11 consecutive days in both experiments. First, animals were habituated for 5min in two different conditioning chambers that shared some contextual cues. In the next nine days, one chamber was designated as the shock-Context (CT+) and other as the no-shock Context (CT-), in a counterbalanced manner. When placed in CT+, rats received a footshock (0.8mA, 1s) after 4min and then were removed after 1min. When placed in CT-, rats were allowed to explore it for 5min and no footshock was delivered. Rats were exposed to one of the contexts in the morning and the other in the afternoon (counterbalanced). On the 11$^{th}$ day, animals were exposed to CT+ and a third context (CTn), totally different from CT+ and CT-, for 4min. Freezing time was measured during all sessions as a fear memory index. Multivariate Analysis of Variance (corrected for multiple comparisons) showed that both SHAM and dHPC+PER groups discriminated between the Contexts from block 2, but the groups with individual lesions of dHPC or PER did not discriminate. In experiment 2, both RSC and dHPC+RSC groups showed a tendency of impairment of the contextual discrimination task. The present results suggest that both PER and RSC are important for a configural representation of the context, but their interaction with dHPC is not trivial. Paradigms that evaluate acquisition of multiple levels of information complexity could better dissect these regions contribution in context representation.

**Title:** microRNA regulation of traumatic memory storage

**Authors: *S. SILLIVAN**, N. JOSEPH, S. JAMIESON, C. MILLER
The Scripps Res. Institute-Florida, Jupiter, FL

**Abstract:** Understanding how the brain maintains a stable memory for months to years has significant implications for disorders perpetuated by pathogenic memory, such as post-traumatic stress disorder (PTSD). Despite the clinical importance of memory storage, mechanisms of long-lasting memory are understudied and elusive. Previously we identified microRNA (miRNA) changes in the amygdala (AMY) that persist a month after learning, suggesting that miRNAs may be key participants in long-term memory storage. Given that a single miRNA has hundreds of predicted targets, their wide-genomic range has the complexity to maintain a lasting "traumatic" memory, which has relevance to PTSD. We recently developed a preclinical PTSD model that employs stress enhanced fear learning (SEFL) by combining an acute stressor with Pavlovian fear conditioning (FC) to recapitulate many hallmark features of PTSD in an inbred mouse strain, including differential vulnerability to stress. The stress susceptible (SS) subpopulation displays persistently elevated, extinction-resistant fear memory. Importantly, we identified a relationship between SEFL behavior and extinction performance to predict SS and stress-resilient (SR) animals. This eliminates a confound of additional behavioral phenotyping and allows for study of the underlying molecular mechanisms, including miRNAs. We used this model to investigate the 'miRNAome' associated with a perseverant "PSTD-like" memory by performing small RNA sequencing (miRNA-Seq) to measure lasting miRNA expression (>30 days) in the AMY after SEFL. 123 miRNAs were differentially expressed between SS and SR animals and 164 between SS and FC animals, with most miRNAs upregulated in SS relative to SR or FC. Only 71 were different between FC and SR, indicating that SR animals are more like FC than SS animals. We then performed quantitative mass spectrometry to identify the proteomic profile of the AMY in SEFL animals and aligned it with the miRNA-Seq data. A general downregulation of proteins was observed in SS mice, relative to SR or FC only, and the proteomic profile of SS vs SR was similar to SS vs FC only mice. The global increase in miRNA levels but decrease in protein levels in SS mice suggests unique miRNA-mediated translational pathways may be recruited for traumatic memory storage. We are currently testing the functional impact of *in vivo* manipulation of candidate miRNA pathways on the maintenance of a 30 day-old PTSD-like memory. Identification of miRNAs participating in the storage of traumatic memory will provide clear targets for selective and immediate disruption of the memory, which has significant therapeutic implications for conditions like PTSD.

**Title:** μ-opioid receptor-mediated attenuation of midline thalamic inputs to the amygdala

**Authors: *L. GOEDECKE**, P. BLAESSE, H.-C. PAPE, K. JÜNGLING
Inst. of Physiol., Univ. of Muenster, Muenster, Germany

**Abstract:** The dorsal midline thalamus (dMT) is implicated in the retrieval of fear memories. It is innervated by a vast array of neuropeptidergic fibers, containing e.g. enkephalin. Moreover, dMT neurons express μ-opioid receptors (MORs), suggesting a neuromodulatory role for the μ-opioid system in this region. Efferent projections of the dMT target a variety of subcortical structures that regulate emotional behavior, among them the basal (BA) and centrolateral (CeL) nucleus of the amygdala. Within the amygdala, BA sends excitatory projections to neurons of the centromedial amygdala (CeM), which mediates conditioned fear behavior via projections to brain stem and hypothalamic nuclei. The CeL, on the contrary, exerts inhibitory control over the CeM. While dMT-projections to the CeL have been shown to be required for fear memory retrieval, the role for dMT-BA synaptic connections is less clear. In order to electrophysiologically characterize dMT-BA and dMT-CeL synaptic connections and investigate how they are functionally modulated by MORs, we performed whole-cell patch clamp recordings in acute brain slices of mice in combination with retrograde tracing or optogenetics. Furthermore, *ex vivo* recordings were conducted to study whether cued fear memory retrieval is associated with changes in glutamatergic synaptic transmission at dMT-BA projections. We found that MORs mediate the hyperpolarization of both BA-projecting and CeL-projecting dMT neurons. In addition, we showed that both BA and CeL neurons receive excitatory input from dMT neurons and generate fast postsynaptic responses (eEPSCs). Activation of MORs attenuated transmission at both dMT-BA and dMT-CeL synapses and, furthermore, reduced dMT-driven feedforward excitation of CeM neurons. Interestingly, dMT-CeL and dMT-BA connections differed with regards to apparent synaptic connectivity, eEPSC amplitude, and modulatory influence of the MOR system. Moreover, preliminary results indicate that cued fear memory retrieval, indeed, affects glutamatergic transmission at dMT-BA syapses. Together, these results suggest that MORs are important negative modulators of synaptic transmission between dMT and amygdala, a circuit that is critically involved in the expression of emotional behaviors such as fear.

**Abstract:** Anxiety and the depressive disorders with which anxiety is frequently comorbid constitute an enormous illness burden in the US and elsewhere. Detailed analyses of response to threat in laboratory rodents suggest that a particular defensive behavior, risk assessment (RA), is prominent in response to potential, rather than clear, threat. Functionally, RA is related to rumination and eye-gaze movement behaviors, both of which have been shown to be aberrant in anxious and depressed individuals, suggesting that it may have potential as a transdiagnostic preclinical model.
Snakes of non-coevolved species provide a model whose threat properties are more ambiguous than are those of coevolved predators. Snakes of species native to South America have been isolated from species such as R. norvegicus, evolving in central Asia, for over 50 million years. Rats confronted by two species of South American snakes showed much higher levels of RA and fewer flight or freezing defenses than those typically seen in encounters with coevolving predator species such as cats: Moreover, as predicted from previous analyses, levels of each type of defensive behavior varied with the activity and directed attack behaviors shown by the snakes. Activity in the rat subjects' brains was evaluated by regional tallies of cells showing expression of the intermediate early gene, c-fos, in 37 different regions of interest (ROIs), including those that have previously been linked to defensive behavior. Regional subcortical activity patterns were similar but not identical to those found in cat encounters, with particular differences found in the ventromedial nuclei of the hypothalamus. Although overall levels of defensiveness, based on instances or durations of a range of defensive behaviors, correlated highly with fos counts in some ROIs, counts in other ROIs suggested differential associations with RA, freezing, and flight. This model may prove particularly interesting in analysis of cognitive aspects of defensiveness, with enhanced relevance to anxiety and anxious depression.

**Title:** A novel naturalistic paradigm to study aerial predatory-induced fear in laboratory rats

**Authors:** ***P. R. ZAMBETTI**[1], E. KIM[1], J. J. KIM[1,2]
[1]Psychology, [2]Program in Neurosci., Univ. of Washington, Seattle, WA

**Abstract:** Despite the breadth of risky situations in nature that demand diversity in fear behaviors, contemporary neurobiological models of fear are based largely on Pavlovian fear conditioning studies that focus on how a particular cue upon pairing with an aversive (usually painful) event becomes capable of eliciting learned fear responses. Ecological studies, however, have maintained that innate fear to sudden stimuli (evolutionarily reliable signals of threat) is vital to guide and shape adaptive behaviors because unlearned fear would provide a competitive advantage over the time-consuming and hazardous process of trial-and-error fear learning (see Pellman and Kim, 2016). One popular innate fear paradigm in rodents (usually mice) employs looming overhead stimuli through either an expanding disc or sweeping bar, to which animals instinctively display freezing and/or flight behaviors in small testing chambers. It has been proposed (Fanselow and Lester, 1988) that rodents would freeze to distal predators to avoid detection, but switch to fleeing to proximal predators, as freezing would be maladaptive. To investigate the dynamics of defensive behaviors in rats, we employed a realistic owl replica that plunges towards animals foraging for food in a large arena. In response to this predatory model, all rats instinctively fled to and froze inside the safe nest area, and no freezing was observed out in the arena. Our aerial predatory paradigm will be useful for investigating how the brain processes and responds to different (i.e., terrestrial vs. aerial) predatory threats.

**Title:** A robot dinosaur as a predator like stressor to highlight susceptibility versus resilience and gender difference in response to acute stress

**Authors: *A. MENIGOZ**[1], C. BATTERMAN[2], D. G. RAINNIE[2]
[1]Psychiatry, Yerkes Natl. Primate Res. Ctr. - Emory Un, Atlanta, GA; [2]Emory Univ., Atlanta, GA

**Abstract:** It is clear that stress affects emotional behavior, however each individual responds differently to adversity. Many resilient individuals display adaptive physiological responses to stress while others will develop depression or other psychiatric disorders. Moreover, there is an overwhelming wealth of evidence from the clinical literature that the prevalence of anxiety disorders is about twice as high in women compared to men. The molecular pathways underlying these differences remain unclear. Here, we used a new stressor, a robotic predator, in a 3 day paradigm (Baseline, Stress and Probe test), to induce acute stress in males (n=14) and females rats (n=12). The time spent interacting with the predator was used to assess the stress response. In males, we found that the interaction time significantly decreased during Stress compared to Baseline (18.28% vs 35.44% $p<0.001$ RM-ANOVA). Interestingly, during Probe about 71% of the males still displayed reduced interaction while 29% showed no difference compared to their Baseline behavior. We could not find a specific behavior during the Stress that could be correlated with the stress response during Probe, suggesting an endogenous component to the resilience. Unexpectedly, in females, a significant proportion of the animals did not display sign of stress in response to the moving predator while about 40% significantly decreased their interaction. Females with decreased interaction during Stress also showed decreased interaction during Probe while resilient animals during Stress displayed normal behavior during probe. We found a significant correlation between the behavior during Stress and Probe (Spearman $r=0.7852$). Previous studies have reported that the light-enhanced startle response in female rats fluctuated significantly with reproductive state. We hypothesized that the fluctuation we observed in response to the stressor might be the result of different estrogen and estrogen receptor levels.
In both males and females, we then investigated the neuronal activation in response to the presentation of the stressor on D2 and D3 as well as the level of estrogen and estrogen receptors and blood cortisol. After identification of the responding neurons, we will use the TRAP technology to characterize their transcriptomic profile and potentially highlight genes involved in stress resilience.

**Title:** Stress neuroadaptation in the bed nucleus of the stria terminalis (bnst) may underlie social defeat-induced depression-related behaviors

**Authors: *S. E. HAYNES**[1,2], A. MENIGOZ[2], C. BATTERMAN[2], D. G. RAINNIE[3]
[1]Behavioral Neurosci. and Psychiatric Disorders, Emory, Atlanta, GA; [2]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [3]Behavioral Neurosci. and Psychiatric Disorders, Emory Univ., Atlanta, GA

**Abstract:** Chronic stress is a key risk factor in the development of Major Depressive Disorder (MDD), yet it is unknown why certain people develop MDD compared with others, despite reporting similar levels of stress. Corticotrophin-Releasing Factor (CRF) has emerged as a molecular substrate that may play a critical role in stress-related depression. Although, CRF's potential role is implicated in a preponderance of preclinical and clinical reports, how stress and CRF play a pivotal role in MDD etiology is not well understood. The Bed Nucleus of the Stria Terminalis (BNST) may be in important in the interrelationship of stress and depression, as it encodes the nature and chronicity of stressful stimuli and mediates behavioral/physiological adaptive responses. Importantly, the oval nucleus of the BNST contains an enriched population of CRF postitive ($BNSTov^{CRF}$) neurons that are stress responsive and serve as an attractive neuronal population to interrogate as providing a molecular link between CRF and depression. In this study, we sought to elucidate CRF neural mechanisms that underlie individual differences in stress susceptibility that arise from unmitigated chronic stress exposure. We hypothesized that individual differences in crf gene expression may correlate with an individual's vulnerability to depression. To test this, we employed the Chronic Social Defeat Stress paradigm in mice that reliably produces stress-resilient (RES) or depressive-like (DEP) phenotypes on the basis of social interaction and sucrose preference. We discovered differential *crf, crfr1,* and *crfr2* gene expression in the anterolateral (oval nucleus containing) region of the BNST of RES and DEP mice. Additionally, these changes in gene expression correlated with immediate early gene, *cfos,* activity selectively in the BNSTov, but not anteromedial or ventral BNST regions. Notably, we observed in crf-tdTomato mice, the co-localization of cfos immunofluorescence with tdTomato, suggesting these changes may be mediated by this CRF-positive neuronal subpopulation. Altogether, these findings provide evidence that the response of BNSTov CRF neurons to

persistent stress may reflect individual tolerance to stress such that hypoactivity may predispose individuals to depression. Alterations in CRF neurotransmission may shift the predisposition of mice toward either stress-resiliency (RES) or stress-induced depressive-like (DEP) phenotypes. In this way, CRF transmission in the BNST may serve as a biomarker in serving to identify populations of individuals with enhanced vulnerability to depression.

**Title:** Genetically modified rabies tracing of global circuit connections to corticotropin-releasing hormone neurons in the hypothalamic paraventricular nucleus

**Authors: *X. XU**[1], P. RIGAS[2], Y. SUN[1], C. A. ITOGA[1], K. LAM[1], J. D. DELGADO[1], E. M. CALLAWAY[3], E. KIM[4]
[1]Anat. and Neurobio., Univ. California, Irvine, Irvine, CA; [2]Anat. and Neurobio., Univ. of California, Irvine, Irivne, CA; [3]Salk Inst., La Jolla, CA; [4]Salk Inst. for Biol. Studies, La Jolla, CA

**Abstract:** Corticotropin-releasing hormone (CRH)-containing neurons in the paraventricular nucleus (PVN) of the hypothalamus play a key role in the hypothalamic-pituitary-adrenal (HPA) axis stress responses. The existing knowledge about PVN circuit connections comes from conventional anatomical studies which tend to have low spatial and cell type resolution. Many aspects of neural circuit organization of CRH+ PVN neurons are poorly understood. Thus we have mapped global synaptic connections to these CRH+ neurons in order to better understand how they integrate stress-relevant signals from brain-wide neural networks to regulate the neuroendocrine response to stress. A new Cre dependent monosynaptic rabies tracing system with the helper AAV expressing optimized glycoprotein (oG) was used to map direct circuit connections to CRH+ neurons in the PVN of CRH-ires-Cre mice. Reproducible results of synaptic input patterns were obtained from 6 high quality cases. We found that these CRH neurons received synaptic connections from more than one hundred brain regions. Hypothalamic regions account for the majority of inputs, as dorsomedial, ventromedial, lateral hypothalamus, lateral and medial preoptic nucleus, and the arcuate nucleus have on average, 11.5%, 10.9%,

8.1%, 17%, and 18% of total labeled presynaptic neurons, respectively. While there are no or little direct inputs from sensory and motor cortex, hippocampus or amygdalar nuclei, there are readily identifiable inputs from infralimbic cortex (0.4% of total labeled presynaptic neurons), the nucleus accumbens (2.8%), anteromedial and ventral thalamus (0.9%), lateral and medial septum (4%), dorsal and ventral subregions of the bed nucleus of the stria terminalis (3.3%), supraoptic nucleus (0.26%), zona incerta (0.7%), periaqueductal gray area (0.9%), periventricular nucleus (0.6%), and mammillary nuclei (0.6%). Antibody immunostaining was used to further identify the excitatory or inhibitory nature of input mapped neurons. All these regions, including previously un-described input sources, have been significantly implicated in emotion, reward and / or stress regulation. Our work aided by the new viral genetic mapping approach, allows for a detailed analysis of global information flow directly impinged on CRH+ PVN neurons and will shed new light on specific neural circuit mechanisms underlying direct control of HPA axis responses.

**Title:** Functional dissection of the dorsal raphe serotonin systems

**Authors:** ***J. REN**[1], D. FRIEDMANN[1], J. XIONG[2], C. LIU[1], K. E. DELOACH[2], R. L. NEVE[3], C. RAN[1], A. PU[4], M. HOROWITZ[2], L. LUO[1,5]
[1]Biol., [2]Dept. of Electrical Engin., Stanford Unibersity, Stanford, CA; [3]MIT, Cambridge, MA; [4]Harker school, San Jose, CA; [5]HHMI, Stanford, CA

**Abstract:** The serotonin system powerfully modulates physiology and behavior in health and disease. The major source of serotonergic innervation of the forebrain originates from the dorsal raphe nucleus (DR). Most previous studies of serotonin regulation of physiology and behavior treat the DR serotonin system as a single entity. Our recent whole-brain mapping of monosynaptic inputs to DR suggested heterogeneity of serotonin neurons with respect to input they receive (Weissbourd et al., *Neuron* 83:645-662, 2014). We now report that retrograde tracing from 8 distinct brain area revealed that serotonin neurons project to specific output sites have a stereotyped cell body locations in the DR. For example, serotonin neurons that project to olfactory bulb and cortical areas such as prefrontal cortex (PFC) and entorhinal cortex are

concentrated in the ventral DR. By contrast, serotonin neurons that project to subcortical areas, such as central amygdala (CeA), thalamus, hypothalamus, tend to distribute in the dorsal DR. Collectively, these data suggest that the DR serotonin neurons consist of parallel sub-systems. We next selected DR serotonin neurons that project to PFC and CeA as two representative sub-systems for further investigation. By combining retrograde viral tracing and iDISCO+-based brain clearance method, we found that PFC- and CeA-projecting DR serotonin neurons have specific collateralization patterns that are largely non-overlapping. We further used cTRIO method we recently established (Schwarz et al., *Nature* 524:88-92) to map the input-output relationship, finding that PFC-projecting DR serotonin neurons have biased input from lateral hypothalamus and medulla, whereas CeA-projecting ones receive stronger input from CeA itself and from the bed nucleus of the stria terminalis. We are currently using fiber photometry and chemogenetics to record and manipulate the activity of these two groups of neurons in behavioral paradigms that may be regulated by serotonin. Together, these experiments begin to decompose the DR serotonin system into distinct sub-systems, each of which likely has unique anatomical, physiological, and functional properties.

**Authors: *J. L. FRONTERA**[1,2], C. MAILHES-HAMON[2], D. POPA[2]
[1]Inst. De Biologie De L'Ens, Paris, France; [2]Dept. de Biologie, Inst. de Biologie de l'Ecole Normale Supérieure, Paris, France

**Abstract:** Fear conditioning is a form of learning that serves as model to study the neurobiological basis of disorders of fear and anxiety. Available data suggest that pathological forms of anxiety result from a deficit in the acquisition, expression or extinction of the emotional responses. The role of brain structures such as the amygdala and the prefrontal cortex in these

phenomena is well established, but recent data indicate an involvement of the cerebellum in emotional disorders. Using a combination of neuroanatomy, behavior, and pharmacogenetics approaches, we are studying the cerebellum and the limbic forebrain circuit in fear conditioning in mice.
We mapped the cells in the amygdala responding to cerebellar stimulations followed by immunolabeling of the early gene Zif/268 to identify neurons activated by the cerebellar stimulation in mice expressiong ChannelRhodopsin in Purkinje cells, L7ChR and we found clusters of labeled cells in the basolateral and central nuclei of the amygdala contralateral to the stimulation.
We also mapped the brain pathways linking the cerebellum to the limbic system using different retrograde markers (Cholera Toxin subunit B-alexa 555, -alexa 488, -CF594) injected in the prefrontal cortex and the amygdala, and anterograde virus (AAV1.CB7.Cl.mCherry.WPRE.rBG) injected in the cerebellar nuclei. We found multiple putative thalamic relays where the fibers from fastigial nucleus as well as somas of neurons projecting to prefrontal areas and amygdala converged. We transiently silenced the neuronal activity of cerebello-thalamic pathway during fear conditioning using pharmacogenetics and we found cerebellar modulation on fear memory consolidation, suggesting that the cerebellum is engaged in the limbic forebrain function and in the processes that take place in fear learning and extinction.

**Abstract:** Anxiety disorders are the most common class of mental disorders. Anxiety is an affective state classically governed by the prefrontal cortex, hippocampus, and the extended amygdala, which includes the bed nucleus of the stria terminalis (BNST). Previous studies suggest that stimulation of glutamatergic BNST efferents in the ventral tegmental area (VTA) is anxiogenic. Further, the VTA can exhibit control of affective state by heterogeneous efferent

terminal activation in certain brain regions. Recently, we showed that the mesointerpeduncular circuit, which consists of VTA dopaminergic (DAergic) neurons that innervate the interpeduncular nucleus (IPN), is an important component in nicotine withdrawal-induced anxiety. The current study further explores the mesointerpeduncular circuitry, specifically DAergic control of the IPN in drug naïve mice. Using cell-attached patch-clamp electrophysiology in acute mouse midbrain slices, we defined two neuronal populations of the ventral IPN by input resistance and response to exogenous application of DA. “Type A” neurons displayed low input resistance and responded to DA with an increase in spontaneous action potential frequency (sAPF), while “Type B” neurons exhibited a higher input resistance and responded to DA with a decrease in sAPF. Whole-cell patch clamp recordings revealed changes in excitatory postsynaptic current frequency, but not amplitude in IPN neurons during VTA terminal stimulation suggesting that DA acts presynaptically to modulate IPN inputs Using viral mediated gene delivery and CRE-Lox technology, we expressed channelrhodopsin-2 (ChR2) specifically in putative DAergic VTA neurons of DA transporter (DAT)-CRE mice. Optogenetic stimulation of VTA neurons resulted in changes in sAPF prominently in the caudal IPN. These responses were blocked by D1-family DA receptor (DRD1) antagonists and were localized to the area where putative DRD1-expressing cell bodies were detected. Dopaminoceptive caudle IPN neurons exhibited significantly higher input resistance compared to Type A or B neurons suggesting a third neuronal subtype, “Type C”. Optogenetic stimulation of putative DRD1-expressing Type C neurons in the IPN of DRD1-Cre mice resulted in responses of ventral IPN Type A and Type B neurons that phenocopied the response to exogenous DA application. Together, our results identify a novel microcircuit by which the VTA controls activity of the IPN to potentially modulate affective behavior.

**Abstract:** Recent reports have shown subcortical neural correlates of psychiatric disorders such as depression and obsessive compulsive disorder. However, investigations to date have mostly consisted of recordings made in brain stimulation paradigms with relatively limited spatial resolution and only in specific clinical scenarios. Additionally, intracranial recording electrodes are generally not indicated for the management of psychiatric disorders, and thus these pathologies are poorly studied in terms of cortical electrophysiology. Here we use cortical surface intracranial EEG (iEEG) recordings in epilepsy patients being monitored for seizure localization to identify cortical neural correlates of major depressive disorder (MDD). Our classification of MDD was predicated upon a clinical diagnosis and reaffirmed with the Beck Depression Index version 2. When comparing across all participants, we found neural correlates of MDD in the left temporal lobe. In particular, we observed significantly lower broadband spectral power in patients identified with MDD, and importantly, it appears that these markers were independent of any seizure activity. These data suggest that dysfunctional cortical mechanisms may contribute to MDD and that further investigation is warranted to elucidate diagnostic and therapeutic approaches to psychiatric disorders in humans.

**Abstract:** The ability to perceive internal bodily states such as hunger, thirst, pain, muscular and visceral sensations, known as interoception, is regarded as a fundamental basis for emotional processing and (embodied) selfhood. For many years, interoception was regarded as a purely bottom-up, sensory-driven phenomenon, based on the representation of afferent sensory input from the body. However, recent accounts suggest that interoception is a top-down, prediction-

driven phenomenon that, as with other sensory modalities, enables the inference of the causes of bodily sensations on the basis of past experiences. In this EEG study we tested this hypothesis investigating the neural responses to heartbeats following expected and unexpected emotional stimuli. We used a modified stimulus repetition task while measuring evoked cortical responses from 17 human participants. During the task, participants observed pairs of facial expressions presented with repeating or alternating emotional content. We manipulated the emotional valence and the likelihood of stimulus repetition. The results of the study showed that the heartbeat-evoked potential, a marker of cardiac interoception, was increased for repeated (and thus, expected) neutral faces, whereas the opposite was observed for negative faces. Our results are in line with recent models of interoceptive predictive coding and help to elucidate the role of emotion in predictive processing underlying interoception. In particular, these results suggest that cardiac interoceptive responses are enhanced when processing an expected, compared with an unexpected, neutral emotional event. In contrast, for negative emotional events, successful top-down prediction appears to result in reduced interoceptive processing and thus, reduced embodied self-awareness.

**Abstract:** Anhedonia is a core symptom of depression, but the underlying neurobiological mechanisms remain unclear. Correlative neuroimaging studies implicate dysfunction within the highly heterogeneous ventromedial prefrontal cortex, but the causal role of specific subregions is unknown. We addressed these issues by combining intracerebral microinfusions with

cardiovascular and behavioral monitoring in marmoset monkeys to show for the first time that pharmacological over-activation of primate subgenual anterior cingulate cortex (sgACC, area 25) causes anticipatory but not consummatory anhedonia, whereas neither over-activation nor inactivation of perigenual ACC (pgACC, area 32) has any effect. The anhedonia induced by sgACC/25 over-activation was replicated using chemogenetic excitatory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), enabling us to localize the source of this anticipatory deficit to over-activity in pyramidal output neurons within sgACC/25. These same chemogenetic manipulations had no effect on sucrose preference in the sucrose consumption test, a common measure of consummatory anhedonia used in rodent studies. We subsequently demonstrated that the anticipatory anhedonic deficit could be ameliorated with ketamine in a time-dependent manner. $^{18}$F-FDG microPET imaging revealed that over-activity in dorsal ACC and anterior insula accompanied the anhedonia induced by sgACC/25 over-activation, changes which were all reversed by ketamine. These results demonstrate a causal role for sgACC/25 over-activity in anhedonia, and ketamine's modulation of an affective network to exert its action.

**Abstract:** Individuals must be able to integrate complex, even conflicting, emotional signals to regulate their emotions depending on their relevance to current, ongoing contextual demands.

Insufficiencies in this type of emotion regulation have been demonstrated across many psychiatric disorders. We made use of intracranial recordings in participants with epilepsy to define the regions and types of neural activity that subserve emotion regulation as elicited in the Emotional Conflict Resolution (ECR) task. The ECR task consistently induced significant widespread activation of the brain across participants (N=15). In addition, we found that ECR task-relevant behavior is significantly correlated to the LFP voltage and theta (4-8 Hz) and high gamma (65-200 Hz) power signal in brain regions predicted by imaging studies, such as the dorsal anterior cingulate cortex (dACC), amygdala, and the rostral anterior cingulate cortex (rACC). Targeting these same regions using high frequency focal neural stimulation, we altered participant behavior bidirectionally depending on which brain regions were stimulated. We then used these results to introduce closed-loop stimulation, such that the ongoing behavior on a trial to trial basis was used to trigger electrical stimulation of brain regions. We found we could alter behavior in closed loop fashion in a participant performing ECR. These results not only support fMRI literature demonstrating the importance of the salience networks' involvement in emotion regulation, but illustrate that neural stimulation in this network can alter behavior and, thus, may eventually provide a therapeutic modality for people suffering from emotion dysregulation.

**Abstract:** How humans respond to emotional stimuli in the face of conflict is influenced by how emotions are regulated internally while responding to emotional stimuli. This can contrast with how humans respond to conflict without emotional stimuli, such as in cognitive tasks. Difficulties with regulating emotion or resolving cognitive conflict have been demonstrated across many psychiatric disorders. Understanding this complex, and highly integrated, process requires we understand neural activity dynamics as individuals switch between non-emotional and emotional tasks. We chose to compare neural activity during the Emotion Conflict Resolution (ECR) task and the Multi-Source Interference Task (MSIT). We wanted to identify the neural correlates of behavior that are either unique or intersectional between MSIT and ECR, particularly in light of whether the underlying state of emotion reactivity, as measured by self-report questionnaires, alters these dynamics. Our findings from intracranial recordings of patients with intractable epilepsy (N=15) align with previous fMRI imaging literature. We were also able to confirm the activation of cortical structures involved in resolving non-emotional conflict by inspecting the size of voltage deflections and changes in theta band (4-8 Hz) power. Lateral pre-frontal cortex (PFC) and dorsal anterior cingulate cortex (dACC) had significant theta band power changes during both tasks ($p<0.05$, fdr corrected t-test). During the resolution of emotional conflict, there was additional activation of dorsal medial PFC and subcortical structures, amygdala and rostral anterior cingulate cortex (rACC). Several of these regions also had changes in high gamma power (65-100Hz) when resolving conflict. There was a significant increase ($p<0.05$, Wilcoxon rank sum) in network connectivity, as measured by theta band coherence, between lateral PFC and other cortical structures during MSIT relative to ECR. During ECR, connectivity increased between rACC and dACC. However, this was only the case for participants with low emotional reactivity, as measured with their questionnaire responses. Those with high emotional reactivity had coherence changes during ECR that were similar to those occurring during MSIT, albeit with smaller magnitude. We interpret this to mean that participants with high emotional reactivity do not utilize the same networks to resolve emotional conflict to perform ECR, instead relying heavily on the networks required to solve non-emotional, or cognitive, conflict. Activating emotional conflict resolution networks may be a therapeutic route for those struggling with emotion dysregulation.

**Abstract:** Recent studies have found success in treating refractory neuropsychiatric disorders through neural stimulation. While actively employed to treat several disorders, including epilepsy and Parkinson's disease, knowledge is sparse regarding the way in which stimulation parameters such as frequency and amplitude influence changes in neural activity. We examine the functional relationship between pulse frequency and current amplitude during short trains of stimulation ranging from 10-200 Hz by evaluating the evoked response in cortical and subcortical brain regions adjacent to sites of stimulation in both human (N= 6) and non-human primates (NHP, N=3). Specifically, we evaluate the evoked response in the amygdala, and the dorsal and rostral anterior cingulate cortices (dACC, rACC) of human participants undergoing invasive monitoring for resective epilepsy surgery, and in the rACC, dACC, and the nucleus accumbens (NAcc) of NHPs chronically implanted with depth electrodes. These methods allow us to better understand the stimulus space for inducing targeted changes in neural activity in brain regions that have been associated with neuropsychiatric disorders, including depression, post-traumatic stress disorder, and addiction. We found that in both humans and NHPs, the peak evoked potential voltage response and the delay of the peak response increases until reaching a stimulation frequency between 90 and 130 Hz, and then either saturates or decreases as we step up to higher stimulation amplitudes and frequencies. Thus, stimulation frequency and current amplitude have a non-linear relationship with the peak response and the delay of this peak response. This non-linear mapping also depends on the brain region being stimulated, particularly in terms of subcortical and cortical targets. Similarly, neither stimulation amplitude nor frequency alone adequately predicted evoked changes in power. Instead, the interaction between stimulation amplitude, frequency, and recording location was important in producing a significant evoked change in power. These results suggest that there exists a set of amplitude and frequency parameters that will result in the highest local evoked responses to short trains of

stimulation at any specific brain region. This information begins to provide the basis for a principled selection of stimulation parameters to achieve maximal therapeutic benefit.

Ctr., Providence, RI

**Abstract:** The brain is a distributed network that operates at small and large spatial and temporal scales to meet the needs of the task at hand. Certain tasks generate conflict by requiring attention to relevant stimuli among distractions. Engagement in conflict-based tasks elicits network activity that differentiates these tasks from other behaviors. Brain states associated with conflict in experimental behavioral contexts may be an important marker of dysfunction related to mental illness, yet there are no documented decoders that predict engagement in conflict-based tasks through invasive, large scale local field potential recordings. In addition, there is evidence that precisely timed deep brain stimulation (DBS) could restore normal task behavior in neuropsychiatric patients; however, these findings are limited to within task features. In the present study, we have developed a decoding strategy to accurately predict task engagement by harnessing canonical correlation analysis (CCA), a measure of functional connectivity between regions, in tandem with a support vector machine (SVM) classifier. Cortical and sub-cortical invasive local field potential recordings were collected from patients engaged in one of two

Stroop-like tasks: the multi-source interference task (MSIT) or the emotional conflict resolution task (ECR). Canonical correlation coefficients were extracted by performing singular value decompositions on windows of data across all channels within each region and transforming the resulting singular vectors in a way that maximally correlates activity between each region pair. These CCA features were used as inputs to an SVM classifier to differentiate functional connectivity between task engagement and free behavior. A mean classification accuracy greater than 95% was achieved for both tasks across 14 patients and a subset of features per patient required to maintain high accuracy were isolated. The reduced feature set can be used to reduce the computational complexities of the algorithm moving forward, which points to potential tractability for driving a simple algorithm to detect task engagement on existing systems. While decoder stability was not achieved over two recordings, classification accuracy improved when trained on both recordings. This increase in accuracy suggests that training the classifier on many temporally separated datasets could improve its stability. Detection of task-associated brain states could ultimately be a closed-loop strategy for delivering real-time therapy to patients with mental illness.

**Title:** Interhemispheric paired associative stimulation of the prefrontal cortex jointly modulates frontal asymmetry and emotional reactivity

**Authors: *S. ZIBMAN**, E. DANIEL, U. ALYAGON, A. ZANGEN
Dept. of Life Sci., Ben Gurion Univ., Beer Sheva, Israel

**Abstract:** Asymmetry of frontal alpha power has a long history of association with emotional regulation and processing. Typically measured by EEG, the relative activation of the right and left lateral prefrontal cortex (LPFC) is correlated to various emotional responses and an imbalance is associated with psychological conditions such as depression and aggression.
A major challenge in determining the role of frontal asymmetry in emotion is that while the

correlation between deficits in lateralization and in cognitive functions has been established, a causal relationship has not been fully demonstrated. One technique that can be used to alter connectivity and establish causality in the brain is paired associative stimulation (PAS) which, through the coordinated stimulation of two regions by two TMS coils, targets the intervening connectivity. The PAS protocol is based on Hebbian plasticity.
Here we investigate the effects of interhemispheric PAS between the left and right LPFC on attentional bias to emotional stimuli. 27 healthy subjects were recruited for a three session, sham-controlled crossover study, receiving left to right PAS (LR-PAS), right to left PAS (RL-PAS) and sham during different weeks. The protocol consisted of 210 pulse pairs with a lag of 8ms. Subjects performed an emotional reactivity task, in which participants are asked to respond to the color of visual stimuli, in this case faces, with different emotional content, assessed by measuring attentional bias, and brain activity was recording with EEG both at rest and in response to single pulse stimulation prior to and following the stimulation period.
Our results reveal that LR PAS increases attentional bias while increasing right frontal asymmetry whereas RL PAS decreased the attentional bias while decreasing right frontal asymmetry ($F(2,24) = 3.266$, $P=0.05$ and $F(2,27) = 5.936$, $P=0.005$ for attentional bias and frontal asymmetry respectively). These results confirm a relationship between frontal alpha asymmetry and attentional bias.
PAS induces an increase in interhemispheric signal propagation (ISP) only in the direction of the PAS protocol (left to right for LR-PAS and right to left for RL-PAS) and not in the reverse direction (3-way ANOVA $F(2,27) = 3.15$, $p = 0.05$ ). This indicates that PAS effects connectivity specifically in the direction of the stimulation.
This is the first demonstration of PAS's effectiveness in inducing cognitive changes by targeting interhemispheric PFC connectivity in a directional manner. Furthermore, by combining TMS with EEG, we provide a toolbox for evaluating effectiveness of PAS protocols that may facilitate development of novel therapies.

**Title:** Childhood exposure to violence predicts altered neural circuitry for emotion regulation in adulthood

**Authors: *S. S. MATTHEISS**, H. J. LEVINSON, N. ABOUKAFF, W. W. GRAVES
Rutgers Univ. Newark, Newark, NJ

**Abstract:** It is often suggested that early experiences of adversity, such as exposure to violence, alter how people process reward and threat. Previous studies of the neural basis of acute and chronic stress have shown alterations in connectivity between frontal and subcortical regions, corresponding to differential reward and threat processing. However, no studies to our knowledge have examined the particular effects of high exposure to community violence during childhood on resting state functional connectivity, a measure of the organization and communication among neural regions. The current study aims to elucidate such effects by conducting a between-group resting state functional connectivity analysis comparing individuals reporting high compared to low exposure to violence during the ages of 3 to 14 years. Participants were undergraduate and graduate students from the Rutgers University community, ages 19 to 32 years. Each group consisted of 14 participants, with socioeconomic status, reported levels of current exposure to violence, gender, verbal intelligence, and age matched between groups. Functional magnetic resonance imaging resting state data were collected while participants viewed a fixation cross in the scanner for seven minutes. The ventromedial prefrontal cortex (vmPFC) was entered as a seed region, given previous research demonstrating that this region regulates subcortical regions involved in threat and reward response. We predicted decreased connectivity between vmPFC and subcortical regions, such as the amygdala, for individuals exposed to high compared to low levels of violence during childhood. Results supported our predictions, with individuals reporting high compared to low levels of exposure to violence during childhood demonstrating negative connectivity with vmPFC and the left amygdala, implicated in threat processing, as well as the bilateral parahippocampal gyrus, implicated in both memory and processing negative affective information. These results suggest that exposure to violence during the ages of 3 to 14 may alter functional connectivity between vmPFC and the amygdala, a neural circuit involved in the regulation of emotional responses. These findings are consistent with previous studies demonstrating alterations in prefrontal-subcortical circuits due to exposure to stress, but extend such findings to include childhood exposure to violence. This study offers evidence supporting the claim that students in urban academic settings, where neighborhood crime rates are high, may benefit from interventions designed specifically to capitalize on such altered neural circuitry.

**Abstract:** Chronic stress can lead to changes in brain connectivity patterns and associated changes in psychological functioning. Greater levels of violence exposure, a type of chronic stressor, is associated with increases in emotion dysregulation and stress reactivity. Affective style reflects one's interpretation of stressful events and can also affect stress reactivity. Resting state functional connectivity (rsFC) is an index of brain connectivity patterns used to identify changes in brain function. Changes in rsFC are associated with deficits in emotion regulation and have been used to assess stress-induced variations in brain connectivity. The present study sought to examine the effects of violence exposure and affect on stress-induced changes in rsFC. Participants completed two 6-minute resting state functional magnetic resonance imaging (fMRI) scans, one prior to (pre-stress), and one after (post-stress) completing an adaptation of the Montreal Imaging Stress Task. FMRI data were obtained using a 3T Siemens Allegra scanner. The amygdala, hippocampus, and ventromedial prefrontal cortex (vmPFC) were used as seed regions for connectivity analyses. A linear mixed effects model analysis was conducted for each region to determine whether amygdala, hippocampus, and vmPFC-whole brain functional connectivity differed pre- to post-stress by cumulative violence exposure (CVE) and affect. All significant clusters were corrected for multiple comparisons ($p_{FWE}$=.05). There was a significant interaction between affect and CVE in predicting changes in amygdala, hippocampus, and vmPFC rsFC pre- to post-stress ($p_{FWE}$=.05). Positive, but not negative affect modulated the relationship between CVE and changes in hippocampus-dorsolateral prefrontal cortex (dlPFC) and amygdala-dorsomedial prefrontal cortex (dmPFC) rsFC. Specifically, those with low positive affect and high CVE exhibited greater changes in rsFC. Negative, but not positive affect modulated the relationship between CVE and changes in vmPFC-dlPFC rsFC such that those with moderate CVE and high, but not low negative affect, exhibited greater changes in rsFC pre- to post-stress. In the present study, the modulatory effects of affect on the relationship between rsFC and CVE suggest that low positive emotions and high negative emotions coupled with higher CVE contribute to greater changes in stress-induced brain connectivity. Findings provide insight into the complexities through which affect and violence exposure affect brain functioning and coincide with the literature that demonstrates that fronto-limbic brain regions mediate the emotional response to stress.

**Abstract:** This Project is funded by a Marie Skłodowska-Curie Post-doctoral Fellowship (Call: H2020-MSCA-IF-2014)
Aging is a primary health concern for the entire world. Pessimistic perspectives characterizing aging as a time of profound physical, cognitive and emotional losses have been relieved by recent research illustrating improved well-being and emotional self-regulation in later life. Specifically, an age-related increase in the preference for positive over negative information in attention and memory, namely the positivity effect, seems to relate to a better cognitive functioning. However, several studies have challenged the reliability of this effect. The objectives of the present study were two-folded. First, to examine one crucial moderator that may affect the consistency of the positivity effect, which is related to the “experimental constraints” imposed by certain tasks. Second, to examine the neural underpinnings of the positivity effect with electroencephalography (EEG). To this end, 30 young and 30 older individuals performed a memory task with emotional material that manipulated low and high cognitive demands while participants were recorded with EEG. Behavioural data was analysed under the frame of the Signal Detection Theory. We employed source reconstruction analysis for EEG data in order to localize age differences in neural activity (work in progress). Our results indicated that older adults exhibit a reduced ability to distinguish old trials from new trials, and they are more prone to respond “old” when the trial is “new”, for positive stimuli compared to young adults in the less demanding condition. This effect is supressed in the higher demanding condition. These findings suggest that positive stimuli may generate higher interference than negative or neutral stimuli in emotional recognition with age. Additionally, cognitive demands seem to modulate such a positivity bias in older individuals. Regarding our EEG results, we expect such a positivity bias to be associated with a time-modulated prefrontal network.

**Abstract:** Blood oxygenation level-dependent (BOLD) signal measured using functional MRI (fMRI) observe spontaneous fluctuations during resting state (rs) even in the absence of an externally prompted task. These fluctuations contain physiological noise consists of cardiac pulsation and respiration, and these noises may influence the functional connectivity. Purpose of this study is to clarify the influence of physiological noise on the rs-fMRI signal, especially on limbic areas. Emotion such as anxiety state affects on respiratory activities, and olfaction which relatively associated with respiratory changes, these emotion-related respiratory changes involve activation of the limbic areas, especially the amygdala. Our hypothesis is that functional connectivity between the amygdala and other limbic areas may be influenced by respiratory-related fluctuation rather than connectivity between other cortical areas. Twelve healthy adults were participated in this study, and an informed consent approved by Showa University Ethical Committee was obtained from each subject. rs-fMRI was measured with a clinical 3T scanner (MAGNETOM Trio A Tim System, Siemens) with a 32-channel head coil. Functional imaging was acquired with multiband (MB = 4) accelerated gradient echo echo-planar imaging exciting four slices with increasing temporal resolution. Cardiac pulse wave and respiration were simultaneously recorded with whole-brain rs-fMRI to retrospectively correct physiological noise using DRIFTER TOOLBOX (SPM8). Functional connectivity between 116 nodes defined by Automated Anatomical Labeling (AAL) during resting sate fMRI time-series was tested with or without physiological noise correction. Pearson's correlations coefficients between nodes where calculated by using DPARSF software, and comparison were performed with analysis of variance and post-hoc using Bonferroni test for three groups' comparisons; session without both

cardiac and respiratory noise correction, session with only cardiac noise correction and session with both cardiac and respiratory noise correction. Our results suggest that the both cardiac and respiratory noise correction increased signal-to-noise-ration, and showing improved functional connectivity, especially, the connectivity between limbic areas para-hippocampus and amygdala, and basal ganglion.

**Title:** Cortical circuit dynamics during punishment-resistant alcohol drinking

**Authors: *C. SICILIANO**, Y. LEOW, X. CHEN, E. Y. KIMCHI, C. M. VANDER WEELE, K. M. TYE
MIT, Cambridge, MA

**Abstract:** A great deal of research has highlighted the role of the medial prefrontal cortex (mPFC) in encoding motivational value and decision making. Further, alcohol-induced plasticity in mPFC has been implicated in aberrant alcohol drinking behaviors; however, we have little understanding of how neurons in mPFC are encoding alcohol related stimuli in real-time, and what downstream circuits are involved. Recently, we identified two projector populations in mPFC, to nucleus accumbens (NAc) or dorsal periaqueductal gray area (dPAG), which divergently route information related to positive and negative unconditioned stimuli, respectively. Here, we sought to dissect the role of these projection-defined subpopulations

within mPFC in associative learning and punishment-resistant alcohol drinking. Using a dual virus approach we selectively expressed the genetically encoded calcium indicator GCaMP6m in mPFC projecting to NAc or dPAG. By implanting a GRIN lens into the mPFC and attaching a miniature head-mounted microscope we were then able to record calcium dynamics with single-cell resolution during a novel Pavlovian conditioning task for alcohol, or alcohol adulterated with the bitter tastant, quinine. Using this alcohol seeking task, where the strength of alcohol conditioned cues and punishment-resistant alcohol consumption were tested before and after binge exposure to alcohol, we found that binge exposure produced wide individual variations in the development of punishment-resistant alcohol drinking. Further, the activity of the pathways tracked stimulus value, and differed between punishment-resistant and punishment-sensitive drinkers where resistance was associated with decreased activity of mPFC:dPAG to aversive stimuli. Together, our results support a model where activation of the mPFC:dPAG circuit encodes aversive stimuli and produces avoidance. Further, dysregulation of this pathway resulting from chronic alcohol use may blunt responsiveness to aversive stimuli and result in inflexible, punishment-resistant alcohol drinking.

**Abstract:** The large spindle-shaped von Economo neuron (VEN) occurs in a specific architectonic area (‘VEN-area’) in the macaque anterior insula (Evrard *et al.*, Neuron, 2012, 74:482-9). Given its relatively large size and localization in layer 5a, the VEN likely projects to

distant brain regions. We recently reported that one of this target is the midbrain periaqueductal gray (PAG). Here we examined the insular projections to another key homeostatic center, the parabrachial nucleus (PBN) using injections of anterograde tracers in AIC and of retrograde tracers in PBN. Injections of biotin-dextran-amine (BDA) in the insular area containing VENs produced sparse but consistent anterograde labeling in both the medial and lateral aspects of the PBN. Injections of retrograde cholera toxin b (CTb) or fluorescent dextran in PBN invariably labeled cortical projections neurons on both side of the neocortex. However, unlike for our prior injections in PAG, the AIC, including the VEN area, was almost the only cortical region labeled. The retrogradely labeled neurons included pyramidal neurons as well as VENs and their companion Fork neurons (FNs). These results are consistent with our microstimulation works showing activation of both left and right PBN with microstimulation of either the left or right AIC (see Smuda et al, this meeting). They are also consistent with our recent collaborative evidence that the human VEN area is strongly functionally connected with PBN and that this functional connection is massively altered in coma patients with a brainstem lesion (Fischer et al., Neurology, 2016, 90:143-51). Finally, they suggest that the relatively large VEN and FN might provide rapid cortical efferent projections for the regulation of brainstem autonomic processing both at the afferent (PBN) and efferent (PAG) stages.

**Abstract:** The anterior insular cortex (AIC) is often regarded as a key “node” of the saliency network with a role in coordinating brain network activity after detection of homeostatic

changes. In addition, distinct areas of the AIC project to homeostatic brainstem centers and could therefore act as a cortical output stage for the concurrent regulation of physiological and behavioral emotional responses to salient events. Given the possible role of the AIC in switching brain network dynamics and in descending autonomic regulations, we combined electrical microstimulation and functional magnetic resonance imaging (fMRI) using a 7T scanner to examine the effect of electrical microstimulation of the AIC on the blood-oxygen-level-dependent (BOLD) signal in both the subcortical homeostatic centers and the neocortex in 5 anesthetized macaque monkeys. Single channel glass isolated iridium electrodes were used to deliver 200-μs biphasic charge-balanced pulses with stimulation frequencies of 5, 40, 60 and 100 Hz during two-shot echo-planar imaging (EPI) with a temporal resolution of 2 seconds (Logothetis et al. Nature Nsci 2010 13:1283-91). Electrical microstimulation of the left or the right AIC produced strong positive and negative BOLD signal changes in both cortical and subcortical regions. In some sessions, there was a distinct but varying activation of all subcortical centers known to receive monosynaptic projections from the AIC (hypothalamus, periaqueductal gray, parabrachial nucleus). However, in most sessions, this pattern was accompanied or replaced with massive activation or deactivation of the neocortex, in particular primary sensory areas, with a trend for the left and right AIC to produce more prevalently cortical activations and deactivations, respectively. These effects, coupled with our tract-tracing and NET-fMRI data, begin to unravel the functional organization underlying the role of the AIC in brain network dynamics and brainstem autonomic control regulation.

**Abstract:** The central representation and the goal-directed control of bodily states are integrated in the anterior insular cortex (AIC) as core processes underlying the 'subjective' component of emotion and cognition. The AIC is often regarded as a key "node" of the saliency network with a role in coordinating brain network activity upon the detection of homeostatic changes. A model proposed that the preferential representation of parasympathetic and sympathetic activity in the left and right AIC underlies appetitive and aversive emotions, respectively (Craig TICS 2005 9:566-71). Given the possible role of the AIC in switching brain network dynamics, we examined whether this asymmetry occurs in functional relation of the AIC with the rest of the brain. To this end we used multi contact laminar electrodes to record neural activity from the left and right AIC in parallel while simultaneously acquiring functional magnetic resonance imaging (fMRI) scans in four rhesus macaque monkeys. The electrodes were placed in the AIC area containing the von Economo neurons (or 'VEN area'), an area shown previously to be larger and independently contain more VENs on the right than on the left side (Evrard et al. Neuron 2012 74:482-9). The ongoing spontaneous neuronal activity was analyzed focusing on the local field potential (LFP) gamma band (56-79 Hz) where frequent increases in amplitude could be observed. These gamma events were in most cases unilateral, with occurrence either in the left or in the right VEN area in the majority of the cases and only few cases where gamma band activity increased simultaneously on both sides. Following the detection of these gamma events, their occurrence was used to trigger and average the blood-oxygen-level dependent (BOLD) signal from the fMRI scans, a method called 'neural-event-triggered fMRI' (NET-fMRI) (Logothetis et al. Nature 2012 491:547-53). The examination and mapping of the BOLD signal change during asymmetric events revealed markedly different patterns of activation and deactivation in vast regions of the brain. These effects might substantiate a fundamental autonomic forebrain asymmetry balancing brain dynamics to produce nurturing and expending behaviors and feelings in a homeostatically optimal manner.

Engin., Univ. of Manchester, Manchester, United Kingdom

**Abstract:** The cortical representation and processing of sensory afferent impulses is crucial for the fine coordination of complex brain and bodily responses to salient events. One specialized brain region, the insular cortex (IC), represents sensory inputs related to interoception and gustation. We examined the functional organization of distinct IC subregions using multi-modal stimuli with fMRI and electrophysiology in macaque monkeys and, to a lesser extent, fMRI in humans. The gustatory pathway was stimulated using various sets of taste stimuli, including sweet, sour and salty tastants applied to the tongue at high- and low-intensity concentrations. Despite individual variations in both species, consistent BOLD signal changes emerged in the anteroposterior mid-dorsal fundus and the most anterior aspect of the fundus, with a distinct separation of several millimeters from the middle representation. We also probed the interoceptive pathway using transcutaneous stimulation of the auricular branch of the vagus nerve (tVNS), rectal distention (RD), and local skin temperature changes in macaque monkeys. Thermal stimulation of the hand and foot consistently produced positive BOLD signal changes in a region posterior to the middle taste representation. Both RD and tVNS variably activated a smaller region near the taste representation and another region in the ventral anterior aspect of the IC, a region which has been related to a network of high-order cognitive functions and top-down influence on the autonomic nervous system. Electrophysiological recordings throughout the insula in macaque monkeys largely confirmed this topography. These non- or minimally-invasive stimulations of the primary interoceptive cortex provide the first multi-modal mapping of bodily functions in the IC. This work is an important first step towards understanding the neurobiology of subjective feelings and the relation of brain and bodily states during high-order emotional and cognitive functions.

**Title:** Characterization of the intrinsic functional connectivity of the habenula in children with adhd

**Authors: *M. ARFUSO**[1,1], A. K. ROY[1], F. X. CASTELLANOS[2], R. SALAS[3]
[1]Integrative Neurosci., Fordham Univ., Bronx, NY; [2]Child and Adolescent Psychiatry, NYU Langone Med. Ctr., New York, NY; [3]Baylor Col. of Med., Houston, TX

**Abstract:** The habenula is a small brain region that is a part of the epithalamus. It directly regulates dopaminergic and serotonergic circuits through the ventral tegmental area and substantia nigra. Both of these circuits are implicated in reward processing, and show deficits in children with ADHD, suggesting that habenula function may be irregular in ADHD. Because the habenula is thought to contribute to reward prediction error, habenular function may also be associated with the lower frustration tolerance often observed in children with ADHD and other disruptive behavior disorders. To test these hypotheses, this study examined the intrinsic functional connectivity (iFC) of this brain region in children (ages 5- 9 years) with (n=41) and without ADHD (n= 45), and in children with low frustration tolerance as evidenced by severe temper outbursts (TO; n=61). Following psychological assessments, children participated in a 6-minute resting state scan. Neuroimaging preprocessing was done using the Configurable Pipeline for the Analysis of Connectomes (C-PAC). Seed-based iFC used 1mm radius habenula regions of interest, identified individually from normalized T1 weighted images. Groups did not differ in age, sex, or movement during the scan. Results showed negative functional connectivity between the left habenula and the putamen in the ADHD group, as compared to positive connectivity in the control group. Additionally, three iFC clusters showing significantly decreased left habenula iFC in the ADHD group as compared to the TO group: the posterior cingulate, precuneus, and superior temporal gyrus. The right habenula analysis yielded two clusters: the posterior cingulate and the precuneus showing negative iFC in the ADHD group and positive iFC in the TO group. Overall, our results suggest that disruption in the iFC in the habenular network of children with ADHD through possible dysregulation of dopaminergic pathways. Further, alternative functional connections of the right and left habenulae with cortical regions appear to play a role in frustration tolerance and possibly emotion regulation.

**Abstract:** Huntington’s disease (HD) is a debilitating neurodegenerative disease that is part of a class of diseases affecting the basal ganglia. Impaired negative emotion recognition is a common and early symptom of HD, and entails the patient being unable to properly identify negative emotions on human faces. Through analysis of cell label patterns in a macaque cortex with a retrograde tracer, a region in the ventral striatum has been identified with the potential to function as a critical hub in the emotion processing networks. This region of the striatum receives projections from cortical and subcortical regions involved with emotion processing, including the amygdala, ventromedial prefrontal cortex, orbitofrontal cortex, anterior cingulate cortex, and temporal lobe. Analysis of the region of the striatum receiving the projections above will be evaluated to provide more insight into the link between the progression of the pathophysiology of HD and the symptoms of HD over time. The identification of this hub has the potential to broaden our understanding of symptomatology and progression in HD, contribute to other projects in neuropsychiatric disorders involving the striatum, and provide further data for the study of brain connectivity as a whole.

**Title:** Cortical connections of primate subgenual cingulate area 25

**Authors: *M. P. JOYCE**[1], H. BARBAS[2]
[1]Hlth. Sci., [2]Boston Univ., Boston, MA

**Abstract:** Area 25 (A25) has been implicated in emotion and mood disorders. This cortical area is found deep in the ventral and posterior aspect of the subgenual cingulate region. To date, only a few studies have reported on some cortical connections of A25, providing valuable information but an incomplete picture. Using neural tracers in rhesus monkeys, we examined the full complement of A25 connections at laminar and cellular resolution. Connections within the prefrontal cortex (PFC) composed the densest pathways to A25, specifically the medial and posterior orbital PFC and the frontal pole (area 10). We found moderately dense A25 afferents from the temporal pole, the medial temporal cortices, and temporal auditory association cortices. A25 targets and receives connections mostly from superficial layers of eulaminate areas that have more developed laminar structure, such as the temporal auditory association areas. Conversely, A25 tends to target and receive connections from middle to deep layers of agranular areas that have more rudimentary lamination, such as the medial temporal cortices and anterior insula. Patterns of A25 connections are consistent with the rules of the Structural Model, which predict laminar specific connections based on differences in laminar structure between linked cortices. A25 is a dysgranular limbic cortex, with strikingly dense deep layers relative to superficial layers. Connections with more elaborately layered cortices support a strong feedback-type role of A25 in corticocortical communication. Because cortical layers uniquely contribute to the columnar microcircuitry and are differentially populated by functionally distinct classes of inhibitory neurons, laminar-specific interactions have major implications for the functional impact of the different corticocortical pathways of A25. Laminar-specific interactions are also relevant for how A25 is differentially recruited in functional networks, such as affective networks or the Default Mode Network (DMN), both of which exhibit functional connectivity with A25. Within the context of the DMN, laminar specific interactions may be relevant for the switch between task-dependent and default modes of processing.

**Title:** Simulating thalamo-cortical dynamics underlying discontinuous tracking in schizophrenia

**Authors: *Y. J. JOHN**[1], B. ZIKOPOULOS[1], D. H. BULLOCK[2], H. BARBAS[1]
[1]Neural Systems Lab., [2]Psychological & Brain Sci., Boston Univ., Boston, MA

**Abstract:** Schizophrenia is a severe psychiatric disorder marked by disruptions to emotional balance, cognition, and perception. As with many psychiatric disorders, no single cause has been associated with the observed symptoms. These symptoms are qualitatively disparate, and therefore do not readily suggest any common neural mechanisms. Genetic, experiential, and environmental factors have been found to correlate with schizophrenic symptoms, but a consensus on how such factors trigger symptoms has proven elusive. However, abnormalities in the cortico-reticulo-thalamic circuit are observed in patients with schizophrenia and in animal models of the disorder. Here we integrate these findings by simulating a formal circuit model of interactions among cortex, thalamus, and the thalamic reticular nucleus (TRN). To demonstrate how the model behaves in both normal and abnormal modes, we simulated behavioral tasks that require smoothly tracking a moving stimulus across a stationary background of distracters. Eye movements patterns in such tasks distinguish schizophrenic patients from healthy controls. In schizophrenic patients, ocular tracking attempts exhibit many discontinuities, which entail frequent catch-up saccades. In the model, TRN neurons enable lateral inhibition of thalamo-cortical neurons, which - if strong enough - mediates maintained target selection and suppression of distracters. Local inhibitory interneurons in cortex regulate the strength and spread of cortico-reticular and cortico-thalamic excitation, and thereby the net strength of lateral inhibition. Our simulations show that weakened inhibition, from cortical interneurons or TRN neurons or both, can lead to discontinuities of smooth tracking that necessitate frequent catch-up saccades. Abnormal oscillatory modes in the thalamus and TRN, such as sleep-related rhythms intruding into the waking state, can also disrupt lateral inhibition and thereby lead to abnormal tracking. If the disordered circuit mechanisms that render tracking discontinuous also act at higher levels of the cognitive hierarchy, they may help explain schizophrenics' disrupted ability to maintain attention on a single organizing representation or theme across the distracting thoughts that often emerge during language production and other rule-guided performances. Thus, the model specifies possible causal mechanisms by which abnormalities in the cortico-reticulo-thalamic circuit may contribute to common behavioral symptoms of schizophrenia.

**Title:** Does nature benefit everyone? Salivary cortisol responses of wilderness therapy clients

**Authors: A. K. EAGLE**[1], *C. L. FRANSSEN[2]
[1]Biol., [2]Psychology, Longwood Univ., Farmville, VA

**Abstract:** Wilderness therapy, a subset of the broader field of outdoor therapy, is used to treat clients with a range of issues from addiction to emotional struggles (Russell, 2001). Wilderness therapy has been shown to effectively reduce mental health symptomology, and investigations are underway in several labs to best understand the type of client most positively affected by this intervention (e.g., Bettmann et al., 2013; Hoag et al., 2014; Russell et al., 2015). Mental health outcomes are routinely evaluated through self-report, family report, and clinician report on standardized measures such as the Y-OQ. In this study, we sought to evaluate changes occurring during a wilderness therapy experience through neuroendocrine measures. In this project, we partnered with Blackwater Outdoor Experiences®, a wilderness therapy group based in Midlothian, VA. We collected saliva samples and survey data before, during, and after a 22-day wilderness therapy trip. Previous studies, such as those listed above, indicate high response rates among patients with primary diagnoses of substance abuse, mood disorders, and behavioral disorders, often with comorbid anxiety or anxiety disorders. Therefore we focus our initial study on stress-related hormones, namely cortisol. Informed by the clinical profiles of wilderness therapy clients, we examined the effects of gender, age, and primary diagnosis on cortisol variation over the treatment program in an effort to further understand the type of client that will benefit most from wilderness therapy. Our findings represent the first integrative analysis of wilderness therapy clients that includes neuroendocrine data.

**Title:** Dezocine for opioid addiction and its molecular targets

**Authors: *R. LIU**[1], F. WU[2], H. BABAZADA[3], X. HUANG[4]
[1]Dept. of Anesthesiol. and Critical Care, Univ. of Pennsylvania, Philadelphia, PA; [2]Second Military Med. Univ., Shanghai, China; [3]Perelman Sch. of Med. at the, Philadelphia, PA; [4]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract: Synopsis:** Opioid dependence continues to be a major public health issue without optimal therapeutics. The present study investigated the therapeutic potential of dezocine, a non-addictive opioid, to attenuate naloxone-precipitated morphine withdrawal syndrome in a rat addiction model. The intensity of the morphine withdrawal syndrome was reduced doze-dependently in rats treated with dezocine comparable to that with buprenorphine. Chronic morphine administration through repeated subcutaneous injections induced astrocytes activation in nucleus accumbens, which was attenuated by dezocine and buprenorphine. Dezocine blocked the agonist-induced kappa opioid receptor internalization, using a fluorescently tagged kappa opioid receptor over-expressed neuroblastoma cells *in vitro.* However, buprenorphine blocked the receptor internalization with higher potency than dezocine. Interrogation of 317 human G protein coupled receptors via a G protein-independent β-arrestin-recruitment and radioligand binding assays for 44 G protein coupled receptors, ion channels and transporter proteins indicated that morphine, dezocine and buprenorphine have different sets of molecular targets. It was revealed that Neurokinin 1 Receptor is potentially novel unique molecular target for dezocine for its anti-addictive properties. Furthermore, while dezocine inhibits norepinephrine and serotonin reuptake as we demonstrated previously, buprenorphine did not interact with norepinephrine and serotonin transporters. Findings in this study suggest that dezocine could be an alternative medication for opioid addiction management and has different molecular targets from that of buprenorphine.
Significance Statement: This study provides evidence that dezocine, a partial mu opioid receptor agonist and kappa opioid receptor antagonist, could potentially be used for addiction management by using a rat morphine dependence model. It is important to note that dezocine is a non-addictive opioid that has been used in clinical practice for centuries. The molecular targets of dezocine are also investigated in parallel of morphine and buprenorphine, providing useful information for science communication in understanding molecular mechanisms for addiction and anti-addiction. Novel molecular targets are revealed for all three molecules. Dezocine is a neurokin 1 receptor agonist, which could potentially relate to its non-addictive property.

**Title:** Methadone induced retrieval extinction procedure inhibits the drug craving and relapse in heroin addicts under methadone maintenance treatment

**Authors: *P. WU**[1,2], J.-L. YUE[3], X.-J. GUO[3], X. LIN[3], S.-J. CHEN[3], L. LU[3,4]
[1]Natl. Inst. On Drug Dependence, Peking Univ., Beijing, China; [2]Beijing Key Lab. of Drug Dependence Res., Beijing, China; [3]Inst. of Mental Health/Peking Univ. Sixth Hospital, Key Lab. of Mental Health, Peking University,, BEIJING, China; [4]Inst. on Drug Dependence, Beijing Key Lab. of Drug Dependence Research/Peking Univ., Beijing, China

**Abstract: Background**: Conditioning between drug-associated environment cues (conditioned stimulus, CS) and drug effects (unconditioned stimulus, UCS) plays a major role in drug addiction, and responses to drug-associated cues persist during prolonged abstinence. We previously reported that CS memory retrieval-extinction procedure decreases relapse of cocaine and heroin seeking in rats and heroin craving in humans. However, the CS retrieval-extinction procedure could only erase drug memory associated with the reactivated CS, and it was not effective after prolonged abstinence. In contrast, the inhibitory effect of UCS retrieval-extinction manipulation on drug seeking in rats was also observed in the presence of cues that were not reactivated or after long-term abstinence. Using methadone as the UCS, the present study investigated the effect of UCS retrieval-extinction on cue induced drug craving and relapse in heroin addicts. **Methods:** Eighty-nine male heroin addicts under methadone maintenance treatment were randomly divided into 3 groups: 1) Methadone, 2) Methadone+10-min delay+ extinction, 3) Methadone+6-h delay+ extinction. The subjects in Group 1 took methadone as usual, while the subjects in Group 2 and 3 underwent extinction sessions 10 min or 6 h after methadone intake 3 times per week for 4 weeks. All the subjects were followed up for 6 m to test the changes of heroin craving, relapse, and dose of daily methadone use. We also conducted morphine urine tests each week during the 4 weeks' intervention and each month during the follow up. **Results:**Seventy-eight heroin addicts completed the intervention and were included for statistical analysis. There was no significant difference in cue induced heroin craving, dose of daily methadone intake, depression, anxiety, as well as demographic characteristics at baseline among the three groups. After 4 weeks' methadone-induced retrieval extinction manipulation, both the subjects in Group 2 and Group 3 showed significantly decreased heroin craving compared with Group 1. The inhibitory effect on heroin craving persisted for 4 m in Group 2, but only persisted for 2 m in Group 3. Both the accumulative drop-out rates and relapse rates of Group 2 were significantly lower than Group 1 and Group 3. **Conclusions**:These findings demonstrated that the methadone induced retrieval extinction strategy could be a promising method for decreasing drug craving and relapse in heroin addicts.

**Title:** Beta-caryophyllene: A promising dietary CB2 receptor agonist for treatment of addiction in experimental animals

**Authors: X.-F. WANG**[1], G.-H. BI[2], Y. HE[3], E. L. GARDNER[4], *Z. XI[3]
[1]Beijing Inst. of Pharmacol. and Toxicology, Beijing, China; [2]Natl. Inst. on Drug Abuse, Baltimore, MD; [3]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD; [4]NIDA/IRP, Baltimore, MD

**Abstract:** Two types of cannabis oils are used by humans - hash oil and hemp oil. *Hash oil* is an oleoresin extracted from the buds, flowers and leaves of female marijuana, while hemp oil is extracted from the seeds of the hemp plants. Since hash oil contains higher levels of delta9-THC, it has addictive potential and is used for medical or recreational purposes. In contrast, hemp oil contains a high level of cannabidiol but a low level of delta9-THC; it is used as a food oil (essential oil) or dietary supplement. Beta-caryophyllene (BCP) is a typical ingredient in essential oils. It has been used as a food additive due to its distinctive taste or as a cosmetic additive in various skin care products due to its pleasant nutty smell. In 2008, it was identified as a selective CB2R agonist (Gertsch et al., PNAS, 2008). We have recently reported that cannabinoid CB2Rs are expressed in midbrain dopamine neurons and functionally inhibit DA neuron activity and cocaine self-administration behavior. In the present study, we investigated the potential utility of BCP in treatment of drug addiction. We found that: 1) low doses of BCP (3-25 mg/kg, i.p.) dose-dependently inhibited nicotine or methamphetamine self-administration, while higher doses (50, 100 mg/kg) of BCP are required to inhibit self-administration of cocaine, heroin or food in rats or mice; 2) Pharmacological blockade or genetic deletion of CB2Rs (in CB2-KO mice) blocked low dose BCP-induced inhibition of nicotine or methamphetamine self-administration, but had no effect on high dose BCP-induced inhibition of drug self-administration, suggesting that both CB2R and non-CB2R mechanisms are involved; 3) high doses of BCP also significantly inhibited cocaine- or cue-induced reinstatement of drug-seeking behavior; 4) This reduction in drug-taking and drug-seeking is not due to sedation or locomotor impairment since BCP, at 3-50 mg/kg, had no effect on open-field locomotion or rotarod locomotor performance; 5) BCP itself failed to maintain self-administration in cocaine or heroin

self-administration rats, suggesting no addictive potential by itself; and lastly, 6) BCP, at 25-50 mg/kg, moderately decreased extracellular dopamine (DA) in the nucleus accumbens, while pretreatment with BCP failed to alter cocaine- or methamphetamine-enhanced extracellular DA, suggesting a non-DA mechanism involved. Together, the present findings suggest that BCP may be a promising dietary cannabinoid for treatment of drug abuse and addiction. (Supported by NIDA IRP)

**Abstract:** There is renewed interest in using electroencephalogram (EEG) as a tool to improve early diagnosis of neurological and behavioral disorders (i.e. ADHD, depression and schizophrenia) and also to assist the preclinical development of related pharmacotherapies. A preclinical assay becomes of value in drug development when effects of new chemical entities can be compared under the same conditions with those of known drugs to provide predictions on potential therapeutic effects. The aim of the current study is to establish an assay to rapidly determine EEG drug dose-effect curves in freely moving rats and evaluate its pharmacological selectivity by characterizing known compounds with different mechanisms of action and behavioral effects. EEG signals were collected from 6 stainless steel screws that served as electrodes implanted on the skull of male Sprague Dawley rats. These electrodes were connected through an electrode-interface board to a connector on the animal's head. During 60 to 150 min experimental sessions, EEG signals were recorded through a digital headstage in which signal was band passed between 0.1 to 250 Hz and digitized at 2 kHz. A pump was used to deliver, through an externalized jugular vein catheter, cumulative doses [mg/kg] of the typical dopamine

uptake inhibitor (DUI) cocaine [0.1-3.2] or methylphenidate [0.1-5.6], the atypical DUI modafinil [1-32], the mu-opioid agonist morphine [0.32-17.8] or the NMDA receptor antagonist ketamine [3.2-17.8]. EEG power spectrum was estimated using the short-time Fourier transform and grouped in 5 bands: Δ [0-4 Hz], θ [4-8Hz], α [8-13], β [13-30] Hz], γ [30-50 Hz]. Power spectral values were then normalized to the pre-infusion interval [baseline] and expressed as % of baseline. All the DUI dose-dependently decreased power of the β band to the same minimum [≈ 70%] while only the atypical DUI modafinil at a large dose increased power of θ waves. Both ketamine and morphine increased power [> 130%] of Δ, θ, α, β. Ketamine but not morphine also increased power of the γ waves. Therefore, typical and atypical DUI and drugs of other classes differentially affected EEG spectra showing distinctive features in the magnitude and direction of the effect on different frequency bands. Taken together these data suggest that the EEG can be used to rapidly screen new chemical entities for potential activity at specific pharmacological targets and to provide valuable information for guiding the early stages of drug development.

**Title:** Exercise-induced down-regulation of D2 autoreceptors in the nucleus accumbens

**Authors:** ***K. BILLS**[1], J. YORGASON[2], S. MCCARTHY[2], M. WOODBURY[2], S. STEFFENSEN[2]
[1]Interdepartmental Program in Neurosci., [2]Brigham Young Univ., Provo, UT

**Abstract:** The current consensus is that the rewarding and addictive properties of drugs of abuse, including alcohol, are mediated by dopamine (DA) neurotransmission in the mesolimbic system. Dopamine neurons express D2 autoreceptors (D2Rs) on cell bodies in the ventral tegmental area (VTA) and terminals in the nucleus accumbens (NAc). Dopamine activation of D2Rs at cell bodies inhibits DA neuron firing and DA activation of D2Rs at terminals decreases release of DA. D2R expression is directly proportional to DA levels and are reportedly in flux as the mesolimbic system progresses along a continuum of acute drug exposure to a state of drug dependence, presumably due to changes in extracellular DA concentrations. Mild to moderate

exercise has been shown to increase DA release in the NAc and high levels of exercise have been associated with various aspects of addiction including increased seeking behavior. Using *ex vivo* fast-scan cyclic voltammetry in the NAc, we evaluated the effects of three levels of exercise on D2R activity. Rats were exercised 5 days per week for 60 min/day day for 8-weeks. We tested paired-pulse responses to electrical stimulation to evaluate D2R activity. Typically, D2R activation results in decreased release during a secondary pulse at the tested intervals (10ms to 1s) causing inhibition of the paired-pulse ratio. We found that paired-pulse responses between 200ms and 1s were potentiated in medium and high intensity exercised rats compared to controls, suggesting a decrease in D2R activity in exercised rats. These data suggest that exercise does exhibit a dose-dependent effect on the mesolimbic DA system. Current studies are underway to examine D2R density changes and the effects of exercise intensity on acute ethanol exposure in naïve rats and withdrawal from chronic exposure in dependent rats.

**Abstract:** Behavioral Economics provides a framework for quantifying drug abuse liability that can inform public health risk, clinical treatment, and research. Hypothetical purchase task questionnaires (HPTs), in which respondents report the number of units of a commodity they would purchase at various prices, provide a low-cost and sensitive method by which to measure and predict the appeal of pharmaceutical drugs that differ by formulation. However, the validity of this type of analysis must be empirically established by comparing essential value (EV) for different drugs across subgroups and time. This pilot study aimed to use hypothetical demand curves and the Exponential Model of Demand to assess the "essential value" (EV) of opioid

medications, specifically, easily tampered formulations vs. tamper-proof formulations. Participants were 25 methadone-maintained opioid dependent outpatients that used heroin as their primary drug prior to entering treatment. Of these, 32% reported experience manipulating prescription opioid pills. Participants filled out HPTs for standard pills, tamper-proof pills, alcohol, and cigarettes; questionnaires were framed within the time of the respondents' heaviest opiate abuse prior to enrolling in treatment. Some participants (n = 16) repeated the tasks after one year. At Time 1, participants had a higher EV for opiates than for the other drugs. Participants with manipulation experience (M) had a higher EV for standard pills than those with no experience (NM), but there was no difference in EV for tamper-proof pills between the two groups. The M group had a lower EV for the tamper-proof opiate pill than for the standard pill, while the NM group had no difference in EV for the two pill types. At Time 2, M participants had significantly higher EV for alcohol and both opiate pills than the NM group, but there was no longer a difference between the standard and tamper-proof pills. There were no differences in maximum demand or breakpoints between the two groups at Time 1 or 2. There was a positive correlation between the EVs of different drugs, and between some behavioral economic indices and treatment outcomes. Our results indicate that tamper-proof opiate pills have less value than standard pills for those who manipulate pills. The ability to accurately assess the abuse potential of opiate pill formulations requires a valid and reliable metric with which to measure the reinforcing value of a drug. HPTs provide sensitive measures of abuse potential that can distinguish between different formulations in relevant sub-populations, and may form the basis of quantitative individual drug demand profiles for predicting clinical treatment outcomes.

**Title:** Serotonin transporter density in binge eating disorder and pathological gambling: A PET study with [$^{11}$C]MADAM

**Authors: *J. MAJURI**[1], J. JOUTSA[1], J. JOHANSSON[1], V. VOON[2], R. PARKKOLA[1], H. ALHO[3], E. ARPONEN[1], V. KAASINEN[1]
[1]Univ. of Turku, Turku, Finland; [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Natl. Inst. of Hlth. and Welfare, Helsinki, Finland

**Abstract:** Behavioral addictions, such as pathological gambling (PG) and binge eating disorder (BED), appear to be associated with specific changes in brain dopamine and opioid function, but the role of other neurotransmitter systems is less clear. Given the crucial role of serotonin in a number of psychiatric disorders, we aimed to compare brain serotonergic function between PG, BED and controls.
Seven BED patients, 13 PG patients and 16 healthy controls were scanned with high-resolution positron emission tomography (PET) using the serotonin transporter (SERT) tracer [$^{11}$C]MADAM. The subjects were matched by sex and age. Both region-of-interest (ROI) and voxel-wise whole brain analyses were performed. ROIs were created using the anatomical parcellation with Freesurfer software. Non-displaceable binding potentials ($BP_{ND}$) were calculated using simplified reference tissue model with the cerebellar cortex as the reference region. Parametric images were normalized to the Montreal Neurological Institute standard space and analysed using general linear model with SPM8 software.
Patients with BED showed increased SERT binding in parieto-occipital cortical regions compared to both PG and controls (Figure 1) with parallel decreases of binding in the nucleus accumbens, inferior temporal gyrus and lateral orbitofrontal cortex. Greatest increases were observed in the superior parietal cortex where BED group had 122% higher $BP_{ND}$ compared to controls and 108% higher compared to PG patients ($p<0.001$). No differences between PG patients and controls were observed. There were no differences in BDI scores between PG and BED patients, and [$^{11}$C]MADAM $BP_{ND}$s did not correlate with BDI scores or body mass index. The results highlight differences in brain SERT function between BED and PG providing further evidence of different neurobiological underpinnings in behavioral addictions that are unrelated to co-existing mood disorder. The results provide a framework for additional studies that aim for development of syndrome-specific pharmaceutical treatments.

**Title:** Infralimbic stimulation reduced cue-induced relapse to Cocaine seeking and normalize cue-induced electrophysiological activity in the rat conflict model

**Authors: S. LOGANATHAN**, T. GULEVSKY, N. BARNEA-YGAEL, *A. ZANGEN
Ben-Gurion Univ., Beer-Sheva, Israel

**Abstract:** Relapse to drug use following a period of self-imposed abstinence is a major hallmark of drug addiction in general, and cocaine addiction in particular. In both humans and animal models, such relapse can be reliably triggered by exposure to drug-associated cues, a phenomenon termed cue-induced relapse (CIR). It has been suggested that CIR is, at least in part, the resultant of drug-induced changes of neuronal activity within the areas of medial prefrontal cortex (mPFC). To further explore this notion, we used a chronically-implanted bilateral linear microelectrode array (LMA) to Prelimbic (PL) and infralimbic (IL) areas of the mPFC in rats trained to self-administer (SA) cocaine or saline. The LMA were used to record local field potentials (LFPs) throughout the experiment, and to induce intracranial electrical stimulations (ICES) as a possible relapse prevention treatment. For the induction of self-imposed abstinence we used the conflict model, in which gradually increasing adverse consequences for drug seeking are represented by an electric barrier between the rat and the Cocaine-associated lever. Four groups of rats (n=9-13) were used: Saline SA + Sham ICES (Saline-Sham), Cocaine-Sham, Cocaine-PL, and Cocaine-IL. Following treatment, rats were subjected to CIR tests, where drug associated cues were presented every 2min, and the electric barrier was activated (conflict condition), while during a free-seeking test, cues were presented but the barrier was not activated. The results indicate that ICES of the IL, but not PL of cocaine-SA rats significantly reduced relapse rates and active-lever presses during CIR tests (compare to sham stimulation). On the other hand, active-lever presses of the Cocaine groups did not differ during the free-seeking test, and were significantly higher than that of the Saline group. In addition, an electrophysiology analysis demonstrates that repeated Cocaine SA is associated with increased cue-induced N1 and P1 amplitudes, and with increased alpha and beta power bands in the IL; but that IL-ICES normalized P1 amplitudes and beta activity. Taken together, it seems that repeated Cocaine SA is associated with increased saliency of the drug-associated cues, a tendency that can be normalized by stimulation of the IL mPFC. More specifically, it seems as IL-ICES can affect the motivation to obtain the drug but does not affect drug craving. Results of this study may provide insights into the mechanisms underlying CIR and offer novel therapeutics alternatives for relapse to drug use in human addicts.

**Title:** Psychological and metabolic effects of naltrexone in rats

**Authors: *H. M. MURPHY**[1], C. H. WIDEMAN[2]
[1]John Carroll Univ. Dept. of Psychol., Cleveland, OH; [2]Dept. of Biol., John Carroll Univ., Cleveland, OH

**Abstract:** Recently, medical methodologies related to palliative care, as well as chronic pain management, have changed in the United States. Correlating with these therapies is a rapid increase in narcotic prescriptions such as methadone, oxycodone, and hydrocodone. The primary effect of these drugs is analgesia as a direct outcome of opioid receptor binding within the central nervous system. Additionally, they have high potency in regard to stimulation of the mesolimbic pathway within the brain. Naltrexone is a synthetic opioid antagonist of the μ and κ receptors which is utilized as both an agent for pain management and as an antinarcotic abuse therapy. A related function of the drug is to help balance the immune system through its interactions with the endorphins. Given the mechanism of action of naltrexone on the mesolimbic pathway, an important consideration is the potential for the drug to elicit an anxiogenic effect. In the current study, a rat model was used to assess potential psychological and metabolic effects of naltrexone. Anxiety effects of the drug were tested employing the elevated plus maze (EPM), while metabolic effects were ascertained through the measurement of food intake, water intake, and body weight gain. Twelve Long-Evans female rats were divided into two groups, control (n=6) and naltrexone-treated (n=6). Rats were exposed to a 12h:12h light-dark cycle and drug administration was implemented at the beginning of the dark period. Naltrexone-treated rats were given a 2mg/kg dose of the drug as a solution within a condensed milk “treat” and control rats were administered water dissolved in condensed milk. The experiment was divided into five weeks, composed of one habituation week and four experimental weeks. EPM testing was performed on the last day of the habituation week and following drug administration on the last day of each test week. Time spent in the open and closed arms was utilized for assessment of anxiety. Results indicated that there were no significant effects on anxiety, body weight, or food intake. A significant difference in water intake was observed between the groups suggesting that naltrexone induces increased thirst. The effect on water intake may be explained by the function of μ opioid receptors on renal function in the peripheral nervous system. Should the findings of the present study transition to human patients, the lack of deleterious side effects significantly enhances the clinical efficacy of the drug. Considering the widespread and unpleasant nature of

chronic pain and drug addiction, naltrexone may serve as a valuable pharmacological agent in palliative care, pain management, and opioid drug abuse therapy.

**Title:** 10-days 20 hz repetitive magnetic stimulation (rtms) recovered functional connectivity in chronic smokers: A pilot study

**Authors: Z.-W. SHEN, 310005**[1], D. CHANG[1], W. PENG[1], J. ZHANG[1], Q. GE[1], X. GAO[1], Y. JING[1], Y. DU[1], Z. ZHAO[1], A. R. CHILDRESS[2], *Z. WANG[1]

**Abstract: Aims:** Chronic smoking/nicotine dependence has been shown to have reduced functional connectivity (FC) especially in the prefrontal brain. Directly modulating brain activity in frontal cortex may help recover FC and improve the long-term smoking cessation rate. The purpose of this study is to examine whether FC in chronic smokers can be improved by high-frequency beneficial repetitive transcranial magnetic stimulation (rTMS) and whether that improvement is associated with smoking cessation. **Methods:** 14 treatment-seeking smokers (>10 cigarettes per day, Fagerstrom score>5, years of smoking>8, times of quitting attempts>3) were recruited for a program of 10 days rTMS treatment (T10) and 25 days follow-up (F25). rTMS treatment started after 24 hours abstinence from smoking. 20 Hz rTMS was applied on left dorso-lateral prefrontal cortex and the superior medial frontal cortex. At each daily rTMS treatment session, each target site received 1000 pulses with a magnitude adjusted to be 90% of the resting motor threshold. Carbon monoxide (CO) level, withdrawal, and craving scales were collected daily during T10 and several times randomly during F25, and again at the end of F25. Resting state fMRI (rsfMRI) was collected at the baseline and T10. FC was calculated from rsfMRI after data preprocessing using standard routine. **Results:** Ten smokers finished the entire treatment program. 9 didn't smoke during the entire 35 days; one relapsed because of non-cooperation. Withdrawal and craving were the same after T10 and F25, both were significantly

($p<0.05$) reduced compared to baseline. Two subjects were successfully followed up for 6 months and were able to keep abstinence. Only 5 subjects finished two rsfMRI scans. As compared to baseline, T10 showed increased FC ($p<0.01$, cluster>150) among frontal brain regions including prefrontal cortex, dorso-lateral prefrontal cortex, rostral/subgenual anterior cingulate cortex (ACC)/medial orbital frontal cortex, amygdala, ventral striatum, basal ganglia, insula, and dorsal ACC. Increased FC was correlated with withdrawal reduction. **Conclusions**: 20 Hz rTMS increased frontal brain FC, which is accompanied by a high smoking cessation rate. These pilot findings need further confirmation, both with 'sham' stimulation and larger sample size.

**Title:** Model-free and model-based reinforcement learning in addiction-related behaviors

**Authors: *S. M. GROMAN**[1], B. MASSI[2], S. MATHIAS[1], D. LEE[2], J. TAYLOR[1]
[1]Psychiatry, [2]Neurosci., Yale Univ., New Haven, CT

**Abstract:** Substance-dependent individuals have difficulties making adaptive, flexible decisions. These decision-making problems may be due to disruptions in reinforcement learning. A large body of work indicates that model-free (MF) learning is disrupted in substance-dependent individuals and in animals exposed to drugs of abuse, but emerging evidence suggests that model-based (MB) learning may also be impaired. It is unclear, however, if these disruptions are a consequence of chronic drug use or are a pre-existing vulnerability for developing an addiction. To address this question, we developed a rodent version of a multi-stage decision-making (MSDM) task. Long-Evans rats were trained to make decisions between two options in each of two successive trial stages. In the first stage, rats are presented with two levers and can respond on a single lever to illuminate two noseports. Responses on one lever result in the illumination of noseports A and B on 70% of trials and noseports C and D on 30% of trials, whereas these

transition probabilities were reversed for the other lever. In the second stage, rats respond to one of the two illuminated noseports to receive probabilistically delivered rewards. Trial-by-trial choice data was analyzed using a logistic regression to quantify the degree of MF and MB reinforcement learning each individual rat used in the MSDM. Rats were trained on the MSDM before and after they were trained to self-administer methamphetamine (or saline). Individual differences in MF, but not MB, reinforcement learning prior to any drug use predicted the rate of escalation in drug-taking behaviors ($R=-0.37$; $p=0.03$). The relationship between MF learning and future drug-taking behaviors was mediated by the degree to which rats used positive, but not negative, outcomes to guide their decision-making ($R=-0.44$; $p=0.01$). Following the self-administration, there was a significant disruption in both MF and MB processes in rats who had self-administered methamphetamine ($p=0.02$). These drug-induced impairments were due to disruptions in the ability of rats to use negative outcomes to guide their choice behavior ($p=0.01$). These data indicate that rats, similar to humans, use both MF and MB strategies to guide their decision-making processes and that specific components in reinforcement-learning strategies may be involved in dissociable aspects of drug addiction. Ongoing studies are examining the neural circuitry and biochemical systems underlying MF and MB strategies. By using a translationally analogous task, our study provides novel insights into the biobehavioral processes that influence the emergence and persistence of addiction-related behaviors.

**Title:** Exploring the neurochemistry of novel dopamine uptake inhibitors structurally related to Modafinil in Swiss-Webster mice

**Authors: *J. KEIGHRON**, M. COGGIANO, J. QUATERMAN, A. DIXON-GLEAVES, J. CAO, R. SLACK, A. H. NEWMAN, G. TANDA
Natl. Inst. On Drug Abuse, Baltimore, MD

**Abstract:** Modafinil and its R-enantiomer have been evaluated as potential pharmacotherapies for treatment of psychostimulant use disorders. However, though positive clinical results have

been observed in subpopulations of cocaine addicted subjects, several clinical trials in cocaine and methamphetamine addicted individuals have failed to support the use of modafinil as a pharmacotherapeutic in this patient population. Novel dopamine uptake inhibitors, structurally related to modafinil, have been designed and synthesized to improve the potential therapeutic effects of their parent drug. These novel analogues, JJC8-016, JJC8-088, JJC8-089, and JJC8-091, in addition to having structural similarities to modafinil bind to the dopamine transporter with affinities similar to or higher than either modafinil or cocaine. Interestingly, like the parent drug, these novel dopamine uptake inhibitors do not produce typical cocaine-like effects in vivo. In this study, we show the effects of these compounds in Swiss-Webster mice on behavioral activity (distance travelled in an open field), tonic (microdialysis) and phasic (Fast Scan Cyclic Voltammetry, FSCV) dopamine changes in the accumbens shell, and calcium mobilization (using fiber photometry procedures). To date, our results show that several of these novel modafinil analogues function as atypical dopamine uptake inhibitors, in agreement with atypical effects shown by their parent compound (Loland et al., Biol. Psychiatry 2012). For instance, they produce little effect on distance travelled or on phasic dopamine output alone compared to cocaine. Furthermore, when given in combination with cocaine they attenuate its effects on phasic efflux of dopamine in mouse nucleus accumbens shell. Characterization of the effects of these compounds on the dopamine system provides mechanistic insight into the design of future medications for the treatment of psychostimulant use disorders.

**Title:** Pharmacological evaluation of potential therapeutics on smoking cessation: behavioral and computational analyses

**Authors: *Q. CHANG**, W. MIN, A. C. HACKETT, M. T. LANG, M. BANSAL, T. HANANIA
PsychoGenics Inc., Montvale, NJ

**Abstract:** This project evaluated the utility of various reference compounds with diverse mechanisms of action as potential treatments for smoking cessation using drug discrimination (DD) and nicotine self-administration (SA) tests. We screened eighteen compounds alone or in combinations to evaluate their efficacy in smoking cessation. Using bioinformatics analysis on

these behavioral data we ranked each compound based on its relative effectiveness and calculated its efficacy score. Our results identified Cytisine (an α4β2 receptor agonist) at 3 mg/kg, bPiDI (an α6β2 receptor agonist) at 3 mg/kg and the combination of Metyrapone (a corticosteroid synthesis blocker, 12.5 and 25 mg/kg) and Oxazepam (a benzodiazepine, 5 and 10 mg/kg) to be efficacious in disrupting nicotine discrimination. In the self-administration assay, Baclofen (a $GABA_B$ agonist) 3 mg/kg, BHF 117 (a $GABA_B$ receptor modulator) 30 mg/kg and MTEP (a mGlu5 antagonist) 3 mg/kg significantly attenuated nicotine self-administration. In addition, being ACh receptor agonists, both Cytisine (3 mg/kg) and bPiDI (3 mg/kg) attenuated nicotine self-administration and showed efficacy in substituting for nicotine in DD model. Put together, our studies identified, among the compounds we have studied, Cytisine and bPiDI to be the best candidates for smoking cessation. Both these compounds displayed efficacy in substituting for nicotine in DD model, caused disruption of nicotine DD as well showed efficacy in suppressing nicotine self-administration. The efficacies of combinations of Metyrapone and Oxazepam, as well as Baclofen, BHF 177 and MTEP will needs to be further evaluated due to their strong efficacy in suppressing nicotine DD or nicotine SA, respectively. *(This project was sponsored by NIDA Grant R44DA035051. **Title:** Exercise induced escalation of alcohol intake is modulated via BDNF/TrkB

**Authors: *A. THORSELL**
Linköping Univ., Linköping, Sweden

**Abstract:** Cross-sensitization is a phenomenon that occurs when drugs acting on the same pathways potentiate or sensitize a behavioral response. This is well-established for drugs of abuse, and increasing evidence indicates that it also occurs for other behaviors, for example sugar intake and exercise. Exercise is psychologically beneficial and leads to positive changes in mood as well as decreased levels of anxiety. ‘Runners high’ which is often experienced immediately after a exercise can be regarded as a state of euphoria, and involves neurobiological substrates regulating reward. The beneficial effects of exercise in the brain are accompanied by an increase in BDNF, a trophic factor associated with cognitive improvement, as well as alleviation of anxiety and depression. Exercise-induced BDNF-expression may be regulated by a

naturally occurring ketone-body, beta-hydoxybutyrate. Beta-hydroxybutyrate induces activity at Bdnf promoters, particularly the activitity dependent promoter I. Here, we examine cross-sensitization between exercise and alcohol in mice. Furthermore, we evaluate the role of BDNF and its receptor, TrkB, in mediating this effect. Mice (C57Bl6, male) were used in all studies. In the first experiment, animals were given access to a running wheel for three weeks followed by behavioral testing (elevated plus-maze, forced swim test, locomotion) and voluntary alcohol intake. In experiment two, animals were given access to a TrkB agonist, 7,8-dihydroxyflavone, or beta-hydroxybutyrate, in their drinking water for three weeks followed by behavioral evalutation. Alterations in BDNF and TrkB levels were evaluated as gene expression changes by realtime-PCR. Exercise in the form of running wheel access increased voluntary alcohol consumption in a two-bottle choice model (at 15% alcohol: exercise: 17.2 ± 0.8 g/kg BW/24hrs; Controls: 13.3 ± 0.7 g/kBW/24hrs; $p<0.01$). Additionally, an anxiolytic-like effect was seen as measured by increased open arm exploration in the elevated plus-maze (Exercise: 26.0 ±.2.7% open arm time; Controls: 15.1 ± 2.8%; $p>0.01$). However, we were unable to reproduce previously shown anti-depressant effects of exercise. Intake of 7,8-dihydroxyflavone or Beta-hydroxybutyrate also lead to subsequent elevation of alcohol-intake, as well as having both anxiolytic and antidepressant effects. Exercise strongly activated BDNF/TRkB in the hippocampus and amygdala, as indicated by elevated gene expression in these regions. In conclusion, we here demonstrate cross-sensitization between exercise and alcohol. This may be mediated by activation of the BDNF/TrkB in brain-areas such as the amygdala.

**Title:** Self-initiated operant ethanol administration in male C57Bl/6j mice

**Authors: *K. P. ABRAHAO**[1], D. M. LOVINGER[2]
[1]Laboratoy of Integrative Neurosci., [2]Chief, Lab. Integrative Neurosci, NIAAA/NIH, Rockville, MD

**Abstract:** Operant conditioning is a learning process in which a new behavior is learned through reward. Mice can be trained to lever press for rewards such as drugs of abuse, and presentation of discriminative cues can foster this learning. However, there are few studies of self-initiated (i.e. cue-independent) “free-operant” responding for ethanol. Although tastant fading procedures

have been used, the initial learned association is not between the mouse's action and ethanol, but between the action and sucrose, saccharin or monosodium glutamate. Therefore**,** it would be advantageous to develop a free-operant paradigm in which the initial learned association is between lever pressing and ethanol. By incorporating aspects of drinking-in-the-dark, intermittent two-bottle choice, and chronic intermittent ethanol exposure procedures, we have been developing an operant self-administration paradigm with levers continuously available**,** no discriminative cues and no requirement of tastant fading. We used overnight intermittent training on a fixed ratio 1 (FR1) schedule for several nights to establish lever pressing levels for water or 10% ethanol. Mice were then moved to an FR3 schedule. The total presses were higher in mice self-administrating ethanol when compared to mice pressing for water. Mice were moved to a contingency degradation (CD) schedule, with water or ethanol delivered at random intervals with no contingency to the lever press. Mice in the ethanol group escalated their lever pressing in the CD condition and showed higher lever pressing rates compared to the water group. When mice were moved back to the FR3 schedule, lever pressing in the water group returned to levels seen during the previous FR3 training nights. In contrast, animals in the ethanol group retained higher lever pressing rates in comparison to the previous FR3 session. In a second experiment, we have been investigating if the outcome-independent self-initiated pressing for ethanol is dependent on the activity of the dorsolateral striatum, a brain region implicated in habitual behavior. We are using Gi coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to inhibit the activity of medium spiny neurons in the dorsolateral striatal. Our findings to date indicate that ethanol promotes outcome-independent self-initiated actions exceeding those driven by another reinforcer (water), and that water-seeking animals can re-establish contingent behaviors while ethanol-seeking mice retain escalated responding. This methodology for self-initiated operant ethanol administration may be useful for examining the neural mechanisms of habitual ethanol seeking behavior.

**Title:** Effects of chemogenetic activation and inhibition of the nucleus accumbens and insula neurons on alcohol drinking in rats

**Authors: M. HAARANEN**[1], S. HAKLI[1], S. IDRISS[1], *P. HYYTIA[2,1]
[1]Dept. of Pharmacol., [2]Univ. of Helsinki, Helsinki, Finland

**Abstract:** Using neuroimaging, we have previously shown that the nucleus accumbens and connecting brain regions, including the insular cortex, are activated during voluntary alcohol drinking in rats. The nucleus accumbens is a key structure involved in mediating motivational and emotional processes, whereas the insula is implicated in interoceptive effects and decision making during goal-directed actions. In order to elucidate the role of these brain regions in the regulation of alcohol drinking further, we used viral-mediated gene transfer of designer receptors exclusively activated by designer drugs (DREADDs) to either activate ($G_q$-DREADD, AAV8-hSyn1-hM3D($G_q$)-mCherry) or inhibit ($G_i$-DREADD, AAV8-hSyn1-hM4D($G_i$)-mCherry) neurons in the nucleus accumbens and insula. We trained alcohol-preferring AA (Alko, Alcohol) rats to drink 10% (v/v) alcohol during 2-h sessions every second day (Mondays, Wednesdays, Fridays) with tap water as the alternative fluid. Once the rats achieved stable baseline drinking, we anesthetized them with isoflurane and microinjected the DREADDs bilaterally (0.75 µl/side) into the nucleus accumbens core or anterior insular cortex. Four weeks were allowed for DREADD expression to accumulate before clozapine-N-oxide (CNO) testing. CNO (10 mg/kg, i.p.) was injected 60 min prior to the 2-h limited access drinking session. At the conclusion of the experiments, we deeply anesthetized the rats with pentobarbital and perfused them transcardially. The expression of DREADDs was verified from coronal brain sections by immunohistochemistry. Silencing the accumbens neurons with the $G_i$-DREADD significantly decreased alcohol drinking, whereas activation with the $G_q$-DREADD tended to increase alcohol intake. No significant effects on alcohol drinking were seen in the EGFP-expressing control group, and none of the DREADDs affected water intake. In contrast, when expressed in the insula, the activating $G_q$-DREADD significantly decreased alcohol drinking. The $G_i$-DREADD and EGFP-expressing groups displayed no changes in alcohol intake, but water intake was slightly increased in all three AAV vector groups. These results provide further evidence that both the nucleus accumbens and insula belong to the intricate forebrain neurocircuitry underlying alcohol reinforcement and consumption. However, the effects of neural activation and suppression in the accumbens differed from those in the insula, suggesting that these brain areas have diverse functions in controlling alcohol drinking.

**Abstract:** Alcohol use disorder is a chronic relapsing disorder, characterized by preoccupation with obtaining alcohol and a narrowing of the behavioral repertoire toward excessive and compulsive alcohol consumption. Repeated alcohol intake leads to neuroadaptations in the mesolimbic and nigrostriatal dopaminergic pathways, which results in drinking escalation, and other addiction phenotypes. Fibroblast growth factor 2 (FGF2) has been shown to interact with the dopaminergic system, and has been implicated in the actions of psychostimulants in the brain, as well as in several psychiatric disorders. The aims of the present study were to **(1)** determine the responsiveness of the *Fgf2* gene to alcohol exposure in rodents; and **(2)** test the effect of recombinant FGF2 (rFGF2) administration on alcohol consumption. We found that acute alcohol exposure (2.5 g/kg, i.p.) increased the mRNA expression of *Fgf2* in the dorsal hippocampus, nucleus accumbens and dorsal striatum. Longer alcohol exposure (7 days X 2.5 g/kg, i.p.) restricted these increases to the dorsal striatum, and we show that this increase is mediated via activation of the dopamine D2 receptor. Long-term excessive voluntary alcohol consumption in the intermittent access two-bottle choice paradigm increased *Fgf2* expression selectively in dorsomedial striatum (DMS). Importantly, we found that systemic rFGF2 administration or local infusions into the dorsal striatum or the DMS led to increased alcohol consumption and preference, with no similar effects on sweetened solution (saccharin) consumption. Our results identify FGF2 as an alcohol responsive gene for the first time. Moreover, we show that FGF2 promotes excessive alcohol consumption, providing a positive regulatory feedback loop of alcohol and FGF2. Hence, our finding suggests that FGF2 may be involved in the development of alcohol use disorder.

**Title:** Rodent ultrasonic vocalizations as biomarkers of future alcohol use: A predictive analytic approach

**Authors: *C. L. DUVAUCHELLE**[1], N. MITTAL[2], W. T. MADDOX[3], T. SCHALLERT[4]
[1]Pharmacol. & Toxicology, Univ. of Texas, Austin, TX; [2]Univ. of Texas At Austin, Austin, TX; [3]Cognitive Design and Statistical Analyses, Austin, TX; [4]Psychology, Univ. of Texas at Austin, Austin, TX

**Abstract:** Excessive alcohol consumption has a vast, negative impact on society. Rodent models have been successful in furthering our understanding of the biological underpinnings that drive alcohol consumption. Rodents emit ultrasonic vocalizations (USVs) that are each composed of several acoustic characteristics (e.g., frequency, duration, power and bandwidth). USVs reflect neurotransmitter activity in dopaminergic and cholinergic neurotransmitter systems and thus serve as non-invasive, real-time biomarkers of dopaminergic and cholinergic neurotransmission. In the present study, we recorded spontaneously emitted USVs from alcohol-naïve Long-Evans (LE) rats and then measured their alcohol intake. We compared the USV acoustic characteristics and alcohol consumption data from LE rats with previously published data from selectively bred high- (P and HAD-1) and low-alcohol (NP and LAD-1) drinking strains from studies with the same experimental method. Predictive analytic techniques were applied simultaneously to this combined data set and revealed that: (a) alcohol-naïve USVs accurately discriminated among high-alcohol consuming, LE, and low-alcohol consuming rat lines, and (b) future alcohol consumption in these same rat lines was reliably predicted from the alcohol-naïve USV profiles. To our knowledge this is the first study to show that alcohol consumption is predicted directly from alcohol-naïve USV profiles. Because USV acoustic characteristics are sensitive to underlying neural activity, these findings suggest that rodent alcohol consumption can be predicted from differences in baseline cholinergic and dopaminergic tone.

**Title:** Effects of voluntary wheel running on Bdnf mRNA expression following chronic intermittent ethanol exposure in C57BL/6J mice

**Authors: *M. G. SOLOMON**[1], J. E. THOMPSON[1], R. I. ANDERSON[2], H. C. BECKER[3]
[2]Ctr. for Drug and Alcohol Programs, [1]Med. Univ. of South Carolina, Charleston, SC;
[3]Charleston Alcohol Resch Ctr., Med. Univ. South Carolina, Charleston, SC

**Abstract:** Repeated cycles of chronic intermittent ethanol (CIE) exposure increases voluntary ethanol consumption and reduces BDNF expression in mPFC of mice. We previously demonstrated that infusion of BDNF into the mPFC of ethanol-dependent mice attenuates CIE-induced escalation of ethanol intake. Our lab has recently demonstrated 2-hr daily running for 6 weeks increases Bdnf mRNA in medial prefrontal cortex (mPFC) and hippocampus dentate gyrus (DG) of C57BL/6J mice. The present study investigates the effects of wheel running on ethanol consumption (at baseline and following CIE exposure) and Bdnf mRNA expression in several brain regions immediately following a 5$^{th}$ CIE exposure cycle. Adult male C57BL/6J mice were divided into 4 groups (N= 11/group): air exposed (AIR), air exposed with wheel (WH), CIE exposed (CIE) and CIE exposed with wheel (CIE+WH). All mice were allowed limited access (2 hr/day Mon-Fri) to 15% ethanol vs water for 6 weeks (baseline). One hour after ethanol was removed, wheel groups (WH; CIE+WH) had 2-hr access to a running wheel (7 day/week). Data collected during baseline replicates and confirms our previous findings that access to an exercise wheel increases ethanol intake compared to non-wheel running mice (Wheel: 1.56 g/kg vs. No Wheel: 1.07 g/kg; $p< 0.05$). After 6 weeks of baseline mice went through weekly cycles of CIE vapor or air exposure (16 hr/day x 4 days) alternated with drinking test weeks. Baseline ethanol intake did not alter daily wheel running, but wheel running increased daily ethanol intake as we have previously seen. Our previous results show 2-hr wheel running increases Bdnf mRNA in mPFC (~35%) and DG (~25%) at the end of baseline. As we previously observed, wheel running resulted in the attenuation of CIE-induced escalation of EtOH intake in CIE+WH group compared to CIE only mice. (CIE group: ~145% increase vs. CIE+WH group: ~50% increase over baseline ethanol intake at end of study; $p< 0.05$). Immediately following the 5$^{th}$ CIE exposure, mice were sacrificed and brains removed and dissected on ice to measure Bdnf mRNA expression by qRT-PCR. Previous and current data suggest exercise can attenuate CIE-induced escalation of ethanol drinking and this effect may be mediated by exercise-induced elevation of Bdnf mRNA expression in mPFC.

**Abstract:** Oxidative-nitrosative stress (ROS/RNS) is a contributing factor to neurodegeneration associated with heavy chronic ethanol consumption. Compelling recent evidence suggests that oxidative stress signaling induced by prolonged drinking not only contributes to cellular injury, but may also influences the motivational states that drive heavy ethanol consumption. Cysteine residues are under-represented in mammalian proteins, but play critical roles in protein folding, antioxidant defense, and redox signaling. ROS/RNS can modify reactive cysteine residues in proteins, which includes the redox-mediated posttranslational modification, S-glutathionylation. S-glutathionylation of cysteine residues can dynamically influence cellular functioning under pathological conditions and is catalyzed by glutathione-S-transferase Pi (GSTP). Previous work has shown that GSTP contributes to cocaine-induced sensitization behavior and may be triggered by redox signaling mechanisms which are shared by all drugs of abuse, including ethanol. The purpose of this study was to determine how chronic intermittent ethanol (CIE) exposure of C57BL/6J mice alters expression of GSTP in the nucleus accumbens core (NAcc) and if this redox-sensitive protein play a role in regulating ethanol consumption. Western blot analysis confirmed that CIE exposure significantly increased GSTP expression in the NAcc. Furthermore, using a fluorescent thiol specific probe, CIE exposure resulted in an increase in cysteine thiol modifications in the NAcc. Examination of intake levels using the drinking-in-the-dark model

revealed that mice with a genetic deletion of GSTP (GSTP KO) consumed significantly more ethanol than their wildtype (WT) littermates. The enhanced intake in the GSTP KO mice was evident during the 2 and 4 hr drinking sessions. Sucrose consumption or metabolism of ethanol (3 g/kg, ig) did not differ between WT and GSTP KO mice. Treatment with carnosic acid (25 and 50 mg/kg), increased glutathione S-transferase pi activity and decreased ethanol consumption. Together, these data demonstrate that CIE exposure of C57BL/6J mice significantly alters GSTP protein expression in the NAcc and that genetic deletion or pharmacological activation of GSTP alter ethanol intake.

**Title:** Lack of LRRK2, a Parkinson’s disease-related protein, promotes compulsive-like and high alcohol intake in mice

**Authors: D. DA SILVA E SILVA**[1], A. B. GODARD[2], *V. A. ALVAREZ[1]
[1]Lab. of Integrative Neurosci., Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [2]Univ. Federal de Minas Gerais, Belo Horizonte, Brazil

**Abstract:** Chronic alcohol exposure alters striatal function and drives action selection towards the compulsive alcohol-seeking despite negative consequences. This behavioral progression from the controlled alcohol use to compulsion is a hallmark of alcohol use disorders and its molecular mechanisms underlying is still unknown. The striatum plays a central role in goal-directed behaviors and addiction, and it is a well-defined substrate to long-lasting molecular and morphological changes evoked in addiction. In order to elucidate the molecular components behind the compulsive alcohol consumption, we evaluated the whole striatal transcriptome of a mouse model of chronic and voluntary ethanol drinking. In this model, outbred mice had simultaneous access to ethanol and water during four stages: Acquisition (alcohol and water access), Withdraw (only water access), Re-exposure (alcohol and water access) and Adulteration (water and quinine-adulterated ethanol solution). Animals were then classified according to their individual alcohol consumption pattern as "Light drinkers" (preference for water throughout

experiment), "Heavy drinkers" (preference for ethanol, but significantly reduction on ethanol intake during taste-adulteration) and "Inflexible drinkers" (preference for ethanol, even after the taste-adulteration). Aversion-resistant alcohol intake in mice has been considered to model compulsive aspects of alcohol consumption in humans. Following the transcriptome analysis, we found that the Lrrk2 gene was upregulated only in animals of the Inflexible drinkers group which show compulsive-like ethanol intake. This gene product is an AKAP protein that regulates the PKA availability in striatal neurons and affect several neuronal process and functions. Further studies showed that Lrrk2 knockout mice (Lrrk2-KO) have enhanced alcohol preference and consumption compared to wild types. Furthermore, Lrrk2-KO mice exert higher effort to gain access to ethanol solution in an operant task during progressive responding ratio schedule, indicating an increased motivation to both seek and take alcohol. In addition, similarly to the “Inflexible drinkers”, Lrrk2-KO mice showed compulsive-like ethanol consumption and maintained high ethanol intake despite pairing with an aversive taste. Taken together, these findings support the hypothesis of the LRRK2 protein is a key substrate involved in regulating alcohol consumption and the transition to compulsive, uncontrolled alcohol intake.

**Abstract:** Once established, alcohol addiction is a chronic relapsing disorder, in which alcohol use becomes compulsive, i.e. continues despite negative consequences. Understanding the transition from controlled to compulsive alcohol use is therefore a critical challenge for addiction research. In humans, only a subset of users transition to compulsive drug use. In contrast, in commonly used animal models, nearly all rats learn to self-administer addictive drugs, including alcohol. This observation points to the possibility that focusing on self-administration alone may be insufficient to identify key mechanisms of addiction. This realization has prompted some

important conceptual advances. For instance, it has been found that most rats will seize to self-administer cocaine when a high-value alternative becomes available, but that a subset of animals will continue their self-administration despite the presence of an alternative. The neurobiological underpinnings of choosing alcohol over a natural reward are presently largely unknown. Here, we set out to identify molecular mechanisms underlying this choice behavior. We first established an exclusive choice-based method to identify rats that continue to self-administer alcohol at the expense of a high-value natural reward, a sweet solution, and assessed whether these animals show other characteristics reminiscent of clinical alcoholism. We then carried out a discovery effort using gene expression profiling, and identified a novel molecular mechanism that appears to mediate compulsive-alcohol drinking at the expense of other high-value options.

**Title:** Role of the transcriptional regulator LMO4 in excessive alcohol consumption

**Authors: R. MAIYA**, *R. O. MESSING
Pharmacol. and Toxicology, Univ. of Texas at Austin, Austin, TX

**Abstract:** Repeated alcohol exposure leads to changes in gene expression that are thought to underlie the transition from moderate to excessive drinking. Gene expression profiling studies have identified a multitude of ethanol-responsive gene networks, but the mechanisms by which these networks are mobilized to a neuroadaptive response are not well understood. One mechanism could involve ethanol regulation of transcriptional co-regulators that bind and modulate the activity of several transcription factors, thereby orchestrating a diverse neuroadaptive transcriptional network. Our results indicate that the transcriptional regulator LMO4 is one such candidate regulator. Mice harboring a gene trap insertion at the *Lmo4* (*Lmo4gt/+*) locus consumed significantly more ethanol and showed enhanced preference for ethanol in a 24-hour intermittent access procedure. Ethanol intake was not significantly different between the two genotypes in a 4-h, limited, intermittent access procedure and in a standard 24-h, continuous access, two-bottle choice procedure. Two-bottle choice sucrose, saccharin, and quinine preference were also not different between the genotypes. Further, LMO4 levels in the nucleus accumbens decreased during intermittent, binge-like ethanol consumption but not during

continuous access ethanol consumption. Knockdown of LMO4 in the nucleus accumbens (NAc) by RNA interference significantly enhanced alcohol consumption without affecting water, sucrose or quinine consumption. We also examined the effects of LMO4 knockdown in the BLA, a brain region where LMO4 functions to regulate cue-reward and fear learning. Surprisingly, knockdown of LMO4 in the basolateral amygdala (BLA) significantly reduced alcohol consumption and preference. Experiments are currently underway to determine whether LMO4 knockdown in these brain regions affects the development of conditioned place preference to ethanol and also to examine transcriptional targets of LMO4 in the NAc and the BLA. In summary, our findings lead to us to conclude that LMO4 is an ethanol-responsive, transcriptional co-regulator that differentially regulates excessive alcohol consumption in a brain region-specific manner. **Abstract:** Alcohol use engages a number of different circuits, including those involved in anxiety and reward. Our data suggests that a neurotensin-containing (NTS+) central amygdala (CeA) projection to the parabrachial nucleus (PBN) plays a role in modulating ethanol consumption and reward behaviors. Using genetically- and virally driven caspase-3 in male NTS-Cre mice, we show that ablation of these neurons resulted in decreased ethanol drinking in both a 2 bottle choice paradigm and in an intermittent access paradigm, without concurrent changes in measures of anxiety.
Moreover, using a Ce-dependent optogenetic approach in our NTS Cre mice we have targeted PBN-projecting NTS+ neurons in the CeA with channelrhodopsin. Mice show a preference for

stimulation in a real-time place preference assay, and will nose-poke for intracranial stimulation of this projection. Stimulation of this projection also promotes ethanol drinking. This data together suggests that this long-distance GABAergic projection is rewarding and plays a role in the reinforcement of ethanol consumption.

**Title:** Viral vector mapping of GABAergic projections stemming from the CeA in vgat-ires-cre and NPY1R-cre mice

**Authors: *M. A. COMPANION**[1], T. E. THIELE[2]
[1]Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC;
[2]Psychology and Neurosci., Univ. North Carolina, Chapel Hill, NC

**Abstract:** Central amygdala (CeA) GABAergic neurons have been shown to play a key role in modulating binge ethanol (EtOH) consumption. GABAergic neurons in the CeA co-release corticotropin-releasing factor (CRF) and express neuropeptide Y1 receptors (NPY1R). First, a Cre-dependent channelrhodopsin viral vector was injection into the CeA of vGat-ires-cre mice on a C57BL/6J background and was used to map GABAergic projections originating from this region. Animals were allowed to remain in home change for about 2 months in order to allow incorporation and spread of the viral vector. We then perfused animals with a 4% paraformaldehyde solution in order to fix tissue and sliced utilizing a vibratome. Every other slice of each brain was mounted and cover-slipped in order to map out projections from these regions. Many expected projections were seen to areas known to be associated with drugs of abuse. A novel GABAergic project from the CeA was to a specific location within the LHb. This same technique was used with an NPYR1-cre line in order to map out projections specifically from the CeA. This mapping analysis also revealed similar projections stemming from the CeA, including a project to the LHb, which is consistent with the hypotheses that GABAergic neurons in this pathway express Y1R. The lateral habenula (LHb) has been shown to play a role in the

negative affective states of drug use including those associated with EtOH. In order to investigate this specific pathway our lab is currently utilizing chemogenetic inhibitory ($G_{i/o}$) and excitatory ($G_q$) Designer Receptors Exclusively Activaed by Designer Drug (DREADD) viral vector technology injected into the CeA while simultaneously cannulating the LHb. **Abstract:** A significant proportion of college students are adult children of an alcoholic parent (ACoA), which can confer greater risk of depression, poor self-esteem, alcohol and drug problems, and greater levels of college attrition. However, some ACoA are resilient to these negative outcomes. The goal of this study was to better understand the psychobiological factors that distinguish resilient and vulnerable college-aged ACoAs. To do so, scholastic performance and psychological health were measured in resilient (not engaged in hazardous alcohol use) and vulnerable (currently engaged in hazardous alcohol use) ACoA college students. Neural activity (as measured by functional magnetic resonance imaging) and cortisol reactivity in response to performing working memory and emotion-based tasks were assessed. Furthermore, the frequency of polymorphisms in candidate genes associated with substance use, risk taking and stress reactivity were compared between resilient and vulnerable groups. College ACoAs currently engaged in hazardous alcohol use reported more anxiety, depression and posttraumatic stress symptoms, and increased risky nicotine and marijuana use as compared to ACoAs resistant to problem alcohol use. Vulnerable and resilient ACoAs were also distinguished by distinct

patterns of activity across the brain in response to visual working memory and emotional processing tasks, particularly in the posterior cingulate. Preliminary findings suggested that polymorphisms of cholinergic receptor and the serotonin transporter genes play a role in risk determination for ACoAs. Overall, findings point to several important psychobiological variables that distinguish ACoAs based on their current alcohol use that may be used in the future for early intervention.

**Title:** Maternal separation reduced prenatal ethanol-induced changes in hyperactivity and extracellular signal-regulated kinase activity

**Authors: *P. C. SWART**, V. A. RUSSELL, J. J. DIMATELIS
Human Biol., Univ. of Cape Town, Cape Town, South Africa

**Abstract:** Children with fetal alcohol spectrum disorders (FASD) face further adverse childhood experiences when living with alcohol-abusing parents. However, the effect between alcohol exposure *in utero* and childhood adversities on the developing brain has not been fully investigated. Hence, combining prenatal-alcohol exposure (PAE) and early-life stress in an animal model may better represent the aetiology of FASD and the associated-behavioural deficits.
Ethanol-dams voluntarily consumed a 0.066% saccharin-sweetened 10% ethanol (EtOH) solution throughout gestation while control-dams had *ad libitum* access to a 0.066% saccharin (sacc) solution. In addition, whole litters were randomly assigned to undergo maternal separation (MS) for 3 h/day from postnatal day (P) 2 to P14 while the remaining litters were left undisturbed (nMS). This resulted in 4 experimental groups: *control* (sacc+nMS), *MS* (sacc+MS), *EtOH* (EtOH+nMS) and *EtOH+MS*. Male rats were used in behavioural tests of learning and memory, as well as anxiety- and depression-like behaviour from P57 - P62. The prefrontal cortex (PFC) and dorsal hippocampus (DH) from non-behavioural male and female rats were used in western blot analysis of extracellular signal-related kinase (ERK) and glycogen synthase kinase-3β (GSK3β).
EtOH rats had reduced body mass compared to control rats. However, EtOH+MS rats tended to have a greater body mass than EtOH rats. Further, MS and EtOH rats were hyperactive during

habituation to the novel object test arena but EtOH+MS rats displayed similar activity levels to that of control rats. MS, EtOH and EtOH+MS rats had an increased number and average duration of 22 kHz ultrasonic vocalizations compared to control rats.
In adult male and female rats there was a significant interaction between PAE and MS on P-ERK/ERK in both the PFC and DH. P-ERK/ERK tended to be greater in MS rats compared to control rats whereas P-ERK/ERK tended to be lower in EtOH+MS rats versus EtOH rats. Further, PAE increased P-GSK3β in the PFC of male rats and increased P-GSK3β/GSK3β in the PFC of female rats.
A FASD-like phenotype was observed in rats exposed to prenatal-ethanol (reduced body mass, hyperactivity and a negative affective state). Importantly, P-ERK/ERK was increased in the PFC and DH after PAE. P-GSK3β and P-GSK3β/GSK3β were also increased by PAE in the PFC. Activation of the ERK signalling cascade with simultaneous *inactivation* of the GSK3β signalling pathway may have contributed to the FASD-like phenotype. MS reduced the hyperactivity in EtOH rats and decreased P-ERK/ERK in the PFC and DH. These results suggest that activation of the ERK signalling pathway plays a role in PAE-induced changes in behaviour.

**Title:** A murine model of female aggression: Escalation of aggressive behavior by ethanol and benzodiazepines

**Authors: *J. F. DEBOLD**[1], M. B. BICAKCI[1], E. L. NEWMAN[1], M. S. LAUZE[1], A. M. CASTANER[1], K. A. MICZEK[1,2]
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci., Tufts Univ., Boston, MA

**Abstract:** Levels of violent crime committed by women have increased, particularly under the influence of alcohol. Estimated annual costs of violent crime alone in the United States exceed three billion dollars. However, a viable animal model for female aggressive behavior has not yet been characterized. Here, we use an ethologically valid model to characterize aggressive interactions in female mice. We aim to explore sex differences in the behavioral profile, and the extent to which alcohol and benzodiazepines augment aggression. Ovariectomized CFW female mice were taught to self-administer a dose of ethanol known to promote aggression in some male mice (1.0 g/kg) and assessed for the presence of alcohol-heightened aggression. Low doses of the

benzodiazepine midazolam (0.1-1.0 mg/kg) were injected IP and females were tested for aggressive behavior in five-minute intruder interactions. Frequency and duration of resident aggressive and non-aggressive behaviors were measured and compared across conditions and across doses. A subpopulation of females (ca. 25%) show heightened aggressive behavior after alcohol consumption. Midazolam also increased aggressive behavior in resident females dose-dependently, similar to what has been demonstrated in male mice. This aggressive behavior, however, was sensitive to intruder novelty and strain. Resident females expressed the greatest levels of aggression toward novel C57BL/6J intruders. Alcohol and midazolam did not induce aggression in historically non-aggressive females. Aggression in female mice without a reproductive history is mediated in a manner similar to that of male aggression. This model can produce female residents with consistent high levels of aggressive behavior.

**Title:** Social defeat stress and escalated ethanol drinking by C57BL/6J mice: Modulation by CRF-R1 and glucocorticoid receptor antagonism

**Authors: *E. L. NEWMAN**[1], P. ANDREW[1], J. G. AULD[1], K. C. BURKE[1], B. KISBY[3], E. Y. ZHANG[1], J. F. DEBOLD[1], K. A. MICZEK[1,2]
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci., Tufts Univ., Boston, MA; [3]Behavioral Neurosci., Northeastern Univ., Boston, MA

**Abstract:** Stressful experiences can increase ethanol (EtOH) consumption in the human population. The present work used systemic pharmacological intervention to identify critical receptor targets associated with stress-escalated drinking in mice. Male C57BL/6J (B6) mice were subjected to ten days of social defeat during which larger, outbred resident males inflicted approximately thirty bites to B6 mice in under five minutes. Ten days after the final defeat, B6 mice received continuous or intermittent two-bottle choice access to 20% EtOH (w/v) and water. During four weeks of EtOH access, defeated mice consistently consumed more EtOH than non-defeated controls. From weeks 4-8, mice received weekly doses of the CRF-R1 antagonist, CP 376,395 (CP; 0-30 mg/kg IP); the 5-alpha-reductase inhibitor, finasteride (0-100 mg/kg IP); the 11-beta-hydroxylase inhibitor, metyrapone (0-50 mg/kg IP); or the glucocorticoid receptor (GR)

antagonist, mifepristone (0-100 mg/kg IP). The highest dose of CP reduced continuous, but not intermittent EtOH intake (g/kg) in defeated mice. Periods of forced abstinence during intermittent access may reduce the potentially therapeutic effects of CP; while CRF-R1 antagonism may diminish the positive reinforcing effects of EtOH, perhaps CRF-R1 is not critical for the negative reinforcing effects of EtOH withdrawal. Mifepristone dose-dependently reduced intermittent access drinking by control animals but had no effect on continuous access. Alternating between days of EtOH access and days of forced abstinence may alter HPA-axis functioning; this may be accentuated in defeated mice, causing these animals to continue drinking despite mifepristone treatment. Finasteride and metyrapone dose-dependently reduced EtOH intake, suggesting that ineffective glucocorticoid signaling in defeated mice with intermittent access to alcohol may be associated with altered receptor expression rather than corticosterone and neurosteroid synthesis. In summary, these findings suggest that CRF-R1 antagonists may be good candidates for the selective reduction of stress-escalated voluntary drinking while GR antagonists may be more effective in reducing alcohol intake that is not escalated by social defeat stress. Future work will tease apart the role of extra-hypothalamic brain regions in stress-escalated drinking through localized infusions of CRF-R1 and R2 antagonists into the central amygdala and ventral tegmental area.

**Title:** Adolescent ethanol exposure increases adult anxiety-like behavior: Involvement of small conductance $Ca^{2+}$-activated $K^{+}$ channels in medium-sized spiny neurons of the nucleus accumbens

**Authors:** L.-L. SHAN, J. C. CARPENTER, K. RYBCZYK, T. DEAK, ***Y. Y. MA**
Psychology, State Univ. of New York, Binghamton, NY

**Abstract:** Alcohol use typically begins early in adolescence, during which neurodevelopment can be interfered, increasing the likelihood of adult mental disorders such as anxiety. However, the cellular mechanisms underlying the consequences of adolescent alcohol exposure remain poorly understood. This study was designed to investigate the prolonged effects of chronic intermittent ethanol (CIE) during adolescence, compared with chronic intermittent water (CIW), on anxiety levels using the light-dark exploration test and determining the intrinsic excitability of medium-sized spiny neurons (MSNs) in the striatum by whole-cell patch clamp recordings in current-clamp mode, followed by *in vivo* and *in vitro* pharmacological manipulations. All measurements were done 3 weeks after adolescent (starting at postnatal 28 days, i.e., P28) or adult (starting at P70) CIE (4 g/kg/day, administered intragastrically under a schedule of 4 cycles of 3 days on and 2 days off) or CIW (same volume of water, administered intragastrically under the same schedule). We found that the cross-over latency from light to the dark side in adolescent CIE rats was significantly reduced relative to adolescent CIW control rats, indicating increased anxiety in rats with adolescent CIE history. Cross-over latency in adult CIE and CIW groups showed no difference from that in adolescent CIW group. In parallel, the excitability of MSNs in the nucleus accumbens (NAc), but not dorsolateral striatum (DLS), from rats with an adolescent CIE history was significantly higher than that of rats with an adolescent CIW history. Furthermore, the amplitude of the medium afterhyperpolarizations (mAHP), assumed to be mediated by small conductance (SK) calcium-activated potassium *channels*, but not the fast AHP, assumed to be mediated by large conductance (BK) calcium-activated potassium channels, was decreased specifically in the adolescent CIE group. Finally, the increased anxiety level and the increased NAc excitability in rats with an adolescent CIE history were significantly reversed by *in vivo* NAc microinjections or slice bath application of SK channel activator 1-ethyl-2-benzimidazolinone (1-EBIO); whereas *in vivo* or slice application of SK channel blocker Apamin in rats with an adolescent CIW history was able to mimic the effects of adolescent CIE treatment, *i.e.*, these CIW rats showed a significantly higher level of anxiety and increased NAc excitability. These results indicate that the high anxiety level in the adult stage after adolescent CIE is mediated by decreased function of SK channels in the NAc, which could be a target to prevent or reverse anxiety disorders induced by adolescent alcohol exposure.

**Title:** Adolescent social isolation increases kappa opioid receptor function in the nucleus accumbens and basolateral amygdala of rats

**Authors: *A. KARKHANIS**[1], J. L. WEINER[2], S. R. JONES[1]
[1]Wake Forest Sch. of Med., Winston Salem, NC; [2]Wake Forest Sch. of Med., Winston-Salem, NC

**Abstract:** Chronic early life stress, such as neglect during childhood, results in increased risk for alcohol use disorders during adulthood. Similarly, rats reared in social isolation (SI) during adolescence show increased ethanol (EtOH) intake in adulthood compared to group housed controls (GH). Acute stress elevates dynorphin levels, a kappa opioid receptor (KOR) ligand, which regulates dopamine (DA). Activation of KORs inhibits DA release in the NAc and BLA. The NAc and BLA are interconnected and play integral roles in the neurobiology of stress, anxiety and reward-seeking behavior. Recent literature shows that the KOR system regulates drug seeking following chronic exposure to ethanol. In order to understand the potential underlying mechanisms driving the isolation-induced increases in EtOH intake, the effects of acute EtOH on DA in the presence and absence of nor-binaltorphimine (norBNI), a KOR antagonist, were examined in the NAc and the BLA. Moreover, the sensitivity of KORs on DA terminals was examined in NAc slices from SI and GH rats.
DA in the NAc and BLA was measured using *in vivo* microdialysis in freely moving rats that were either housed in groups (4 rats/cage) or individually (1 rat/cage) for six weeks (PD 28 – 74). After reaching adulthood, acute EtOH was administered after establishing stable DA baselines. A separate group of rats was treated with norBNI (10 mg/kg; i.p.) 24 hrs prior to EtOH challenge. To investigate the KOR system further, *ex vivo* voltammetry was used to record the effects of U50,488 (10 – 1000 nM), a KOR agonist, on DA release in NAc slices from GH and SI rats.
Baseline levels of DA were significantly lower in the NAc and BLA of SI compared to GH rats. KORs increased baseline DA levels in both NAc and BLA. The SI rats showed increased DA responses to EtOH (2 g/kg) in both NAc (200% of baseline) and BLA (280% of baseline) and this increase was significantly greater in BLA than NAc. EtOH augmented DA responses in the NAc of SI rats pre-treated with norBNI, but attenuated responses in the BLA. The inhibitory effects of U50,488 on DA release were enhanced in the NAc of SI rats suggesting that chronic stress increases the functional responsiveness of KORs.
Increased DA elevations after EtOH in both regions of SI rats are consistent with the stimulant literature, however the mechanisms behind the distinct effects of EtOH-induced DA in the presence and absence of norBNI in NAc and BLA are unclear. It is possible that KOR differences may explain in part the effects of EtOH on behaviors related to specific brain regions, for example, augmentation of DA in the NAc results in increased reinforcement, whereas augmentation in DA in the BLA may contribute to decreased anxiety.

**Title:** Manipulation of fear memories as a treatment for comorbid AUD and PTSD

**Authors:** ***C. E. SMILEY**, J. T. MCGONIGAL, R. J. NEWSOM, T. VALVANO, J. T. GASS
Med. Univ. of South Carolina, Charleston, SC

**Abstract:** Alcohol Use Disorder (AUD) and Post-Traumatic Stress Disorder (PTSD) are highly comorbid, with rates as high as 41-79%, and share many overlapping neural circuits. One of the critical needs in this field is the development of novel pharmacological interventions to help treat these co-occurring disorders. Furthermore, research into the sex differences of AUD/PTSD needs to be investigated since prevalence rates for AUD/PTSD comorbidity differ between males and females and this has yet to be thoroughly studied in rodent models. The current studies examined the impact of chronic intermittent ethanol (CIE) exposure on fear conditioning, extinction learning and recall, and cue induced ethanol consumption in both male and female rats. Rats were first exposed to a rodent model of PTSD using fear conditioning with an “ABA” experimental design. After fear conditioning rats were exposed to either CIE or air for two weeks. Rats were then exposed to an extinction training regimen consisting of daily sessions of 10 extinction trials using tone (conditioned stimulus) presentations only. After reaching extinction criteria, rats were exposed to an extinction recall test. Two days after the extinction recall test, a “contextual” recall test was performed in the original fear conditioning environment. It was found that CIE exposed female rats acquired fear conditioning at a faster rate compared to all other groups. However, both male and female rats exposed to CIE showed a deficit in their ability to extinguish their fear behavior with this deficit being greater in male CIE exposed rats. These extinction learning deficits were recovered when rats from both sexes were treated with the positive mGlu5 modulator, CDPPB, during extinction. Sex differences were also observed in extinction recall and alcohol consumption. For example, CIE exposure resulted in a deficit in extinction memory recall in male rats only. Additionally, exposure to fear related cues significantly increased alcohol consumption in male CIE exposed rats. These results suggest that exposure to chronic alcohol after fear learning has differential effects in males and females, and some of these effects can be prevented by modulation of mGlu5. Currently, we are exploring the ability to disrupt reconsolidation of a fear-related memory through optogenetics to prevent alcohol-induced deficits in fear behaviors. Together, these results suggest that manipulation of

fear memories, through enhanced extinction learning via mGlu5 modulation or disruption of fear memory reconsolidation, can serve as a novel approach to treat individuals who suffer from AUD/PTSD comorbidity.

**Abstract:** Heritable differences in alcohol use disorders have been recognized for several decades. Many animal models have been employed to define genes variants and biochemical networks that predispose individuals to alcohol-related problems. This includes approach, initial consumption, change or elevation in the amount consumed, and dependence. Few animal models exist that address individual differences in initial exposure, consumption, and change following exposure. To this end, we tested female mice from 36 BXD recombinant inbred strains for initial and continuing alcohol consumption using the drinking in the dark (DID) method. All animals were between 60 and 80 days of age at the start of the study. DID follows a 4-day routine on a weekly schedule. On days 1–3 (Tues–Thurs in our case) water was removed 3h after lights out and replaced for 2h with alcohol (20% v/v from 95% EtOH). On the 4$^{th}$ day, treatment was repeated, but animals had 4h exposure. For this study, we followed this routine for five weeks. For the first 2h exposure, we observed wide variation in EtOH consumed from a low of 1.08 to 3.20 g/kg. For the first 4h exposure we observed a similar wide variation from 2.50 to 6.73 g/kg across 36 strains. The correlation for consumption between these exposures was $r = 0.69$, $p < 0.01$. Mapping of strain variation in DID for both exposures revealed the same suggestive locus near the telomere of chromosome 1. A possible candidate gene is *Gm821*, gene model 821 (NCBI). This gene is *cis*-regulated and its expression correlates with alcohol consumption *r*

>0.60, $p$ <0.01. For the 5th 4h exposure (following 5 weeks of DID), the range of consumption was 3.0 to 7.2 g/kg. The correlation between the first and fifth 4h DID was $r$ = 0.62, $p$ <0.01. For this trait, we detected suggestive loci on chromosomes 16, 18 and 19, but no strong candidate genes. In comparing the 5th 4h exposure to the 1st exposure, ten strains increased their consumption over the 5 weeks, but no strains decreased their consumption.

**Title:** Voluntary oral ethanol consumption as emotional self-medication

**Authors: *M. R. PAPINI**[1], R. DONAIRE[2], M. J. FERNANDEZ[2], C. MERINO[2], A. REINA[2], C. TORRES[2]
[1]Dept of Psychology, Texas Christian Univ., Fort Worth, TX; [2]Univ. of Jaen, Jaen, Spain

**Abstract:** In the early stages of drug addiction, individuals may develop a preference for a substance because of the substance's ability to reduce negative affect—the emotional self-medication (ESM) hypothesis. ESM was demonstrated in rats by exposing animals to an induction task involving reward devaluation (a downshift from 32% to 4% sucrose), followed by access to 2% ethanol and water in a 2-h, two-bottle choice preference test. Ethanol consumption increased after reward devaluation sessions in comparison to control groups either not exposed to devaluation or exposed to devaluation but given access to water. Two experiments tested the assumption that ethanol consumption increased because ethanol downregulates negative affect induced by reward devaluation. In Experiment 1, rats received access to ethanol under the same conditions that produced evidence of ESM and this was followed by a 32-to-4% sucrose downshift. Previous access to ethanol did not reduce the behavioral effects of reward devaluation. In Experiment 2, rats were first exposed to the 32-to-4% sucrose downshift, then to an ethanol preference test, and finally to the elevated plus maze. Reward devaluation significantly increased ethanol consumption, and this ESM effect increased general activity in the elevated plus-maze relative to water controls. Experiment 3 tested whether an anxiolytic

action of oral ethanol on subsequent reward devaluation would require repeated experience with reward devaluation. Animals had daily access to ethanol, immediately followed by repeated cycles of 32-to-4% sucrose downshift. Access to ethanol in the preference test reduced the effects of repeated reward downshifts relative to water controls, suggesting that previous ethanol consumption can reduce negative affect after repeated reward devaluations. Overall, these results provided limited support for the assumption underlying ESM that ethanol consumption increases after reward devaluations because ethanol reduces the ensuing negative affect. The origin of addictive behavior is often linked to the rewarding effects of drugs of abuse. The ESM hypothesis offers an alternative explanation based upon the ability of many of such drugs (e.g., ethanol) to alleviate negative affect.

**Title:** Investigating the temporal relationship between chronic mild stress and alcohol intake in rats

**Authors: *C. S. BAILEY**[1], A. K. PATTERSON, 37614[2], C. A. BRADLEY[3], S. G. MALONE[2], M. I. PALMATIER[3]
[1]Psychology, East Tennessee State Univ., Watauga, TN; [2]Psychology, [3]East Tennessee State Univ., Johnson City, TN

**Abstract:** There is a substantial comorbidity between alcohol use disorders (AUDs) and anxiety-related disorders, but the directional onset and temporal nature of this interaction is not well understood. To investigate the temporal relationship between stress and alcohol consumption, we adapted a model of chronic mild stress (CMS) to a home cage alcohol drinking paradigm. We hypothesized that rats exposed to CMS would show an increase in anticipatory ethanol intake as a strategy for coping with an impending stressor. CMS was used because despair models (forced swim and social defeat) decrease anticipatory alcohol intake. Rats were randomly assigned to one of two groups (Stress, n=8 or Control, n=8), both groups had access to 10% (v/v) ethanol. The Stress group was exposed to a mild stressor (e.g., wet bedding, puddled cage, cage tilt, predator urine) in a novel cage outside the colony for 3 h each test day. Control rats were transported to a novel cage outside the colony for 3 h each test day. A red ambient light was

illuminated for 2 h before the stress/novel cage exposure as an anticipatory cue. No fluids or food were available in the stress/novel cage. Alcohol intake was recorded during 3 periods every 24 h - at 0900 ethanol and water consumption from the preceding 17 h (overnight drinking), at 1100 after transport to the stress/novel cage (anticipatory drinking), and at 1600, 2 h after rats were returned to the home cage (post-stress drinking). Stress and alcohol exposure recurred over 6 days each week for 9 weeks, on the seventh day of each week no alcohol was available and rats remained in the colony. The 3 h deprivation (during stress/novel cage housing) initially increased water intake during the post-stress drink session, but this increase declined across the first 3 weeks of testing. Ethanol intake increased after deprivation - the overnight drink on the first day of testing each week. However, initial ethanol intake levels were so low, it was not clear that rats experienced the intoxicating effects of ethanol (approx. 0.4 g/kg during anticipatory and post-stress drinks). There were no initial differences in ethanol intake, but preliminary evidence suggested that both groups increased alcohol drinking during the anticipatory period. Future studies are needed to determine if the novel cage manipulation is sufficient to produce mild stress or if access to ethanol impacted the development of the stress response.

**Title:** Early life stress-induced alcoholism may be overcome through novel pharmacological manipulation: Implications on behavior and neurochemistry

**Authors: *O. O. KALEJAIYE**[1,2], R. BASSEY[1,2], I. BAMIDELE[1,2], V. TIRUVEEDHULA[3], J. M. COOK[3], M. C. GONDRÉ-LEWIS[1,2]
[1]Dept. of Anat. and Dept. of Psychiatry and Behavioral Sci., [2]Developmental Neuropsychopharm. Lab., Howard Univ. Col. of Med., Washington, DC; [3]Univ. of Wisconsin, Milwaukee, WI

**Abstract:** Stress-related psychiatric disorders are positively correlated to the propensity for alcoholism. Stress is particularly detrimental to brain development when it occurs during vital neurodevelopmental stages and may severely impact emotion and reward processing centers. Maternal separation stress (MS) has recently been shown by our laboratory to induce binge alcohol drinking in adult rodents. It was postulated that one neurochemical basis for this

heightened alcohol drinking behavior could be via $GABA_A$ receptor ($GABA_AR$) upregulation. This study aims to present novel $GABA_AR$-targeted pharmacological interventions which manipulate neurochemistry to rescue aberrant behavior. 3-propoxy-carboline hydrochloride (3-PBC), a $GABA_AR$ acting compound and 3 of its isoforms, BCCt, 3-IsoPBC and Cyclo-PBC, administered at doses of 10, 20, and 40mg/kg, were utilized as drug treatments. MS was induced in Sprague-Dawley pups by their daily separation from dams starting at postnatal day (PD) 2 until PD21. During early adolescence from PD28-35, behavior was tested on elevated zero maze (EZM), open field locomotor activity (OFLA) and forced swim test (FST). The rotarod test was conducted during late adolescence. At PD60 rats were trained for alcohol drinking in an operant conditioning chamber. $GABA_AR$ modulators dose-dependently and sex-specifically attenuated MS-induced increases in distance traveled, ambulatory time, stereotypy, and time spent in the center field; behaviors consistent with hyperactivity. These findings were paralleled in the EZM which showed a reduction in risk taking behavior, exhibited by an MS-induced increased time spent in the open arms. These $GABA_AR$ modulators also attenuated MS-facilitated increased immobility in the FST, a measure of depressive-like behavior. Previously, we showed that MS induced an increase in alcohol intake and now we show that females MS rats exhibit increased alcohol intake per kg body weight when compared to males. In general, $GABA_AR$ modulators had varying degrees of efficacy on behaviors, especially in alcohol consumption, with Cyclo-PBC>3Iso-PBC>3PBC>BCCt. This study presents a compelling argument that stress experienced during early life may serve as a key indicator of binge alcohol drinking later in life. Additionally, stress may have more severe behavioral ramifications in females when compared to males thus treatment profiles may be deferentially effected. Furthermore, we show that $GABA_AR$ dysregulation in ELS may be sexually dimorphic. The translational relevance of this study points to the need for adjunctive GABA-targeted pharmacological therapies which account for gender differences in humans.

**Title:** Chronic intermittent ethanol alters hypothalamic synaptic plasticity and HPA axis hormonal, as well as behavioral responses to repeated stress

**Authors: *V. N. MARTY**, Y. MULPURI, K. NGUYEN, S. LELE, I. SPIGELMAN
UCLA, Los Angeles, CA

**Abstract:** Alcohol use disorders are associated with a persistently dysregulated hypothalamic-pituitary-adrenal (HPA) axis and corticotropin-releasing factor (CRF) signaling that leads to inappropriate stress responses, thereby increasing relapse susceptibility in abstinent alcoholics. Our goal is to identify the neuroadaptive mechanisms responsible for the dysregulation of the HPA axis. Using whole-cell patch-clamp recordings, we showed that stress induces a CRF-dependent depression of NMDAR function in parvocellular neurosecretory cells (PNCs) in the paraventricular nucleus of the hypothalamus (PVN), which allows for short-term potentiation (STP) of AMPAR-mediated evoked excitatory postsynaptic currents (eEPSCs) following high-frequency stimulation (HFS, 100Hz for 1sec, x4). This stress-induced STP can be evoked for several days and provides a mechanism by which the HPA axis responds adaptively to subsequent stressors. Here, we found that chronic intermittent EtOH (CIE, 30 doses, 5-6 g/kg EtOH, oral gavage) and 40 days of withdrawal decreased action potential threshold in PNCs. While the frequency and amplitude of AMPAR-mediated EPSCs were unchanged, we found that CIE increased the paired-pulse ratio and potentiated NMDAR function in PNCs. Hypothalamic CRF mRNA expression was increased in CIE rats. Interestingly, the inhibitory effect of CRF on NMDAR was absent in CIE rats. Since NMDAR and CRF play a critical role in the physiological responses to stress, we investigated the effects of CIE on PNCs in rats exposed to restraint stress. We found that HFS-induced STP was impaired in PNCs of stressed CIE rats. Loss of HFS-induced STP was also found in PNCs of stressed rats exposed to intermittent EtOH vapor for 6 weeks and 40 days of withdrawal. NMDAR inhibition by intracellular MK-801 restored stress-induced STP suggesting that the loss of CRFR1-mediated NMDAR blockade in CIE rats may prevent stress-induced STP. To relate the expression of STP to the HPA axis hormonal response, we examined ACTH and CORT plasma levels in response to repeated (at 72hr-intervals) restraint stress. In CIE rats, the ACTH response to the 3$^{rd}$ stress was blunted, and the CORT response to the 3$^{rd}$ stress recovered faster to baseline compared to the 1$^{st}$ stress. Stress-induced increases in self-grooming behavior, an adaptive response involving CRF-expressing PNCs that reflects the process of restoring behavioral homeostasis disturbed by stressors, were impaired in CIE rats. These data implicate altered CRF and NMDAR signaling mechanisms in CIE-induced maladaptive HPA axis behavioral and hormonal responses to repeated stress.

**Title:** Functional neurocircuitry of vasopressin-mediated alcohol withdrawal-induced anxiety

**Authors: *R. K. BUTLER**[1], D. J. KNAPP[2], H. E. CRISWELL[2], G. D. STUBER[3], G. R. BREESE[4]
[1]Bowles Ctr. for Alcohol Studies, [2]Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [4]Departments of Psychiatry & Pharmacol., UNC Sch. of Med., Chapel Hill, NC

**Abstract:** Chronic ethanol exposure induces neurobehavioral maladaptations in the brain, yet the precise characteristics of these changes have not been fully explored. The vasopressin receptor system in the central amygdala (CEA) regulates anxiety-like behavior ("anxiety") and may regulate alcohol effects. We explored whether adaptations occur due to chronic ethanol exposure in the CEA vasopressin receptor system or the afferent functional amygdala neurocircuitry which leads to anxiety in rats. Previously it has been demonstrated that 15 days of continuous 4.5% ethanol exposure or chronic intermittent ethanol (CIE) exposure comprised of three cycles of 4.5% ethanol for 5 days followed by 2 days of withdrawal induce social interaction deficits (elevated anxiety) in adult Wistar rats, effects we confirm in this study. Chemogenetic deactivation of projection neurons (previously determined to be $Ca^{2+}$/calmodulin-dependent protein kinase II-positive) in the basolateral amygdala (BLA) reduced anxiety following 15 days of continuous ethanol exposure. Vasopressin microinjected into the bilateral CEA (4 nmol in 0.5 µL ACSF per side) in lieu of the first two cycles of ethanol with CIE was sufficient to induce anxiety. Microinjection of a vasopressin receptor antagonist into the bilateral CEA (SSR149415; 5µg in 0.5 µL ACSF per side) at the start of the first two withdrawal cycles suppressed anxiety in this model. Preliminary data suggest that chemogenetic activation of projection neurons of the BLA in lieu of the first two cycles of CIE are sufficient to induce anxiety–an effect not observed with vasopressin receptor antagonism. Slice electrophysiology suggests that there are adaptations to the release of vasopressin and not vasopressin receptor function in the CEA as a result of CIE. Taken together, this study demonstrates a role of CEA vasopressin and the BLA to CEA circuit in the development of anxiety induced by chronic ethanol withdrawal. Such information is valuable for elucidating the co-morbidity of anxiety and alcohol withdrawal and for identifying novel therapeutic targets for associated disorders.

**Abstract:** Chronic ethanol use in alcoholic beverages including beers, wines, spirits, liquors and traditional brew remain a global challenge including among HIV-infected patients on treatment regimens. Study determined effect of chronic alcohol intake on total plasma proteins, total globulins and albumin among HIV-infected patients on d4T/3TC/NVP treatment regimen in Uganda. A case control study using repeated measure design with serial measurements model was used. WHO alcohol use disorders identification test (AUDIT) tool and chronic alcohol use biomarkers were used to recruit study participants. Study was approved by relevant IRB and Helsinki declaration on use of human subject in research was followed. Alcohol use biomarkers standardized gender differences in alcohol use. Total of 41 patients (21 alcohol and 20 control group) were followed up for 9 months with blood sampling at 0, 3, 6 and 9moths. Plasma proteins levels were determined by Cobas Integra 400 Plus analyzer system. Mean total plasma proteins levels in biomarkers group were higher in alcohol group during 9 month follow up with highest levels (83.12±12.41g/l) observed in $9^{th}$ month and were above normal reference ranges (64.0-83.0g/l); and were statistically significant ($p \leq 0.05$) in $6^{th}$ and $9^{th}$ month. Similar trend was observed in AUDIT tool group, were within normal reference range though statistically insignificant ($p \geq 0.05$). Mean plasma albumin levels in both AUDIT and biomarkers groups were higher in alcohol group and were statistically significant ($p \leq 0.05$) for biomarker group during entire follow up period. Similar trends was also observed in mean total globulins levels and were above normal reference range (25.0-35.0g/l) in $3^{rd}$, $6^{th}$ and $9^{th}$ of follow up and were statistically significant in $6^{th}$ and $9^{th}$ month of follow up in biomarker group. Chronic alcohol use by HIV-infected patients on d4T/3TC/NVP treatment regimen affected the total plasma proteins, total globulins and albumin levels in HIV-infected patients.

Grad Sch. of Med., Kobe, Japan

**Abstract:** OBJECTIVE: Adverse life experiences are associated with an increased risk of developing alcohol use disorders (AUD). Female drinking levels and drinking problems are increasing and more closely approximating those seen among men. One factor that has not been adequately examined in previous studies of the genetic contributions to AUD is sex, which is a substantial shortcoming in the field given that there are significant influences of sex on alcohol consumption patterns and alcoholism in humans and in animal models. Genetic factors, such as allelic variation in opioid receptor system genes, have a substantial influence on alcohol consumption, but only a limited set of such genetic influences on behavioral activity associated with forced drinking have been examined. In our previous study, disturbances of mu-opioid receptors influenced the effects of isolation-rearing on ethanol consumption in a sex-dependent manner. The preset study was based on the hypothesis that the effects of restrain stress on ethanol consumption, would be also influenced by both sex and the functioning of mu-opioid receptor systems. METHODS: The effects of restrain stress on ethanol intake were assessed using a two-bottle home-cage consumption (8% v/v ethanol vs. water) paradigm in male and female wild-type and mu-opioid gene knockout mice. Body weight and food, ethanol, and water consumption were measured daily. Furthermore, male and female wild-type and mu-opioid receptor gene knockout mice were studied during forced ethanol drinking, continuous access to ethanol (8% v/v) for twelve days, after which all mice were tested for locomotor activity in an open field apparatus. RESULTS: Restraint stress modestly increased ethanol consumption in female mu-opioid knockout mice but not in female and male wild-type mice. Ethanol consumption was stable in the non-stress group over the 14-day period of observation. In female mu-opioid mice, ethanol intake was greater during the stress period compared to the non-stress

mu-opioid knockout mice. On the beginning day in the first two-bottle test, food intake and water consumption were significantly reduced in all mice. The locomotor activity with forced alcohol drinking among male and female wild-type and mu-opioid knockout mice were not significantly different. CONCLUSIONS: The study shows that disturbances of mu-opioid receptors influences the behavioral consequences of ethanol consumption following stress in a sex-dependent manner.

**Title:** Sex differences in alcohol consumption, object recognition and rearing in male and female high alcohol drinking (had-1) rats

**Authors: *N. MITTAL**[1], A. MARTINEZ[2], S. M. FLEMING[4], W. MADDOX[5], T. SCHALLERT[3], C. L. DUVAUCHELLE[6]
[1]Univ. of Texas At Austin, Austin, TX; [2]Dept of Psychology, [3]Univ. of Texas at Austin Behavioral Neurosci., Austin, TX; [4]Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [5]Dept of Psych, Univ. of Texas at Austin Dept. of Psychology, Austin, TX; [6]Pharmacol. & Toxicology, Univ. of Texas, Austin, TX

**Abstract:** Excessive alcohol consumption has a negative impact on social and emotional well-being and the ability to think and reason. Rodent models such as selectively bred high alcohol-consuming rat lines, such as the “HAD-1” lines have been successful in furthering our understanding of the biological underpinnings that drive alcohol consumption. The present work examined sex differences in alcohol consumption, object recognition and rearing in male and female HAD-1 rats. Naïve male and female HAD-1 rats were tested in an object recognition test (ORT), followed by 4 wks of 24-hr alcohol consumption sessions. The ORT was performed in two phases, a Training Phase and a Testing Phase. For the Training Phase, each rat was placed in an open field for 600 seconds. The floor of the arena was divided into four sections labeled A-D and two identical objects were placed in Section A. Rats were videotaped while exploring the open field for 10 minutes. The rat was then removed, placed back in the homecage for one hour

and then entered the Test Phase. Here, all procedures were identical except that one of the objects was replaced with a novel object. Time in each section, time in contact with each object, and number of rears were recorded for training and testing phases. One week later, animals were given 24-hour 3-bottle access (water, 15% EtOH, 30% EtOH) every other day for 4 wks. Results: during Training, female HAD-1 rats spent significantly more time in Section A with the objects than male HAD-1 rats [$t(14)=4.51$, $p<0.001$], they actively investigated the objects more [$t(14)= 3.91$, $p<0.002$] and made significantly more rears than males [$t(14)=4.18$, $p<0.001$]. During Test, females showed a marginally significant increase in time spent in Section A compared to males [$t(14) = 2.063$, $p=.058$], but object investigation time and number of rears did not statistically differ between females and males. Female HAD-1 rats also consumed significantly more alcohol than their male counterparts [$t(14) = 2.770$, $p<0.02$]. Moreover, across all animals there was a significant correlation between exploratory behavior and alcohol consumption levels. These results indicate significant sex differences in cognitive and/or emotional reactivity and alcohol consumption female and male HAD-1 rats.

**Title:** Late-aging alters behavioral sensitivity to ethanol in a sex specific manner in Fischer 344 rats

**Authors: A. E. PERKINS**[1], A. S. VORE[1], E. I. VARLINSKAYA[2], *T. DEAK[3]
[2]Dept Psychol, [1]Binghamton Univ., Binghamton, NY; [3]Behavioral Neurosci. Program, Dept. of Psychology, Binghamton University-SUNY, Binghamton, NY

**Abstract:** Early developmental differences in numerous ethanol (EtOH)-related effects are now well established, with adolescents showing reduced sensitivity to the sedative effects of ethanol, whereas they exhibit enhanced sensitivity to the social facilitating aspects of EtOH. However, late aging-related differences in sensitivity to ethanol have been largely unexplored. Furthermore, whether aged males and females differ in the response to EtOH is unknown. Thus, two experiments were conducted to examine the behavioral responses to EtOH across a range of

doses in adult (3-month) and aged (18-month) male and female Fischer (F) 344 rats. First, a within-subjects design was used to assess social behavior in response to Vehicle, 0.5 g/kg ethanol, and 0.75 g/kg EtOH, with a day off between tests. Rats were injected (i.p.) and immediately placed into a testing apparatus for 30 min, after which a novel sex-matched adult conspecific was introduced for a 10 min social interaction test. Social investigation and contact were lower in aged animals overall and higher in females, relative to males. Interestingly, in aged females, social contact was increased following a 0.5 g/kg EtOH injection, whereas the same dose suppressed social contact in aged males. Additionally, total social behavior (investigation + contact) was decreased in both males and females following a 0.75 g/kg EtOH injection. After a 1-2-week washout period, the same rats were used to assess aging-related differences in behavioral sensitivity to the sedative effects of EtOH using Loss of Righting Reflex (LORR). All rats were administered 3.5 g/kg EtOH, i.p. Latency to lose the righting reflex and sleep time were measured. Although latency to lose the righting reflex did not differ as a function of age or sex, aged rats took substantially longer to awake relative to young adult animals. This was accompanied by significantly lower BECs at awakening, indicating increased sensitivity to the sedative effects of ethanol. In addition, females recovered faster than males and had lower BECs at awakening, consistent with reduced sensitivity to ethanol. Taken together, late aging is associated with altered sensitivity to the social facilitating effects and sedative effects of ethanol. Future studies will explore the role of aging-related inflammation in mediating the behavioral response to ethanol in late aging.

**Title:** Alcohol intake affects ketamine self-administration in a sex-dependent manner

**Authors: *C. E. STRONG**, K. N. WRIGHT, M. KABBAJ
Biomed. Sci., Florida State Univ., Tallahassee, FL

**Abstract: Abstract:** In clinical settings**,** ketamine provides rapid and sustained antidepressant relief in patients considered to have treatment-resistant depression (TRD). More recently, ketamine has also shown promise in reducing drug craving in people suffering from substance

use disorders (SUD). Additionally, both preclinical and clinical studies demonstrated a clear interaction between ketamine and alcohol, two drugs that are recreationally abused. It is therefore critical to investigate the potential interaction of ketamine and alcohol and the potential mechanisms of this interaction. In the present study, we used the intermittent alcohol 2-bottle choice (IA2BC) paradigm and ketamine self-administration (0.5 mg/kg/infusion) to examine interaction between alcohol and ketamine. Male and female Sprague-Dawley rats were maintained on the IA2BC paradigm for ten week, with ketamine self-administration nested from week four to seven. The final three weeks of the IA2BC paradigm were used to examine the effects of alcohol on the incubation of ketamine craving. Our preliminary results indicate that alcohol affects ketamine self-administration in a sex-dependent manner, however both sexes displayed enhanced drug craving. Further work will investigate nucleus accumbens (NAc) protein expression of plasticity biomarkers such as AMPA-receptor 1 (GluA1) and postsynaptic density protein 95 (PSD95) expression as well as dendritic spine density of NAc medium spiny neurons. Together, our work will provide some insight on the mechanisms mediating interaction between alcohol and ketamine in both male and female rats.

**Authors: *A. K. RADKE**, B. DAMES, J. FRANKEL, A. NADER, O. RAMSEY, D. SCHLEICHER, J. SETTERS, R. D. WHITE
Psychology, Miami Univ., Oxford, OH

**Abstract:** One characteristic of alcohol use disorder is persistent seeking and taking of alcohol despite negative consequences. This “compulsive-like,” “aversion-resistant,” or “inflexible” drinking is often modeled in rodents by adding the bitter tastant quinine to alcohol (Lesscher and Vanderschuren 2012). While this approach is commonly employed in both rats and mice, there have been few examinations of aversion-resistant alcohol drinking in female animals. This gap in the literature persists despite the fact that both human and animals studies suggest females are

more vulnerable to addictive behaviors, including initiation, escalation, and relapse of drug-seeking (Anker and Carroll 2010). Here, we investigated aversion-resistant alcohol-drinking in male and female C57BL/6J mice. We used a version of the "drinking in the dark" procedure to model binge-like drinking (15% ethanol vs. water for 2 hours, 3 hours into start of the dark cycle) and tested for aversion-resistant drinking by adding quinine (100 or 250 µM) to the ethanol solution (EtOH+Q). We also assessed the role of the nucleus accumbens (NAc) in aversion-resistant drinking with chemogenetic inhibition. The DREADD vector AAV-hSyn-hM4D(Gi)-mCherry (ADDGENE) was expressed in the NAc and mice were tested for aversion-resistant drinking following injections of the DREADD ligand clozapine-n-oxide (CNO, 1 mg/kg i.p.) or vehicle. Our results demonstrate increased alcohol consumption and escalation of drinking in female vs. male mice. There were no sex differences in consumption of EtOH+Q. Finally, NAc inhibition increased consumption of EtOH+Q, and females were more sensitive to this effect than males. Additional experiments will assess the effects of inhibiting dorsal striatum on aversion-resistant drinking. Together, our results provide insight into the neural mechanisms of alcohol use despite negative consequences. **Title:** Sex differences in the effect of acute alcohol treatment on tyrosine hydroxylase immunoreactivity in the mesolimbocortical dopamine pathway in mice

**Authors: *E. RHINEHART**[1], D. E. WILSON[1], N. KOMARA[1], M. LATOURETTE[1], J. E. GRISEL[2]
[1]Dept. of Biol., Susquehanna Univ., Selinsgrove, PA; [2]Dept. of Psychology, Bucknell Univ., Lewisburg, PA

**Abstract:** There is a notable sex difference in how alcohol effects physiology and behavior. Females require less alcohol to become intoxicated and may have an enhanced susceptibility to addiction. Alcohol increases dopamine signaling in the mesolimbocortical dopamine reward pathway, but this could occur in a variety of ways, such as increased release, increased receptor density or decreased reuptake transport. In addition, alcohol stimulates GABA signaling, which

indirectly affects dopaminergic signaling in the reward pathway. Another possible way that alcohol could stimulate dopaminergic signaling in the reward pathway is by increasing in the production of tyrosine hydroxylase, the rate-limiting enzyme for dopamine synthesis. Therefore, we hypothesized that acute alcohol intoxication increases tyrosine hydroxylase protein expression to stimulate dopaminergic signaling in the reward pathway in a sex-dependent manner. To test this hypothesis, male (n=16) and female (n=16) wild-type Swiss Webster mice were injected intraperitoneally with 2g/kg ethanol or saline. Two hours post-injection animals were sacrificed by overdose with sodium pentobarbital and perfused with saline followed by 4% paraformaldehyde. Brains were removed and post-fixed in 4% paraformaldehyde followed by a 30% sucrose sink. 35 micron thick brain sections were processed for immunohistochemical staining for tyrosine hydroxylase (Anti-TH, 1:3000, EMD Millipore). In female mice, ethanol treatment increased tyrosine hydroxylase positive cells in the ventral tegmental area (139 $\pm$ 20 vs. 191 $\pm$ 25 cell number, $p<0.05$) and increased tyrosine hydroxylase fiber immunoreactivity in the nucleus accumbens (19 $\pm$ 9 vs. 56 $\pm$ 15, A.U., $p<0.05$). Tyrosine hydroxylase expression in the reward pathway was unaffected by ethanol treatment in males. The results of this study indicate that the reward pathways in the brain respond differently to acute ethanol intoxication in males and females, and it has further implications for understanding mechanisms underlying alcohol addiction.

**Title:** Sensitivity to ethanol-induced hypnosis varies across estrous cycle: Mediating role of progesterone, mGluR5 and $GABA_A$ receptors

**Authors: *N. CAMERON**, D. POPOOLA
Dept. of Psychology, Binghamton Univ., Binghamton, NY

**Abstract:** Sensitivity to ethanol-induced hypnosis is modulated by endogenous gonadal hormones levels and both the γ-aminobutyric acid (GABA) and glutamate systems. This study examined associations between variations in female sensitivity to ethanol-induced hypnosis,

across estrous cycle and fluctuations in gonadal hormones levels as well as GABA type-A ($GABA_A$) and metabotropic glutamate (mGlu) receptors functions.
Experiment 1a tested female rats at proestrus, estrus, metestrus or diestrus stages of the estrous cycle for sensitivity to an acute 3.5g/kg ethanol dose-induced hypnosis using the loss of righting reflex (LORR) paradigm. Experiment 1b tested sensitivity to motor impairment induced by gaboxadol, a selective $GABA_A$ δ subunit agonist, across the estrous cycle. Experiment 2 investigated the specific role of progesterone in sensitivity to ethanol-induced hypnosis, by administering 1000ug of progesterone to adult male rats, five times at 12-hour intervals and testing them for LORR. Brain and plasma were collected from experiment-naïve adult female rats to quantify plasma and cerebro-cortical progesterone levels in experiment 3a. Experiment 3b quantified cerebro-cortical $GABA_A$ α1and δ subunits and metabotropic glutamate receptor subtype 5 (mGluR5) expressions.
Experiment 1a revealed that female rats were more sensitive to ethanol-induced hypnosis at proestrus compared to all other estrus cycle stages, and at metestrus compared to estrus and diestrus. In experiment 1b, females were more resilient to gaboxadol-induced motor impairment at diestrus compared to estrus. In experiment 2, progesterone-treated males demonstrated longer LORR-duration compared to the vehicle-treated group. Experiment 3a revealed that plasma progesterone was highest at both proestrus and metestrus compared to estrus and diestrus, and cerebro-cortical progesterone was highest at metestrus compared to estrus and diestrus. Lastly, in experiment 3b, $GABA_A$ δ expression was lowest but mGluR5 was higher at proestrus compared to estrus and a trend compared to diestrus.
Sensitivity to ethanol-induced hypnosis is greater when progesterone levels are highest in both sexes. In females, plasma progesterone levels are highest at proestrus and metestrus. At proestrus in the cerebral cortex, $GABA_A$ δ and mGluR5 expressions suggest their contribution in the alcohol-induced sensitivity effect. Therefore, variations in female sensitivity to ethanol-induced hypnosis varies across the estrous cycle and may be primarily mediated by variations in progesterone and the activity of mGluR5 and $GABA_A$ receptors in the cerebral cortex.

**Title:** Influences of experimental conditions and stress on the escalation of ethanol consumption in male and female mice

**Authors: *D. MUSKIEWICZ**[1], N. FROMMANN[1], B. PATEL[1], A. SIMON[1], F. S. HALL[2]
[1]Pharmacol., The Univ. of Toledo, Toledo, OH; [2]Pharmacol., Univ. of Toledo Col. of Pharm. and Pharmaceut. Sci., Toledo, OH

**Abstract:** Background: Escalation of ethanol intake is an important criterion for the diagnosis of alcohol dependence. Previous conditions have produced doubling of ethanol intake over 2 weeks. However, to produce escalation that models alcohol dependence in humans, an examination of the conditions that produce maximum escalation of ethanol intake in mice was needed. Previous studies have also shown that the dopamine transporter (DAT) may play a critical role in ethanol consumption (Hall, 2003) including escalation (Houston-Ludlam and Hall, unpublished findings). DAT expression is also altered by chronic mild stress (CMS), which increases ethanol consumption in heterozygous (HET) dopamine receptor D2 knockout (KO) mice (Deli, 2015). Therefore, the effects of CMS on ethanol consumption were also examined in HET DAT KO mice. Methods: Experiments 1-3 uses adult male and female C57BL/6J mice (N=10/group) while Experiment 4 used adult male and female wild-type (WT) and HET DAT KO mice (HET) (N=5/group). Experiment 1 examined the effect of different EtOH concentrations (4%, 8%, 16% and 32% v/v) using two-bottle, 24-hr access, 2 days/wk. Experiment 2 examined different intervals of availability of 16% EtOH (1, 2, or 3 days of 24-hr access, or continuous access). Experiment 3 examined the effects of a 4 bottle preference (4%, 8% and 32% EtOH v/v; and water) with 3 days of 24-hr access/wk. Experiment 4 included 4 groups: HET control (HETC), WT control (WTC), HET + CMS, and WT + CMS. Escalation was assessed using the optimal procedure defined in Expts 1 and 2. Stressors included the following schedule each week for four weeks: damp bedding (200 ml water; 2x 9-hr and 1x15-hr), 45º cage tilt (2x 15-hr and 1x 24-hr), food deprivation (3x 9-hr), strobe lighting (300 flashes/min; 2x15-hr), and water deprivation (2x 9-hr). Results: Escalation in a 2-bottle test (Expts. 1 and 2) was dependent on concentration, interval, and sex. In Experiment 3, greater levels of consumption were observed, > 15 g/kg in males and > 20 g/kg in females, but no escalation was observed. In experiment 4, female HETC produced the greatest escalation, an effect dampened by CMS. Discussion: Both interval and concentration in a limited access procedure affected escalation of ethanol consumption over time. A 4-bottle procedure did not produce escalation of ethanol intake, but did produce very high levels of ethanol intake. The ideal conditions for escalation of ethanol intake appear to be 16% ethanol 3 days/week in C57BL/6J mice. HET DAT KO was found to affect ethanol escalation after CMS in female mice only. Further experiments are needed in order to clarify the role of DAT in stress-induced alcohol consumption and escalation.

**Title:** Gender differences in binge-like ethanol drinking and dendritic spines in the nucleus accumbens of adolescent C57BL/6 mice

**Authors: *R. I. MELENDEZ**
Dept. Anat. and Neurobio., Univ. of Puerto Rico, Med. Sci. Campus, San Juan, PR

**Abstract:** Despite the progress in delineating major aspects of adolescent brain development (e.g., enhanced synaptic glutamate plasticity and vulnerability to ethanol abuse), there are no studies addressing the impact of gender as it related to excessive ethanol drinking behavior. As such, the present study examined the impact of adolescent ethanol drinking on dendritic spine density in the nucleus accumbens of male and female C57BL/6 mice. Notably, dendritic spines are postsynaptic specializations that regulate the strength of synaptic glutamate transmission and plasticity, which is heightened during adolescent brain development. Initially, adolescent mice (P30 at start) were given every-other-day (EOD) access to 15% ethanol and water (two-bottle choice) for 2 weeks (i.e., 7 drinking sessions total); ethanol-naïve mice served as aged-matched drinking controls (n=13/group/gender). One day (24 h) after the final ethanol drinking session, mice were euthanized, the brains removed and prepared for Di-I labeling of dendritic spines in the accumbens core (n=3/group/gender). Imaris 3D imaging software was used to quantify the total number of spines and spine-class density between mushroom (‘mature’) and long-thin (‘immature’) spines. Intermittent EOD access to ethanol resulted in significant escalation (binge-like) ethanol intake in both male and female mice during the early (1-4) and late (5-7) sessions of ethanol exposure. However, the rate of escalation (slope) and propensity for consumption (intake) was significantly greater in females relative to males. The mean ethanol intake values following EOD sessions 5-7 were (in g/kg) 15.7 $\pm$ 0.9 for females and 12.9 $\pm$ 0.7 for males ($p < 0.05$). In ethanol-naïve mice, we showed no gender differences in the total number (density) of spines. However, a gender x spine class interaction was observed with females showing greater mushroom spines, compared to elevated thin spines in males. Also, the head and neck size of thin spines were significantly greater in females relative to males. Following EOD drinking, the analysis revealed a significant increase in total spine density in both males and females. Interestingly, however, the class of spines up regulated by EOD drinking also depended on gender, such that females showed elevated thin spines compared to elevated mushroom spines in males. Together, these findings indicate unique gender differences in the expression of both

ethanol escalation and dendritic spine density and morphology during adolescence. Future studies are aimed at determining the potential glutamatergic receptors and signaling proteins involved.

**Title:** Sex differences in ethanol consumption for alcohol preferring rats

**Authors: P. J. DARIUS**, *M. C. GONDRE-LEWIS
Anat., Howard Univ. Col. of Med., Washington, DC

**Abstract:** Excessive alcohol drinking is a nationwide problem, which has not been extensively and specifically investigated in women. Epidemiological studies suggest that among the heaviest drinkers, women experience a greater number of problems as a result of their drinking than men do. The NIAAA published that female alcoholics have death rates 50 to 100 percent higher than those of male alcoholics, including deaths from suicides, alcohol-related accidents, heart disease, stroke, and liver cirrhosis. In the current study, we focus on quantifying sex differences in alcohol drinking behavior using an operant self-administration model in rodents. Genetically alcohol-preferring (P) and non-preferring (NP) rats 3-5 months old were trained in an operant drinking chamber to lever press for a 10% ethanol reward. Ethanol delivery was set to an FR4 schedule; i.e., the rats must press the lever 4 times to receive 2 sec of access to an ethanol drinking cup. Rats were placed in the operant drinking chamber for three thirty minute sessions with two forty-five minute break periods. The number of lever presses and volume consumed were recorded as a reflection of the motivation to seek and consume ethanol. Our results showed that over a three week period, females typically lever pressed ~30% less and consumed ~17% less volume than males. When males lever pressed more robustly than females, they regularly exhibited less operant efficiency meaning that for every mL of ethanol consumed, the operant registered a greater percentage of lever presses by males than females. Interestingly, our results also revealed that while male rats usually consume more absolute volume of ethanol, female rats consistently drink ~36% more ethanol per kg of bodyweight than males do. These results suggest that while male rats are likely to work harder to consume slightly more ethanol, females are still more prone to consume significantly more ethanol than males given their size. These data provide an innate biological basis for studies on sex differences in functional brain mechanisms

following excessive alcohol consumption. It is likely that female circuitry is differentially activated in the presence of alcohol.

**Title:** Alcohol specific effects of progesterone cycling on the amplitude of the P300 ERP component in adolescent human females

**Authors: *A. DOMINGO**, N. M. CAMERON, S. LASZLO
Dept. of Psychology, Binghamton Univ., Vestal, NY

**Abstract:** Prior research has demonstrated that the amplitude of the P300 component of the Event-Related Potential (ERP) is reduced in adolescents who are at risk for developing substance use disorders. This effect, the P3AR (P300 Amplitude Reduction), is longitudinally predictive of the development of substance use disorders in adolescents. Here, we investigated whether the relationship between the P300 and alcohol responsivity, in particular, might be modulated by progesterone cycling in adolescent females. The luteal (high progesterone) phase of the menstrual cycle has previously been shown to be associated with greater alcohol consumption. We therefore hypothesized that the P3AR, as a potential predictor of substance abuse, might be larger during the luteal phase. To examine this hypothesis, we collected ERPs from 28 adolescent females (mean age=16.3 years ± 2.5 years) while they performed two oddball P300 tasks: one to detect rare alcohol images in a stream of images of non-alcoholic drinks, and one to detect rare meat images in a stream of images of foods with no meat in them. In addition to ERPs, we collected saliva samples for subsequent progesterone assay. Participants were asked to return to the lab 2 or 6 weeks after their first visit (i.e., in the obverse of their menstrual cycle) and saliva samples and ERPs were once again collected. Results indicate that the P3AR is larger during the luteal phase of progesterone cycling, and that this is true only for alcoholic stimuli, indicating that the progesterone sensitivity of the P3AR is at least somewhat alcohol

specific. An important interpretation of this result is that if P3AR is to be used as a predictor of adolescent substance use, progesterone is a moderating factor that should be considered along with raw P3AR measures.

**Title:** Factors influencing the acquisition and retention of spatial memories in juvenile rats

**Authors: *N. TZAKIS**, B. HOFFE, M. R. HOLAHAN
Carleton Univ., Ottawa, ON, Canada

**Abstract:** The neural mechanisms by which environmental stimuli are consolidated and stored as stable, long-lasting memory representations in the brain remain elusive. Investigations into the neural structures that mediate memory processing, and the development of connectivity patterns within those structures, have provided the foundation required to gain insight into the memory consolidation process. An understanding of how memories are stored, consolidated and used during the juvenile period, along with the variables that can influence and/or ameliorate those abilities, will provide the next step to answering the fundamental questions concerning the transference of short-term memories into remote stores. The main objective of the current work was to gain insight into the factors that can improve acquisition and retention of spatial memories. Rats were trained on the Morris water maze for 3 consecutive days and then tested either recently (24 hours after training) or remotely (3 weeks after training). The labeling of c-Fos was used as a marker for neuronal activation in the hippocampus and anterior cingulate cortex to assess the contribution of these brain regions in the expression of the recent and remote memories. P50 rats showed enhanced acquisition and recall, while P20, P22, and P24 rats showed facilitated acquisition compared to P18 rats. Rats that were mass trained showed similar acquisition to those that were space trained, however, the space training appeared to facilitate the retention of both recent and remote memories compared to the massed training. Regional analyses of c-Fos in the hippocampus and anterior cingulate will be presented. Based on the behavioral data, we conclude that we conclude that the acquisition and retention of spatial memories improves as the rat develops, and that the retention of spatial memories can be facilitated be space training.

**Abstract:** Obesity is associated with adverse cognitive outcomes. Its growing prevalence during adolescence is alarming, because this is a period of radical neurocognitive shaping. In rodent models, it was recently shown that adolescence is particularly vulnerable to the effect of high-fat diet (HFD)-induced obesity leading to impaired hippocampal-dependent memory associated with altered glucocorticoid system. However, the mechanisms underlying these cognitive deficits remain elusive. The endocannabinoid system (ECS) and type-1 cannabinoid receptors (CB1R) participate in obesity, regulate memory processes and are under the control of glucocorticoids. Thus, we assessed in mice whether the effects of adolescent HFD consumption on memory function are dependent on the ECS.
We first showed that adolescent HFD consumption impaired long-term, but not short-term, object recognition memory when mice were trained without habituation to the training context. Training induced higher 1) circulating corticosterone, 2) hippocampal endocannabinoid levels (specifically anandamide) and 3) c-Fos activation in the hippocampus, perirhinal cortex and basolateral amygdala in HFD-fed mice than in control mice. Systemic post-training blockade of glucocorticoid receptors or CB1R prevented HFD-induced memory deficits and normalized c-

Fos over-activation specifically in hippocampus. Interestingly, training-induced occlusion of in vivo hippocampal long-term potentiation was absent in HFD group but rescued after CB1R blockade. Finally, hippocampal CB1R deletion and chemogenetic inhibition of hippocampal glutamatergic cells both rescued recognition memory in HFD-fed mice suggesting that CB1R-dependent disinhibition of principal hippocampal neurons is responsible for HFD-induced memory deficits.
Together these results clearly demonstrate that HFD consumption during adolescence alters the hippocampal ECS leading to impairment of hippocampal synaptic plasticity and memory consolidation.

**Abstract:** The cognitive ability to generalize previous experiences allows animals to select appropriate behaviors when confronting similar situations. However, overgeneralization of fear responses to similar experiences could lead to the development of different anxiety disorders. In fact, overgeneralization has been considered an important biomarker for Posttraumatic stress disorder (PTSD). Studies in our lab have shown a relationship between memory generalization and hippocampal dependency; in that case, hippocampus is necessary for precise memory retrieval but no longer involved during retrieval of generalized memories. Nowadays, the first-line pharmacological treatment for PTSD is fluoxetine, an antidepressant of the selective serotonin reuptake inhibitor (SSRI) class. Since overgeneralization is an important characteristic for the diagnosis criteria of PTSD and fluoxetine a hallmark of pharmacological treatment, here we investigated the effects of chronic administration of fluoxetine on hippocampal dependency and memory generalization and subsequent effects during fear extinction.

Rats were trained in the contextual fear conditioning (4 footshocks, 0.7mA/1s) and treated with fluoxetine (10mg/kg, I.P) during 22 days following to training. In order to evaluate memory precision, animals were tested in both the aversive and novel context after the last administration. The next day, animals underwent an extinction protocol by exposure to the training context during 30min. In order to verify the appropriate fear memory suppression, animals were tested 24h after extinction and retested 21d after extinction in order to evaluate spontaneous recovery. Additionally, chronic treatment of fluoxetine was performed only after the extinction in order to test the effects during spontaneous recovery.
Our results showed that chronic administration of fluoxetine prevents context fear generalization. This effect was strongly associated with hippocampal dependency. Interestingly, memory precision resulting from fluoxetine treatment enhances fear extinction. Despite this effect, both groups expressed spontaneous recovery, a phenomenon that can be reverted by the chronic treatment with fluoxetine between the extinction protocol and spontaneous recovery test. These results suggest that chronic treatment with
fluoxetine facilitates memory precision as well as hippocampal dependency, thus allowing the attenuation of aversive memories through fear extinction. The possibility to enhance fear extinction via preventing fear generalization or spontaneous recovery shows a dual therapeutic window to attenuate aversive fear memories.

**Abstract:** Reconsolidation is the process by which an established memory becomes stable again after being reactivated. Long-term memory stabilisation relies on structural modification and the cellular mechanisms of reconsolidation have been extensively studied. Despite the fact that new neurons are continuously added to the brain and that this adult neurogenesis play an important

role in memory processes, reconsolidation has never been addressed in the context on ongoing hippocampal neurogenesis. The goal of this study is to determine the role of adult-born neurons in memory reconsolidation. We used a behavioural protocol in the Morris water maze to demonstrate that spatial learning undergoes reconsolidation. We then found that, unlike neurons born during development, adult-born neurons that are mature or immature at the time of learning are activated by reconsolidation. In order to investigate a causal relationship between adult neurogenesis and spatial memory reconsolidation, we designed a DREADD retrovirus. When injected into the dentate gyrus of rats, this retrovirus allows us to specifically and reversibly inhibit new neurons during the reconsolidation process. Our preliminary data show that inhibiting, at the time of reactivation, mature neurons that were activated by learning, has no effect on memory retention. However, inhibiting, during reconsolidation, the population of new neurons that was immature at the time of learning and not activated by learning impairs memory retention. These results suggest that adult-born neurons may be necessary for remote memory reconsolidation. All together our results show a clear involvement of hippocampal neurogenesis in spatial memory reconsolidation.

**Abstract:** Mixed evidence exists regarding the role of NMDArs in memory reconsolidation. Some evidence suggests that antagonism of NMDArs is sufficient to disrupt memory reconsolidation, while other evidence suggests that activity downstream of NMDArs is critical for the induction of memory lability. The present work addresses this question using a context fear discrimination approach in which one context (CTX+) is consistently paired with footshock

while the other (CTX-) is never reinforced. Omission of a footshock during the reactivation session constitutes a prediction error, a critical boundary condition gating the induction of reconsolidation. We show that pre-reactivation administration of the NMDAr antagonist MK-801 attenuates freezing behavior during the reactivation session. Additionally, we show that pre-reactivation systemic NMDAr antagonism, combined with post-reactivation intra-BLA protein synthesis inhibition, disrupts the reconsolidation of a context fear discrimination memory—but this pattern of results only emerges following extinction training. Further, NMDAr or protein synthesis inhibition alone produce no effect. These data suggest that NMDArs play a role in memory reconsolidation, but antagonism alone may be insufficient to disrupt reconsolidation. We posit that the deficit emerging following extinction is attributable to a behavioral ceiling induced by strong behavioral training. This deficit is only detectable after the memory is sufficiently weakened by the acquisition of a competing extinction memory. Thus, it may be worthwhile to extinguish behavior following apparently null results (a common outcome in reconsolidation research), as the deficit may be obscured.

**Title:** Involvement of hippocampal cannabinoid type-2 receptors in the reconsolidation of specific and generalized contextual fear memory

**Authors: *R. S. SILVA**, M. GIACHERO, L. J. BERTOGLIO
Pharmacol., UFSC, Florianopolis, Brazil

**Abstract:** The endocannabinoid system plays a key neuromodulatory role during aversive memory processing. Both type 1 (CB1R) and type 2 (CB2R) cannabinoid receptors are highly expressed in many brain regions, including the dorsal hippocampus (DH), a crucial brain region for contextual fear memory reconsolidation. The central CB1 receptor has been shown to contribute on this process. Despite the presence of CB2 receptor in the DH, its role in the reconsolidation of specific or generalized fear memories remains to be understood. The aim of this study was to investigate this matter using the contextual fear conditioning. The protocol consisted of familiarization, fear conditioning (3 shocks of 1.0 mA/3s) and reactivation. One and 7 days later, animals were briefly re-exposed to the paired Context A (Tests A1 and A2). They

were also briefly exposed to a novel Context B one day after Tests A1 and A2 (Tests B1 and B2). Freezing behavior was measured as an index of fear memory. In experiment 1, rats received a bilateral infusion of vehicle (VEH) or the CB2R antagonist (AM630; 1.0 µg/side) into the DH immediately after reactivation. The AM630 treatment reduced freezing time when compared to control during both Tests A1 and A2 (Test A1: 84 ± 4% vs. 33 ± 4%; Test A2: 78 ± 3% vs. 40 ± 5%). No changes were observed during Tests B1 and B2. In experiment 2, a generalized fear memory was induced by systemic administration of yohimbine (YOH), an $\alpha_2$-adrenergic antagonist, and the effect of post-reactivation CB2R infusion into DH was assessed. Rats received a systemic administration of VEH or YOH (2.0 mg/kg) after fear conditioning, and VEH or AM630 intra-DH infusion (1.0 µg/side) or systemic administration of clonidine (CLO; 0.3 mg/kg) after the reactivation session. YOH administration potentiated the fear memory that became resistant to interference by CLO after a reactivation session. However, the post-reactivation AM630 treatment promoted fear memory reconsolidation impairment, leading to a reduction of freezing (Test A1: YOH/VEH = 91 ± 1%, YOH/AM630= 48 ± 2%; Test A2: YOH/VEH = 86 ± 2%, YOH/AM630 = 33 ± 4%). YOH also increased generalized fear response which was also attenuated by AM630 treatment after reactivation (Test B1: VEH/VEH = 17 ± 1%, YOH/VEH = 46 ± 4%, YOH/AM630 = 22 ± 3% / Test B2: VEH/VEH = 17 ± 1%, YOH/VEH = 32 ± 2%, YOH 2.0/AM630 = 10 ± 1%). Altogether, the present results highlight the contribution of DH cannabinoid type-2 receptor on reconsolidation of specific or generalized fear memory, suggesting a relevant modulatory role of CB2R in this contextual fear memory process, otherwise CB1R plays an opposite function over this process.

**Title:** Sex differences in blocking after context fear conditioning

**Authors: D. E. FELDMAN**, A. A. KEISER, *N. C. TRONSON
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

**Abstract:** Previous studies from our laboratory demonstrated that females show stronger generalization after context fear conditioning, suggesting that memory retrieval is different in males compared with females. Here we aimed to determine whether the information that is retrieved in context fear conditioning differs between the sexes. Distinct brain regions mediate different aspects of fear conditioning. The hippocampus compiles distinct features of a fear-

conditioning chamber into a single context representation, the basal amygdala is critical for associations between the context representation and footshock, and the nucleus accumbens plays a role in general expressions of fear and acquisition of context fear conditioning. To examine activation of these brain regions after retrieval of context fear, we assessed cFos activation in hippocampus, basal amygdala, and nucleus accumbens after retrieval of context fear-related memory in males and females. We have previously demonstrated that males show stronger activation of dorsal hippocampus, whereas females show stronger activation in basal amygdala during retrieval of context-fear. In the nucleus accumbens, we observed strong cFos activation during retrieval in both sexes. These data demonstrate sex-specific recruitment of hippocampus and amygdala in retrieval of context fear and suggest a role for nucleus accumbens in both males and females during retrieval. To examine whether the information that is being retrieved in context fear conditioning is different between the sexes we used a blocking paradigm. Both males and females showed strong expression of context fear conditioning, however only males exhibited blocking of a subsequent tone-fear memory. These data suggest that males retrieve a context-shock association that interferes with further learning, whereas females utilize a different strategy during retrieval of context fear conditioning. Overall, our findings demonstrate unique but overlapping patterns of circuit activation between the sexes, and suggest that retrieval of context fear conditioning triggers different cognitive processes in females compared with males.

**Title:** Context fear memory: Escaping the hippocampus

**Authors: S. KISHUN**, *H. LEHMANN
Psychology, Trent Univ., Peterborough, ON, Canada

**Abstract:** Distributed contextual fear conditioning episodes makes the memory become HPC independent, meaning increasingly reliant on non-HPC memory structures. It is unclear, however, whether distribution of the conditioning episodes alone is sufficient or whether a combination of distribution and high conditioning saliency is necessary to make the context fear memory become HPC independent. To resolve this issue, rats were trained under a distributed contextual fear conditioning protocol using either a low (0.4 mA), intermediate (0.7 mA) or high

(1.0 mA) saliency shock, after which they received either sham or neurotoxic lesions of the HPC. Approximately two weeks after the surgery, the rats were given a context fear retention test during which freezing, complete immobility except for breathing, was used an index of memory. Moreover, the study aimed to determine the brain structures supporting the HPC-independent memory by assessing post-test expression of the immediate early gene c-Fos, a commonly used marker of neural activity. During the retention test, it was found that the low saliency (0.4 mA) condition failed to induce a context fear memory. The intermediate saliency (0.7 mA) condition induced robust contextual fear conditioning, as the control rats showed high levels of freezing. The HPC-lesion group in this condition, however, showed significantly less freezing, suggesting that context fear memory, despite being acquired over repeated episodes, was HPC dependent. In the high saliency (1.0 mA) condition, both the control and HPC groups showed high and comparable levels of freezing during the test, suggesting that context fear requires “strongly salient” and distributed episodes to become HPC independent. Importantly, quantification of c-Fos expression across several structures, using unbiased stereology, revealed greater amygdala activation in the rats from the high saliency condition, including the lesion group expressing the HPC-independent context fear memory. Moreover, the c-Fos findings revealed that, regardless of saliency, the repeated conditioning increased the recruitment of the perirhinal and anterior cingulate cortices. Hence, an increased context representation in the perirhinal and anterior cingulate cortices as well as a strengthened fear representation in the amygdala can support an HPC-independent context fear memory.

**Abstract:** Hippocampal formation (HPC) is largely recognised as a brain structure involved in spatial memory. Recently, behavioural and molecular evidence also highlighted the importance of the ventral striatum (VS) in this process. Interestingly, the HPC and the VS are anatomically

connected through ipsilateral glutamatergic projections, arising mainly from the ventral subiculum (vSUB). The purpose of the study was to investigate the role of this pathway in memory consolidation and learning-induced plasticity. To this aim, first we retrogradely traced the vSUB/VS pathway and analysed the amount of spatial learning-induced c-fos expression within this pathway. Next, to demonstrate a causal relationship between the vSUB/VS communication and memory consolidation, we used a pharmacological disconnection approach. Mice were massed trained in the Morris water maze and immediately after training administered with the NMDA receptor inhibitor, AP-5, unilaterally in the vSUB and in the contralateral VS; control mice were injected ipsilaterally in the two brain regions. Only mice contralaterally administered in the vSUB and in the VS were impaired when tested for their ability to locate the platform in probe test 24 hrs later. These findings demonstrate for the first time a functional role of vSUB/VS pathway in spatial memory consolidation. Finally, we found that post-training administration of AP-5 in the vSUB blocks spatial learning-induced increase in dendritic spine density in the VS. Overall our findings suggest that the off-line communication between the vSUB and the VS is a necessary condition for spatial memory formation and learning induced neuronal plasticity in the VS

**Authors: *P. BELLO-MEDINA**, A. C. MEDINA, G. L. QUIRARTE, R. A. PRADO-ALCALA
Inst. de Neurobiología-UNAM, Queretaro, Mexico

**Abstract:** It has been found that interference with neural activity after a consolidated memory is retrieved produces an amnestic state; this has been taken has indicative of destabilization of the

memory trace that would have been produced by a putative process of reconsolidation (allowing for maintenance of the original trace). However, a growing body of evidence shows that this is not a reliable effect, and that it is dependent upon some experimental conditions, such as the age of the memory, memory reactivation procedures, the predictability of the reactivation stimulus, and strength of training. In some instances, where post-retrieval treatments induce a retention deficit (which would be suggestive of interference with reconsolidation), memory is rescued by simple passing of time or by repeated retention tests. We now report that post-training and post-retrieval inhibition of transcription and translation in dorsal striatum, a structure where both of these manipulations have not been studied, produce interference with consolidation and a transitory retention deficit, respectively. These results do not give support to the reconsolidation hypothesis and lead to the conclusion that the post-activation deficiencies are due to interference with retrieval of information. **Title:** Retrieval-relearning: exploiting reconsolidation to strengthen contextual fear memories

**Authors: *J. L. LEE**, L. CASSINI, C. R. FLAVELL
Univ. Birmingham, Birmingham, United Kingdom

**Abstract:** The reactivation of a previously-learned memory, in addition to enabling expression of that memory, can lead its destabilisation. Memory destabilization necessitates subsequent reconsolidation of the memory in order to restabilize it and integrate new information. While pharmacological disruption of the reconsolidation process results in experimental amnesia, behavioral treatment can experimentally update the memory also to diminish subsequent memory expression. However, such reconsolidation-update has thus far been explored almost exclusively in retrieval-extinction procedures. Here, we tested the hypothesis that the reconsolidation-based updating process might also be harnessed to strengthen weakly-learned

memories, using a conceptually analogous retrieval-relearning procedure. A peri-threshold level of contextual fear conditioning was employed that resulted in little subsequent contextual freezing. Brief re-exposure to the conditioned context (retrieval), followed 60 min later by a second peri-threshold conditioning session (relearning) resulted in a strong and persistent contextual fear memory. Reversal of the order of the retrieval and relearning sessions had no such memory strengthening effect. Nor was memory strengthening observed with a more extended 6-hr interval between retrieval and relearning; the latter session thereby falling outside the "reconsolidation window". The retrieval-relearning effect was critically dependent upon cellular mechanisms of hippocampal contextual fear memory destabilization. Infusion of the proteasome inhibitor clasto-lactacystin-β-lactone into the dorsal hippocampus prior to memory retrieval, but not prior to relearning, prevented the effect of retrieval-relearning to strengthen the contextual fear memory. Moreover, the retrieval session engaged cellular mechanisms of destabilization and reconsolidation, including elevated hippocampal Zif268 protein levels. Therefore, memory retrieval that leads to memory destabilization allows memories to be strengthened by subsequent additional learning. The fact that these memory gains exceed those of retrieval alone or relearning alone suggests that retrieval-relearning is a highly effective mnemonic strategy to maximise memory strengthening.

**Title:** On the transition from reconsolidation to extinction of contextual fear memories

**Authors: *L. F. CASSINI**[1], C. R. FLAVELL[1], O. B. AMARAL[2], J. L. C. LEE[1]
[1]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Abstract:** Retrieval of an associative memory can lead to different phenomena. Brief reactivations tend to trigger reconsolidation, whereas more extended re-exposures tend to trigger extinction. Interestingly, in both appetitive and fear cued pavlovian memories, an intermediate "null point" period has been observed, where neither process seems to be engaged. Here we investigated whether this phenomenon extends to contextual fear memory. Adult male rats (lister-hooded) were subjected to a contextual fear conditioning (CFC) paradigm, consisting of training on day 1, reactivation on day 3 and test on day 4. The duration of the reactivation session varied across experiments, lasting for 3, 5, 10, 20 or 30 min. Immediately after reactivation, the amnestic agent MK-801 was injected intraperitoneally (0.1 mg/kg). The aversive response (freezing) was automatically recorded during all sessions and used as index for memory expression. We observed that MK-801 had a significant effect with the 3-min and 30-min reactivation sessions, impairing reconsolidation and extinction, respectively. However, it did not have any significant effect with 5, 10 or 20-min sessions. To investigate if the lack of MK-801 effect was a result of late drug administration, we injected MK-801 30 min prior a 10-min reactivation session. Again, there was no observable effect of the drug, suggesting that the CFC memory is insensitive to disruption at intermediate reactivations regardless of the timing of the intervention. Finally, to determine whether the results observed here reflected a subpopulation effect rather than a genuine "null-point" (i.e. MK-801 impairing reconsolidation in some animals and extinction in others leading to no overall population effect) we performed 5- and 10-min reactivations using large cohorts of animals and correlated the freezing during reactivation and test. We expected the two parameters to correlate in controls, while such correlation would be disrupted if there were subpopulations of animals differentially affect by MK-801. These and other analyses indicated, however, that the lack of effect of MK-801 at the intermediate re-exposure durations is not likely to be a result of subpopulations effect. Rather, our results strongly indicate that in contextual fear memories there is a genuine and extended "null point" between the parameters that induce reconsolidation and extinction, in which the memory is insensitive to any effect of MK-801.

**Title:** Prelimbic cortex is critical for encoding contextual fear memory storage

**Authors: S. SWARNKAR**[1], V. RIZZO[1], K. TOUZANI[1], B. L. RAVEENDRA[1], J. C. LORA[2], B. M. KADAKKUZHA[1], X.-A. LIU[1], C. ZHANG[3], D. BETEL[3], R. W. STACKMAN, JR[2], *S. V. PUTHANVEETTIL[1]

**Abstract:** Prefrontal cortex (PFC) plays a significant role in the consolidation of long-term memories (LTM). However, the cellular and molecular mechanisms critical for memory consolidation within the medial prefrontal cortex (mPFC) microcircuit are poorly understood. Here we investigated the role of new protein synthesis in the mouse mPFC during encoding of contextual fear memory.
We assessed the changes in polyribosome-associated mRNAs in the mPFC following contextual fear conditioning (CFC) in the mouse. We performed polyribosome profiling in the mPFC to identify differentially expressed gene. The role of new protein synthesis in the mPFC was determined by focal inhibition of protein synthesis and by manipulating Homer 3, a candidate identified from polyribosome profiling in the prelimbic cortex. We identified several mRNAs that are differentially and temporally recruited to polyribosomes in the mPFC following CFC. Inhibition of protein synthesis in the prelimbic (PrL) cortex, but not in the anterior cingulate cortex (ACC) region of the mPFC immediately after CFC disrupted encoding of contextual fear memory. Intriguingly, inhibition of new protein synthesis in the PrL 6 hours after CFC did not impair encoding. Furthermore, expression of Homer 3, an mRNA enriched in polyribosomes following CFC, in the PrL constrained encoding of contextual fear memory.
In conclusion, our study identified several molecular substrates of new protein synthesis in the mPFC and established that encoding of contextual fear memories requires new protein synthesis in the PrL subregion of mPFC. This study provides direct implication of the PrL cortex in the encoding of contextual fear memories and reveals a complex temporal and spatial regulation of translation in the mPFC.

**Title:** Reconsolidation of episodic memory processing

**Authors: *K. TAY**[1], J. LEE[2], M. WIMBER[2]
[1]Sch. of Psychology, [2]Univ. of Birmingham, Birmingham, United Kingdom

**Abstract:** Memory reactivation can lead to two phenomena: memory updating/reconsolidation with possibility of having inaccurate memories and memory strengthening. In Study 1, we attempted to replicate previous findings of episodic-like memory reconsolidation that re-exposure to the initial learning context is sufficient to induce reconsolidation. In a visual list-learning paradigm, participants learned 2 lists in different ways on 2 days. The experimental group learned both lists in the same room and with the same experimenter. The control group learned the two lists in different rooms with different experimenters. At test, participants were returned to the original context and recalled images from the 1st day of learning. ANOVA unexpectedly showed no difference in intrusions of Day 2 items into Day 1 recall between Experimental and Control groups, thereby failing to replicate published findings. While the Control Group had poorer recall of Day 1 items compared to a no interference control, performance in the Experimental Group was preserved. This may reflect an effect of training context re-exposure to strengthen the memory and mitigate against the deleterious impact of interfering material. In Study 2, we tested directly the capacity of memory reactivation to facilitate memory strengthening. Participants learned visual object-scene paired associated and two days later were subjected to a retrieval test and/or further learning in the same room and with the same experimenter. When subsequently tested on the paired associate recall, participants that received retrieval followed by relearning, relearning followed by retrieval, or two relearning episodes all had greatly improved performance. Groups that received one or two retrieval episodes performed as poorly as a control group, with all three groups showing evidence of memory decay. Finally, participants that received a single relearning episode performed at an intermediate level, with mild improvement. An idea of implementing 6 hours interval in between Day 2 sessions was suggested, aimed to determine whether or not the learning effect is mediated by reconsolidation processes, showing that participants in retrieval-6 hours-relearning and relearning-6 hours-retrieval groups had improved their performance, in the same manner as retrieval-relearning and relearning-retrieval group. The common effects of retrieval-relearning, relearning-retrieval, relearning-relearning, retrieval-6 hours-relearning, relearning-6 hours-retrieval to strengthen episodic memory may reflect different underlying processes, one or more of which might be related to memory reconsolidation.

**Title:** Boundary conditions on instrumental memory reconsolidation

**Authors: *C. CHENG**, J. LEE, M. EXTON-MCGUINNESS
Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

**Abstract:** Long-term memory can integrate new information through a mechanism called reconsolidation. When reactivated, a memory can destabilize into a labile state, necessitating reconsolidation to restabilize the memory again. Instrumental memories, which associate a particular action with an outcome, have recently been shown also to undergo reconsolidation. Importantly, there appears to be a requirement for prediction error in order to destabilize the instrumental memory. Here, we studied further the behavioral regulation of instrumental memory destabilization. First, we tested the hypothesis that different memories conditioned during training compete at reactivation, thereby influencing destabilization. In particular, training could also result in context-reward learning which competes for destabilization via trace dominance. Thus, if contextual memory is weakened the instrumental memory may be easier to destabilize. Adult male rats were trained to lever press for sucrose reward for 10 days, following which memory was destabilized by shifting the reinforcement schedule to a variable-ratio (VR5). A post-training context-extinction session rendered a subsequent VR5 reactivation session sufficient to destabilize the instrumental memory, as evidenced by an amnesic effect of pre-reactivation systemic injection of MK-801. MK-801 given 6h after VR5 reactivation, or in the absence of prior context extinction, had no impact on later long-term instrumental performance. However, it may not be the context extinction session itself that is necessary, as a simple day off prior to VR5 reactivation was also sufficient to render memory labile. We hypothesized active forgetting of the contextual memory during the day off may take place. To test this we injected memantine on the day off to prevent active forgetting. Interestingly, this facilitated, rather than impaired, instrumental memory destabilization. Moreover, we tested whether the VR5 reactivation could destabilize the contextual memory, thus enabling a second reactivation to destabilize the instrumental component; however, amnestic treatment was ineffective in this, indicating the memory did not destabilize in first reactivation session. Therefore, while there are two behavioural methods, context extinction and a simple day off, which both facilitate

instrumental memory destabilisation, the mechanisms by which they do so and whether they are phenomenologically similar, remain unclear.

**Title:** Reconsolidation-disruption of instrumental lever pressing memory reduces spontaneous seeking for sucrose, cocaine and nicotine reward

**Authors: *M. T. EXTON-MCGUINNESS**, M. L. DRAME, C. R. FLAVELL, J. L. C. LEE
Psychology, Univ. of Birmingham, Birmingham, United Kingdom

**Abstract:** A key obstacle in treating addiction is the high propensity for relapse. Following advances in our understanding of memory, it has been suggested that the propensity for relapse could be reduced by weakening the maladaptive memories that support substance abuse disorders. This is made possible by disrupting the process of reconsolidation, such that an appropriately destabilised memory can be attenuated. We recently demonstrated that instrumental lever pressing memory for both sucrose and cocaine can be destabilised and reconsolidation disrupted, resulting in diminished reward seeking. Here we aimed to expand this finding, investigating whether strongly established reward memories for sucrose, cocaine and nicotine could be disrupted to reduce persistent seeking behaviour. Rats were trained to lever press for either sucrose, or an intravenous drug infusion of cocaine or nicotine; each reward delivery was paired with a short conditioned stimulus (CS) presentation. Following training rats were injected with the NMDAR antagonist MK-801 (or vehicle) 30 minutes prior to a short reactivation session, in which rats were re-exposed to the training scenario except the reward contingency was shifted; this is hypothesised to trigger a prediction error responsible for destabilising the memory trace and initiating the reconsolidation process. Rats treated with MK-801 significantly reduced their subsequent lever pressing for reward, in an extinction test the next day. Interestingly, performance was rescued by contingent presentation of the CS (a conditioned reinforcer); suggesting memory disruption was selective for the instrumental component of memory only. Our work supports not only that the mechanisms of reward-seeking are likely shared between different reinforcers, but that these reward memories can be disrupted

to reduce rates of seeking. This firmly establishes reconsolidation-disruption as a viable therapeutic avenue for reducing relapse in substance abuse disorders.

**Title:** Effects of infralimbic cortex inactivation on performance of moderate and intense inhibitory avoidance training: Anterograde amnesia, state-dependency, or both?

**Authors: *M. E. TORRES GARCÍA**, A. C. MEDINA, G. L. QUIRARTE, R. A. PRADO-ALCALÁ
Dept. de Neurobiología Conductual y Cognitiva, Inst. de Neurobiología, UNAM, Querétaro, Mexico

**Abstract:** We have shown that intense training protects memory from treatments that interfere with memory consolidation, administrated systemically or into specific brain regions, such as hippocampus, striatum, and amygdala. The medial prefrontal cortex (mPFC) has been proposed as a modulator of memory, particularly of aversive events. mPFC includes the anterior cingulate, prelimbic, and infralimbic (IL) cortices, and dissociable roles in memory have been described for each one of them. The aim of this work was to determine whether intense inhibitory avoidance (IA) training also has a protective effect on memory consolidation in rats treated with tetrodotoxin (TTX) in the IL. Rats were trained in IA using a foot-shock of moderate or high intensity (1.0 or 3.0 mA). TTX (3 ng/0.3 µL) or its vehicle (VEH, NaCl 0.9%/0.3 µL), was administered 25 min before training. Thirty min or 48 h later retention was measured. For a state-dependency test TTX or VEH was administered twice: 25 min before training and 25 min before the retention session. Fifteen min and 60 min after training corticosterone levels and c-Fos expression, respectively, were evaluated in rats of all groups. TTX administration impaired retention of IA trained with both moderate and high foot-shock intensities. However, this amnestic effect was state-dependent when the high foot-shock was used. In additional groups, administration of TTX immediately after training induced an amnesic effect in the 1.0 mA group,

while in the group that had been trained with 3.0 mA TTX did not produce alterations in memory consolidation. High retention scores cannot be explained by a learning impairment, as TTX-treated rats showed good retention at 30 min post-training. The corticosterone levels were significantly higher in the group that showed state-dependency. c-Fos expression was inhibited in all the TTX groups as compared with the VEH groups. These results provide evidence that IL is involved in memory consolidation only in moderate training conditions. The unexpected state-dependent effect observed after TTX infusion into IL should be looked for in other cortical areas, as, to the best of our knowledge, it has only been described as occurring in subcortical structures.

**Title:** Remote memories are enhanced by COMT activity trough the dysregulation of the cannabinoid system in the prefrontal cortex

**Authors: *G. CONTARINI**
Dept. Scienze del Farmaco, Univ. of Padua, Padova, Italy

**Abstract:** The prefrontal cortex (PFC) is a crucial hub for the flexible modulation of recent memories (executive functions) as well as for the stable organization of remote memories. Dopamine in the PFC is implicated in both these processes and genetic variants affecting its neurotransmission might control the unique balance between cognitive stability and flexibility present in each person. Functional genetic variants in the catechol-O-methyltransferase (COMT) gene result in a different catabolism of dopamine in the PFC. However, despite the established role played by COMT genetic variation in executive functions, its impact on remote memory formation and recall is still poorly explored. Here we report that transgenic mice overexpressing the human COMT-*Val* gene (*COMT-Val-tg*) present exaggerated remote memories (>50 days),

while having unaltered recent memories (<24-hour). COMT selectively and reversibly modulated the recall of remote memories as silencing the COMT Val overexpression starting from 30 days after the initial aversive conditioning completely normalized remote memories. *COMT* genetic over-activity produced a selective overdrive of the endocannabinoid system within the PFC, but not in the striatum and hippocampus, which was associated with remote memories. Indeed, pharmacological blockade of CB1R on remote recall in *COMT-Val-tg* mice was sufficient to rescue memory alterations. These results demonstrate that COMT genetic variations modulate the PFC-dependent retrieval of remote memories through the dysregulation of the endocannabinoid system in the PFC.

**Abstract:** It is well known that interference with neuronal activity in structures associated with memory consolidation after moderate inhibitory avoidance training produces an amnestic effect. However, when animals are trained under intense training conditions such interference becomes innocuous. To further analyze the protective effect of intense training against amnesic treatments, groups of Wistar rats received local administration of the protein synthesis inhibitor

anisomycin (ANI) or its vehicle (VEH) in the dorsal striatum, and then were trained in a one-trial step-through inhibitory avoidance task, using moderate or high electric foot-shock intensities (1.0 or 3.0 mA). Forty-eight hours after training retention latencies were recorded. Moreover, measurements of serotonin and acetylcholine were made in this structure. We also determined the area and intensity of inhibition of anisomycin measuring Arc (Activity-regulated cytoskeletal associated protein) protein expression in rats that received ANI or VEH. The results showed that administration of ANI produced amnesia in the group that had been trained with the moderate foot-shock intensity, but retention was not impaired when the high foot-shock intensity was used. Furthermore, the administration of ANI did not change acetylcholine content, but, in contrast, there was a significant increase in serotonin. These findings suggest that de novo protein synthesis in the dorsal striatum is not necessary for the consolidation of intense emotionally arousing experiences, and, interestingly, ANI has a differential effect on the content of acetylcholine and serotonin, both of which are involved in striatal-dependent memory consolidation of moderate inhibitory avoidance training. **Title:** Estrogen depletion in female rats decreases glia expression in hippocampus and amygdala and affects memory formation in a “single trial learning” test

**Authors: S. ERCAN**, R. L. DAVIS, *K. S. CURTIS
Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

**Abstract:** Decreased estrogen has been linked with impairments in several types of hippocampal-dependent memory, including spatial working memory and object recognition, in postmenopausal women. In contrast, studies of a role for estrogen in a different aspect of memory formation - encoding, consolidation and recall - have generated controversy and conflicting findings. In animal models, open field and object recognition tests are used to assess short-term memory, or long-term memory after prolonged training. Thus, these tests have limited applicability to long-term memory which is encoded by single trial acquisition and cued-recall

and more closely mimics everyday learning experiences. The long-term synaptic plasticity that underlies many forms of memory involves not only neurons, but also astrocytes and microglia; however, it is unclear whether estrogen-induced changes in glia may be important in long-term memory associated with single trial acquisition and cued-recall. Accordingly, we evaluated these relationships in adult female rats that were ovariectomized (OVX; n = 5) or remained intact (n = 5). Rats were habituated to the test arena on Day 1-7 (10 min/day of free exploration). On Day 8, a novel object (plastic cylinder) was placed in the arena, along with the presentation of a novel odor (cinnamon) and a sound recording (146.83 Hz/10 sec duration/1 min intervals). Three days later, a 10-min recall test was conducted in the arena with only odor and sound cues present. Rats' behaviors on both days were videorecorded and evaluated offline using EthoVision software. Rats were sacrificed after the recall test; brains were removed and frozen prior to taking tissue punches from the hippocampus and amygdala to analyze markers of astrocytes (GFAP) and microglia (CD68) activation using Western blots. OVX rats oriented to and explored the location that previously contained the novel object significantly more than did intact rats during the recall test. Interestingly, after 3-4 visits to that location, the latency between subsequent visits increased more rapidly in intact rats. CD68 and GFAP expression in the hippocampus and amygdala was significantly less in OVX rats than in intact rats. These results suggest that estrogen deficiency does not impair cue-triggered, long-term memory of an object under these testing conditions, and may enhance it. Alternatively, estrogen deficiency may lead to perseveration of exploratory behaviors in response to odor and sound cues in the absence of the object. In either case, alteration of these processes occurred in parallel with changes in astrocytes and microglia expression in CNS areas classically implicated in learning and memory.

**Authors: *J. M. POVROZNIK**, J. W. SIMPKINS, E. B. ENGLER-CHIURAZZI
Physiol. and Pharmacol., West Virginia Univ., Morgantown, WV

**Abstract:** Neurological disorders are associated with substantial medical, financial, and human costs. Tools for facilitating the assessment of functional consequences of brain diseases and their therapeutic interventions are increasingly needed. One commonly utilized rodent test of episodic memory is object recognition (OR), a task with high translational validity often chosen given its ease of implementation, the short duration of testing required, and the interpretability of the simple behavioral output. This test relies on the natural proclivity of rodents to seek out and explore novelty. In brief, after an acclimatization period in an open field, animals are presented with two objects on two discrete trials. For the first trial, objects are identical. After a delay period (1-48 hours), animals are again placed in the open field and presented with two objects, one novel and one from the first trial. On these delay trials, animals with intact memory predominantly explore the new object while memory-impaired animals will not differ in their object exploration. However, inter-laboratory inconsistencies in apparatus set-up and nuances in procedural aspects of testing have led to reliability and replicability challenges within the field of pre-clinical learning and memory. To address the issues in the context of the current emphasis in reproducibility and rigor in the conduct of scientific studies, we evaluated a procedure for conducting OR that addresses two important components that often vary between laboratories that utilize this task: 1) rodent acclimatization procedures and 2) objects used during test sessions. In a series of studies, during rodent acclimatization, male mice were acclimated to both the open field apparatus, as well as a 3D-printed training object for 5-min durations for 7 consecutive days. To acclimate to the objects used during testing sessions, male mice were placed in the OR apparatus with two differently-shaped, 3D-printed objects that were both novel to the mouse for 5-min testing sessions. We sought to identify behavioral benchmarks for appropriate acclimation levels among experimental subjects prior to testing. We generally observed low levels of object exploration following this acclimation process, limiting the ability to interpret object-object differences in exploration. Importantly, this finding suggests that apparatus acclimation procedures play an important interactive role in behavior performance on OR, and provides insight into optimizing this process. It is our hope that our findings will reduce variability within an experiment and support increased replicability both within and between laboratories.

**Title:** Medial prefrontal cortex and secondary motor cortex are critical for the performance of an olfactory working-memory task in mice

**Authors: *A. BELLAFARD**, P. GOLSHANI
Univ. of California Los Angeles, Los Angeles, CA

**Abstract:** Working memory is defined by the ability to store information for short periods of time (seconds) in the absence of ongoing sensory input. While a number of brain regions vital for working memory have been identified, and persistent activity in these regions has been recorded during working memory tasks, we still do not understand the mechanisms by which an ensemble of neurons generate these ongoing activity patterns. To gain more insight into this problem, we have trained head-fixed mice to perform an olfactory working-memory task, in which head-fixed mice compare the identity of two discrete odors separated by a five second delay period. We show that mice learn the task reliably and rapidly, allowing us to assay network dynamics during both learning and performance of the task. To determine which brain regions were critical for task performance, we made stereotactic injections of muscimol into different brain regions and tested behavioral performance on the task. Muscimol injections into medial prefrontal and secondary motor cortices greatly worsened task performance, while muscimol injections into posterior parietal cortex had no effect. Using in vivo two-photon calcium imaging in mice expressing the genetically encoded calcium indicator GCAMP6s, we recorded the activity patterns of hundreds of neurons over multiple days. We find task-modulated activity in a subset of neurons during the delay period. We address the question of whether and how the ensemble of neurons can generate sequential activity, and how this activity is linked to the working-memory.

**Abstract:** The prefrontal cortex, particularly its most ventral regions, i.e., prelimbic cortex (PLCx) and infralimbic cortex, has been associated with mnemonic, emotional, and cognitive processes, as well as in the modulation of encoding of fear memory. In this work we studied the participation of PLCx in the process of memory consolidation. It has been found that with moderate intensities of an aversive reinforcer, administration of inhibitors of protein synthesis during the consolidation phase, in different structures such as the striatum and hippocampus, causes an amnestic effect; however, with higher intensities of the reinforcer memory is protected against this amnestic effect. There are no published data regarding this protective effect after interference with protein synthesis in PLCx. In the present experiment anisomycin (31.25 mg/0.5 ul) or saline (vehicle), was administered into PLCx cortex of male rats of the Wistar strain 30 minutes before training in an inhibitory avoidance task, with a moderate (1.0 mA), intermediate (2.0 mA) or intense (3.0 mA) foot-shock. Anisomycin produced an amnestic state only in the group that had been trained with 1.0 mA. Results of control manipulations demonstrated that the amnestic effect was not due to state-dependency, or to alterations in acquisition. These data indicate that the normal activity of the PLCx is essential for memory consolidation of moderate learning, but not in conditions of intense training.

**Abstract:** Rottlerin is a multifunctional drug that has been used to treat cancer cells in the preclinical trials. It inhibits eukaryotic elongation factor 2 kinase (eEF2K), which increases the brain-derived neurotrophic factor (BDNF) protein levels in the hippocampus. The eEF2K, which phosphorylates eukaryotic elongation factor 2 (eEF2), isone of the downstream signaling molecules of the *N*-methyl-D-aspartic acid receptor (NMDAR).Moreover, rottlerin is a mitochondrial uncoupler that affects many protein kinases, such as PKC, Akt/PKB, and extra cellular-signal-related kinases 1/2 (ERK1/2).Likewise, MK-801, a non-competitive antagonist of NMDAR, exerts a fast-acting antidepressant-like effect through the eEF2K inhibition-mediated increase of BDNF protein in the hippocampus. Both the NMDA receptor and PKC have long been implicated in the normal function of learning and memory. Blockade of NMDA receptor prevents long-term potentiation(LTP), a cellular mechanism underlying learning and memory. Furthermore, the NMDA receptors in the dorsal hippocampus are involved in the establishment of long-term memory of passive avoidance (PA) task.
PA is a one-trial learning task used to assess aversive learning and memory. It is also widely used in the preclinical research to measure avoidance/aversive behavior, which is one of the symptom clusters in the posttraumatic stress disorder (PTSD). We sought to examine the effect of two antidepressants, rottlerin and MK-801, on memory acquisition, consolidation/reconsolidation, and retrieval of the PA task. Since both rottlerin and MK-801 increase BDNF protein in the hippocampus, which plays an essential role in enhancing long-term memory, we next examined whether the effects of rottlerin and MK-801 on PA is *via* changes in BDNF and/or other biochemical mechanisms in the hippocampus.
Our results indicate that systemic rottlerin impaired memory acquisition and consolidation of PA, but had no effect on memory retrieval. Systemic MK-801 impaired acquisition of the same aversive memory, which may be confounded by drug-induced change of shock sensitivity. Intriguingly, MK-801 facilitated memory consolidation and retrievalof PA. We also found that the intra-hippocampal infusion of rottlerin significantly impaired memory acquisition and consolidation of PA, indicating the effects of rottlerin are *via* the hippocampus. However, the biochemical mechanisms in the hippocampus underlying the effects of rottlerin and MK-801 on PA memory are currently under intense investigation.

**Title:** Sex difference in the effect of rimonabant on cocaine memory in mice

**Authors: *M.-L. LAI**, H.-A. CHANG, W. DAI, S.-J. HU
Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

**Abstract:** Cannabinoid $CB_1$ receptors are implicated in various forms of learning and memory, including cocaine-associated memory. Rimonabant is well recognized as a $CB_1$ receptor antagonist/inverse agonist. We previously found that systemic or intra-medial prefrontal administration of rimonabant facilitates memory consolidation of conditioned place preference (CPP) induced by a low-dose cocaine, but impairs that induced by a high dose in male wild-type mice. The current study aimed to investigate the receptor and hormone mechanisms underlying the facilitating effect of rimonabant on cocaine-induced CPP. We first examined whether $CB_1$ receptors mediates rimonabant's effect by using $CB_1$ knockout mice. We found that rimonabant neither facilitated memory consolidation of a low-dose (10 mg/kg) cocaine-induced CPP nor impaired that induced by a high dose (20 mg/kg) in male $CB_1$ knockout mice. However, it is intriguing to find that rimonabant impaired 40 mg/kg cocaine-induced CPP memory in male wild-type and $CB_1$ knockout mice, implying other receptors may be involved when cocaine dosage is high as 40 mg/kg. Moreover, rimonabant did not affect cocaine CPP memory in female wild-type and $CB_1$ knockout mice. Furthermore, the facilitating effect of rimonabant on cocaine-induced CPP was found to be mediated by increase of the plasma corticosterone levels in male wild-type mice. Next, to examine whether estrogen is involved in this sex difference effect, we examined the effects of rimonabant on a low-dose cocaine-induced CPP in vehicle-treated *vs.* estrogen-treated ovariectomized (OVX) female wild-type mice and found two interesting results. First, estrogen replacement in the OVX mice *per se* enhanced the low-dose cocaine-induced CPP memory. Second, rimonabant facilitated cocaine-induced CPP memory in the OVX mice supplied with sesame oil, while impaired the same memory in the OVX mice when combined with estrogen. Taken together, our results indicate: 1) The modulatory effect of rimonabant on cocaine-induced CPP is mediated by $CB_1$ receptors and corticosterone in male wild-type mice; 2)

Estrogen is involved in sex difference in the facilitating effect of rimonabant on cocaine-associated memory.

**Title:** Effects of the retrieval-extinction and extinction-retrieval procedures on cocaine-associated memory

**Authors: *Y.-C. CHEN**, H.-A. CHANG, M.-L. LAI, S.-J. HU
Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

**Abstract:** Substance abuse has been a serious health issue. Millions of people in the world are suffering adverse consequences of substance abuse. Numerous studies have tried to solve drug addiction problems by pharmacological methods. However, most of the drugs in clinical use either are less effective or cause aversive side effect. It is of importance to note that there is no pharmacological intervention available for cocaine addicts. Recently, several studies suggest that a specific behavioral procedure, a reactivation followed by an extinction, effectively attenuates drug-associated memory. Nevertheless, the underlying mechanism of this behavioral procedure is challenged under some circumstances. We therefore underwent the aforementioned behavioral procedures with some modifications on cocaine-induced conditioned place preference (CPP) paradigm in mice and examined whether the behavioral procedures are as efficient as previously described. The modifications included the reverse sequence of reactivation and extinction, the elevation of cocaine dosage, the insertion of a re-training session, and the comparison with naïve mice. Our findings indicate that there is no significant difference among the extinction only, the retrieval-extinction, and the extinction-retrieval procedures. However, we found that the effects of the behavioral procedures depend on the dosage of cocaine used in the CPP paradigm. The behavioral procedures effectively suppress the cocaine-associated memory induced by the high-dose cocaine. Furthermore, mice received all three different behavioral procedures express the same level of resistance to high-dose cocaine in the re-training and the priming sessions. On the

other hand, the behavioral procedures only attenuate the low-dose cocaine-induced CPP tested 24 h after the procedures, but not the memory tested 24 h after the re-training and immediately after the priming sessions. Therefore, the effects of the retrieval-extinction and related behavioral procedures on cocaine-associated memory reconsolidation awaits further investigation.

**Abstract:** OBJECTIVE: Investigate the impact of Mozart's music (k448) in the short and long term memories of an adult animal. METHODS : 20 young adults Wistar male rats, weighing between 120 and 180 g and 28 days old, from the laboratory of the Medical School of Itajubá,separated in two experimental groups, Mozart (n = 10) and Control (n = 10) . The Mozart group was exposed to the piano Sonata k448, for 8 hours daily, from 10 p.m. until 6 a.m. for 30 days. The Control group was exposed to ambient sound in the same period. Prior to the test, a habituation period was carried out for three days. After two days of these habituation, the rats were placed for 5 minutes in the arena to explore 2 identical objects. After 1 hour and 30 minutes of training, the animals were subjected to a Short Term Memory Test in which they explored the arena for 5 minutes in the presence of a familiar object (object A) and a new one (object B). 28 days after the Short Term Memory Test, the animals were subjected to Long Term Memory Test for 5 minutes for 5 consecutive days in which they explored a familiar object (object A) and a new object (object C). The values obtained were analyzed by Test t. Significance was defined as $p < 0.05$. RESULTS: The exploration percentage of the new object B, during the Short-term Test (2 days after the Object Recognition Training), revealed that rats of the group Mozart presented higher value (Mozart = 79.22%) when compared to the Control group (Control = 58.87%);

showing statistically significant difference (p <0.05). The exploration percentage of the new object C, during the long-term test (28 days after the Object Recognition Training), did not indicate statistically significant differences between the groups after the analysis with Test t (p> 0.05). CONCLUSION: The effect of Mozart's Sonata had significant impact on the short term memory of the rats.

**Title:** Effects of hypergravity exposure on recent and remote associative memory in rats

**Authors: J.-L. MOREL**[1], A. PULGA[1], A. VANDEN-BOSSCHE[2], *B. BONTEMPI[1]
[1]Inst. of Neurodegenerative Diseases, CNRS UMR 5293, Bordeaux, France; [2]Sainbiose, UMR INSERM 1059, Saint Etienne, France

**Abstract:** Prolonged exposure to decreased gravity experienced by astronauts during extended spaceflights (i.e. microgravity) and its counterpart, hypergravity, which is induced at the time of lift-off and spacecraft re-entry, have been reported to alter spatial memory as measured in several ground-based rodent models of altered gravitational states. However, dissociating the effects of gravity changes on spatial memory per se from those related to alterations in spatial perceptions or locomotor activity has proven challenging. Another nongravitational factor is stress, a physiological parameter known to interfere with cognitive functions. To reduce the impact of these potential confounds, we sought to characterize the effects of hypergravity on the organization of recent and remote memory in adult Sprague Dawley rats submitted to the social transmission of food preference task (STFPT) tailored to probe nonspatial associative olfactory memory in their home cage. Chronic exposure to hypergravity at 2G was achieved by placing rats into a centrifuge. Control rats were kept in normogravity (1G). In a first protocol, hypergravity exposure lasted 60 days prior to memory testing in the STFPT. Memory retrieval

was probed either 1 day (recent) or 30 days (remote) after social interaction. Results show that control and hypergravity groups interacted similarly upon encoding. Retrieval performance was comparable, indicating that encoding, consolidation and retrieval processes were left unaffected by chronic hypergravity exposure. In a second protocol, the impact of hypergravity was restricted to the memory consolidation process. Rats were centrifuged at 2G during the 21 day post-encoding period and tested for memory retrieval at 30 days. Again, no significant difference in performance between control and hypergravity rats was observed, indicating a lack of effect of hypergravity on the formation of remote memory. Upon testing in both protocols, control and hypergravity rats exhibited comparable levels of corticosterone, ruling out any persistent effect of stress. Taken together, our results reveal no deleterious effects of hypergravity on recent and remote memory and point to mild hypergravity exposure as a potentially useful countermeasure following extended spaceflights to restore microgravity-induced physiological alterations.

**Title:** Nucleus reuniens activity during consolidation influences fear memory specificity and long-term maintenance

**Authors: *L. J. BERTOGLIO**, M. A. BICCA, F. TROYNER
Univ. Federal Santa Catarina, Florianopolis, Brazil

**Abstract:** The nucleus reuniens (NR) has been identified as a hub for functional connectivity between the medial prefrontal cortex and the hippocampus. Hence, one could anticipate that activity in this thalamic subregion would be decisive for processes in which both brain regions have been implicated, such as memory consolidation. The objective of the present study was to investigate whether temporary NR inactivation immediately after acquiring a contextual fear memory could interfere with its features, namely specificity and long-term maintenance. Male Wistar rats were fear conditioned to context A with three shocks and then infused intra-NR with vehicle (VEH) or the GABA-A receptor agonist muscimol (MUS). Animals were re-exposed to the paired context A (Test A) and to a novel and unpaired context B (Test B) at recent (on days 1 and 2) or remote (on days 21 and 22) time points. In both cases, MUS-treated animals presented a statistically significant increase ($p < 0.05$) in freezing time (%) during Test B when compared with VEH-treated animals ($37 \pm 3$ vs. $16 \pm 3$ and $26 \pm 4$ vs. $11 \pm 3$, respectively), indicating

impaired contextual specificity. MUS-treated animals also spent significantly more time freezing than those treated with VEH during Test A (83 ± 4% vs. 61 ± 9%) at the remote time point, which indicates increased fear memory persistence over time. When context A was paired with a single shock, behavioral pattern was consistent with that abovementioned: MUS-treated animals expressed generalized fear at both time points evaluated and higher freezing time during Test A at the remote time point. We questioned whether augmented freezing time during Test B resulted from changes in anxiety-related behaviors and/or general exploratory activity. To investigate this possibility, additional animal groups were infused with VEH or MUS into the NR immediately after contextual fear conditioning. On day 1, both groups performed Test A, and 24 h later, they were tested in the elevated plus-maze (EPM) to coincide with the temporal window used to assess freezing time during Test B. Behavioral assessment in the EPM showed no significant MUS effects on inhibitory avoidance, risk assessment or general exploratory activity, indicating the MUS-induced increase in fear expression during Test B is unrelated to altered levels of anxiety and general exploratory activity. Altogether, present results indicate that NR activity during consolidation of a fear memory modulates its specificity and long-term maintenance.

**Title:** Autophagy inhibition is required for long term depression in hippocampus

**Authors: *H. SHEN**[1], Z. LI[2]
[1]Nantong Univ., Jiangsu, China; [2]national of institute, Bethesda, MD

**Abstract:** Autophagy is a process of self-degradation that involves the formation of a membrane around a portion of the cytoplasm, sequestering proteins and organelles, and the fusion of the resultant vesicle with lysosomes for degradation. Our laboratory recently found that autophagy contributes to the turn over of synaptic vesicles. However, the significance of autophagy for postsynaptic plasticity remains unclear. Here, we show that autophagy inhibition is required for

LTD and AMPA receptor internalization in hippocampal neurons. LTD and AMPA receptor internalization are blocked by pharmacologically activating autophagy with rapamycine (RAP). In hippocampal slices from the CA1 region specific Atg5 knockout mice, in which the autophagic activity decreases in postsynaptic neurons, LTD is facilitated whereas LTP remains intact. Furthermore, contextual fear conditioning is impaired in the CA1 region specific Atg5 knockout mice. These data indicate that there is an unexpected link between autophagy and postsynaptic plasticity.

**Title:** Testing for cognitive impairments in a mouse model for congenital muscular dystrophy

**Authors: *A. SAYED**[1], R. B. SHER[2], G. A. COX[3]
[1]The Jackson Lab., Bar Harbor, ME; [2]Stony Brook Univ., Stony Brook, NY; [3]Jackson Lab., Bar Harbor, ME

**Abstract: Background:** Congenital muscular dystrophies (CMDs) include over 30 types of autosomal recessive muscular disorders with an onset at birth and rapidly progressing symptoms. Clinical manifestations of CMD symptoms result in muscle weakness and resulting delayed/arrested motor abilities. Many of these disorders include respiratory, cardiac illnesses and delayed speech development.
**Our Focus:** In our project, we plan to concentrate on Congenital Muscular Dystrophy with Megaconial Myopathy (MDCMC), a rare type of CMD, in which patients manifest muscular dystrophy with enlarged mitochondria localized at the cellular periphery and severe cognitive impairments. MDCMC has been shown to arise as a result of mutation in the Choline Kinase beta (*CHKB*) gene that codes for the enzyme choline kinase beta, which helps in phosphorylating choline to phosphocholine in the Kennedy pathway in skeletal muscles. We have discovered a C57BL/6J mouse with a 1.6kb deletion in the choline kinase beta gene, which showed a phenotype as described above, making it an excellent model for the study of MDCMC. Since, then we have engineered a transgenic muscle-specific rescue mouse by injecting mouse *Chkb* gene under the control of titin promoter. Following this, and using behavioral assays and equipment, we tested for muscle strength and function in our muscle-specific rescue mice, proceeding to use them to test for cognitive impairments seen in patients.

**Results and Future Directions:** Our muscle-specific rescue mice were rescued for mitochondrial size and number as seen in our transmission electron microscopy. Muscle-specific rescues showed muscle strength and function similar to those of our controls but were not significantly different from the control mice in cognitive function. We will continue to explore cognitive function with an intensive Lipidomics analysis of tissue from brain, skeletal muscle and liver of our muscle-specific rescue and control mice using mass spectrometry. Encouraged by the success of our transgene in the rescue of MDCMC, we are now developing a gene therapy strategy with AAV vectors for direct translation in humans. Along with gene therapy we have also looked at methods of dietary modifications for the rescue and /or alleviation of MDCMC disease symptoms.

**Authors: M. SHYFUL ISLAM**, S. MORIMOTO, *S. KOMAI
Nara Inst. Sci. and Technol., Ikoma, Japan

**Abstract:** Behavior is an important language for social communication, which promotes mutual interactions in social context. In many neuro-developmental disorders in human, such as autism spectrum disorder (ASD), social interaction is disrupted. Appropriate diagnosis and treatment is very important for the improved quality of life of ASD patient. The diagnosis of ASD is made by its behavioral criteria, determined by a physician, which depends on her/his experience. If a physician is lack of experience, she/he may end up with a wrong diagnosis. Even in animal model of autism, classical analyses of behavior are carried out by human. Disadvantages of that are some of the important features behind the background, which are not apparently visible (subtle behavioral changes), may be overlooked, or are not analyzed due to the complexity of the behavioral connection during human performance. In addition, it is very laborious and prone to lead misinterpretation of behavioral data. To overcome laborious process, and analysis of maximum features of behavioral data (both conspicuous and subtle) for correct diagnosis of ASD, advantage of modern technology (motion feature extraction and analyzing system) can be employed. In order to preliminary screening of feasibility of employment of this system in

diagnosis of ASD, we performed computer aided motion feature extraction system for analysis of behavioral features in our present study on ASD model of mice. ASD model in mice was induced by sodium valproate. The model mice were video-recorded in an open field either in single or in paired. Then, behavioral features were extracted and analyzed. The results, obtained by using this system, clearly distinguished the subtle changes in the motion of locomotor activity of mice and even identified behavioral transition in ASD model mice from control mice. Thus, it lays the pavement for the potentiality of generalized use of this method both for animal model and for human in future.

**Authors: *A. SHARP**[1,2], S. LERTPHINYOWONG[1,2], S. BULIN[1,2], D. PAREDES[1,2], A. SULLIVAN[2,3], I. THOMPSON[3], R. LEACH[3], J. GELFOND[3], T. JOHNSON-PAIS[3], D. MORILAK[1,2,3]
[1]Pharmacol., [2]Ctr. for Biomed. Neurosci., [3]Cancer Therapy & Res. Ctr., UT Hlth. San Antonio, San Antonio, TX

**Abstract:** Androgen deprivation therapy (ADT) is a standard treatment for prostate cancer, but ADT induces lasting and profound cognitive impairment in a majority of patients, significantly reducing quality of life for survivors and their families. Neuroimaging studies indicate reduced grey matter volume and hypoactivity in the medial prefrontal cortex (mPFC) after ADT. Further, cognitive impairment persists and increases in severity throughout the duration of treatment, suggesting that it may be possible to slow or reverse the impairment. Vortioxetine is a novel, multi-modal antidepressant drug, which has been shown to improve cognitive impairment in depressed patients. We have shown previously that chronic vortioxetine treatment rescues deficits in reversal learning on the Attentional Set Shifting Test (AST) induced by chronic cold stress in rats. In the present study, we investigated whether ADT by physical castration in male Sprague-Dawley rats causes deficits in mPFC function, and if chronic dietary vortioxetine treatment reverses these deficits. ADT induced a deficit in cognitive set shifting on the AST, a mPFC-dependent cognitive flexibility task, and chronic treatment with vortioxetine

(28mg/kg/day) rescued this deficit (both $p<0.001$, n=6-12). We are currently investigating changes in functional plasticity in the mPFC by recording field potentials evoked by stimulating excitatory afferents from the medial dorsal thalamus. Preliminary data (n=4-6) suggest that castration induced a decrease in afferent-evoked response in the mPFC, and vortioxetine normalized the response in castrated males. We also investigated changes in gene expression in the mPFC using a microarray assay. Principle components analysis of gene expression patterns in brains from all groups confirmed a prominent effect of castration, as gene expression in the mPFC of the castrated group fed control diet was clearly distinct from the other groups. Intact rats fed both diets clustered together, and vortioxetine treatment normalized the gene expression pattern in castrated rats to an extent, bringing them closer to the intact groups. Ingenuity pathway analysis showed that genes in several pathways involved in neuronal plasticity were regulated in opposite directions by castration and vortioxetine. Experiments are underway to assess changes in dendritic morphology in mPFC after ADT and vortioxetine. These results indicate that cognitive impairment after ADT may be due to changes in plasticity-related processes in mPFC that are regulated by testosterone, and that chronic treatment with the novel antidepressant drug, vortioxetine, may be effective in reversing these deficits.

**Title:** Attention and its underlying neuronal circuitry in both sexes of a rat model of Fragile X syndrome

**Authors:** *C. GOLDEN[1], ***C. GOLDEN**[1], H. HARONY-NICOLAS[3], S. SONAR[2], M. BREEN[2], M. G. BAXTER[4], J. D. BUXBAUM[5]
[1]Psychiatry, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Dept. of Psychiatry, Icahn Sch. of Med., New York, NY; [4]Dept Neurosci., Mount Sinai Sch. Med., New York, NY; [5]Mt Sinai Sch. Med., New York, NY

**Abstract: Background**: Fragile X Syndrome (FXS) is a neurodevelopmental disorder that is considered to be the most common identified monogenic cause of autism spectrum disorder (ASD) and intellectual disability (ID). FXS is caused by a reduction in the Fragile X Mental Retardation Protein (FMRP), which is encoded by the FMR1 gene. FXS patients exhibit severe deficits in attention, which is subserved by the prefrontal cortex (PFC). Additionally, prefrontal grey and white matter, as well as regional volumes, are aberrant. These abnormalities in FXS are associated with PFC-dependent cognitive impairments.
**Method**: We investigated the effects of Fmrp loss on PFC-dependent behavior and anatomy in *Fmr1* knockout (KO) rats. In order to assess attention *Fmr1* KO male and female rats were trained and tested on the five-choice serial reaction time task (5-CSRTT). In order to examine the grey and white matter integrity and volume of prefrontal regions we used magnetic resonance imaging (MRI).
**Results**: Male *Fmr1* KO rats show an increase in omissions while training on the 5-CSRTT and female *Fmr1* KO rats show an increase in omissions during baseline testing. These deficits suggest that sustained attention is impaired in *Fmr1* KO rats. Furthermore, using diffusion tensor imaging, we see increased mean and radial diffusion in the thalamus, cerebellum, hypothalamus and neocortex of *Fmr1* KO male rats compared to WT male rats. These results will be corroborated by analysis of T2 images. We will also analyze the specific PFC subregions that are known to be involved in attention, which were not independently analyzed previously.
**Conclusion**: This multi-level approach will allow for a better understanding of the neural mechanisms affected in FXS-related cognitive impairments.

**Abstract:** The hypoxia-ischemia (HI) occurs due to complications in the perinatal period and is frequently associated with cognitive impairments. In animal models, learning and memory

deficits are well-described following neonatal HI and more recently, we have also demonstrated attentional deficits. Thereby, we recognized the face validity of the HI model to the study of attention-deficit/hyperactivity disorder (ADHD). To consider the predictive validity, it is necessary to evaluate the effects of the treatment used in the clinic for ADHD in the HI model. Thus, the aim of the study was to investigate the effect of methylphenidate (MPD) in different memory protocols and attentional flexibility in young rats submitted to neonatal HI (Ethical approve 29750). Male Wistar rats were divided into four groups (n=12-13/group): control treated with saline (CTS), CT treated with MPD (CTMPD), HIS and HIMPD. On the 7$^{th}$ postnatal day (PND), the HI procedure was performed according to the Levine-Rice protocol. From the PND 30, animals were evaluated in the novel-object recognition (NOR) task, Morris water maze (MWM) and attentional set-shifting (ASS); MPD administration (2.5mg/kg, i.p) occurred 30 minutes prior to behavioral sessions. In the NOR task, we observed a trend toward the factor lesion and treatment, indicating a lower novel-object preference index in the HIS group as well as in the MPD groups. The MPD appears to disrupt the recognition of the novel object in CT animals and did not improve the lower novel-object preference index of HI animals. In the MWM, HI groups performed poorly throughout the training compared to CT groups, being the HIMPD group similar to CT groups in days 1 and 2. In the test phase, HIS group made fewer crossings over the original platform place in relation to CTS group and the HIMPD performed similar to the other groups. In the ASS task, in Test 1, the CTMPD group had a higher number of trials and errors than CTS and HIMPD groups, demonstrating again a disruption of task performance by the MPD in control animals. In Test 2, which assess attentional flexibility, the HIS group made a larger number of trials in a longer time than all other groups, indicating that MPD administration reversed the attentional deficit of HI animals. Considering these results, we can infer that MPD clearly reverses the attentional deficit observed in HI animals but partially recovers some learning and memory parameters. Besides, the MPD treatment could, in some cases, disrupt the performance of control animals. Thus, in view of the efficacy of MPD in reversing attention and some memory deficits caused by neonatal HI, we can consider the predictive validity of the animal model of HI for the study of the ADHD.

**Title:** Low level laser therapy improves comorbidity of posttraumatic stress disorder in rat

**Authors: Y. LI**[1], Y. DONG[1], L. YANG[1], D. TUCKER[1], *Q.-G. ZHANG[2]
[1]Augusya Univ., Augusta, GA; [2]Augusta Univ., Augusta, GA

**Abstract:** Posttraumatic stress disorder (PTSD) is a pathologic response after exposure to a traumatic event. Symptoms of PTSD include intrusive memories, avoidance, negative changes in cognition, and hyperarousal. PTSD patients easily develop depressive disorders, anxiety disorders and substance use disorders, collectively named as PTSD comorbidity. The current PTSD treatment includes psychotherapy, a cognitive behavioral therapy to relieve PTSD symptoms, and pharmacological therapy, primarily antidepressants and anti-anxiety medication to relieve PTSD comorbidity. However, many patients display no beneficial effect from antidepressants and anti-anxiety medication, and the side effects are of significant concern. The aim of this study is to investigate the potential beneficial effects of Low-level laser therapy (LLLT) on comorbidity of PTSD. Three groups of Adult Sprague-Dawley rats were designated: control group, PTSD model group induced by under-water trauma (UWT), PTSD+LLLT treatment group. Immediately after model induction, PTSD+LLLT group animals were treated with LLLT for two minutes (808 nm, 25 mW/cm2, 3J/day, at cerebral cortex tissue level) which was repeated daily for 7 consecutive days. We found LLLT generates acute anti-anxiety effects with a single dose of transcranial laser treatment right after UWT. LLLT treated rats show significantly increased open arm time and entries in the elevated plus maze (EPM) test 6h post trauma. LLLT also demonstrates chronic effects after seven successive doses of laser treatment over seven days, which not only improved anxiety-like behavior in EPM, but ameliorated depression-like behavior in the force swim test. It is well established that LLLT functions via stimulating mitochondrial complex IV activity and ATP production. The potential mechanisms underlying LLLT's beneficial effects on PTSD and the connections to mitochondrial function is under investigation. In summary, our study suggests that LLLT may serve as a noninvasive and alternative medicine to alleviate the anxiety and depression comorbidity of PTSD.

**Abstract:** It has been shown that prenatal ethanol exposure (PE) leads to attention deficits, but the underlying mechanisms remain unclear. Using a choice reaction time task in rats to evaluate sustained attention, we demonstrated an increase in premature response, and an increase in skewness of reaction-time distribution in PE rats. These results show PE impairs preparatory attention and increases lapse of attention.
The prelimbic (PL) area of the medial prefrontal cortex (mPFC) in rats corresponds to the dorsolateral PFC in humans, which plays a significant role in regulating sustained attention. In order to understand the potential cellular mechanisms for PE-induced impairment, we investigated the synaptic function of Layer V pyramidal neurons in the mPFC, which integrate all inputs to the mPFC and are the major output neurons of this brain area.
The results from the *in vitro* patch clamp recordings show that the excitatory synaptic strength increased in Layer V PL neurons from PE rats, compared to that from controls, illustrated by a left shift of the input-output curve. In addition, PE did not lead to changes in the probability of presynaptic glutamate release, indicated by unaltered paired pulse ratio and coefficient of variation. Taken together, these results indicate that PE enhances excitatory synaptic strength in the Layer V PL neurons by upregulating glutamate receptors. This mechanism may underlie attention impairment caused by PE.

**Abstract:** Fetal alcohol spectrum disorder (FASD) is a leading cause of developmental disability and has been linked to impairments in aspects of executive function including attentional processing. In the present study, we use a rodent model of FASD to determine if this model can recapitulate the attentional deficits found in humans. Neonatal ethanol (5.25 mg/kg/day; ETOH) was administered from postnatal day (PD) 4-9 in both male and female rats. First we assessed the impact of this treatment on attentional set shifting during early adolescence. The intradimensional/extradimensional set-shifting (ID/ED) task was selected because it assesses the formation of an attentional set, the shifting of attentional set, and aspects of response inhibition. We found that the performance on all stages of the ASST was unchanged by neonatal exposure to ethanol in both male and female rats. Because our prior work has shown that neonatal exposure to alcohol confers a resistance to distraction in adult males, we aimed to replicate and extend this finding in two ways. First we assessed the effects of ETOH treatment on adult females in addition to males. Second, we tested the sensitivity of all rats to low doses of a muscarinic antagonist, scopolamine (0.0, 0.01, 0.025 and 0.05 mg/kg/mL). This drug was chosen because of the strong link to the corticopetal, cholinergic system to distractibility. As shown before by our group, ETOH males are less susceptible to distraction that sham-intubated (SI) controls after injection of vehicle. In contrast, ETOH female rats were more distractible than SI females after vehicle injection. The effects of increasing doses of scopolamine were also sex-specific. The lowest dose of scopolamine produced a stronger effect in ETOH than SI males. However, in females, there was no difference in the response to drug. Overall, these data reveal age and sex-specific effects of neonatal ethanol in a rodent model of FASD. These data suggest that differences in attentional function may reflect changes in muscarinic receptor density or function but future studies are required to better elucidate the neurochemical and neuroanatomical bases for these studies.

**Title:** Restoring prefrontal inhibition to treat cognitive symptoms of schizophrenia

**Authors: *L. CHAMBERLIN**, B. R. FERGUSON, E. MCEACHERN, W.-J. GAO
Neurosci., Drexel Univ. Col. of Med., Philadelphia, PA

**Abstract:** Schizophrenia (SZ) is an intractable mental disorder, affecting patients' mood, cognition, and sensory perceptions. Antipsychotics can offer relief from hallucinations and delusions, but there is currently no effective treatment for cognitive symptoms. This is especially concerning given the significant impact of poor cognition on the severity of functional impairment. The neuropathology underlying such deficits remains poorly understood, but alterations in GABAergic interneurons are believed to play an essential role. One such alteration that has been found in both human patients and animal models is a reduction in the number of parvalbumin (PV)-expressing fast-spiking (FS) interneurons in the prefrontal cortex (PFC). These PV-FS cells are important for gamma oscillations, which in turn support working memory and cognitive flexibility, all of which are disrupted in SZ patients. To explore this in rats, we use MK801, an NMDA antagonist that reproduces many of the morphological and cognitive endophenotypes observed in SZ including a deficit in prefrontal PV neurons. We hypothesize that the loss of PV cells leads to a decrease in prefrontal GABA release, thus decreasing the power of gamma oscillations and impairing performance on a working memory task. Our preliminary data suggests that there is decreased GABAergic release in MK801-treated animals compared to controls, as measured by reductions in spontaneous inhibitory post synaptic currents (sIPSCs) in medial PFC pyramidal neurons during whole-cell recordings. Thus, we investigate here whether upregulating PV interneuron activity works as a strategy for ameliorating GABAergic deficits and cognitive impairments. We have developed a novel DREADD that expresses the excitatory $hM3D_q$ receptor under a PV promoter (PV-$hM3D_q$). We will transfect MK801-treated animals with this PV-$hM3D_q$ DREADD with the goal of normalizing GABAergic signaling in the mPFC and ameliorating cognitive deficits. This study helps to elucidate the mechanisms of cognitive dysfunction in SZ, potentially pointing the way to effective therapeutics. Future directions include *in vivo* measures of local field potentials during behavior to probe alterations in gamma oscillations associated with our MK801-treated rats and pharmacogenetic upregulation of PV interneuron activity.

**Title:** Performance of heterozygous dopamine transporter mice in a 5-choice serial reaction time test for studies of attention deficit hyperactivity disorder

**Authors: *F. RESENDIZ GUTIERREZ**, D. MUSKIEWICZ, B. PATEL, A. SIMON, O. CHAKER, Y. SABER, F. S. HALL
Dept. of Pharmacol. and Toxicology, Univ. of Toledo, Toledo, OH

**Abstract: Background**: The 5-choice serial reaction time task (5-CSRTT) is used to study attention and impulsivity in mice. The test involves a specialized operant chamber in which 5 visual stimuli can be presented, which indicate which of 5 response (nose-pokes) will result in the presentation of a reinforcer. The mouse must attend to the appropriate stimulus in order to make a correct response (a measure of attention), avoid premature responses (a measure of impulsivity), or omissions (also a measure of attention). The procedure has been used to study a number of models of frontostriatal disorders in mice, including Attention Deficit Hyperactivity Disorder (ADHD). The aim of this study is to test performance in heterozygous Dopamine Transporter Knockout mice (DAT (+/-)) , a potential animal model of ADHD, with the ultimate aim of testing the effects of pharmacological treatments on attentional deficits. **Methods**: 4 Female DAT (+/-), 4 Female DAT (+/+), 4 Male DAT (+/-) and 3 Male DAT (+/+) were tested. After initial task performance is established, the subjects are tested for attentional impairments by varying the stimulus duration (SD), in order to identify conditions that are optimal (i.e. there are attentional impairments) for the testing of potential ADHD medications. Across 80 trials, stimulus duration is varied pseudo-randomly (16 trials each of 2, 1, 0.5, 0.25, 0.12, sec stimulus duration). SD is adjusted downwards so that performance is sub-optimal at the lowest durations. The goal is to establish a range of performance that degrades from optimal performance at high SD to sub-optimal performance at low and variable SD. **Results:** Female DAT (+/-) mice made more errors of omission than their (+/+) counterparts, but Male (+/-) mice made less than (+/+). There were no differences in number of premature or correct responses. **Discussion**: This paradigm will be altered in order to further assess behavioral differences between groups and be used to test the effects of both novel and putative treatments in heterozygous DAT knockout model of ADHD in both male and female subjects.

**Title:** A test for social behaviour in the common marmoset

**Authors: *J. CARRIOT**[1], R. J. NICOLSON[2], J. C. MARTINEZ-TRUJILLO[3]
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Departments of Psychiatry, Paediatrics, Psychology and Med. Biophysics, Western Univ., London, ON, Canada; [3]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

**Abstract:** The marmoset monkey (Callithrix jacchus) is a promising animal model for exploring social behaviors typical of humans and other primates. Here, we developed a test for assessing social preference behavior in marmoset monkeys based on pre-existing tests (e.g., the three chambers test for rodents). Two plexiglass chambers were attached to a housing cage that hosted a minimum of two animals. One of the chambers include an exercise ladder (play room) and the other chamber contained a screen showing a movie with i) peers marmosets in their natural habitat, 2) natural predators (snakes, jaguar) or 3) a pattern of squares. Animals had free access to the chambers during different experimental sessions: 1) play room vs peers, 2) play room vs predators, and 3) play room vs squares. A camera (Go-Pro Hero 4) recorded videos of the animals during several sessions that lasted a minimum of 1 hour a day. The videos were analyzed by human observers that quantified the amount of time the animals spend in each one of the chambers. Results show that during the sessions, animals spent more than 60% of the time in the experimental boxes (vs 40% of the time in the housing cage). The box showing the peers was the most interesting with a ratio of 0.79 (time in the peers box/total time in boxes during condition 1). Surprisingly, the second most interesting box was the one showing the predators with a ratio of 0.6 (vs 0.4 in the play room; condition 2). Finally, animals equally prefer the movie with the squares and the play room ($p>0.05$; condition 3). Other variables including, time of first entry, number of entries or absolute time in the chamber corroborated these results. Our results provide a relatively simple test for exploring social behavior in marmosets. They also confirm known similarities between marmosets and humans regarding their social behavior.

**Abstract:** Attention Deficit and Hyperactivity Disorder (ADHD) is the most diagnosed psychiatric disorder among children and adolescents and may persist into adulthood. Currently, the animal model most widely used in preclinical studies, of this disorder, is the Spontaneously Hypertensive Rats (SHR) strain. Although very valuable, this strain has limitations, not being able to cover all the issues raised in ADHD research. Thus, we developed a congenic strain named SLA16 (SHR.LEW-*Anxrr16*). In these recombinant animals, the background genome is from SHR rats and the portion of Chromosome 4 (~86Mb or 45%) came from Lewis rats. In the present study, our main goal was compare SHR and SLA16 rat strains, in order to propose an alternative genetic model of ADHD. For this, we tested male SHR and SLA16 rats in the plus-maze discriminative avoidance task (PMDAT), open-field (OF), object recognition (OR), spontaneous alternation (SA), fear conditioning (FC) and mean arterial pressure. Moreover, we treated animals, via intraperitoneal, with caffeine (CAF) 2 mg/kg, or saline (0.9%), twice a day (12h/12h), from postnatal days 24-45, in order to evaluate locomotor activity, emotionality and working memory, at the end of treatment and a month later. For this, we used the OF and Morris water-maze (MWM) 4 trials/day, 5 days. Our results showed that SLA16 strain displayed lower levels of anxiety/emotionality and arterial pressure, higher locomotor activity and deficits in learning/memory in comparison with SHR strain. The treatment with CAF, during adolescence, appeared to decrease the locomotor hyperactivity of SLA16 and improve the working memory of SHR. Thus, we concluded that SLA16 strain represents a valuable tool in the search for genetics and neurobiological pathways of ADHD. And the treatment with CAF, during adolescence, could be an alternative way to improve endophenotypes related to ADHD.

**Title:** The role of brain serotonin in social and cognitive abilities : Lessons from tryptophan hydroxylase 2-deficient rats

**Authors: *L. ALONSO**[1], P. PEEVA[2], Y. WINTER[1], N. ALENINA[2], M. RIVALAN[1]
[1]Humboldt Univ. Berlin, Berlin, Germany; [2]Max Delbrück Ctr., Berlin, Germany

**Abstract:** In clinical settings, selective serotonin reuptake inhibitors are often used as treatments of depression, suicide related behavior, impulse control disorder and substance use disorder. Patients with these disorders share common cognitive and social impairments such as poor decision-making abilities, risk taking tendencies, cognitive inflexibility, motor and cognitive impulsivity and higher aggression. In rats, genetic, pharmacological, and behavioral studies have suggested, testing one function at a time that a central serotonin hypofunction could lead to impairments in each of these cognitive and social functions. It is, however not yet studied how hyposerotonergia simultaneously affects the expression of these behaviors in the same animal. In humans more than one function is usually impaired in a given individual. The goal of this study was to take a more translational approach and to investigate the role of serotonin in the concomitant expression of cognitive and social abilities in rats. To model the serotonin hypofunction we used recently generated rat line lacking tryptophan hydroxylase 2 (TPH2), the rate limiting enzyme of serotonin synthesis in the brain. TPH2-deficient (*TPH2-/-*) rats are completely depleted of serotonin in the central nervous system, but have normal levels of the monoamine in the periphery. Although *TPH2-/-* rats exhibit marked growth retardation during first 5 weeks of postnatal life, the size of the animals is normalized thereafter and serotonin depletion does not affect the morphology of the adult brain. We subjected these animals to six cognitive and social tasks : the Rat Gambling Task and reversed Rat Gambling Task, the Fixed interval-Extinction schedule of reinforcement, the Delay and Probability Discounting tasks, and the Visible Burrow System. As expected Tph2-/- rats showed an increased level of aggression. Intriguingly, *TPH2-/-* rats presented unexpected high levels of cognitive abilities and they were able to establish a social hierarchy. This study is challenging the historical role attributed to serotonin and its importance for the concomitant expression of cognitive functions.

**Title:** Topologically invariant manifolds of *C. elegans* pan-neuronal activity

**Authors: *C. BRENNAN**, A. PROEKT
Neurosci., Univ. of Pennslyvania, Philadelphia, PA

**Abstract:** It is still unknown to what extent brain activity is driven by stochastic versus deterministic dynamics. Studies in vertebrates exposed evidence for both types of regimes, but the sheer complexity of the vertebrate brain makes this question experimentally intractable. The expectation is that by recording the activity of all the neurons in a nervous system the true behavior of the neuronal network can be elucidated. With the advancement of neuronal imaging techniques it is now possible to create such recordings for the simplest of organisms. What type of methodologies does one use to extract the underlying forces driving the evolution of the system? Do single neurons represent one unique piece of information? Combinations of multiple neurons? Are the pan-neuronal activity of all neurons even enough to fully describe the network? Here we show that in the simple nervous system of C. elegans, we can construct single trial models that capture both the dynamic and stochastic elements of the network. However, these models fail to generalize from across multiple worms, which may seem to argue that the neuronal dynamics of each worm are unique. Using delay embedding, we discover that the long time-scale flow of neuronal activity is confined to a topologically invariant manifold. In contrast to neuronal activity, this manifold is highly conserved among individual worms. The manifold consists of two interlocked cycles of activity. While the system evolves along a cycle its behavior is well approximated by a fully deterministic model. In contrast, when the system nears the junction between two cycles, the trajectories diverge and stochastic processes dominate. We provide a method for the extraction of such topologically invariant manifolds from neuronal time series data and as a test for generality we also obtain similar results from simulated systems.

Sch. of Med., Hangzhou, China

**Abstract:** Mental strength and history of winning play a role in the determination of social dominance. However, the neural circuits mediating these intrinsic and extrinsic factors have remained unclear. We identified a dmPFC neural subpopulation showing effort-related firing during moment-to-moment competition in the dominance tube test. Optogenetic ctivation or chemogenetic inhibition of dmPFC induces instant winning or losing respectively. Notably, *in vivo* optogenetic-based long-term potentiation or depression experiments establish that the mediodorsal thalamic (MDT) input to dmPFC mediates long-lasting changes in the social dominance status impacted by history of winning. The same neural circuit also underlies transfer of dominance between different social contests. These results reveal synaptic plasticity at the MDT-dmPFC circuit as an important neural substrate mediating both the intrinsic dominant state and extrinsic winning experience for social hierarchy determination, thereby providing a new framework for understanding the circuit basis of adaptive and pathological social behaviors.

**Title:** μ-Opioid receptor activation in the locus coeruleus increases synchronization of the male, but not female medial prefrontal cortex

**Authors: *H. M. GUAJARDO**[1], A. L. CURTIS[2], S. BHATNAGAR[3], R. J. VALENTINO[4]
[1]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA; [3]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA; [4]Div. of Neurosci. and Behavior, Natl. Inst. of Drug Abuse, Rockville, MD

**Abstract:** Stress-related neuropsychiatric pathologies are more prevalent in females compared with males. Activation of the locus coeruleus (LC)-norepinephrine (NE) system is a component of the stress response that is thought to affect cognition. Evidence suggests that endogenous opioid neuropeptides are released during stress to restrain LC activation and to facilitate a return to baseline activity when the stressor ends. Sex differences in this opioid influence could be a bases for sex differences in stress vulnerability. We previously demonstrated decreased μ-opioid receptor (MOR) mRNA and protein in the LC of female compared to male rats. As a result, LC neurons of female rats were less sensitive to inhibition by the μ-opioid receptor (MOR) agonist, DAMGO. Because the LC-NE system affects cognitive function through its projections to the medial prefrontal cortex (mPFC), the present study determined whether LC-MOR activation translates to changes in mPFC neural activity and whether there are sex differences in this effect. Local field potential (LFPs) were recorded from the mPFC of freely behaving male (n=4) and female (n=4) rats before and following local LC microinjection of DAMGO (10 pg). LFPs were analyzed as power spectral density plots and the power at different frequency bands (delta 2-4 Hz, theta 4-8 Hz, alpha 8-12 Hz, and beta 12-20 Hz) was analyzed and compared between sexes. Intra-LC DAMGO resulted in a time-dependent synchronization of mPFC activity in male but not female rats. Two-way repeated measures (rm) ANOVA with post-infusion time as the repeated measure revealed a sex X time interaction for power in delta ($F(3,6)=28.4$, $p<0.005$), a trend for sex X time interaction for power in theta ($F(3,6)=6.2$, $p=0.05$), and a sex X time interaction for power in alpha ($F(3,6)=6.9$, $p<0.05$). LC microinfusion of ACSF had no effect on mPFC activity in either male or female rats. Together, the results are consistent with previous evidence for decreased MOR function in the LC of female rats and demonstrate that this translated to a diminished effect on cortical activity. Decreased LC-MOR function in females could contribute to greater stress-induced activation of the LC and increased vulnerability of females to hyperarousal symptoms of stress-related neuropsychiatric pathologies.

**Title:** Impaired task-related firing and long-range 4 Hz synchrony of dopamine neurons underlies working memory deficits in a mouse model of cognitive dysfunction

**Authors: *S. DUVARCI**[1], E. H. SIMPSON[2], G. SCHNEIDER[3], E. R. KANDEL[4], J. ROEPER[5], T. SIGURDSSON[5]
[1]Goethe-University Frankfurt, Frankfurt, Germany; [2]Columbia University/ NYSPI, New York, NY; [3]Inst. for Mathematics, Goethe Univ., Frankfurt, Germany; [4]Dept. of Neurosci., Columbia Univ. / HHMI, New York, NY; [5]Goethe Univ. Frankfurt, Frankfurt, Germany

**Abstract:** The dopamine (DA) system plays a major role in cognitive functions through its interactions with several brain regions including the prefrontal cortex (PFC). Disturbances in the DA system contribute to cognitive deficits in psychiatric diseases including schizophrenia, yet exactly how they do so remains poorly understood. To address this question, we recorded single units and local field potentials (LFPs) in the ventral tegmental area (VTA) and the PFC in mice overexpressing the D2 dopamine receptor in the striatum (D2R-OE mice), a well-characterized model of dopamine-related cognitive dysfunction. Recordings were made while animals performed a non-match-to-sample spatial working memory task in a T-maze. Each trial of the task consisted of two phases. In the 'sample phase', mice ran up the center arm of the T-maze and entered one of the goal arms to collect reward, while the other arm was blocked. After a brief ~10s delay, the mice again ran up the center arm, but now both goal arms were open ('choice phase'). To obtain a reward, animals had to enter the goal arm not visited during the sample phase. As previously shown, D2R-OE mice required more training to reach criterion performance indicating a deficit in working memory (WM). To investigate the neural circuit disturbances underlying this deficit, we examined neural activity in the VTA and PFC during task performance. Specifically, we compared activity in the choice phase, where the animals had to use WM to guide their behavior, to the sample phase, where animals performed the same overt behavior but without the WM requirement. In control animals, we found that 4 Hz oscillations emerged in the PFC and VTA during the choice phase of the task. This was accompanied by increases in the phase-locking of VTA and PFC neurons to local 4 Hz oscillations. In the VTA the increase in phase-locking was specific to putative DA neurons, and was not seen in putative GABA neurons. The increase in phase-locking was observed between neurons in one structure

and 4 Hz oscillations in the other, demonstrating that 4 Hz oscillations mediate long-range synchrony between the VTA and PFC. This was further supported by a selective increase in 4 Hz LFP coherence between the two structures during the choice phase. Strikingly, we found that these WM-dependent increases in local and long-range 4 Hz VTA-PFC synchrony were absent in D2R-OE mice. Furthermore, the magnitude of this synchrony deficit correlated strongly with the behavioral deficits in the D2R-OE mice. We also found a selective disruption in the task-related firing patterns in VTA DA, but not GABA, neurons. These results identify how altered DA neuron activity contributes to cognitive impairments.

**Title:** Impact of task-phase specific optogenetic silencing of the medial prefrontal cortex on spatial working memory

**Authors: *P. VOGEL**, S. DUVARCI, T. SIGURDSSON
Inst. of Neurophysiol., Goethe Univ. Frankfurt, Frankfurt am Main, Germany

**Abstract:** Spatial working memory, the ability to store and update spatial information in the short term, is an essential feature of goal-directed behavior. Lesion and inactivation studies suggest that the medial prefrontal cortex (mPFC) plays a key role in the execution of spatial working memory tasks. However, little is known about the temporal structure of mPFC involvement during these tasks, that is during which phase (encoding, maintenance, and/or retrieval) it is actually engaged. In the current study we addressed this issue by recording from and optogenetically silencing mPFC neurons in a temporally specific manner while animals performed a spatial working memory task. To this end, an adeno-associated virus expressing either the neural silencer ArchT (AAV2/5-CamKII-ArchT-GFP, n=15) or eGFP (AAV2/5-CamKII-eGFP, n=6) was bilaterally injected into the mPFC of C57BL/6N mice. Two optic fibers (200 micrometer diameter) were also implanted bilaterally into the mPFC, one of which was attached to recording electrodes. Following recovery from surgery animals were trained on a non-match-to-sample spatial working memory task in a T-maze. Each trial of the task began with a “sample phase” in which mice entered one of the two goal arms to obtain a reward. After a ~10s “delay phase”, the “choice phase” began in which mice had to choose between two open

goal arms and only obtained a reward if they entered the goal arm not visited during the sample phase. Once animals had learned the task, testing sessions began in which we illuminated the mPFC with yellow light (594nm, 16mW) on half of the trials. In each testing session light delivery was temporally restricted to one of the three phases of the task (sample, delay or choice) in order to examine the contribution of the mPFC to different task components. In mice expressing ArchT light application inhibited 87% of putative pyramidal cells. Light application in ArchT animals in any of the three phases of the task also impaired spatial working memory performance while the same treatment in eGFP control animals had no significant effect on behavior. However, illuminating the mPFC in only half of the sample phase did not impair task performance. Interestingly, when the mPFC was silenced during the whole sample phase, neural activity in the following "laser-free" choice phase was increased. Our results suggest that the mPFC is involved in encoding, maintenance, and retrieval of spatial working memory content. We are currently investigating how mPFC projections to downstream structures contribute to different aspects of spatial working memory.

**Abstract:** Working memory (WM) is an ability of the brain to retain sensory information in such form that it is still available after a short time delay during which it is not directly perceived. During WM tasks, elevated neural firing rates, as well as specific modulation of oscillatory activity are observed [1,2]. During presentation of to-be-memorized stimuli, gamma oscillatory power increases and beta activity is suppressed. Subsequently beta oscillation rebounds, reaching its maximum in the middle of the delay period [2,3]. Experiments identified two cell populations ("Encode/Decode"-cells and "Maintenance"-cells), whose firing rate time-course are strikingly similar to the gamma and beta dynamics, respectively [3]. Using a computational model of working memory storage, we clarify the role of gamma and beta activity sequence in gating information to WM. Our low-dimensional model is constructed as a coupled circuit of excitatory-inhibitory neural populations: a stimulus sensitive S-population reactive to external stimuli, and a bistable "delay" D-population that incorporates short-term plasticity [4] and thus performs WM retention. The S-population exhibited gamma-band resonance, while the D-population has resonance in the beta range. Our simulations showed that stimulus-driven gamma-modulated transient input to the S-circuit provides sufficient excitation to the D-population to bring it close to the memory-retained state, while subsequent external beta-band bursts transmitted to the D-population (which represent experimentally observed post-stimulus beta rebound) completes the loading process. Thus, our model shows that memory gating is a two-step process where both the gamma-modulation of the input stimulus, and a subsequent external beta-entrainment of D-population are required in our model to successfully load information into working memory. Additionally, our model intrinsically reproduces several other features of persistent delay activity seen during working memory tasks, e.g. increase of gamma and beta power during the delay period.

**Abstract:** It has been proposed that animals construct models of their environment to better adapt their behaviour and increase their chances of survival. To achieve this goal, animals have to search for patterns even when the adaptive value of a behavioural responses not only depends on the current scenario, but also in the history of events. In this regard, the Serial Reversal Task (SRT) is a behavioural paradigm in which two rules alternate over time, demanding the animal to keep track of previous events in order to maximize reward. Traditional neural network models cannot explain learning in the SRT because learning of one rule usually erases previously acquired information. The goal of this work is to find the essential properties required by stochastic spiking neural networks to solve a SRT. We found that the SRT cannot be solved if the integration of stimulus information and the decision process occur in the same neural population. This limitation is independent of the number of neurons, neuronal dynamics or plasticity rules, and stems from the fact that plasticity is locally computed at each synapsis, and that all stimulus/response pairings are equally reinforced. We propose a biologically plausible neural network model which solves the SRT, based on separating the function of integration of stimulus information from the function of response selection. The results shed new light about the functioning of decision-making brain structures like the prefrontal cortex, and highlight the importance of characterizing neural circuits based on their connectivity and the degree of plasticity modulation with the reward.

**Abstract:** The cerebellum plays an integral role in cognitive function both in the lateral cerebellar nuclei (LCN) and through its interactions with the frontal cortex. A subset of neurons in the LCN express D1 dopamine receptors (D1DRs) that are thought to be involved in cognitive processes. The precise role of these neurons remains unknown. Here we investigate how D1DR-expressing neurons in the LCN influence cognition and neuronal activity in the frontal cortex and cerebellum. Timing requires executive processes such as working memory, attention, and planning and is known to rely on both the frontal cortex and cerebellum making it an optimal task to probe cognition. We use an interval timing task where animals estimate the passage of a period of several seconds by making lever presses for a water reward. We have previously shown that a cue-evoked burst of low-frequency activity signals ramping activity, or monotonic increases or decreases, of firing rate over time in single neurons in the frontal cortex and cerebellum. These patterns of activity are essential for efficient interval timing performance. Here we explored how blocking LCN D1DRs using microinfusions of D1 dopamine antagonist SCH23390 influences timing and neural activity in the frontal cortex and cerebellum. We report that blocking LCN D1DRs impairs interval timing performance. Additionally, ramping activity and low-frequency rhythms were significantly attenuated in both the medial frontal cortex and cerebellum. These data provide insight into how the cerebellum influences medial frontal networks and the role of cerebellar dopamine in cognitive processing.

**Title:** Role of endocannabinoids during generalization of habituation between non-nociceptive and nociceptive pathways

**Authors: *A. D. HANSON**[1], B. D. BURRELL[2,3]
[1]Basic Biomed. Sci., [2]Basic Biomed Sci., Univ. of South Dakota, Vermillion, SD; [3]Ctr. for Brain and Behavior Res., Vermillion, SD

**Abstract:** Repetitive non-nociceptive stimulation is known to reduce the perception of painful stimuli and is the basis for transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation (SCS) therapies. How such stimuli produce long-lasting decreases in nociceptive signaling is poorly understood. We hypothesize that decreases in nociception following repetitive non-nociceptive stimulation represents a form of habituation, a simple form of learning in which an animal learns to de-emphasize responses to repeated or redundant stimuli. Specifically, we propose that repetitive non-nociceptive stimulation results in generalization or transfer of habituation to the nociceptive stimulus-response pathway. Following habituation training using non-nociceptive stimuli (von-Frey fibers), responses to noxious thermal stimuli (Hargreaves apparatus) were reduced in *Hirudo verbana* (the medicinal leech). Previous physiological studies in *Hirudo* have shown that repetitive stimulation of non-nociceptive afferents produces synaptic depression in nociceptive synapses that is mediated by endocannabinoid transmitters acting on a TRPV-like receptors. Consistent with these findings, injection of tetrahydrolipstatin (THL), which blocks synthesis of the endocannabinoid 2-arachydonoylglycerol (2-AG), prevented transfer of habituation from the non-nociceptive to the nociceptive pathway. Injection of the TRPV1 receptor antagonist, SB336719 (SB), also prevent transfer of habituation. Neither THL nor SB affected habitation to the non-nociceptive stimulus itself. Next, the duration of this habituating effect was examined. Surprisingly, this anti-nociceptive effect lasted longer (at least 6 days) following one block of habituation training compared to four blocks of spaced habituation training (1 day). Injection of THL and SB blocked this persistent habituation effect indicating that this long-lasting memory required TRPV and 2-AG. Preliminary studies indicate that 2-AG/TRPV signaling is required for acquisition of the habituation memory, but not its maintenance. These findings support the idea that habituation learning mechanisms contribute to the anti-nociceptive effects of repetitive non-nociceptive stimulation and may have implications for the application of TENS or SCS therapies to treat clinical pain conditions.

**Abstract:** Temporary lapses in memory recall during consolidation of long-term memory have been observed in many species, including humans, raising questions about their function in the phenomenon of memory lability. Our previous experiments suggested that lapses might represent windows of opportunity for one memory to be replaced by another. To examine this hypothesis, we induced a primary memory and then examined the effects of the formation of a second memory. We found that ability to induce memory replacement depended on the timing of the second training. When the secondary training is applied at the lapse points of primary consolidation, a secondary long-term memory was formed and the primary memory was lost. When applied at non-lapse points the primary memory persists and the secondary memory was not formed. Electrophysiological experiments in the isolated nervous system provide a systems level substrate for memory replacement and a cellular mechanism for memory maintenance.

**Title:** Genetic, cellular, and behavioral dissociations of associative learning and sensory integration in *Caenorhabditis elegans*

**Authors: *G. S. WOLFE**[1], V. W. TONG[1], D. MERRITT[1], G. W. STEGEMAN[2], S. FLIBOTTE[3], D. VAN DER KOOY[4]
[1]Inst. of Med. Sci., [2]Ecology and Evolutionary Biol., Univ. of Toronto, Toronto, ON, Canada; [3]Zoology, Univ. of British Columbia, Vancouver, BC, Canada; [4]Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** The mechanisms of learning and memory can be studied by taking advantage of model organisms such as *Caenorhabditis elegans*. We have characterized an EMS derived mutant strain, *lrn-2,* which shows deficits in both sensory integration and a wide variety of associative learning paradigms. Mapping, sequencing, complementation tests and wild type gene rescue have localized this mutation to the gene *scd-2.* The primary assay of sensory integration involved overcoming an aversive copper barrier to reach an attractive diacetyl odorant. The primary learning assay involved associating the pathogenicity of *P. aeruginosa* bacteria with its odor. We have shown that sensory integration and associative learning can be dissociated at three different levels of investigation and thus predict that behavioral responses to sensory integration and associative learning are driven by separately encoded representations of sensory cues within the worm "mind". There is dissociation at the genetic level because we have demonstrated that sensory integration and associative learning use separate molecular pathways. While *scd-2* is downstream of *fsn-1*, a gene that produces part of a ubiquitination complex, in the sensory integration pathway, we performed epistasis experiments showing that *scd-2* has a different epistatic relationship with *fsn-1* in associative learning. There is dissociation of the neuronal circuits driving sensory integration and associative learning. While sensory integration requires expression of *scd-2* in AIA interneurons, associative learning uses a different neuronal pathway, likely involving NSM serotonergic neurons. Finally, we have shown that *scd-2* mutants can fail at integrating copper and diacetyl cues while simultaneously successfully forming an associative memory of the same cues. This was demonstrated by testing *scd-2* mutant behavioral response to copper after initial exposure to copper paired with diacetyl. While mutants could not initially cross a copper barrier to reach diacetyl, this exposure led to an increased attraction to copper, indicative of an association between the two cues. These experiments demonstrate a dissociation between sensory integration and associative memory. Even though both psychological processes require detection of sensory cues followed by a modified behavioral response, they require separate genetic and cellular pathways, and can occur both simultaneously and independently from each other.

**Title:** Nitric oxide erases/destabilizes existing memory during reconsolidation in snails and rats

**Authors: *P. M. BALABAN**, M. RYSAKOVA, A. VINARSKAYA, V. IVANOVA, A. ZUZINA, N. BAL
Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

**Abstract:** It is well known that reactivation of consolidated fear memory under boundary conditions of novelty and protein synthesis blockade results in an impairment of memory, suggesting that the reactivated memory is erased/destabilized and requires synthesis of new proteins for successful reconsolidation. The role of nitric oxide (NO) in the development of memory was repeatedly described in a range of animal models. Recently in terrestrial snails it was shown that contextual fear memory was significantly impaired 24 hrs after memory reactivation under injection of a protein synthesis blocker anisomycin (ANI), but similar reactivation of memory under a combined injection of ANI and a range of NO-synthase inhibitors (or the NO scavenger) demonstrated absence of impairment of the long-term contextual memory. Blockade of NO prevented erasure/destabilization of long-term memory. These results evidence that NO is involved in the destabilization (erasure) of a consolidated context memory in mollusks (Balaban *et al.*, 2014). In the present work, we tested the hypothesis of the NO involvement in memory destabilization during the reconsolidation process in rats using memory reactivation under different conditions. We report that administration of NO-synthase selective blockers 3-Br-7-NI or ARL in the conditions of reactivation of memory under a protein synthesis blockade prevented destabilization of fear memory to the conditioned stimulus. Obtained results support the role of NO signaling pathway in the destabilization of existing fear memory triggered by reactivation, and demonstrate that the disruption of this pathway may prevent memory reactivation-induced changes in long-term memory. It was suggested that the mechanism of memory destabilization either may be a direct local S-nitrosylation of the peptides participating in memory maintenance, or may be triggering of the proteasomal degradation of proteins by NO. We investigated influence of endogenous nitric oxide production on proteasomal protein degradation. We have shown that nitric oxide synthase blockade prevents decline of the GFP-based proteasomal protein degradation reporter in neuronal processes of the hippocampal primary culture. It suggests that nitric oxide may regulate ubiquitin-dependent proteasomal protein degradation in neurons. Obtained results suggest that nitric oxide is involved in the protein degradation in proteasomes in physiological conditions.

**Abstract:** Higher-order conditioning phenomena, including context conditioning and blocking, occur when conditioning to one set of stimuli interacts with conditioning to a second set of stimuli to modulate the strength of the resultant memories. In blocking, a first conditioned stimulus (CS1), when associated with an unconditioned stimulus (US), prevents subsequent learning of a second conditioned stimulus (CS2) to the US when trained in the presence of CS1. In context conditioning, association of a CS to the US is recalled only when tested in a context similar to that it was learned in. Here we analyze these phenomena in the nematode worm *Caenorhabditis elegans*, demonstrating for the first time the presence of blocking in this animal, and identifying conditions that behaviorally dissociate it from simultaneous context conditioning. We present an initial genetic dissection of context conditioning and blocking in a model benzaldehyde/$NH_4Cl$ aversive learning paradigm, and demonstrate that blocking occurs independent of retrieval of CS1, but dependent on its sensation, and that at least the initial stages of the CS2 memory are formed even in blocking conditions. While traditional explanations of blocking posit that storage of the CS2 memory is impaired in situations in which the US is already predicted by CS1, our findings suggest a fundamentally different explanation. We propose that blocking may work to interfere with subsequent retrieval of the CS2 memory in *C. elegans*, rather than interfering with its storage, and that this process occurs independent of retrieval of the CS1 memory during CS2 training - that is, that CS1 prediction of the US is not required for CS2 blocking. Our findings suggest a fundamental reinterpretation of blocking, and position *C. elegans* as a powerful model organism for the study of higher order conditioning.

**Title:** Dactylobiotus dispar as a model organism to study the metabolic necessity for memory storage

**Authors: S. Y. ZHOU**, P. M. DWIVEDY, J. P. DEFRANCO, D. M. ZIMMET, M. MAGDITS, *T. C. DUMAS
Psychology, George Mason Univ., Fairfax, VA

**Abstract:** Tardigrades, also known as water bears, are microscopic eight-legged animals that live in various aquatic and terrestrial environments. They are known for their resilience to extreme conditions due to their ability to enter cryptobiosis. This rare property presents an opportunity to explore principle components of memory storage; for instance, does the storage of memories require ongoing metabolism or can they be stored purely in structure? Thus, the purpose of this project is to use tardigrades to determine metabolic necessity for memory storage. Dactylobiotus dispar tardigrades were trained in a delayed fear conditioning paradigm to associate a blue light (conditioned stimulus) with a mild shock (unconditioned stimulus). Following pairing, the animals display the conditioned response (curling) upon presentation of the blue light only, reflecting a learned association between the blue light and the shock. To confirm that this was associative learning, various control experiments are performed (shock only, blue light only, reverse pairing). Animals are being conditioned multiple times to produce long-lasting memories. Half of these animals will undergo cryptobiosis (tunning), while the other half does not. Upon revival, the tunned tardigrades will be compared to the control tardigrades with respect to memory integrity and duration. If fear conditioning memories rely on metabolism, then memory performance is expected to be impaired in the tunned animals. However, if memory storage does not rely on metabolism, then no difference in memory performance should occur. Finally, tunned tardigrades might show improved memory performance due to a stasis effect on memory decay. We are also developing methods to rapidly and reliably tun and revive this species of tardigrades. This research opens a new area of neurobiology may provide a new perspective on the neural bases of learning and memory.

**Abstract:** Lateral and medial parts of entorhinal cortex (EC) convey nonspatial ‘what’ and spatial ‘where’ information, respectively, into hippocampal CA1, via both the indirect EC layer 2→ hippocampal dentate gyrus→CA3→CA1 and the direct EC layer 3→CA1 paths. However, it remains elusive how the direct path transfers distinct information and contributes to hippocampal learning functions. Here we report that lateral EC projection neurons selectively form direct excitatory synapses onto a subpopulation of morphologically complex, calbindin-expressing pyramidal cells (PCs) in the dorsal CA1 (dCA1), while medial EC neurons uniformly innervate all dCA1 PCs. Optogenetically inactivating the distinct lateral EC-dCA1 connections or the postsynaptic dCA1 calbindin-expressing PC activity slows olfactory associative learning. Moreover, optetrode recordings reveal that dCA1 calbindin-expressing PCs develop more selective spiking responses to odor cues during learning. Thus, our results identify a direct lateral EC→dCA1 circuit that is required for olfactory associative learning.

**Title:** Expression patterns of DD2R in different dopaminergic neuronal clusters and its role in *Drosophila* larval olfactory learning

**Authors: *C. QI**, D. LEE
Biol., Ohio Univ., Athens, OH

**Abstract:** Dopamine (DA) plays a critical role in conditional learning via interacting with two receptor subfamilies: excitatory D1- and inhibitory D2-like receptors. In *Drosophila melanogaster*, postsynaptic D1 receptors are known to be involved in associative olfactory learning in both adults and larvae. However, whether modulation of synaptic DA release by presynaptic D2 autoreceptors plays a crucial role in olfactory learning is still unknown.
In addition to DA receptors, different DA neural circuits are involved in different olfactory learning (i.e. appetitive and aversive). Former studies showed in larval brains, dopaminergic neurons (DAN) in the dorso-lateral 1 (DL1) cluster innervating into the vertical lobe of mushroom body (MB) are necessary for aversive olfactory learning, while DANs in the primary protocerebral anterior medial (pPAM) clusters innervating into the medial lobes of MB are important for appetitive learning. Based on this, we aimed to examine whether *Drosophila* Dopamine 2 Receptors (DD2R) are expressed in different DA neuronal clusters (i.e. DL1 vs pPAM), and whether these DD2Rs are involved in different *Drosophila* olfactory learnings.
By using a GFP-tagged DD2R strain, the expression patterns of DD2R were explored in DANs (including pPAM and DL1). To investigate the role of DD2R in distinct DANs, we drove expression of DD2R-RNAi under distinct DAN-specific drivers. The olfactory learning assay showed aversive learning is totally impaired in larvae with DD2R knockdown under TH-GAL4 driver (including DL1, but not pPAM), while the appetitive learning is partially impaired. This is consistent with our results of DAN-to-MB GRASP (split-GFP Reconstitution Across Synaptic Partners) using TH-GAL4: more intensive GRASP signals were observed in the vertical lobes than those in the medial lobes, showing more functional synapses between DANs and vertical lobes of MB. These results demonstrated DD2Rs in the DANs under TH-GAL4 have an important role in larval aversive learning. On the other hand, knockdown of DD2R under a pPAM-specific driver (R58E02-GAL4) totally impaired appetitive learning, which indicates DD2Rs in pPAM clusters have an important role in appetitive learning. Our findings revealed DD2R auto-receptors in distinct DAN clusters have different functions in *Drosophila* larval olfactory learning. To investigate possible mechanisms of DA mediated learning, we are currently studying how DD2R knockdown induced impaired olfactory learning at the level of synaptic neurotransmission.

**Title:** Inhibition of protein degradation enables the induction of associative memory following sleep deprivation

**Authors: E. J. NOAKES**, H. C. KRISHNAN, *L. C. LYONS
Dept. of Biol. Science, Program in Neurosci., Florida State Univ., Tallahassee, FL

**Abstract:** Sleep deprivation and sleep disorders constitute a significant public health problem in the United States and worldwide. Sleep deprivation results in cognitive and performance impairments in adolescents and adults. Though recent research has begun to uncover the molecular mechanisms through which sleep deprivation impacts memory formation, a clear understanding has yet to emerge. The marine mollusk *Aplysia californica*, with its well-established learning paradigms and diurnal consolidated sleep pattern (Vorster et al., 2014), represents an excellent model for investigating the interaction of sleep and memory. *Aplysia* exhibit decreased responsiveness to sensory stimulation during sleep and rebound sleep following nine hours sleep deprivation (Vorster et al., 2014). Recently, we demonstrated that acute and chronic sleep deprivation inhibit the induction of short and long-term operant memory formation using the learning that food is inedible paradigm (Krishnan et al., 2016). As research in mice suggests that sleep deprivation impairs memory consolidation through the suppression of protein synthesis (Tudor et al., 2016), we hypothesized that sleep deprivation may affect the induction of memory through an imbalance in protein synthesis and protein degradation. Previously, we demonstrated that maintenance of steady state protein levels through dual inhibition of protein synthesis and protein degradation permitted long-term memory formation (Lyons et al., 2016). If sleep deprivation affects protein regulation through either decreased protein synthesis or increased protein degradation, then potentially inhibiting protein degradation may restore conditions to permit the induction of memory. To test whether the inhibition of protein degradation mitigates the effects of sleep deprivation on memory, animals were sleep deprived for nine hours using contextual changes and tactile stimulation and injected with the proteasome inhibitor MG-132 or vehicle three hours prior to the end of sleep deprivation. Animals were then trained using the learning that food is inedible paradigm 1 h following sleep deprivation and tested either 30 minutes later for short-term memory or 24 hours later for long-term memory. Remarkably, MG-132 treated animals exhibited robust short-term and long-term memory while the vehicle treated animals failed to show any memory. These results suggest that sleep deprivation may inhibit the induction of memory through misregulation of the balance of protein synthesis and protein degradation.

**Title:** Chronic and acute exposure of honey bees to fipronil reduces synaptic density in the mushroom bodies

**Authors: *J. J. PRIVITT**[1,2], S. E. FAHRBACH[2]
[1]Neurobio. & Behavior, Cornell Univ., Ithaca, NY; [2]Biol., Wake Forest Univ., Winston Salem, NC

**Abstract:** Fipronil, a commonly used insecticide, is a GABA receptor antagonist that induces hyperexcitability in the central nervous system of insects. Its use is controversial because it is a suspected contributor to the global decline of non-target pollinator populations. Sublethal doses of fipronil reduce colony fitness and impair learning and memory in the honey bee, *Apis mellifera*. The mushroom bodies (MB), insect brain regions required for learning and memory, receive GABAergic inputs that may be sensitive to fipronil. The synaptic organization of the MB was investigated in adult worker honey bees exposed to fipronil as larvae and/or as adults using immunolabeling of the pre-synaptic marker anti-synapsin I and laser scanning confocal microscopy. This permits the visualization of synaptic complexes called microglomeruli. Exposure to fipronil at field-realistic (1 ppb), as well as low (0.1 ppb) and high (4 ppb) concentrations decreased the density of microglomeruli in the MB lip (olfactory) and collar (visual) regions in adult- and larval-treated honey bees. These data indicate that sublethal doses of fipronil alter the structure of the adult honey bee nervous system, possibly through induced synaptic pruning. These results potentially link impaired learning with abnormal synaptic organization, suggesting a mechanism by which fipronil reduces the fitness of honey bee foragers and, ultimately, colonies.

**Title:** Molecular correlates of components of training with inedible food in *Aplysia*

**Authors: V. LUCHINSKY-BRISKIN**, R. LEVY, I. HURWITZ, *A. J. SUSSWEIN
Bar-Ilan Univ., Ramat-Gan, Israel

**Abstract:** Many combinations of stimuli and responses may be experienced while learning. These may affect different regions of the nervous system, and can trigger different molecular cascades. We used learning that food is inedible in *Aplysia* to determine which aspects of a complex training paradigm produce changes in expression of different genes in different ganglia. Memory that a food is inedible in *Aplysia* arises from 3 contingent stimuli: 1) food stimulating the lips; 2) attempts to swallow; 3) failure to enter the gut. Training animals until they stop responding takes 15-20 min, and produces both short- and long-term memories. Treatment with an NO donor substitutes for failed attempts to swallow: lip stimulation for 15-20 min paired with an NO donor produces 24 h memory. Stopping the training after 3 min is ineffective in producing 24 h memory. However, a 3 min training paired with an NO donor produces 24 h memory. A 3 min lip stimulation paired with an NO donor produces no memory.
To dissect molecular correlates of different components of training, we examined changes in mRNA expression after a 3 min training, either paired or unpaired with an NO donor, and of a 3 min lip stimulation, paired or unpaired with an NO donor. A 3 min training (independent of the NO donor) produced increases in mRNA expression of C/EBP, CREB1, CREB1α and of CREB1β in the buccal but not cerebral ganglia. This is consistent with previous findings that localized molecular correlates of training to the buccal ganglia. The NO donor (independent of training) produced increases of the same 4 mRNAs, and of sensorin, in the buccal ganglia, and also produced increases in these 4 mRNAs, and of CREB2 in the cerebral ganglion. The extensive changes in gene expression produced by the NO donor alone in the cerebral ganglion suggests that the primary site at which NO affects memory formation may be in the cerebral ganglion, perhaps on targets of nitrergic neuron C2.
For C/EBP and CREB1 in the buccal ganglia, increases after a 3 min training plus the NO donor were the sum of the increases produced by each stimulus alone. For CREB1α and CREB1β increases after 3 min training plus the NO donor were larger than the sum of the individual increases, indicating that these increases are a correlate of memory formation.

**Abstract:** Previously, we reported that the long-term memory (LTM) for behavioral sensitization in *Aplysia* can be reinstated by abbreviated (partial) training following its disruption by reconsolidation blockade or inhibition of PKM (Chen et al., 2014). Recently, we found that LTM can be induced by partial training after disruption of memory consolidation by protein synthesis inhibition (PSI) begun shortly after training (Pearce et al., 2017). Here, we asked: What are the molecular and cellular processes recruited by partial training that reverse the retrograde amnesia caused by posttraining PSI? To address this question, we first disrupted original memory consolidation by injecting anisomycin, a protein synthesis inhibitor, into animals shortly after full sensitization training; we then tested whether a second injection of anisomycin, prior to or immediately after, partial training disrupted the induction of LTM. The initial, full sensitization training consisted of five spaced bouts of electrical shocks (5X training) delivered to the tail via implanted electrodes. Immediately after the 5X training, either anisomycin or vehicle solution was injected into the hemocoel of the animals. After a posttraining test at 24 h, some animals received partial sensitization training, which consisted of three spaced bouts of tail shocks (3X training). A second injection of anisomycin/vehicle solution was given prior to, or immediately after, the partial training. As previously reported, we found that LTM was fully induced by partial training following retrograde amnesia produced by anisomycin treatment begun shortly after 5X training. But inhibition of protein synthesis, either during or shortly after partial training, blocked the ability of partial training to reverse the retrograde amnesia. Our data indicate that partial training reverses the amnestic effects of posttraining PSI on original sensitization memory through a protein synthesis-dependent process.

**Title:** Modulation of learning-induced long-term behavioral plasticity by prolonged food deprivation and extended sensitization training in *Aplysia*

**Authors: *R. MOZZACHIODI**, K. MAC LEOD, A. SEAS, M. L. WAINWRIGHT
Dept. of Life Sci., Texas A&M Univ. Corpus Christi, Corpus Christi, TX

**Abstract:** Following exposure to aversive stimuli, an organism budgets its behaviors by augmenting defensive responses and suppressing non-defensive behaviors. However, this process must be flexible to accommodate modifications in the animal's internal and/or external state that require the normal balance between defensive and non-defensive behaviors to be adjusted. For example, the mollusk *Aplysia* budgets its behaviors by concurrently enhancing defensive withdrawal reflexes (i.e., sensitization) and suppressing feeding, when exposed to noxious stimuli. In particular, sensitization and feeding suppression are co-expressed across different training protocols and share common temporal domains, suggesting that they are interlocked.

This project focused on the co-expression of the long-term sensitization and feeding suppression and aimed to "uncouple" them using: 1) manipulation of the animal's motivational state through prolonged food deprivation and 2) extended training that induces sensitization lasting for weeks. First, we examined the effects of 14-day food deprivation on the long-term (24 h) co-expression of sensitization and feeding suppression that is commonly induced by a 4-trial training protocol (ITI: 30 min). Four groups of animals were included: trained/14-day food deprived (T-14), untrained/14-day food deprived (UT-14), trained/2-day food deprived (T-2) and untrained/2-day food deprived (UT-2). For each group, the duration of the tail-induced siphon withdrawal reflex (TSWR) and the number of bites in response to a food stimulus were measured prior to and 24 h after training. Sensitization was absent in T-14 animals, whereas it was observed in T-2 animals. Interestingly, feeding suppression was significantly reduced in T-14 animals, when compared to T-2 animals, but it was not completely abolished.

Second, we employed an extended training protocol (4 trials per day x 4 consecutive days) to determine whether feeding remained suppressed as long as sensitization was expressed. The TSWR duration and the number of bites were measured prior to and at 24 h, 72 h and one week in trained and untrained animals. A dissociation between the expression of sensitization and feeding suppression occurred: feeding suppression and sensitization were co-expressed only at the 24-h time point. Feeding suppression was no longer observed at 72 h or later, while sensitization was still present one week after training.

These findings indicate that sensitization and feeding suppression are not interlocked and that their long-term co-expression can be altered by internal (prolonged food deprivation) and external (extended aversive training) factors.

**Title:** Role of ribosomal S6 kinase (RSK) in long-term facilitation (LTF) at sensorimotor (SN-MN) synapses of *Aplysia*

**Authors: *R.-Y. LIU**, L. J. CLEARY, J. H. BYRNE
Dept. of Neurobio. and Anat.,, McGovern Med. Sch. of UTHSC At Houston, Houston, TX

**Abstract:** Coffin-Lowry syndrome (CLS), a type of cognitive disorder that is associated with deficits in learning and memory, is caused by X-linked mutations in the ribosomal S6 kinase 2 (RSK2) gene (Delaunoy et al. 2006). In vertebrates, RSK is activated by ERK and phosphorylates CREB. Although the RSK2 gene has been identified in *Aplysia*, and serotonin (5-HT) appears to activate RSK via the ERK pathway (Philips et al. 2013), the RSK signaling cascades and their roles in long-term synaptic facilitation (LTF) have not been completely examined. In the present study, we used immunocytochemistry to measure the phosphorylation of RSK and found that a standard repeated treatment with 5-HT enhanced phosphorylation of RSK in isolated sensory neuron (SN) cultures. This effect was attenuated by the MEK inhibitor U0126, indicating that it depended upon the MEK-ERK pathway. Moreover, U0126 attenuated 5-HT-induced phosphorylation of CREB1. These results suggest an important role for RSK in the induction of LTF. Next, we targeted this protein using siRNA knockdown, and determined the effect of decreasing RSK expression on CREB1 phosphorylation and LTF. RSK protein levels were assayed by immunofluorescence 96 h after injection of either RSK siRNA or scrambled-siRNA (Con siRNA). RSK protein levels in the SNs injected with RSK siRNA were 28 ± 6.0 % less than those in Con siRNA injected SNs. Moreover, in the SNs injected with RSK siRNAs, 5-HT-induced increases in pCREB1 levels were reduced 31 ± 5.6 %, compared to the Con siRNA-injection group. Finally, injection of RSK siRNA into SNs of SN-MN co-cultures resulted in a significant reduction of LTF (changes in EPSP at 24 h after 5-HT: Con siRNA 90 ± 24 %; RSK siRNA 16 ± 5.6 %). These data suggest that RSK is required for the induction of LTF. Our results suggest that the isolated sensory neuron is an effective system to investigate methods for restoring RSK-related deficits in neuronal function that may occur in CLS.

**Title:** Biphasic regulation of p38 MAPK by serotonin in *Aplysia* sensory neurons

**Authors: *Y. ZHANG**, P. SMOLEN, D. A. BAXTER, J. H. BYRNE
McGovern Med. Sch. of UTHSC At Houston, Houston, TX

**Abstract:** Mitogen-activated protein kinase (MAPK) pathways play critical roles in mediating diverse forms of synaptic plasticity. In *Aplysia*, the ERK isoform is required for long-term synaptic facilitation (LTF), whereas the p38 MAPK isoform is required for long-term synaptic depression (LTD). To better understand the roles of ERK and p38 MAPK, we previously quantified the dynamics of their activation and investigated their interactions (Zhang et al. 2017; ENEURO.0373-16.2017). Following a single 5-min pulse of 5-HT, ERK activity peaked ~45 post-treatment and returned to basal levels by 60 min post-treatment, consistent with results in Philips et al. (2013). In contrast, 5-HT induced a transient inhibition of p38 MAPK, followed by a delayed activation between 25 and 45 min, and a return to basal level at 60 min. Finally, a MAPK kinase inhibitor (U0126) blocked activation of both ERK and p38 MAPK and a p38 MAPK inhibitor (SB203580) blocked the decrease in ERK activity. These data indicate complex interactions between the two pathways. Here, we examined the activity of p38 MAPK at different times after five pulses of 5-HT with regular interstimulus intervals (ISIs) of 20 min. Biphasic regulation of p38 MAPK activity was observed, with a late phase of activation emerging hours after treatment. Compared to vehicle control measurements at the same time points, phosphorylated p38 MAPK (p-p38 MAPK) was elevated by +22.4 ± 6.2% (n = 7) at 1 h after treatment, followed by a decrease to -13.3 ± 9.7% (n = 6) 2 h after treatment. A second increase in p-p38 MAPK levels was evident at 5 h (+15.9 ± 8.9%, n = 6), and p-p38 MAPK levels were also elevated at 24 h (+8.3% ± 6.5%, n = 6). These results indicate that p-p38 MAPK exhibits complex dynamics that could have profound consequences on the effectiveness of different training protocols employed to induce LTF and LTM.

**Title:** Visualizing a lateral amygdala engram

**Authors: *E. KRAMER**[1], J. R. EPP[2], P. W. FRANKLAND[3], S. A. JOSSELYN[4]
[2]Program in Neurosciences and Mental Hlth., [3]PGCRL - NMH 5th floor, [4]Neurosci. & Mental Hlth., [1]Hosp. For Sick Children, Toronto, ON, Canada

**Abstract:** An engram or memory trace may be defined as the neural substrate of stored information that results from past experience and bestows organisms with the ability to express memory in their behaviour. Previous research implicates the amygdala, in particular the lateral nucleus of the amygdala (LA), in encoding and storing associative fear memories. To image the memory trace, previous research relied on the use of antibodies directed against immediate early genes (IEGs; e.g., c-Fos, Arc, etc.). In traditional methods, tissue must be prepared in thin slices, and therefore the three-dimensional aspect of an engram is lost. To observe molecular markers of neuronal activity throughout the LA, we have developed a method to tag and image a fear memory engram in intact, three dimensional tissue. Tissue is processed using a modified Clear Lipid-exchanged Anatomically Rigid Imaging/immunostaining-compatible Tissue hYdrogel (CLARITY) protocol, where samples are embedded in a fixative solution with low hydrogel concentration and passively cleared using detergent before RNA fixation. Small probes are hybridized to the IEG *Arc* and *Homer1a*, and signal is amplified using hybridization chain reaction, where fluorescently tagged nucleic acid hairpin sequences self-assemble into detectable fluorescent polymers. Expression of each IEG allows for identification of neurons active 5 min, and 30 min before sacrifice. Samples are then imaged with either confocal or light-sheet microscopy and processed for detection of nuclei and IEG signal in 3D. We then use this data to examine the number and spatial distribution of neurons that are required to encode and recall memories. This technique allows for the observation of an LA engram in its entirety, and can allow for examination of engram properties in three dimensions. Further analysis will allow us to compare the specific neural signals of memory to behavioural expression of memory recall in mice.

**Title:** Modelling the impact of new learning and neurogenesis on memory stability in the hippocampus

**Authors:** ***L. M. TRAN**[1,2], S. A. JOSSELYN[3], B. A. RICHARDS[5], P. W. FRANKLAND[4]
[1]Neurosciences & Mental Hlth., Sickkids PGCRL, Toronto, ON, Canada; [2]Physiol., Univ. of Toronto, Toronto, ON, Canada; [3]Neurosci. & Mental Hlth., [4]PGCRL - NMH 5th floor, Hosp. For Sick Children, Toronto, ON, Canada; [5]Biol. Sci., Univ. of Toronto Scarborough, Scarborough, ON, Canada

**Abstract:** In neural networks, the stability of stored information may be compromised by a) changing the neural architecture, and b) adding new memories. We tested these ideas in a three layer feed-forward neural network. In this network the input, middle and output layers represent the entorhinal cortex, DG and CA3 regions, respectively. We presented the network with input patterns, drawn from two partially overlapping distributions A and B. The network was trained to transform these A and B input patterns into one of two discrete output patterns. The ability of the network to generalize was assessed by presenting novel input patterns that were either drawn from the A and B distributions, and asking whether it could correctly categorize them. Following initial training, we either a) added new neurons to the middle layer, or b) trained the network on two new distributions, C and D. Changes in neural architecture induced by either a) new neuron addition or b) new learning impaired AB categorization performance, consistent with previous modeling and experimental data. Moreover, increasing excitability and connectivity (input and output) of the new neurons exacerbated these forgetting effects. We next examined how these factors interact. In this experiment, we trained the network on distributions A and B and then added new neurons, as above. We then retrained the network on the new distributions C and D. In this case, the addition of new neurons weakened memory for the original AB categorization, but, at the same time, enhanced learning of the new CD categorization. By exploring how new

neuron addition impacts stored memories, and new memory storage, our results begin to help us understand how adult neurogenesis in the hippocampus influences cognition.

**Abstract:** New tissue clearing and imaging methods are allowing cellular signals to be visualized across whole intact organs. However, the datasets that emerge from these types of analyses are complex, and one major challenge is to develop efficient computational approaches that can be applied to a broad range of datasets (e.g., different clearing methods, different species etc). To date, analysis pipelines have been developed for analyzing whole brain gene expression in iDISCO-cleared mouse brains (ClearMap) and neuronal projections in CLARITY-cleared mouse brains (CAPTURE). Inspired by these tools, we have developed a robust pipeline for imaging, segmenting and analysing cellular signals across the brain that can be used in different model organisms, and following different types of clearing technique. Brain tissue from the adult mouse and zebrafish were collected and processed using either CLARITY or iDISCO clearing techniques. Cleared samples were then imaged and processed for signal quantification. Images were acquired using a commercial light-sheet microscope with parameters optimized for specific clearing and fluorophore methods. Next, image stacks were segmented automatically into distinct brain regions. This portion of the pipeline was constructed using PydPiper, a python tool for building image registration pipelines. Cellular signals were automatically quantified using a popular-vote from several classifier algorithms implemented in python. Cell signal and brain regions were then transformed into region specific cell counts and densities allowing for comparisons between experimental groups as well as between brain areas. We validated our computational approach using ground truth counts from distinct regions and a range of signal sources (i.e., reporter mouse lines and immunohistochemical signals). Finally, we apply our

pipeline to examine neural circuits engaged during fear memory formation and retrieval, and how these circuits are altered in diseased states.

**Title:** Identification of an inhibitory hippocampal-thalamic pathway that is necessary for remote memory retrieval

**Authors: *G. VETERE**[1], F. XIA[2], S. A. JOSSELYN[3], P. W. FRANKLAND[4]
[1]Program In Neurosci. & Mental Hlth., [3]Neurosci. & Mental Hlth., [4]PGCRL - NMH 5th floor, [2]Hosp. For Sick Children, Toronto, ON, Canada

**Abstract:** Systems consolidation requires time-dependent reorganization of brain regions that are necessary for memory retrieval. But how the memory retrieval circuits change over time is not fully understood. The anterodorsal thalamic nucleus (ADn) has been shown to be important for short-term spatial and working memory performance. However, how the role of ADn changes during systems consolidation, and its involvement in remote memory retrieval are unknown. We first show that the activity of ADn during contextual fear memory retrieval decreases over time (1 vs. 28 days post-training). While this could suggest that ADn is no longer necessary during remote memory retrieval, an intriguing alternative is that inhibition of ADn is required to allow successful retrieval at the remote time point. To explore the latter possibility, we first identified regions with monosynaptic projections to the ADn using retrograde tracers (retrobeads and fluorogold). Then we specifically labeled those projections that are inhibitory by infusing a cre-recombinase-dependent adeno-associated virus (AAV) carrying the fluorescence tag EYFP in various brain regions of VGAT-Cre mice. We identified strong inhibitory projections from CA3 to the ADn that could mediate the inhibition of ADn. To test whether this CA3-ADn inhibitory pathway is necessary for remote memory retrieval, we bilaterally infused a cre-recombinase-dependent AAV carrying the inhibitory opsin iC++ in CA3 of VGAT-Cre mice to specifically inhibit GABAergic projections from CA3 to ADn. We trained mice in contextual

fear conditioning, then inhibited the CA3-ADn projections during retrieval test. When we inhibited these projections 28 days, but not 1 day, post-training, mice showed memory deficits. These results suggest that the CA3 inhibition of ADn is required for remote memory retrieval. Our findings provide support for the time-dependent reorganization of memory retrieval circuits, and we show, for the first time, that a CA3-ADn inhibitory pathway is gradually recruited during consolidation and becomes increasingly necessary for fear memory retrieval over time.

**Abstract:** In the lateral amygdala (LA), memory allocation is a competitive process governed by changes in both excitatory and inhibitory neuron activity that can occur prior to learning. While these changes can be sustained (<6h) as a result of previous experience (Rashid et al, 2016), it is not known whether transient increases in activity are also sufficient to drive the events required for allocation to occur. To characterize the time frame in which activity can influence allocation before a learning event, we virally co-expressed the inhibitory and excitatory opsins eNpHR3.0 and ChR2(H134R) in the LA of mice (~10% of neurons) using a herpes simplex virus vector (HSV-NpACY). Transiently increasing the excitability of opsin-expressing neurons with blue light activation of ChR2 6h before auditory fear conditioning was sufficient to induce cause allocation to those neurons, as indicated by the ability to attenuate memory expression with red-light activation of NpHR. In contrast, memory could not be inhibited if the increase in activity occurred 24h prior to fear conditioning.
Increases in activity that drive memory allocation are also accompanied by inhibition of surrounding neurons, presumably through activation of parvalbumin+ interneurons. We hypothesized that this was a form of feedforward inhibition such that neurons with increased

activity inhibited their neighbors. To examine this possibility, we virally expressed NpACY fused to tetanus toxin light chain (NpACY-Tx) in the LA, which prevented neurotransmission from opsin-expressing cells without interfering with their ability to receive input. Optogenetically activating principal neurons expressing NpACY-Tx before fear conditioning was unable to induce allocation, evidenced by the inability to inhibit freezing during NpHR stimulation relative to mice expressing only NpACY. Furthermore, nuclear mRNA levels of the neuronal activity marker *Arc* revealed that blocking the output of excitable principal neurons increased the size of the memory trace by permitting the recruitment of neighbouring cells, similar to previous studies that inhibit LA interneurons after training. Our findings suggest that in the LA, local interactions between excitatory and inhibitory neurons can govern memory allocation well before learning, and that highly excitable principal neurons may suppress the activity of neighbouring cells through a disynaptic circuit mechanism to become the engram.

**Title:** Optogenetic recovery of memories 'lost' to infantile amnesia

**Authors: *A. GUSKJOLEN**, S. A. JOSSELYN, P. W. FRANKLAND
Sick Kids Hosp., Toronto, ON, Canada

**Abstract:** Infantile amnesia refers to the inability of adults to remember episodic events from the earliest years of their lives. Previously, we showed that high rates of hippocampal neurogenesis during infancy contribute to this accelerated forgetting, likely by remodeling hippocampal circuits in which memories are embedded. Here, we tested whether this forgetting is due to a deficit in memory storage or retrieval. To do this, we trained infant mice in contextual fear conditioning and tested them 1-90 days later. Contextual fear memory was robust when tested 1 day after training. However, a dramatic decease in conditioned freezing occurred 15 days following training, and was close to floor levels by days 30-90, indicating that comprehensive forgetting had occurred. To test whether this forgetting was due to a failure of retrieval, we next tested whether environmental reminders could recover these lost memories. To do this, infant mice were trained as before, placed back into the same context 15-90 days later, and given a reminder shock. At all delays, the reminder shock induced freezing in the previously trained mice (but not age-matched naïve controls). This result suggests that the engram supporting this memory is not completely degraded and is recoverable with appropriate cuing. If this is the case,

then artificial activation of the engram should be sufficient to recover the memory 'lost' to infantile amnesia. To test this possibility, we trained infant mice in which we could indelibly tag populations of neurons that were active at the time of encoding with ChR2 (Arc-cre$^{ERT2}$ x ChR2). Reactivation of tagged neurons in the dorsal dentate gyrus (DDG) was sufficient in reinstating the memory 15, 30, and even 90 days following training. Memory retrieval is thought to engage neuronal populations in distributed networks extending far beyond the DDG. To evaluate whether neural activation of tagged DDG neurons 15-90 days post-training induced reactivation of tagged neurons elsewhere in the brain, we examined induction of the immediate early gene c-Fos following testing. We found that light stimulation of tagged DDG increased reactivation of tagged neurons in a variety of neural regions known to be important for memory retrieval (including the CA1 and CA3 subregions of the hippocampus, retrosplenial cortex, anterior cingulate cortex, and basolateral amygdala), suggesting that a brain-wide pattern completion like process was engaged. Together, these results suggest that infantile amnesia is due to a retrieval failure and that either environmental cuing or direct engram activation promote a pattern completion process that leads to successful recovery of memories lost from infancy.

**Abstract:** Adult zebrafish are an increasingly popular and important animal model in neuroscience research. As a genetically tractable vertebrate with a sophisticated behavioral repertoire and high genetic similarity to humans (70%), zebrafish are an ideal system for the study of neurobiology and behavior in both health and disease. However, although a comprehensive brain atlas for adult zebrafish was published over 20 years ago in book form, the field is lacking a digital brain atlas necessary for whole brain mapping studies. Here, we report

on our progress in creating such an atlas by combining tissue clearing techniques with light sheet microscopy, automated image registration, and manual parecellation. We anticipate that the generation of such an atlas will significantly increase the utility and sophistication of adult zebrafish as an animal model in neuroscience research.

**Title:** Communication between retrosplenial cortex and auditory cortex is necessary for the expression of remotely-acquired fear to an auditory cue

**Authors: *M. Y. JIANG**, T. P. TODD, N. E. DEANGELI, D. J. BUCCI
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

**Abstract:** Prior studies have shown that secondary sensory cortical areas are needed for the recall of remotely-acquired (28 days after training) but not recently-acquired (1 day after training) cue-specific fear memories. Similarly, our lab has recently discovered that the retrosplenial cortex (RSC) is also necessary for the recall of remote, but not recent tone-fear memories. RSC receives strong unimodal sensory input from various sensory modalities and is positioned as an interface between cortical sensory regions and a hippocampal/parahippocampal regions, leading us to propose that RSC may function as a ‘hub’ for the integration of sensory information in the service of recalling remotely-acquired memories. If so, we hypothesize that communication between RSC and regions of sensory cortex should be needed for recalling remote memories. To test this, male Long-Evans rats received 3 pairings of a tone and foot shock in a single training session. Twenty-eight days later, rats were randomly assigned to one of three groups. In the ‘asymmetric’ lesion group, the RSC and secondary auditory cortex (AC2) were fully disconnected by lesioning the RSC in one hemisphere and secondary auditory cortex (AC2) in the opposite hemisphere. The ‘symmetric’ lesion group received unilateral electrolytic lesions of RSC and AC2 in the same hemisphere, thus leaving communication in one hemisphere intact. Control rats received sham-lesions. After recovering from surgery for 2 weeks, all rats were re-

exposed to the training context and to the tone (in a different environment) to assess contextual and cue-specific fear memory, respectively. Compared to the control group, rats with asymmetric cortical lesion exhibited a severe impairment in freezing to the auditory cue, while rats with symmetric lesions exhibited an intermediate impairment. In contrast, rats in the two lesion groups exhibited comparable impairments in freezing to the context. Together, these results indicate that communication between RSC and AC2 is necessary for the retrieval of remote auditory fear memory, but not remote context fear memory. These findings have particular relevance for understanding the neural substrates of PTSD, in which individuals experience abnormally strong fear memories for events that happened in the distant past.

**Title:** Communication between retrosplenial cortex and prefrontal cortex is necessary for inhibitory learning and behavior

**Authors: *M. EDDY**, R. HUSZAR, D. J. BUCCI, PhD
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

**Abstract:** The ability to modify behavior based on environmental information and feedback is critical for survival. Indeed, an essential aspect of adaptive behavior is to be able to recognize and use information about the current environmental setting, or *context*, to guide behavioral responding. In this way, contextual cues often indicate whether or not a particular response will result in a favorable outcome, and if not, that it should be inhibited. To date, a substantial amount of research has focused on the involvement of the prefrontal cortex (PFC) in response inhibition. At the same time, research from our laboratory and others has revealed that posterior cortical areas, such as retrosplenial cortex (RSC), are essential for encoding and retrieving contextual information. However, these two lines of research have proceeded relatively separately and it remains largely unknown if and how PFC and RSC interact to support the use of contextual information to guide behavior. Here we tested the hypothesis that contextual information provided to PFC from RSC is essential for effective behavioral inhibition. In Experiment 1, rats with RSC lesions were tested on an extradimensional set-shift task in which responding based on a previously learned rule must be inhibited and new rules applied, a process known to rely upon the PFC. Rats with RSC lesions were impaired at the shift portion of this task, but performed

similarly to sham-lesioned rats during the initial discrimination. In Experiment 2, we targeted and selectively inhibited neurons projecting from RSC to PFC during a test of operant extinction to further scrutinize the importance of contextual information provided by the RSC to the PFC. Rats were trained to lever press in one context (context A) and then extinguished in a different context (B). Testing occurred in extinction (no reward available) in both contexts, during which neurons in the PFC that receive projections from RSC were inhibited. Selective inhibition of this pathway resulted in increased responding (compared to controls) in both the acquisition (A) and extinction (B) contexts, indicating an inability to inhibit lever pressing. Taken together, these results suggest that projections from the RSC to PFC are critical for inhibitory control of behavior.

**Title:** Damage to postrhinal cortex has no effect on the expression of remote cue-specific fear memory but does impair the renewal of conditioned fear

**Authors: *D. FOURNIER**[1], N. E. DEANGELI[2], D. J. BUCCI[3], T. P. TODD[2]
[1]Program of Exptl. and Mol. Med., [2]Dept. of Psychological and Brain Sci., [3]Dept. of Psychological and Brain Sci. & Program in Exptl. and Mol. Med., Dartmouth Col., Hanover, NH

**Abstract:** The postrhinal cortex (POR) is part a network of posterior cortical regions that provide the hippocampus with processed sensory information. Prior studies have demonstrated that POR is critically involved in hippocampal-dependent processes, such as contextual fear conditioning. Specifically, lesions of the POR carried out either prior to, or at various times after fear conditioning (e.g., 1, 28 or 100 days) impair the expression of fear to the training context. In contrast, pre-training lesions of POR do not affect the expression of fear to a discrete cue (e.g. a tone) that was paired with foot shock. However, it is currently unknown whether POR damage that occurs after training affects cue-specific fear memory. This is important to address because recent evidence indicates that over time, cue-specific memories can become dependent on polymodal cortical associations areas that are associated with the hippocampus. Furthermore, it is unknown if the POR is necessary for the extinction and/or renewal of cue-specific fear

memories. This is also a significant gap in the literature since renewal is not impacted by hippocampal damage in certain cases, suggesting that extinction and renewal of conditioned fear might also depend upon other regions such as the POR. To address these questions, rats received a single conditioning session in Context A, with three cue-shock pairings. Twenty-eight days later, rats received lesions of the POR. After recovering from surgery, rats were placed back in Context A (no shocks) to assess contextual fear memory, and the next day, the tone was presented 20 times in Context B (no shocks). Rats in the lesion group exhibited reduced contextual fear (consistent with prior studies) but intact fear to the tone. Rats then underwent three days of extinction training with 20 tones presentations in Context B each day. Following the last day of extinction training, renewal of extinguished fear was tested in Context A via 20 presentations of the tone. We found that POR lesions did not impact extinction training, but did result in lack of renewal of conditioned fear to the tone.

**Title:** Retrosplenial cortex is required for the retrieval of remote fear memory for visual cues

**Authors: *D. J. BUCCI**, M. Y. JIANG, N. E. DEANGELI, T. P. TODD
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

**Abstract:** A significant body of literature has demonstrated that damage to the retrosplenial cortex (RSC) impairs contextual and spatial learning in humans as well as laboratory animals. In contrast, memory for individual stimuli (cue-specific memory) appears to be largely intact following RSC lesions or temporary inactivation. In our own lab, for example, RSC damage that occurs either prior to, or 1 day after, auditory fear conditioning impairs the subsequent recall of contextual fear memory but not tone fear memory. However, a small but growing number of studies indicate that RSC may in fact have a role in cue-specific memory under certain circumstances. For instance, we recently found that manipulations of RSC at more remote times after training (28 days) impair both context and tone-specific fear memory. Based on this finding, and the known interconnectedness of RSC with a variety of unimodal cortical sensory regions, we posit that over time, cue-specific memories may become more dependent on RSC. If

so, we might expect that this function also applies to cues of sensory modalities other than audition. To test this, rats underwent fear conditioning in which a visual stimulus (a light) was paired with footshock during a single training session. Either 1 day (recent memory) or 28 days later (remote memory), rats received lesions of RSC and were allowed to recover before being re-exposed to the training chamber to test context fear memory, and to the light (in a different chamber) to test fear memory to the light. Control rats received sham-lesions. We found that RSC lesions impaired the expression of fear to the light when they took place 28 days after training, but not 1 day after training. In contrast, lesions at both time points impaired contextual fear memory. These findings replicate our prior results using an auditory stimulus, thus further supporting the notion that RSC has a selective, time-dependent role in expressing fear memory to specific cues. In contrast, the effects of RSC damage on context fear memories have repeatedly been shown to be independent of the training-to-lesion interval.

**Title:** Characteristic neocortical circuits encode different visual shape discriminations

**Authors: *A. I. GELLER**[1], G. ZHANG[1], H. ZHAO[1], N. COOK[1], M. JAN[1], E. CHOI[1], M. SVESTKA[1], R. G. COOK[2]
[1]LSUHSC, New Orleans, LA; [2]Tufts Univ., Medford, MA

**Abstract:** Synaptic plasticity and neural network and theories specify that the essential information for cognitive discriminations is encoded in different neuronal ensembles. But these ensembles are poorly characterized. One critical issue is if a specific discrimination is encoded in a characteristic ensemble among multiple individuals. In this study (Behav Brain Res In Press), we used a genetically-modified circuit that encodes essential information for a cognitive task to

show that characteristic ensembles encode specific visual shape discriminations.
For the model system, using a virus vector, we delivered a constitutively active protein kinase C into several hundred glutamatergic or GABAergic neurons in a multimodal associative area, postrhinal (POR) cortex, that has a critical role in visual object discrimination learning (J Neurosci 2005 *25* 8468-81). This intervention resulted in phosphorylation of specific PKC substrates that have important roles in synaptic plasticity. Further, activation-dependent neurotransmitter release was increased. Of note, this intervention supported enhanced the learning rate and accuracy for specific visual shape discriminations learned after gene transfer. The genetically-modified circuit encodes some of the essential information for performance (PNAS 2010 *107* 14478-83). Following gene transfer and learning image sets, we made neurochemical lesions that ablated the genetically modified circuit, ~21 % of POR cortex, centered on the gene transfer site. These lesions selectively reduced performance for discriminations learned after gene transfer.
During learning, neurons in the genetically-modified circuit exhibit increased activity, as shown by activity-dependent gene imaging. Quantifying these neurons showed that the essential circuit was small, ~500 neurons, and was sparse coded, with a coding density of ~3 %, consistent with neural network theory.
By analyzing the locations of the active neurons, we found that different image sets are encoded in characteristic and different ensembles of neurons (Behav Brain Res In Press). Specifically, there was a bilaminar pattern of active neurons. One layer of active neurons was near the surface of POR cortex, in layers 2, 3, and the superficial part of layer 4; and the second layer of active neurons was deeper, in the deeper part of layer 5 and in layer 6. Further, for one image set ([] vs. +) the superficial layer contained more active neurons than the deeper layer. But, for a second image set (/ vs. \), the two layers contained similar numbers of active neurons. Thus, different discriminations are encoded in characteristic and different neuronal ensembles.

**Abstract:** Working memory (WM) is a cognitive system that contains internal representations of recent events for a pending action. Clinicians rely on subjective measurements of WM for diagnosis and treatment of memory disorders like Alzheimer's Disease and dementia with Lewy bodies. Our work shows that a signature of working memory may be derived from analysis of oscillatory neuronal population activity from monkeys and that this signature allows differentiation between healthy and impaired WM. First, we use supervised machine learning to identify sparse feature representations of local field potentials (LFPs) recorded from prefrontal and posterior parietal regions during the delay period of a delayed match-to-sample (DMS) task with both correct and incorrect performance by macaque monkeys. Then, these sets of feature representations serve as dictionaries for correct and incorrect WM neuronal population activity, respectively. The dictionaries are characterized by their spectral composition. Next, we develop a discrimination algorithm to predict whether novel trials contain correct or incorrect responses. The correct performance dictionary contains significantly different spectral components than the incorrect performance dictionary. We conclude that delay-period LFP activity during the DMS task allows for successful discrimination between correct and incorrect response classification, and that the monkey’s correct responses represent healthy WM and the incorrect responses represent impaired WM. Thus, our results establish that different spectral components characterize healthy and impaired WM, and that delay activity during a WM task can discriminate between healthy and impaired WM. The signature of WM will be tested in the human EEG in future studies of the same task.

**Title:** Neuromodulatory predictions: Comparison of forebrain cholinergic and midbrain dopaminergic responses during reinforcement learning

**Authors: *J. F. STURGILL**[1], S.-J. LI[2], B. HANGYA[3], A. KEPECS[2]
[1]Neurosci., [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]Dept. of Cell. and Network Neurosci., Inst. of Exptl. Med., Budapest, Hungary

**Abstract:** Basal forebrain (BF) cholinergic (ChAT) neurons project throughout cortex and, by modulating cortical plasticity, may support learning. Yet the principles governing ChAT neuron activation, and the precise relationships of cholinergic signals to learning and other neuromodulatory signals have remained obscure. Recent work from our lab revealed that ChAT neurons respond rapidly (~20ms) to reinforcers (reward, punishment) and are modulated by reinforcement expectation or surprise. A putative role in reinforcement prediction invites comparison to dopamine neurons for which a key conceptual advancement was that they compute reward prediction error (RPE): the difference between reward expectation (as informed by a predictive stimulus) and reward received. Here, we adopt an analogous behavioral and computational approach to understand the principles governing ChAT neuron activation. Do ChAT neurons respond only to reinforcers or also to outcome-predictive sensory cues? Are the outcome-related responses modulated by the degree of surprise, as for dopamine neurons? And computationally, do ChAT responses represent an unsigned counterpart to dopaminergic RPE? Using single and dual fiber photometry, we simultaneously monitored the responses of BF ChAT neurons and midbrain dopamine neurons in a cued probabilistic outcome task. As a reference point, we measured bulk GCaMP responses of dopaminergic neurons, which showed the canonical features of RPE, and confirmed that ChAT neurons respond to both reward and punishment. During learning we found that ChAT neurons rapidly acquire cue responses to predictive stimuli. We further demonstrated that outcome responses of ChAT neurons are diminished by reward expectation. Using dual fiber measurements in a reversal learning paradigm, we examined the fine-scale relationships between ChAT and dopamine neuron activity and observed a striking but partial correspondence between the two systems within and across learning trials. Our results demonstrate that BF ChAT neurons provide a cortical prediction error signal computationally distinct from but coordinated with dopaminergic RPE.

**Abstract:** Recognition memory is the ability to assert the familiarity of things previously encountered; one of the most important survival skills that animals have developed through evolution is taste-recognition memory. Using taste memory model such as preference test and conditioned taste aversion (CTA), the neural pathways involved in learning have been well described by several electrophysiological and anatomical studies. Recently, evidence in rodents showed that long-term sugar consumption produces changes in the appetitive and aversive learning processes and suggests that, prolonged sugar intake, could trigger an escalating consumption of sweet taste due to changes in several brain areas involved during taste learning and reward responses. Mouse imaging studies show that learning alters the volume of specific brain regions. For example, environmental enrichment and spatial learning are associated with increases in hippocampal volume at a scale detectable with mouse MRI, providing an insight into anatomical changes and interactions between brain areas induced by long-term memory. However, volume changes related with taste learning and prolonged exposure of sweet taste, have not yet been described. Therefore, we used *in vivo* manganese-enhanced MRI (MEMRI), in healthy adult mice that undergo two weeks of voluntary sugar solution drinking, to map the macroscopic structure changes related with high familiar taste appetitive learning, as well as their correlation with the ability to achieve new taste aversive associations. MEMRI images were acquired 1 and 3 days before taste presentation (baseline), as well 1 and 2 weeks after mice were exposed to 10% sucrose solution or water as the only liquid available. Subsequently, to evaluate the latent inhibition of CTA induced by sucrose exposure, two more MEMRI were done, after CTA retrieval and one week later when aversive memory was completely extinguished. Automated image processing algorithms were used to detect volume changes associated with long term sugar consumption. The results showed volume changes in the brain areas directly related with taste memory formation, particularly insular cortex and amygdalar complex, and several significant interactions with reward pathway-related areas.

**Title:** Evaluation of neuronal activity patterns at the population level during contextual fear discrimination learning

**Authors: *A. CORCHES**, A. HIROTO, T. BAILEY, J. SPEIGEL, J. PASTORE, J. MAYER, E. KORZUS
Univ. of California, Riverside, Riverside, CA

**Abstract:** Discriminatory fear learning involves fear conditioning, a form of classical Pavlovian conditioning which has become the best studied behavioral model for associative learning along with its underlying synaptic and circuit level plasticity. Fear behavior is differentially regulated by the prelimbic (PL) and infralimbic (IL) subdivisions of the mPFC via fear excitation and inhibition, respectively, which may be due to differential connectivity with amygdala. Current research investigates how the PFC is able to act through multiple pathways to exert both excitatory and inhibitory influences on fear responses under the central hypothesis that accuracy of fear memory is attained via extinction of fear responses to non-reinforced stimuli. Neuronal activity at a population level can be effectively studied in the brain using calcium imaging or Arc gene-based TetTag bi-transgenic mice, in which neuronal activities can be persistently labeled during a specific time window. We evaluate large-scale neuronal activity patterns in response to dangerous and safe contextual stimuli within relevant brain regions including the hippocampus, the mPFC and the amygdala during different phases of fear discrimination learning to uncover the neural mechanisms underlying ability to distinguish between danger and safety. Understanding how fear memories are encoded and kept resistant to confusion is clinically relevant because fear memory generalization is a hallmark of phobias, PTSD and generalized anxiety disorder.

**Abstract:** The thalamic reticular nucleus (TRN), a shell of GABAergic neurons surrounding the thalamus, provides one of the most significant inhibitory inputs to the thalamus, thereby playing a pivotal role in sensory processing, attention control, and sleep modulation. Although previous anatomical data suggest a potential role of the TRN in emotional processing, this issue remains unexplored. Here, we show that a specific subregion of the TRN is critical in fear extinction. We conducted neural tracing experiments in mice and observed that the rostroventral part of the TRN (TRNrv) projected to the limbic thalamus, including the paraventricular nucleus of the thalamus (PVT), known to be important in fear regulation. By contrast, the neighboring rostrodorsal part of the TRN (TRNrd) projected to the centrolateral thalamus (CL). Our behavioral studies showed that optogenetic inhibition of TRNrv neurons suppressed fear extinction, whereas inhibition of TRNrd neurons did not affect fear extinction. Our *in vivo* recordings demonstrated an increased firing rate of TRNrv neurons during fear extinction learning, and boosting the firing rate led to enhanced fear extinction. Moreover, optogenetic inhibition of TRNrv terminals in the PVT resulted in the persistent elevation of fear. Our results reveal a previously unknown role of the TRN, control of emotional behavior, and a critical circuit for fear memory modulation.

**Abstract:** The rodent perirhinal cortex has an established role in object recognition, but the role of perirhinal cortex in associative learning is less well explored. Electrical recordings in perirhinal cortex have identified neurons that represent objects [Burke et al., Hippocampus (2012) 22(10):2032-2044], but how such representations develop with learning and are influenced by contextual cues remains unknown. To study the role of the perirhinal cortex in associative learning, we used a miniature fluorescence microscope to record perirhinal ensemble neural calcium dynamics in freely behaving mice as they learned a task requiring mastery of a bi-conditional rule. This behavioral task involved two visuo-tactile stimuli that were independently presented in two different spatial contexts. In each context, only one of the two stimuli signaled the presence of a reward; thus, to receive rewards successfully in both contexts the mouse had to learn two different context-stimulus associations. With 8-10 days of training mice learned to perform this task well, even when rapidly alternating between the two contexts. As the mice performed the task, the dynamics of perirhinal neural ensembles encoded task-relevant variables such as stimuli and context, and these representations remained distinct and stable throughout the learning process. By varying stimulus locations within and across the two contexts, we found that stimulus representations in the perirhinal cortex were invariant to location and reward contingency, unlike what we had found previously in hippocampus, where neural coding was more dynamic. Together, the invariant coding in perirhinal cortex and the more dynamic coding in hippocampus may jointly support an animal's ability to recognize stimuli reliably across different contexts while responding in a context-specific manner.

**Abstract:** Previous studies have shown changes in membrane properties of neurons in rat deep cerebellar nuclei (DCN) as a function of development, but due to technical difficulties in obtaining viable DCN slices from adult animals, it remains unclear whether there are learning-related alterations in membrane properties of DCN neurons in adult rats. We performed whole-cell patch clamp recordings on DCN neurons in rats aged P25-26 given delay eyeblink conditioning or unpaired stimulus presentations. One day after electromyography electrode implantation, adult rats received either four sessions of delay eyeblink conditioning or four sessions of unpaired stimulus presentations with a tone as conditioned stimulus and a shock as unconditioned stimulus. Compared to rats given unpaired stimuli, rats given eyeblink conditioning showed a rapid increase in conditioned responses across sessions. Whole cell recordings from the rats given eyeblink conditioning revealed significant changes in membrane properties of DCN neurons including a reduction in afterhyperpolarization amplitude (-10.23 ± 1.00 vs -13.71 ± 1.27 mV, $p<0.05$) and an increase in input resistance (118.59 ± 13.14 vs 85.88 ± 13.43 MΩ, $p<0.05$) - indexes of membrane excitability that have been shown to be important for eyeblink conditioning in hippocampus and prefrontal cortex. This is the first report of learning-related changes in membrane properties of adult DCN neurons which may underlie acquisition of eyeblink conditioning.

**Abstract:** Working memory (WM) is the ability of actively maintaining and manipulating information in the brain and important for cognitive behaviors (Baddeley 2012). Many previous studies have shown that persistent neural activity of many brain regions are important for WM (Fuster 1997, Pasternak and Greenlee 2005, Jonides, Lewis et al. 2008, D'Esposito and Postle 2015, Eriksson, Vogel et al. 2015, Christophel, Klink et al. 2017). However, how to improve WM is less clear. In the current study, head-fixed mice were trained to perform an olfactory delayed paired association (DPAL) task, in which sensory information was required to be maintained during a delay period of 5-10 seconds.. The activity of lateral orbitofrontal cortex (LOFC) was optogenetically suppressed during the delay period in blind design. Surprisingly, the performance of mice was improved during the learning phase. The phenomenon was consistently observed with different parameters, including varying delay duration or using ibotanic-acid lesion to suppress LOFC activity. The improvement was regionally specific, because suppressing ventral or medial part of orbitofrontal cortex did not modulate performance. The effect was also temporally specific, because suppressing LOFC during the decision making period had no effect to performance. To determine downstream pathways of LOFC in improving WM performance, we expressed optogenetic virus into LOFC and used light to separately suppress the activity of axonal terminals in different downstream brain areas, including dorso-medial caudate/putamen (dmCP) of striatum, ventral tegmental area (VTA), perirhinal cortex, and secondary motor cortex. Among the four regions, only suppression the activity of LOFC-dmCP projection improved WM performance. To determine the neural correlates of LOFC in the WM task, we extracellularly recorded single-neuron activity by tetrode. We found that the neuronal activity in LOFC clearly encoded the odor identity during the delay period, especially during the early delay period. Therefore the presence of neural correlates in LOFC negatively regulated WM performance. In summary, the results discovered a surprising improvement in WM performance by optogenetic suppression of LOFC-dmCP pathway. Baddeley, A. (2012). Annu Rev Psychol **63**: 1-29.Christophel, T. **Title:** The effect of a high sugar diet on context-dependent memory and neuroinflammation in rats

**Authors: *K. N. ABBOTT**[1], M. J. MORRIS[2], R. F. WESTBROOK[1]
[1]Sch. of Psychology, [2]Sch. of Med. Sci., UNSW Sydney, Sydney, Australia

**Abstract:** The hippocampus binds the individual elements of a context (e.g. a room) into a unique integrated representation that facilitates subsequent discrimination of that context from other similar contexts and, thus, displays of context-appropriate behaviour. Research in rodents demonstrates that excessive sugar consumption impairs hippocampal-dependent spatial memory, and that this deficit may be mediated by diet-induced neuroinflammation. It remains unknown however whether these deficits in spatial memory extend to the formation of unified context representations and retrieval of context-dependent memory. In this research, we used a rodent model to assess the effect of a high sugar diet on context-dependent memory and neuroinflammation. Rats were provided ad libitum access to chow and water (control diet; CD) or chow, water, and 10% (w/v) sucrose solution (high sugar diet; HSD). Spatial memory was assessed after four weeks diet using an object-and-place recognition memory test. After six weeks, rats were assessed for their ability to discriminate a context where they had received a mild aversive foot shock from a similar yet distinct context. After eight weeks, rats were sacrificed and neuroinflammation within the hippocampus was assessed using an Interleukin-1-beta (IL-1β) Enzyme Linked Immunosorbent Assay. Analysis revealed that rats consuming a HSD had impaired hippocampal-dependent spatial memory and context-dependent memory, as well as increased levels of the neuroinflammatory marker IL-1β. There were no correlations between deficits in spatial memory, context-dependent memory, and level of neuroinflammation, irrespective of diet condition. This research provides reasonable evidence that high sugar consumption negatively influences the ability of the hippocampus to form context

representations, and that this can lead to displays of context-inappropriate behaviour. Further research is required before neuroinflammation can be excluded as a mediator of these diet-induced cognitive deficits.

**Abstract:** Group living animals can use public information when making decisions about the presence of threat in the environment. Social cues from conspecifics can be used not only to trigger a response but also as unconditioned stimulus (US) that can be paired with other cues in the environment (that will become conditioned stimuli, CS) in order to predict the presence of threat in the environment through associative learning (observational conditioning). The evolution of a specialized neural module to process social information has been the focus of much debated in comparative cognition literature. In this study we tested the occurrence of observational conditioning in zebrafish, and characterized its neuromolecular mechanisms. We found that chemical (alarm cue) but not visual (sight of conspecifics freezing) was effective as a US in the observational conditioning task. Next, we characterized the pattern of brain activation associated with olfactory observational conditioning using the expression of an immediate early gene (c-fos) as a marker of neuronal activity. Differential activation patterns were observed between learners and non-learners in olfactory bulb and dorsal medial telencephalon (Dm, teleost homologue of the basolateral amygdala in mammals). We created a transgenic zebrafish line that expressed the yeast Gal4 transcription factor in a specific neuronal population in Dm, and used it for the selective inactivation of Dm (by expressing a neurotoxin gene via the Gal4-UAS system). Then we tested the involvement of this brain region in observational learning (i.e. when a social US is used), and found that inactivation of the neuronal population impaired fear conditioning using the alarm cue as US.We showed that the same neuronal population is essential for fear conditioning using an electrical shock as US (Lal et al. submitted). Thus, our results support the

existence of a common neuronal population that mediates both observational and non-social fear conditioning.

**Authors: *U. DAG**, J. LE, Z. LEI, A. WONG, K. KELEMAN
Janelia Res. Campus, HHMI, Ashburn, VA

**Abstract:** *Drosophila melanogaster*, fruit flies, can associate either aversive or rewarding stimuli with odors to form aversive or appetitive olfactory memories, respectively. In addition to this simple form of associative learning, flies are also able to associate their behavior with its outcome. In courtship conditioning paradigm, *Drosophila* males learn to suppress their courtship towards either receptive virgin or unreceptive mated females after being persistently rejected by unreceptive females. Previously, we have shown that activity of dopaminergic aSP13 neurons that innervate the tip of the mushroom body gamma neurons, is required and sufficient for acquisition of the short-term courtship memory. More recently, we determined that activity of the same aSP13 neurons, after memory acquisition, is also sufficient and necessary for long-term courtship memory consolidation. To investigate the mechanisms underlying consolidation of this memory we examined the role of sleep in this process. We have established that sleep is both necessary and sufficient for memory consolidation in a manner similar to that of aSP13 neurons. More specifically, we identified neurons in a brain region implicated in homeostatic control of sleep, to be involved.

**Abstract:** Current theories of functioning in lateral hypothalamus (LH) restrict this region to promoting the innate drive to feed. This has been supported by evidence that LH stimulation promotes an increase in food consumption, recently demonstrated by stimulation of LH GABA cells alone. But this increase in feeding could reflect a more complex learning process. We are not born with a drive to approach particular foods; we have to learn that the sight and smell of such foods are associated with the rewarding aspects of their consumption for them to motivate future behavior. Using a novel GAD-Cre rat, we took advantage of the temporal specificity of optogenetics to dissociate a role for LH GABA in learning about food associates from a more traditional role in promoting feeding. In a Pavlovian conditioning procedure, we first showed that inhibition of LH GABA cells during cue presentation and not during reward delivery impaired the ability of rats to use the cue to predict future reward. Secondly, we showed that inhibition of LH GABA cells after normal learning had taken place reduced responding to the reward-predictive cue, suggesting LH is a site involved in the development and expression of cue-reward associations. We next examined how this cue-elicited expectation may be utilized at the circuit level. Here, we demonstrated that inhibition of LH GABA terminals in the ventral tegmental area (VTA) during cue presentation augmented learning. This is consistent with the notion that LH GABA sends cue-elicited expectations to VTA to modulate prediction errors, where depriving VTA of this signal resulted in persistent errors, driving greater learning about the antecedent cue. Finally, inactivation of VTA dopamine projections to LH during reward delivery also impaired learning, suggesting activity from VTA DA during reward is relayed back to LH to update cue-elicited expectations. These data demonstrate that the LH GABA- VTA circuit is critical for learning to use environmental stimuli to predict future rewards.

**Title:** The ventral-striatum's role in learning from gains and losses

**Authors: *C. TASWELL**[1], V. D. COSTA[2], R. VICARIO FELICIANO[4], K. ROTHENHOEFER[5], B. B. AVERBECK[3]
[1]Unit on Learning and Decision Making, NIH/NIMH, Bethesda, MD; [2]Lab. of Neuropsychology, [3]NIMH/NIH, Bethesda, MD; [4]Natl. Inst. of Health/NIMH, Bethesda, MD; [5]NIMH, NIH, Bethesda, MD

**Abstract:** Much of the literature on reinforcement learning (RL) suggests that the ventral striatum (VS) is crucial to the learning process. However, recent evidence suggests that this is not the case, and that the VS may have a more specific role in RL than previously thought. To assess the role of the VS in RL, we tested rhesus macaques with VS lesions on deterministic and stochastic two-arm bandit learning tasks. Typically, RL studies assessing the VS focus on appetitive learning treating lack of reward as aversive. Without studying both the appetitive and aversive side of RL one cannot assess what role the VS plays in aversive learning. To account for this, we conditioned tokens as reinforcers in a task where animals could both gain and lose tokens. This allowed us to assess learning from gains and losses. We ran three experiments; two used deterministic reinforcement and one used stochastic reinforcement. In each experiment there were three different types of conditions, gain gain (gg), gain loss (gl), and loss loss (ll). In the first deterministic experiment, for each new block of trials we introduced four novel images, where each image led to a different outcome when chosen (+2, +1,-1,-2). On each trial, monkeys were presented with a pair of images differing in value (six possible conditions). In this experiment, monkeys with VS lesions showed no significant behavioral deficits in any of the conditions relative to matched controls. The second experiment was the same as the first, except we added a cue with a value of 0 to the set (+2, +1, 0, -1, -2). This resulted in ten conditions. In this experiment, monkeys with VS lesions showed significant behavioral deficits in the gg condition (+2 vs +1), only. The final experiment was just like the first except it was under a stochastic reward schedule such that 75% of the time the outcome was the value of the cue, and 25% of the time the outcome was 0. In this experiment, monkeys with VS lesions again showed significant behavioral deficits only in the gg condition. Across the three experiments, no deficits were observed when choosing between a gain and a loss stimulus. Thus, the VS does not play a

general role in all forms of reinforcement learning, but plays a specific role in learning to select between rewarded outcomes.

**Title:** Medial prefrontal cortex lesions increase vulnerability to uncontrollable stress, resulting in cognitive impairments

**Authors: *J.-C. PARK**, D.-H. CHOI, J.-S. HAN
Konkuk Univ., Seoul, Korea, Republic of

**Abstract:** Exposure to uncontrollable stress may lead to cognitive impairments observed in post-traumatic stress disorder (PTSD) by affecting hippocampal functions. In recent years, it has been reported that medial prefrontal cortex (mPFC) plays an important role in the development of PTSD pathophysiology. However, it is unknown whether dysfunction of mPFC might influence cognitive status of the animals experiencing an uncontrollable stress. Therefore, the present experiment was conducted to examine whether mPFC lesions affect susceptibility to uncontrollable stress-induced memory impairments. After lesion surgery, rats were subjected to either 20-min restraint + 20 tail shock (20-min stress), which is ineffective in inducing memory impairments, or 60-min restraint + 60 tail shock (60-min stress) resulting in memory impairment. Cognitive status of these stressed rats was examined using novel object recognition task. Regardless of the mPFC lesion, rats that received 60-min stress exhibited impairments in object recognition memory compared with unstressed rats. Sham- operated rats with 20-min stress showed intact recognition memory, however, 20-min stress reliably led to impairments of recognition memory in rats with mPFC lesion. Next, the activity of the amygdala, measured by the expression of the c-fos protein, was analyzed 60 min after 20-min stress treatment. Compared to unstressed rats, the number of cells expressing c-fos was increased in both sham operated and lesioned rats. However, the increment of c-fos positive cells in mPFC lesioned rats was significantly higher than that in sham operated rats, indicating that mPFC lesion could predispose amygdala to hyperactivity in the stressful circumstance. These findings suggest that absence of mPFC, a loss of the ability to regulate the amygdala activity, increase vulnerability to traumatic stress effect on hippocampus and contribute to the development of behavioral phenotypes

associated with PTSD. Supported by the National Research Foundation of Korea grants 2015M3C7A1031395 to J.S.H.

**Title:** Effects of long term sugar or high fructose corn syrup (HFCS-55) consumption withdrawal on anxiety and corticosterone levels: Correlation with glutamate realase in the insular cortex during new aversive learning

**Authors: *D. BADILLO JUAREZ**, M. I. MIRANDA
behavioral and cognitive neurobiology, Inst. De Neurobiología UNAM, Queretaro, Mexico

**Abstract:** Taste recognition memory is a crucial ability to associate taste-related properties with the consequences of food ingestion; therefore, the consumption of palatable caloric food has a significant impact on learned habits and preferences. The withdrawal of sugar after several weeks of intermittent feeding schedule in rodents induce significant behavior changes associated with increases in anxiety and stress hormones, and with changes in some neurotransmitters in overlapping brain circuitry that regulates food processing, as well as learning and memory; suggesting that reinforcers, such as sugars, stimulate similar neural systems. In this regard, the insular cortex has a crucial role during taste memory formation and food integration consequenses; particularly, glutamatergic activity is involved in signaling aversive visceral information during conditioned taste aversion (CTA). Furthermore, corticosterone (CORT) levels play an important role during taste aversive memory consolidation and the expression of anxiety behaviors. Thus the goal of this research was to evaluate in rats, the effects of long-term (21 days) permanent or intermittent sugar (10%) or HFCS-55 (8%) consumption, and their withdrawal, on preference taste and CTA, as well as on CORT plasma levels and anxiety-like behaviors, by means of elevated plus maze (EPM). Furthermore, we evaluated glutamate activity in the IC during new aversive learning (CTA) with the same sweetener. The results showed that consumption schedules induced significant differences in taste preference and CTA, but neither sugar nor HFCS-55 schedules, nor their withdrawal induced any change in EPM parameters or CORT levels. Microdialysis results in control groups revealed similar release of glutamate in the

IC induced by a visceral malaise agent (LiCl) during CTA. The results suggest that changes in taste memory after withdrawal of sugar or HFCS-55 permanent or intermittent long-term consumption are not related with anxiety behaviors or changes in stress hormone levels.Acknowledgments: Technical assistants Gabriela Vera and Alejandro Rangel-Hernández

**Abstract:** Cognitive theories suggest that working memory maintains not only the identity of recently-presented stimuli but also a sense of the elapsed time since the stimuli presentation. Previous studies of the neural underpinnings of working memory have focused on sustained firing, which can account for maintenance of the stimulus identity, but not for representation of the elapsed time. We analyzed single-unit recordings from the macaque lateral prefrontal cortex (lPFC) during performance of a delayed-match-to-category task. The sample stimulus triggered a consistent sequence of neurons, each neuron in the sequence firing during a circumscribed period of time. The sequences initiated by different sample stimuli were distinct but overlapping, with the degree of overlap reflecting the visual similarity of the stimuli that caused the sequences. These sequences of neurons encoded both stimulus identity and the elapsed time. The temporal code became less precise as the sample stimulus receded into the past. These findings suggest that working memory is maintained as a compressed timeline, consistent with longstanding cognitive theories of human memory. We describe also a neuro-cognitive computational model,

providing a neural mechanism that could give rise to the observed conjunctive coding over the log-compressed time.

**Title:** Distinct patterns of neural co-ordination support the binding of multi-modal memories across multiple brain circuits

**Authors: *A. J. MORLEY**[1], D. DUPRET[2]
[1]MRC BNDU, [2]Univ. of Oxford, Oxford, United Kingdom

**Abstract:** In order for a memory to be useful it must be bound across multiple modalities. Here we recorded from multiple memory-associated regions in freely-behaving mice while they performed a task that requires the binding of auditory, valence and contextual/visual information. We show that, in this task, recall is accompanied by distinct short-term modes of co-ordination between these regions. These modes of co-ordination were identified from patterns found in the spike-train cross-correlations and are better predictors of both trial-identity and behaviour than the firing rate of the neurons alone. We thus hypothesize that they reflect efficient information routing across this memory-associated circuit and so support a rapid behavioural response.

**Title:** Hippocampal area CA3 is necessary for ripples and place field responses

**Authors: *H. DAVOUDI**[1,2,3,4], D. J. FOSTER[1,2,4]
[1]Dept. of Psychology, UC Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [3]Dept. of Biomed. Engin., [4]Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

**Abstract:** The hippocampus has a critical role in the formation of new memories. The local field potential in hippocampal area CA1 exhibits high frequency (100- 250 Hz) events known as sharp-wave ripples (SWRs) which occur during both slow-wave sleep and awake rest. During exploration, CA1 pyramidal cells, which receive excitatory inputs from entorhinal cortex and hippocampal area CA3, show location-specific activity known as place fields. Previous studies have suggested that direct entorhinal input to CA1 is sufficient for the expression of ripples and ripple-asociated spiking in CA1 during rest, and for place field responses in CA1 during running. However, these studies used chronic manipulations allowing the possibility of compensatory mechanisms. Here we used an acute strategy, combining optogenetics and multi-tetrode recording, to suppress CA3 input to CA1. An AAV5 was delivered stereotaxically to CA3a and b, to drive subsequent expression of the light-sensitive proton pump eArchT3.0 in CA3 terminals onto CA1 cells. Drives consisting of 40 adjustable tetrodes and 2 adjustable optical fibers were targeted bilaterally to the pyramidal cell layer and stratum radiatum, respectively. Although the viral injection technique allowed for the possibility of uptake by nearby CA2 cells, the targeting of light to the stratum radiatum likely avoided suppression of CA2 inputs. Suppression of CA3 input revealed a severe reduction in CA1 ripples and ripple-associated unit activity. Further, in the absence of CA3 input, CA1 place field responses during running were greatly reduced with many cells ceasing to fire altogether. By contrast, hippocampal theta rhythm was enhanced during exploration, while theta phase precession remained intact. These findings shed light on the distinct contributions of different circuits to hippocampal information processing.

**Title:** Effects of early experience on spatial representation of large-scale environments in the bat hippocampus

**Authors: S. R. MAIMON**, T. ELIAV, L. LAS, *N. ULANOVSKY
Weizmann Inst. of Sci., Rehovot, Israel

**Abstract:** The proper function of brain circuits depends both on processes that require normal experience, and on processes which are independent of experience. The long-term effects of altered sensory experience on the brain have been extensively studied, but very little is known about the long-term physiological effects of abstract, cognitive experiences. The hippocampus offers an excellent substrate for addressing this question, because this high-level brain region is very far removed from the sensory periphery, and it contains abstract representations of space - yet, despite their abstractness, these spatial codes are amenable to detailed quantification. A number of studies have examined the normal development of spatial representations in the hippocampal formation of rat pups, during ontogeny; however, it is unknown how alterations in early experience affect spatial representation in the adult hippocampus - and in particular, the representation of naturalistic environments. We are addressing this question by investigating adult spatial representation of a very large environment in the hippocampus of laboratory-born bats, which were never exposed to large-scale environments (larger than a few meters) - and compare it to wild-born adult bats, which were exposed to very large spatial scales when they were flying outdoors. The main difference between these two groups of bats is in a very abstract parameter - the spatial scale of the environment that they experienced - whereas the sensory and motor experiences are normal for both groups of bats. We are using a miniature wireless electrophysiology system to record place cells in hippocampal area CA1 of laboratory-born bats that are flying in a very long 200-m tunnel, in comparison to wild-caught adult bats performing the same task in the same tunnel. Here we will present preliminary neuronal recordings that aim to elucidate how hippocampal representations are shaped by abstract features of early experience.

**Title:** Gating and scaling of the head-direction signal by angular velocity

**Authors: *A. FINKELSTEIN**[1,2], H. ROUAULT[1], S. ROMANI[1], N. ULANOVSKY[2]
[1]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [2]Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

**Abstract:** Orientation in space requires a sense of direction that is thought to rely on head-direction cells - neurons that respond when the animal's head is facing a particular direction in space, analogously to a compass. A critical requirement for network models of head-direction cells is the ability to accurately track the head-direction at different turning velocities. Here we

recorded the neural activity in the dorsal presubiculum of Egyptian fruit bats, and found that contrary to the common view, head-direction tuning was strongly affected by angular velocity. First, the majority of recorded cells exhibited *gating* of head-direction tuning by angular velocity - whereby sharp head-direction tuning emerged at some angular velocities, but was completely absent at other velocities. Second, we also found a graded *scaling* of directional firing as function of turning velocities, i.e. a change in tuning-depth - with more neurons having a larger response at fast angular velocities. The scaling phenomenon was primarily manifested by a *redistribution* of spikes between the preferred and null directions of the neuron - such that the tuning-depth has changed dramatically but the total spike-count did not change as function of angular velocity. We further show that classical 'ring models' of head-direction tuning cannot explain these heterogeneous modulation properties of head-direction cells as function of angular velocity. We propose an alternative recurrent network model for head-direction cells, which comprises populations of neurons with heterogeneous cell-intrinsic properties. In this model, neurons with linear current-to-activity transfer functions exhibit tuning scaling by a redistribution of spikes, whereas neurons with sharper non-linearities scale by changes in the overall spike-count. We speculate that the presence of heterogeneities may improve the responsiveness of the head-direction system to sensory-based corrective signals.

**Title:** Representation of 3D space in the entorhinal cortex of flying bats

**Authors: *G. GINOSAR**, A. FINKELSTEIN, L. LAS, N. ULANOVSKY
Weizmann Inst. of Sci., Rehovot, Israel

**Abstract:** Grid cells exhibit spatially-periodic firing fields, and are thought to be important for navigation. When recorded in animals moving on a 2D plane, these cells fire when the animal passes through the vertices of a hexagonal grid spanning the 2D environment. Despite extensive research on 2D grid cells, there is an ongoing debate regarding the function of these fascinating neurons - namely, whether they encode the position of the animal or the distance it travelled. Moreover, many animals navigate through 3D space, but no studies to date have attempted to characterize the 3D volumetric firing of grid cells. Here, we conducted experiments in flying bats to elucidate the grid code in 3D. We trained Egyptian fruit bats (Rousettus aegyptiacus) to fly in a large flight room, while we wirelessly recorded single-neuron activity in medial entorhinal

cortex (MEC). Our results revealed structured firing in the 3D firing-rate maps, with multiple firing-fields. The spacing between firing-fields was more variable than in perfect synthetic 3D lattices (such as FCC or HCP sphere-packing grids), but was substantially less variable than for randomly-distributed fields - namely, 3D grid-cells seem to exhibit a fixed distance scale, without forming a global lattice. We also found a number of other spatial cell types in the MEC, including 3D border cells and 3D head-direction cells. Interestingly, we also found a subset of MEC neurons that tended to fire around balls on which the bat landed or took off. These neurons fired either as the bat took off or as the bat landed, but not in both cases; some of these cells showed even larger specificity and fired near a particular ball, but did not fire near other balls. Taken together, these data suggest a rich 3D spatial representation in the MEC of flying bats - including coding of 3D space by grid cells, coding of 3D geometry by border cells, as well as an object-related coding in the MEC.

**Title:** Social place cells in the bat hippocampus

**Authors: *D. OMER**, S. R. MAIMON, L. LAS, N. ULANOVSKY
Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

**Abstract:** Social animals need to know the spatial position of conspecifics, both because it is important for them to know the locations of socially-dominant animals, and for purposes of group navigation. However, nothing is known about how the location of other animals is represented in the brain. Here, we addressed this question by studying bats - highly-social mammals that excel in observational-learning and are also outstanding navigators. We designed an observational-learning task for Egyptian fruit bats (*Rousettus aegyptiacus*), where animals were trained in pairs: In each trial, one bat (‘observer’) had to observe and remember the flight-trajectory of the other bat (‘demonstrator’). After a short delay, the observer had to imitate the demonstrator and fly along the same flight-trajectory to receive a reward - which required the observer to pay close attention to the demonstrator’s position. We recorded neurons in hippocampal area CA1 of the observer bat during this task, using a tetrode-microdrive and a miniaturized wireless electrophysiology system that allowed recording of individual neurons in freely behaving bats. A total of ~350 neurons were recorded in 5 bats. To control for the known

spatial properties of hippocampal place-cells, we did two things: first, the observer hung at a fixed position while it was observing ('space-clamp'); and second, we used a nine-axis motion sensor on the observer to exclude neural activity due to head-movements. We found CA1 neurons in the observer's hippocampus that represented the position of the demonstrator bat. About half of these cells represented the bat's own position (place cells) as well, but the other half did not. Further, the spatial representation of the demonstrator bat was unaffected by removal of spikes during sharp-wave-ripples - which have been linked to spatial 'preplay' and trajectory planning - and hence it cannot reflect spatial planning by the observer bat. Finally, we also found neurons in CA1 that represented the position of inanimate moving objects; this representation was different from the representation of the conspecific bat. Taken together, these data indicate a possible role for the hippocampus in social-spatial cognition.

**Title:** Representation of large-scale spaces in the hippocampus of flying bats

**Authors: *T. ELIAV**, L. LAS, N. ULANOVSKY
Weizmann Inst. of Sci., Rehovot, Israel

**Abstract:** Most animals navigate daily over distances spanning from hundreds of meters to many kilometers. However, for the last forty years, hippocampal electrophysiological research has typically focused on spatial representations in small laboratory environments. Nothing is known about hippocampal neural codes for large spatial scales - in environments spanning hundreds of meters or kilometers - the scales of natural navigation of rodents, bats and other mammals. Here we aimed to address this fundamental question for the first time, by developing a unique recording setup that includes a large-scale ethologically relevant environment. We are using the Egyptian fruit bat as our animal model, because bats are excellent navigators over large natural scales, and because bats were shown to have rodent-like hippocampal spatial representations in small laboratory environments. So far, we took the following steps: First, we developed an on-board wireless neural-logging system, which allows recording single-units over unlimited distances. Second, we built a 200-m long tunnel where bats can fly freely. Third, to track the bat's position we utilized an RF localization device that measures distances to a ground-based antenna-array - yielding a spatial accuracy of ~10-cm, much better than GPS. Behavioral experiments showed that bats fly volitionally back-and-forth along the tunnel - more than 100 laps per session (>20-km total flight distance). Preliminary recordings of CA1 neurons

in the 200-m tunnel showed the following: (i) Individual hippocampal CA1 cells exhibited many fields per neuron. (ii) We found very large fields in dorsal CA1 - up to 20-30 meters. (iii) A given neuron could exhibit multiscale spatial coding - with different place-fields of the same neuron having very different sizes, ranging from 1 m to 20-30 m. (iv) Some of the firing properties, such as directionality and field-asymmetry, were similar to findings in small-scale environments in the laboratory. Taken together, most of the firing properties of CA1 neurons in this large-scale environment suggested a representation that is very different from findings reported so far in the laboratory - in any species.

**Title:** Place cell ensemble function in a mouse model of chronic stress

**Authors: *T. INDERSMITTEN**[1], M. SCHACHTER[2], R. WYATT[1], N. WELTY[1], S. YOUNG[1], S. CAMPBELL[1], S. OTTE[2], J. NASSI[2], P. BONAVENTURE[1]
[1]Neurosci., Janssen Res. & Develop., San Diego, CA; [2]Inscopix, Inc., Palo Alto, CA

**Abstract:** Chronic stress can lead to clinical depression, yet little is known about the underlying neuronal circuit dysfunctions in this complex mental disorder. The hippocampus, a structure essential for spatial navigation and memory, undergoes anatomical and functional changes during chronic stress. Here we utilized *in vivo* miniature fluorescence microscopy to examine place cell properties in the hippocampus and investigated how chronic stress perturbs hippocampal function. We implanted transgenic mice expressing the genetically encoded calcium indicator GCaMP6f in CA1 pyramidal neurons with microendoscope GRIN lenses and operant conditioned them to run on a linear track. To model physiological conditions of chronic stress, these mice were chronically administered with either 400 µg/ml of hydrocortisone, 10 mg/kg of the selective serotonin reuptake inhibitor Citalopram, or both. Hippocampal ensemble calcium event activity was recorded with nVista miniature microscopes (Inscopix, Inc.) during linear track navigation over several days. Hydrocortisone-treated mice exhibited symptoms typically observed during chronic stress, including anhedonia and reduced adrenal and spleen weights. Most properties of place cell function were unchanged in hydrocortisone-treated mice. We trained Bayesian single neuron and ensemble decoders to estimate mouse location on the linear track from neuronal calcium imaging event data. Single neuron decoder performance was

lower in hydrocortisone-treated mice compared to Citalopram-treated mice. Unlike the single neuron decoder, ensemble decoder performance, which estimates mouse location based on the entire population of imaged cells, was unaffected by drug treatment. The dysfunction observed at the single-neuron level indicates that chronic stress may impair the ability of the hippocampus to encode neural representations and memories of the animal's spatial location, a function pivotal in forming an accurate navigational map of the animal's external environment. However, the hippocampal ensemble as a whole is resilient to any hydrocortisone-induced insults to single neuronal place cell function on the linear track.

**Title:** Mechanisms of synchronization of hippocampal oscillations

**Authors: *K. SAFARYAN**[1], M. R. MEHTA[1,2,3,4]
[1]Departments of Physics and Astronomy, Neurology, Neurobio., UCLA, Los Angeles, CA; [2]UCLA; W. M. Keck Ctr. for Neurophysics, Los Angeles, CA; [3]UCLA; Integrative Ctr. for Learning and Memory, Los Angeles, CA; [4]UCLA; Brain Res. Inst., Los Angeles, CA

**Abstract:** Hippocampal neural activity is modulated by several rhythms, including theta, beta, gamma and sharp-wave ripples. These oscillations are shown to be crucial for learning and memory by modulating hippocampal single unit and population responses. In particular, hippocampal theta modulation is especially prominent during active exploration, when spike timing of hippocampal pyramidal cells is robustly encoded by theta phase. In turn, this temporal code is thought to be crucial for inducing synaptic plasticity via STDP (Mehta et al., 2002). Hence, for a better understanding hippocampal learning and memory it is important to understand the mechanisms that regulate the frequency of theta rhythm and its long-range synchronization across hippocampus.
The frequency of theta oscillations increases with running speed when rats run on a linear track in the real world. In contrast, we recently showed that when rats ran in virtual reality, the frequency of theta rhythm does not increase with running speed (Ravassard et al., 2013). Yet,

theta phase precession is comparable between one dimensional real world and one dimensional virtual reality. Further, in two dimensional real world, hippocampal neurons showed significant phase precession during passages through the place field, and this passage-dependent phase precession was intact in two-dimensional virtual reality despite the impaired spatial selectivity (Aghajan et al., 2015). We hypothesized that these differential patterns of hippocampal activity could arise due to difference in synchronization of theta oscillations in the real world and virtual reality. To test this, we measured the hippocampal activity across multiple recording sites while rats ran in real and virtual worlds. We then developed analysis methods that can provide unbiased estimates of synchrony of theta fluctuations across different sites of recording. The results show significant differences in synchronization of low-frequency oscillations as a function of real or virtual tasks.

**Title:** A generalized linear model approach to dissociate object-centric and allocentric directional responses in hippocampal place cells

**Authors: *M. SHAHI**[1,2,3,4], R. SANDLER[1,2,3,4], S. DHINGRA[1,2,3,4], R. RIOS[1,2,3,4], C. VUONG[1,2,3,4], L. ACHARYA[6], A. HACHISUKA[1,2,3,4], M. R. MEHTA[1,2,3,4,5]
[1]Dept. of Physics and Astronomy, [2]W. M. Keck Ctr. for Neurophysics, [3]Integrative Ctr. for Learning and Memory, [4]Brain Res. Inst., [5]Departments of Neurology, Neurobio., UCLA, Los Angeles, CA; [6]Neurosci. Dept., Baylor Col. of Med., Houston, TX

**Abstract:** Primate and human hippocampal neurons show visually evoked, object-centric responses. But, visual cues are thought to generate allocentric responses in the rodent hippocampus.
Furthermore, it has been commonly believed that head direction does not influence hippocampal single units during 2D random foraging in the rodent hippocampus. However, our group has demonstrated significant allocentric head direction modulation (Acharya et al., 2016).
This raises an important question: do rodent hippocampal place cells also exhibit object-centric responses, as seen in primates? To address this, we measured hippocampal place cell responses while rats were doing a random foraging task on an open platform in the real world, with one prominent, 10 degree wide visual cue on one wall. We then developed generalized linear model (GLM) technique to decipher the hippocampal responses in the allocentric (room) frame, or in the object-centric (with respect to the visual cue) frame. These two variables are highly

correlated; hence we developed analysis methods to dissociate their respective contributions to CA1 place cells.
However, in this condition, there is only a small difference between the object-centric and allocentric frames. To dissociate this further, we suspended a prominent visual cue above the maze, while rats foraged for randomly scattered rewards, regardless of the visual cue. We then estimated the independent influence of object-centric and allocentric head direction on hippocampal responses, along with the contribution of position and running speed. The method also provided an estimate of the relative magnitudes of these variables. One-third of hippocampal neurons showed significant directionality in the object-centric frame with respect to the visual cue. Moreover, analysis of the object-centric directionality of individual of neurons showed that the ensemble of object-centric maps was tuned towards the visual cue.
These results thus provide novel insights about the mechanisms governing place cells, and have important implications for theories of hippocampal function.

**Abstract:** Hippocampal CA1 cells show allocentric spatial selectivity, which has been extensively investigated since 1971. We recently showed the presence of directional selectivity in the CA1 cells during random foraging in the real and virtual worlds (Acharya et al., 2016). In this work, using novel experimental and analytical techniques, we have been able to disentangle

the contribution to the directionality of the CA1 cells from the two independent frames of reference - one that is aligned with the room, i.e. the allocentric frame, and the other that is centered on the rat's body, i.e. the object-centric frame (see Shahi et. al. SfN abstract, 2017). The tasks used in this work involved random foraging on an open platform in 2D environments, in Real World (RW) and Virtual Reality (VR), where only distal visual cues are provided, without any reward association to these cues. One such task had one prominent 10 degree wide visual cue on one wall far away from the platform, while the other had a similarly sized and shaped visual cue suspended above the platform. Depending on the nature of the visual cues provided in the room, we can dissociate the allocentric and object-centric tuning of the cells, which under some conditions might not be possible. For analyzing the data, we make use of generalized linear model (GLM), which provides an estimate of the independent contributions from different tuning parameters, such as position, allocentric and object-centric directionality, speed etc. Firstly, we find overlapping, yet slightly different, population of neurons in CA1 which exhibit spatial, allocentric and object-centric tuning to visual cues. Secondly, with only a visual cue on the wall, the contributions from the allocentric and object-centric frames on the tuning of the cells are highly correlated and cannot be dissociated. On the other hand, with the cue suspended above the platform, the contributions from the two frames can be easily dissociated, and about a third of the population responds individually to the two frames in RW. These responses change drastically in the VR, where majority of the spatial and allocentric directional tuning is lost, and about half of the population responds to the object-centric frame of reference. Thirdly, we find that for environments with the suspended cue, the object-centric responses are ensemble-wide, with not only the significant, but even the non-significant cells' responses are tuned towards the suspended visual cue. These results show that contrary to common belief, distal visual cues not only generate allocentric responses, but are also sufficient to generate object-centric responses in CA1, in individual cells and across the entire ensemble.

**Title:** Rapid increase in navigational performance and hippocampal neural activation during a virtual water maze task

**Authors: *M. R. MEHTA**[1,2,3,4], J. J. MOORE[1]
[1]Departments of: Physics & Astronomy, Neurology, Neurobio., Univ. of California at Los

Angeles (UCLA), Los Angeles, CA; [2]W. M. Keck Ctr. for Neurophysics, [3]Integrative Ctr. for Learning and Memory, [4]Brain Res. Inst., UCLA, Los Angeles, CA

**Abstract:** The Morris Water Maze is a widely-used behavioral test of spatial learning, memory and navigation. Yet the neural basis of this behavior is not well characterized, because it is difficult to do single unit recordings in this task and because animals typically do few trials in a day which makes robust statistical analysis difficult. Hence, we have recently developed a noninvasive virtual water maze task [1]. With this system, rats can run more than 100 trials in a single session, which allows us to measure within-session changes in behavior and the underlying neural coding mechanisms. Despite good navigational performance in this task, we find relatively little allocentric spatial selectivity in pyramidal units in dorsal CA1, the traditional "Place Cells." Instead, neural activity is tuned to other navigationally-relevant, egocentric parameters, e.g. distance traveled, heading direction, linear speed, and angular speed [2]. Here, we investigate within-session changes in behavioral performance and neural activity. Extensive studies have shown that hippocampal neural activity is altered with experience, with a significant increase in the number of active neurons [3] and their firing rates [4, 5] within the first few trials, even in a familiar environment [3,4, 5]. However, these were done in the absence of task demand.We find that during the virtual navigation task, behavioral performance improved rapidly within the first 5-10 trials each day, even though rats were well-trained on the task. Simultaneously, the mean firing rate of CA1 pyramidal neurons and the total number of neurons active also increased. Finally, behavioral performance was positively correlated with neural activation and firing rate. Thus, even though there is little allocentric spatial selectivity in the hippocampus during this task, experience-based changes in the egocentric neural activity are correlated with experience-based improvements in behavior. These experience-based changes may be driven by similar mechanisms of synaptic plasticity [4,5] demonstrated in earlier studies on linear tracks [3, 4, 5], thus linking behavioral learning with hippocampal activity and cellular mechanisms of plasticity. 1. **Title:** Large, sustained, dendritic depolarizing events in freely behaving rats

**Authors: *J. J. MOORE**[1,2,3,4], M. R. MEHTA[1,2,3,4,5]
[1]W. M. Keck Ctr. For Neurophysics, Los Angeles, CA; [2]Integrative Ctr. for Learning and Memory, [3]Brain Res. Inst., [4]Dept. of Physics and Astronomy, [5]Departments of Neurology, Neurobio., UCLA, Los Angeles, CA

**Abstract:** Neural dendritic arbors make up the majority of surface area and volume of neocortical neurons, but most information about neural activity in freely behaving animals is obtained through extracellular action potentials. *In vitro* studies have demonstrated that dendrites support nonlinear integration of inputs via sodium spikes and calcium spikes [1, 2]. Measurements in anesthetized, head-fixed animals support these findings and suggest that dendritic nonlinearities may affect neural activity *in vivo* [3]. We recently reported the first chronic electrical measurements of dendritic membrane potential in unanesthetized, freely-behaving rats [4, 5]. In those experiments, we observed dendritic action potentials (DAP) firing at high rates, that were modulated by subthreshold fluctuations that were many times larger than the accompanying DAP. Dendritic subthreshold fluctuations and DAP in posterior parietal cortex, a major neocortical input to the hippocampal-entorhinal system, also encoded egocentric representations of movement with a similar degree of precision compared to somatic spikes. The presence of these two very different but interacting signals suggests a mixture of analog and digital coding in the dendrites. Here, we investigate the structure of these large, slow fluctuations.

We observed that the slow subthreshold fluctuations were not random, but contained large, discrete events of sustained depolarization during slow-wave sleep. These depolarizations were approximately 50 ms in duration, similar in duration to calcium spikes reported *in vitro*, but in many instances persisted for several seconds. While DAP fired at rates far exceeding those of somatic spikes detected extracellularly, large depolarizations occurred at lower rates, typically < 1 Hz. Large depolarizations were also present during active running, and they contributed to the subthreshold representation of egocentric movement in posterior parietal cortex. The coexistence and interaction between high-rate, medium-amplitude DAP and low-rate, high amplitude depolarizations suggests that dendrites may encode complimentary information through different mechanisms. These different nonlinearities may also control the spatial extent of integration in the dendritic tree in a dynamic fashion.

**Title:** Memory recall induced hyperactivity of place cell populations in hippocampal CA3

**Authors: *F. ZITRICKY**, K. JEZEK
Fac. of Med. in Pilsen, Charles Univ., Plzen, Czech Republic

**Abstract:** Hippocampal autoassociative network in CA3 stores large number of place cell activity patterns that are believed to be a substrate of spatial memories. They behave as network activity states with attractor properties. Memory recollection on the network level is then conceptualized as a shift from whatever present activity pattern towards another state that reflects the actual input information. Mechanisms underlying this process are largely unknown. We examined development of CA3 population activity during retrieval of memory for spatial context in rats using 'teleportation' protocol, where memory recall was induced by a sudden switch between two sets of distinct light cues defining two familiar environments. Previous study described the competitive nature of spatial map transition with network state temporarily alternating in a theta paced manner between the original (old) and correct (new) representation. Here we report a new effect of transient hyperactivity (approx. 30% increase) in CA3 hippocampal network accompanying the recall of stored hippocampal representation. The hyperactivity was driven by an increased recruitment of place cells per theta cycle, rather than an increase of spiking activity only and it persisted for few seconds before it dropped back to baseline level. Considerably, hyperactivity in the network selectively occurred only during expression of the correct representation as it didn't accompany an occasional reactivation of the original spatial map. We found that this effect was driven mainly by an increased recruitment of place cells at the periphery of their firing fields. In consequence, decoded momentary spatial position from the new representation ensemble activity rendered an increased coding error. Despite the expression of both network states showed an attractor-like behavior, teleportation experience substantially increased emergence of data bins where cells from both 'old' and 'new' ensembles mixed together.
We show that network recall of spatial memory state triggers a transitory hyperactivity of CA3 neuronal population. Temporary conflict of sensory input may contribute to altered spatial

properties of place cells shortly after introduction of the new environment. We argue that enhanced, albeit less position-specific recruitment of place cells may support the new representation in competition with the original ensemble, and possibly reinforce transition between the corresponding attractor states.

**Abstract:** The lateral entorhinal cortex (LEC) and medial entorhinal cortex (MEC) provide the major inputs to the hippocampus, which plays an essential role in spatial and episodic memory. The discovery of cell types with various spatial properties in MEC, e.g, grid cells, greatly enhances our understanding of functional circuitry in the medial temporal lobe. However, much less is known about the function of LEC. Previous studies showed that cells in LEC carry much less spatial information than MEC, but the introduction of objects in the arena significantly increases the spatial information content of LEC neurons. We investigated whether other behavioral variables, e.g. head direction, can modulate the firing of LEC neurons. We recorded 68 LEC cells in 2 rats and 111 MEC neurons in 3 rats, in which the subjects were foraging freely in an open-field arena. The experiment was first performed while the subjects foraged in a 0.58-m x 0.58-m box in the center of a 1.35-m x 1.35-m box. The walls of the small box were removed after 6 minutes and rats were able to navigate freely in the large box. We found a large number of LEC neurons showed egocentric bearing selectivity relative to certain reference points in the arena. Most of the reference points were close to the center of the box, and the egocentric bearing selectivity was manifested as preferences for clockwise, counterclockwise, inward, or

outward movement relative to the center. We applied a Generalized Linear Model (GLM) to account for the potential confounds introduced by uneven sampling of head direction and space. Models with (a) conjunctive spatial and egocentric bearing tuning around an external reference point and (b) with conjunctive spatial and allocentric head direction tuning were fit to the data. LEC neurons were significantly different from MEC cells ($p < 0.001$, Wilcoxon rank-sum test), with LEC neurons showing a greater preference for egocentric bearing than allocentric head direction tuning ($p < 0.001$, Wilcoxon signed-rank test) and MEC cells showing a greater preference for allocentric head direction ($p < 0.001$, Wilcoxon signed-rank test). These results show that LEC neurons carry information about the rat's current movement behavior relative to an external location in an egocentric framework, suggesting the "what" versus "where" dichotomy for explaining the functions of LEC and MEC needs a major revision. We hypothesize that while MEC mainly represents spatial information about the location of "self", LEC conveys information about "non-self" ("what is out there") (Lisman 2007; Knierim et al. 2014).

**Title:** Surface texture boundaries alter firing rates of CA1 place cells in 2-dimensional environments

**Authors: *C.-H. WANG**, G. RAO, J. J. KNIERIM
Krieger Mind Brain Inst., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Surface textures have been used to examine the influence of local cues over place-cell firing. Manipulations of differently-textured surface patches (e.g., rotation or reconfiguration of the patches) can lead to corresponding place field rotation, rearrangement, or remapping (Shapiro et al., 1997; Brown and Skaggs, 2002; Knierim, 2002). However, these studies have not addressed how local surface boundaries can alter the structure of the spatial representations of the larger environment. In a heterogeneous environment composed of differently textured surfaces, the space can be demarcated by the boundaries between different textures and

segmented into different compartments. We therefore hypothesized that the surface boundaries are encoded in the cognitive map and influence the precise firing locations of place cells. We previously reported that both CA1 and CA3 place fields tend to terminate near texture boundaries when rats foraged on a circular track (Wang et al., SFN Abstracts, 2016). To further study this phenomenon, we recorded the activity of place cells as rats foraged in 2-dimensional open fields with discrete surface textures and tape lines defining geometric shapes and boundaries. We first collected data from 5 rats on a 1 x 1 m platform with a complex pattern of shapes and boundaries. The platform was divided in half along its diagonal. One half was covered by textured patches (such as sand paper, rubber mats, and cork material) and the other half replicated the same geometric pattern by outlining the shapes with yellow tape. Anecdotal observations indicated that the edges of many CA1 place fields coincided with the boundaries, and a small proportion of fields appeared to match the geometric shapes on the platform. However, the complexity of the pattern and the large number of boundaries on the board limited the ability to perform quantitative analyses of this data set. Thus, we recorded from 2 additional rats on a simple 1 x 1 m platform containing only two texture patches separated by a single linear boundary. The CA1 place cell populations had stronger average firing rate changes near the boundary than at locations away from the boundary. These results suggest that CA1 spatial representations emphasize surface boundaries in the environment, which may enable segmentation/compartmentalization of experiences by natural environmental boundaries.

**Abstract:** In a companion abstract (Chen, Wang, et al., SFN Abstracts, 2017), we show that lateral entorhinal cortex (LEC) neurons are significantly more selective for egocentric bearing

relative to an external reference point than medial entorhinal cortex (MEC). Those experiments did not address whether there were any biases for particular external locations to serve as reference points. We predicted that behaviorally relevant locations would be over-represented as reference points for egocentric tuning in LEC but not in MEC. Two experiments were performed to test this prediction. In Experiment 1, 159 LEC unit recordings and 111 MEC unit recordings were obtained while 7 rats foraged freely in a 1.2-m x 1.5-m open field with multiple objects placed inside the arena. A Generalized Linear Model (GLM) was applied to remove spurious tuning which could arise from biased trajectory and spatial selectivity. LEC cells demonstrated significantly more egocentric bearing tuning around certain reference points than MEC cells ($p < 0.001$, Wilcoxon rank-sum test). We then used the locations of the objects as reference points and found that LEC neurons showed significantly more egocentric bearing relative to objects than MEC cells ($p < 0.001$, Wilcoxon rank-sum test). In Experiment 2, 199 recordings were obtained while 2 rats navigated in a 1.37-m x 1.37-m box with a fixed food well. Food reward was available sporadically in the food well and at random unmarked locations in the arena. The position of the food well was manipulated across sessions. For the cells with the largest egocentric bearing tuning relative to some locations, we found a significant overrepresentation of the current or previous goal location compared to an expected random distribution ($p < 0.001$, Monte Carlo simulation test). A number of cells shifted their reference points with the food well. These results provide strong evidence that LEC represents egocentric bearing information about behaviorally relevant locations away from the subject. Thus, in addition to nonspatial information about “what” the animal experiences during an event, LEC also represents “where” information in an egocentric frame of reference that is fundamentally different from the predominantly allocentric spatial representations of MEC.

**Abstract:** The rodent hippocampal formation combines information from both landmark and self-motion cues to create an allocentric representation of its environment. We used a planetarium-style virtual reality dome to examine the relative influence of these two classes of information on the firing fields of place cells.
We tested whether the brain recalibrates the relationship between self-motion cues perceived by the rat during movement, and the update of the position encoded by CA1 place cells. We call this relationship the 'internal gain' of the path integrator (r), and hypothesize that this is a plastic variable learned via feedback from landmark cues.
Previously (Jayakumar et al., 2016, Madhav et al., 2015, SFN Abstracts) we presented evidence from experiments in which a constellation of visual landmarks was rotated continuously as a ratio of the rat's movement speed along the perimeter of a circular platform. This ratio was called the experimental gain (g). We observed that CA1 place fields 'locked' to the landmarks (N = 5 rats), indicating that the visual landmarks exerted a strong influence on the hippocampal representation of place. However, in the absence of landmarks, place fields gradually drifted, reflecting cumulative path integration error. This drift was the same across simultaneously recorded place cells, revealing a cohesive representation of position amenable to population decoding.
Here, we investigated whether the internal gain (r) of the path integrator could be recalibrated by continuous exposure to an experimental gain (g) of the landmarks relative to the rat's movement. At the beginning of an experiment, g was set to zero (stationary landmarks), but gradually increased or decreased to a certain value (processing / precessing landmarks) that subsequently remained constant (for ~30 laps, < 1 hour). Using a decoding technique based on the spatial frequency of place fields, we confirmed quantitatively that the place fields were locked to the landmark frame of reference. When the landmarks were turned off, the place fields drifted relative to the landmark frame. Through the same decoding technique, we estimated the effective internal gain (r) of the place field ensemble and showed that the internal gain had a value in the same direction as the experimental gain but lower in magnitude ( $0 < |r| < |g|$ ). Indeed, this recalibrated gain (r) of the place fields maintained a linear relationship to the experimental gain (g) of the landmarks (N = 4 rats). These results indicate that visual landmarks calibrate how self-motion cues are integrated to update the hippocampal representation of place, and this calibration occurs over relatively small time scales.

**Title:** Preconfigured, plastic networks: Unified view on integration of Hebbian and homeostatic processes during learning

**Authors: *G. DRAGOI**, U. FAROOQ, J. SIBILLE, K. LIU
Psychiatry, Yale Univ., New Haven, CT

**Abstract:** The demonstration that hippocampus is crucial for rapid learning and memory formation in humans, non-human primates and other species, most notably rodents, has sparked a major, concerted effort toward identification of electrophysiological signatures underlying these cognitive functions. Electrophysiological signatures of hippocampus role in learning and memory were successively attributed to post-experience increases in spontaneous firing rate, neuronal cofiring, and incidence of spatial sequence and trajectory replay. The temporal sequence hallmark for learning has, however, remained equivocal, with proposals ranging from de novo Hebbian creation of temporal sequences from blank-slate networks to selection and editing of largely homeostatic preconfigured sequences. Here we show that de novo spatial experiences essentially induce Hebbian firing rate and cofiring increases within neuronal ensembles, which are integrated into largely stable, homeostatic ensemble temporal dynamics expressed similarly pre- and post-experience. Furthermore, we demonstrate that former proposals of pre-experience blank-slate networks using sequence analyses falsely arise from incorrect statistical assumptions and offer solutions to amend them. Our results coherently unify previously divergent views of ensemble signatures of learning and memory and provide strong support for hippocampal preconfigured, plastic networks that integrate Hebbian learning within largely homeostatic processes.

**Title:** Ontogeny of ensemble spatial representation in the hippocampus

**Authors: *U. FAROOQ**, G. DRAGOI
Yale Univ., New Haven, CT

**Abstract:** Hippocampal pyramidal cells - known as 'place cells' - are active in distinct, specific locations along the trajectory of the animal during locomotion within an environment. Populations of place cells exhibit temporal coordination beyond their single cell response characteristics by firing in compressed temporal sequences during motion, awake rest and sleep. These sequential population phenomena (i.e. theta sequences, replay and preplay) are widely considered as the neural substrates for spatial cognition, and episodic memory formation and consolidation in adult animals. Recent work has shown that place cells are already present when rodents ethologically begin to exhibit behaviors involving extended forays out of their nest (in the beginning of third postnatal week), albeit their metrics of spatial tuning improve with age and experience over the next couple of weeks. Intriguingly, the upstream entorhinal grid cells emerge later and have a delayed developmental timeline compared to place cells. Whether and when ensembles of place cells can display different sequential population phenomena at these ages remains unknown. To this end, we performed high-density *in vivo* electrophysiology in freely moving pre- and post-weanling rats throughout the third and fourth weeks of development and recorded simultaneously from up to 70 CA1 hippocampal neurons during active behaviors on novel linear tracks, and pre- and post-experience sleep. Our experiments have enabled us to probe the developmental stages of ensemble spatial representation in the hippocampus and provide insights into how the first traces of episodic memories are being formed in the brain.

**Authors: *K. LIU**, J. SIBILLE, G. DRAGOI
Yale Univ., New Haven, CT

**Abstract:** Mammalian navigation uses internal models to predict and represent the spatial-temporal statistical regularity of the sequence of environmental locations. The internal representation process has been described in rodents by the sequential activation of neuronal

ensembles of ‘place cells’ in the hippocampus, which together form a ‘cognitive map’ of the external world. Attractor-network models of hippocampal activity during animals’ spatial exploration have suggested that place cell assemblies can be used to represent locations in any arbitrary environments via auto-associative dynamics during theta oscillations. Hippocampal-dependent internal representations are believed to emerge upon transitions from auto-associative attractor networks representing discrete locations into hetero-associative sequential attractors representing temporally-compressed trajectories, particularly in association with 200 Hz oscillations ‘ripples’. These transitions occur spontaneously during epochs of awake immobility and slow-wave sleep and can replay past and preplay future trajectories at ~20 times accelerated, 5-8 m/s velocities. Previous research leveraged on the activity expressed during a novel navigation experience to seek for correlative temporal sequence patterns in the following (replay) and preceding (preplay) rest and sleep epochs. Consequently, the predictive capacity of hippocampal networks during sleep/rest and their spontaneous organization into associative attractors that lead to networks active during future spatial navigation have remained unknown. Here, we develop a novel predictive coding model to reveal the internal structure of functional neuronal connectivity exclusively during pre-experience sleep in naïve rats and use the connectivity probability to predict the future place cell sequences during subsequent encoding of novel spatial experiences. We find that connectivity probability during preceding sleep has significant predictive value over future sequential activity during run while post-experience sleep exhibits a higher prediction performance. These results indicate that neuronal sequence activity expressed during a future novel experience can be generated based on intrinsic connectivity probability that is further refined during and after the experience.

**Title:** Grid scale drives the scale and long-term stability of place maps

**Authors:** ***C. S. MALLORY**[1], K. HARDCASTLE[2], J. S. BANT[1], L. M. GIOCOMO[1]
[1]Neurobio., Stanford Univ., Stanford, CA; [2]Neurobio., Stanford Univ., Palo Alto, CA

**Abstract:** Medial entorhinal cortex (MEC) grid cells fire at regular spatial intervals and project to the hippocampus, where place cells are active in spatially restricted locations. A cardinal feature of the grid population is the increase in grid scale along the dorsal-ventral MEC axis. However, the difficulty in perturbing grid scale without impacting the properties of other functionally-defined MEC cell types has obscured how grid scale influences hippocampal coding and spatial memory. We used a targeted viral approach to knock out HCN1 channels selectively in MEC, causing grid scale to expand while leaving other MEC spatial and velocity signals intact. Grid scale expansion resulted in place scale expansion predominantly in fields located far from environmental boundaries and reduced long-term place field stability. To better understand the mechanism through which grid scale influences long-term place field stability we implemented a computational model of place cell formation, in which place fields are formed via a winner-take-all competition. In the model, place cells received two types of input: modular grid cell inputs, whose firing field locations remained static across days, and non-stable spatial inputs whose preferred firing location varied from day to day. Recapitulating our experimental findings, the stability of place fields declined as the scale of the grid input increased. Mechanistically, the combined input from smaller-scale grid cells tended to overlap more in space, rendering the resulting place fields more resistant to fluctuations in other types of spatial inputs, and ultimately more stable across sessions. Finally, we found that spatial memory was impaired in these mice, likely due to the decreased long term stability of their place cells. Together, these experiments illuminate how grid scale impacts place coding and spatial memory.

**Title:** Coordinated modulation of grid and speed cells by self-motion cues

**Authors: *M. G. CAMPBELL**[1], C. S. MALLORY[2], L. M. GIOCOMO[2]
[2]Neurobio., [1]Stanford Univ., Stanford, CA

**Abstract:** To calculate self-location, the brain must integrate multi-sensory cues regarding environmental landmarks and the animal's motion relative to those landmarks. The medial entorhinal cortex is a proposed locus for the calculation of position, with different cell types integrating different combinations of self-motion and landmark cues. In particular, grid cells are thought to integrate self-motion cues (path integration), whereas border cells are thought to respond to environmental landmarks. However, the mechanism by which self-motion influences grid cells, as well as the way in which diverse self-motion cues are combined (e.g., visual and locomotor), is not well understood. To study these questions, we recorded entorhinal cells during exploration of a virtual linear track and manipulated the gain of the closed-loop transformation from locomotion to motion of the visual cues. These experiments revealed that grid cells integrate self-motion cues whereas border cells remain fixed to visual landmarks. Furthermore, they enabled us to calculate the relative weighting of visual and locomotor cues in grid and speed cell tuning curves and showed that this weighting is condition-dependent. Finally, in response to the gain manipulations, the speed and grid tuning of conjunctive grid-speed cells were significantly correlated, but the speed and grid cell populations as a whole were uncorrelated. This suggests that only a subset of linear speed signals in the MEC is relevant for grid cell distance calculations.

**Title:** Environmental deformation causes commensurate changes in grid, head direction, and speed cells in entorhinal cortex

**Authors: *R. G. MUNN**[1], C. MALLORY[1], D. M. CHETKOVICH[2], L. M. GIOCOMO[1]
[1]Neurobio., Stanford Univ., Stanford, CA; [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

**Abstract:** The tessellating firing fields of grid cells in the medial entorhinal cortex (MEC) are thought to underlie the ability of animals to determine distance travelled and navigate through space. Exactly how these cells gain their firing characteristics remains to be fully understood. Continuous attractor models are a leading model for grid cell formation. These models propose that directional and speed inputs could combine to translate the activity pattern across the grid cell network (Burak and Fiete, 2009). In these experiments, we rapidly compressed or expanded an open arena along one axis while recording single unit activity in the MEC of mice. This type of environmental deformation has been shown to change grid cell spacing (the distance between grid cell firing nodes). Grid spacing decreases or increases along the axis that is compressed or expanded, but is preserved in the orthogonal, invariant axis (Barry et al., 2007). In continuous attractor models, grid spacing can be driven by the amplitude of the directional and speed signals, a hypothesis we tested by recording grid, head direction and speed cells prior to, and during environmental deformation. For environmental compression, we found that the length of the directional vector decreased in the majority (~65%) of MEC head direction cells (average decrease = 38.2%) and became significantly less directionally stable. The remaining ~35% of head direction cells increased in vector length by an average of 163.5%, while maintaining their directional stability. We found that the head direction cells that increased directional specificity were bimodally distributed, with preferred firing orientations that are closely aligned with the axis of deformation. On the other hand, cells that decreased in specificity had preferred firing orientations in all directions. Similarly, MEC speed cells preferentially modulated the gain of their firing rate/running speed relationship in the direction of environmental deformation. Ongoing work is examining whether head direction and speed signals respond in a complementary manner during environmental expansion. These findings are broadly in support of predictions made by the continuous attractor model that speed and directional inputs can drive the translation of the neural sheet, and thereby drive grid cell spacing.

**Title:** Grid symmetry and bursting along the dorsoventral axis of medial entorhinal cortex

**Authors: *J. S. BANT**, K. HARDCASTLE, L. M. GIOCOMO
Neurobio., Stanford Univ., Stanford, CA

**Abstract:** Neurons in the medial entorhinal cortex (MEC) encode spatial location, head direction, and speed (Hafting et al., 2005; Sargolini et al., 2006; Kropff et al., 2015), signals that may benefit from the higher information transfer rates conferred by high-frequency bursts of activity. Previously we reported that fractions of non-inactivating voltage-gated sodium conductances, which play a key role in the genesis of high-frequency activity, are higher in the dorsal end of MEC. (Bant and Giocomo, SfN 2015; Bant and Raman, 2010). This generates the in vivo prediction that cells in dorsal MEC will fire at higher frequencies than cells in ventral MEC. To test this prediction, we considered a set of 837 layer II/III putative excitatory MEC neurons recorded as mice explored large open arenas. First, we examined grid cells, which can fire high-frequency bursts that reach over 300 spikes/s, some of the fastest firing of excitatory cells reported in cortex. As a population, grid cells had significantly higher bursting values (% of ISI < 10 ms) compared to border or head direction cells, consistent with recently published work on the inter-spike interval differences amongst these populations of cells (grid = 8.2 ± 0.6%; border = 4.0 ± 0.4%; head direction = 5.6 ± 0.3%) (Latuske et al., 2015). Interestingly, as predicted by our in vitro voltage-clamp and current clamp data on specialized Na current kinetics and propensity to burst, bursting percentage across the grid cell population decreased as a function of dorsal-ventral depth ($r = 0.15$, $p < 0.001$). This dorsal-ventral organization in bursting percentage was not present in head direction cells ($r = 0.02$, $p = 0.76$) or border cells ($r = 0.17$, $p = 0.12$). Functionally, bursting significantly correlated with grid symmetry, as well as the stability and coherence of grid patterns, suggesting that bursting in grid cells enables robust spatial coding. This increased spatial fidelity in bursting grid cells, compared to non-bursting grid cells, occurred across multiple running speeds and became more pronounced at very high running speeds. Combined, these data raise the possibility that the gradient in sodium current kinetics is related to the emergence of a grid cell population that codes robustly at high speed. Ongoing analyses aim to address the mechanistic relations between speed, coding accuracy, and bursting as we connect intrinsic conductances that vary across the dorsal-ventral axis of MEC to a functionally important burst coding gradient in vivo.

**Abstract:** While animals are exploring an environment their hippocampal pyramidal cells tend to fire in a spatially specific manner within a small area of space called a “place field”. Furthermore, the hippocampal representation of space is dynamic: place cells can be active outside their classical place fields. In particular, during resting periods in the behavioral task this sequential activity can reflect both previously explored behavioral trajectories and subsequent ones. Complex patterns of hippocampal bursting activity can represent a diversity of spatial trajectories, some of which were classified as replay and some of which were correlated with planning of future events. However, it remains uncertain which cognitive function is subserved these events and what information they encode. To investigate whether visual stimuli can trigger bursting activity reflecting replay or planning-related activity we trained rats on a task which demands activation of neural networks that are collectively capable integration of self-motion information, environmental information (e.g. visual cues) and predictions about future reward. Four Lister-Hooded rats were trained on an automated custom-built maze with easily modifiable, dichotomous trajectories (spatial exploration trajectories, SET). The maze had two observation decks elevated with a respect to a start chamber that was separated from the SET with a sliding transparent door. LEDs were positioned underneath the SET and could be switched on and off at different stages of the trial. The behavioral task was constructed such that rats visually inspected their future paths while one of the two potential trajectories was illuminated by LEDs, indicating the path leading to reward when chosen. We constructed novel SET configurations every three days during recordings.
We obtained ensemble recordings (16 recording tetrodes) from dorsal hippocampus, CA3 area, while rats were engaged in the behavioral task. From isolated single units (total of 831 cell), multiunit activity (MUA) histograms were formed and events of increased MUA activity (IMUA’s) were identified. We investigated occurrences and spatial representation of IMUA intervals. We observed that stimulus onset (SET path illuminated by LEDs) increases IMUA in the hippocampal network. Further, we used a Bayesian decoding algorithm to investigate if place-cell sequence events can be detected in IMUA’s and if they represent replay or prospective events across familiar and novel environments.

**Title:** Distinct hippocampal place codes for goal-directed behavior in a two-dimensional open field

**Authors: *Y. AOKI**, H. IGATA, T. SASAKI, Y. IKEGAYA
Univ. Tokyo, Tokyo, Japan

**Abstract:** Hippocampal place cells show strong goal-directed tuning within their place fields when animals engage in goal-directed behavior. To address the detailed characteristics of goal-directed tuning, spiking patterns of hippocampal cells were recorded while rats performed a goal-directed task where rats were required to run toward a light-cued goal port to obtain a reward in an open field. Enhancing the degree of freedom of moving directions by utilizing the two-dimensional space allowed us to analyze animal's trajectories from various provenance toward goals. A population of hippocampal cells increased their firing rates when the rats approached to a specific goal port, termed goal-directed cells. When switched to the pseudo-random foraging task where the rats freely searched randomly scattered reward in the same field, some of the goal-directed cells fired at the identical locations, termed non-remapped cells, whereas the others exhibited highly differentiated firing fields in the two contexts, termed remapped cells. In the foraging task, the non-remapped cells more strongly fired as the rats passed through the place field at higher running speed toward the previous goal port, indicating that goal-directed signals are integrated onto spatial firing of these cells. These results demonstrate that there are distinct types of hippocampal cell ensembles for encoding goal-directed behavioral contexts.

**Abstract:** Hippocampal network coordination of the relationship between theta rhythmicity and neuronal firing has been thought to be a critical element for spatial cognition. For example, the precision of place cell firing relative to theta rhythm is thought to enhance place cell accuracy and the navigational ability of the rat. To our knowledge, this hypothesis has not been tested in functional studies. Our preliminary data suggests that while optogenetic stimulation of the medial septum (MS) can adjust the rhythmic frequency of hippocampal theta, and leave the spatial firing of hippocampal neurons intact, it disrupts the coordination between these physiological events. Specifically, we measured the theta phase preference angle and magnitude of place cells during conditions of varying spatial demand, including both cued and uncued versions of the place accuracy navigation task. These cued and uncued sessions coincided with either continuous experimental or control 6 Hz optogenetic MS stimulation. Preliminary results indicate that ensemble levels of place cell phase preference increase during the uncued version of the task in comparison to the cued version of the task. Moreover, experimental MS stimulation abolished place cell phase preference and affected both the behavioral strategy and accuracy of the spatial task. Control MS stimulation did not affect either of these variables in either cued or uncued versions of the task. While further research is necessary, the results indicate the necessity of phase preference, and therefore temporal coordination of neurons in the hippocampal circuit, may be necessary for both self-localization and spatial navigation in the place accuracy task.

**Title:** The statistics of hippocampal CA1 place field activity in large virtual environments

**Authors: *J. LEE**, J. BRIGUGULIO, S. ROMANI, A. K. LEE
HHMI / Janelia Res. Campus, Ashburn, VA

**Abstract:** The location of an animal within its environment can be decoded from the activity of hippocampal CA1 place cells. In a small environment, most CA1 pyramidal neurons are active at a single location (place field) or not at all (silent cells). Rich et al. (Science 345: 814-7, 2014) reported that, in a large environment (48 m long track), the distribution of rat CA1 place fields was well-described by a gamma-Poisson model such that (1) many cells had few or no place fields while a few cells had many place fields (gamma-distributed), and (2) the place fields of each cell were randomly distributed across the environment (Poisson-distributed). To further examine the properties of place cells and place fields in large environments, we performed 2-photon imaging of hippocampal CA1 neurons in head-fixed, GCaMP6f-expressing transgenic mice (Dana et al. (PLoS One 9:e108697, 2014) running on a spherical treadmill in a visual virtual reality system (Dombeck et al., Nature Neuroscience 13: 1433-40, 2010). Virtual environments were 40 m long and 2-photon imaging allowed the spatially tuned calcium activity of >500 simultaneously imaged cells to be followed over days. This enabled statistical assessment of place field activity and stability at the population level, with implications for both the mechanisms underlying place field generation, as well as the structure of spatial representations.

**Authors: *S. YAGI**, H. IGATA, Y. SHIKANO, Y. AOKI, T. SASAKI, Y. IKEGAYA
Lab. of Chem. Pharmacology, Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

**Abstract:** Hippocampal pyramidal neurons specifically increase their firing rates when an animal visits a particular location of the environment, termed place cells. In general analyses, firing patterns of place cells have been characterized based on a spatial distribution of firing rates averaged over an entire recording session. A place cell, however, emits variable numbers of

action potentials even when the animal visits the same place field. In this study, we analyzed such trial-to-trial variability of place cell firing recorded from rats performing a linear track task. As a possible source of the variability of place cell firing, we focused on lap-by-lap changes in synchronous reactivation patterns of neuronal ensembles during consummatory periods at a track end. Similar sets of neurons, including both spatial and non-spatial cells, tended to repeatedly participate in neuronal synchrony within a single consummatory period, whereas different neuronal populations emerged in different consummatory periods. A linear regression analysis revealed that such time-varying reactivation patterns of neuronal populations during individual consummatory periods could predict the firing rates of a place cell observed during running immediately after the consummatory periods. The results suggest that place cell firing is not simply triggered by static inputs representing external environments but is subject to time-varying internal states of neuronal populations.

**Title:** Sleep spindle topography in 6.5 month-old human infants is sexually dimorphic, correlated with language measures, and functionally left-lateralized

**Authors: *S. E. PETERS**, A. A. BENASICH
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

**Abstract:** Sleep spindles are patterned bursts of oscillatory brain activity, visible in the scalp EEG, associated with NREM sleep, neuroplasticity and cortical development. In adults, spindles are typically defined by a slow or fast frequency, with fast spindles having a predominantly centro-parietal topography. Adult spindles are sexually dimorphic: in females, fast and slow spindle amplitude are positively correlated with IQ, whereas in males, posterior fast spindle density is negatively correlated. Females also show higher spindle activity in the left frontal region, in both adults and infants. Recently, sex-specific patterns of sleep spindles and cognition have been shown in adolescents and children, with fast and slow spindle amplitude and density

correlating with measures of IQ, in females. In infants, spindles are a biomarker of maturation, first appearing about 4-9 weeks of age, reaching peak duration and density between 3 and 6 months-of-age. During this time, infants are developing pre-linguistic auditory cortical maps that support emerging language. Mini-puberty, a burst of gonadal hormones that occurs at about 8 weeks-of-age, concurrent with spindle onset, impacts later language development via positive estradiol and negative testosterone. Might infant sleep spindles comprise a sensitive measure of individual differences in network development, thus contributing to group-level sex differences in neural processing of language? In this study, we mapped the topography of spectral power in the spindle frequency range (10-16Hz), using 124-channel EEG (EGI, Inc.), during daytime naps in a typically developing cross-sectional group of infants aged 3.5-4 and 6.5-7 months. We administered a standardized behavioral assessment, the Bayley Scales of Infant and Toddler Development, Third Edition (Bayley-III), on the same day as the nap recording, allowing us to examine sex-based differences between topographical spindle spectral power and its association to standardized measures of behavior and cognition. Females showed higher spindle-band spectral power in left-lateralized central and frontal electrode clusters. Slow spindle-band power was positively correlated with expressive language in females, whereas fast spindle-band power was negatively correlated with receptive language in males. These data suggest that early language-based neural network development is associated with emerging sleep spindle topography and frequency. We hypothesize that the burst of gonadal hormones during mini-puberty, could be mediating the dimorphic development of sleep spindles and their correlation with language development.

**Title:** Direct brain recordings from children and adolescents reveal diverse patterns of PFC involvement in memory formation

**Authors: *E. L. JOHNSON**[1,2], Q. YIN[2], L. TANG[2], M. MALIK[2], E. ASANO[2,3], N. OFEN[2]
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Wayne State Univ., Detroit, MI; [3]Children's Hosp. of Michigan, Detroit, MI

**Abstract:** Human declarative memory improves remarkably across childhood and adolescence, concomitant with the maturation of the neocortex and widespread neocortical connectivity.

Prevailing functional MRI evidence points to the importance of protracted development of the prefrontal cortex (PFC) in the development of memory function. Until recently, however, it was not possible to detail the precise timing of PFC activity in the developing brain. We provide rare insight from individuals aged 5-17 (n = 12) undergoing direct cortical monitoring as part of clinical management (i.e., ECoG), which yields data with unprecedented spatiotemporal precision in the study of neurocognitive development. Subjects studied pictures of scenes, and judged whether each scene was indoors or outdoors in preparation for a recognition memory test. We analyzed task-evoked activity between 20-300 Hz to track PFC responses with millisecond precision during the encoding of scenes that were subsequently remembered. Importantly, activity in the gamma (>30 Hz) and high-frequency broadband (HFB; >70 Hz) ranges is correlated with the functional MRI BOLD response in humans, and HFB activity has been linked to neuronal spiking in the primate cortex. Spectral decomposition was performed using a multi-tapering approach with logarithmically spaced center frequencies and 1/3 fractional bandwidth, and 250-msec sliding time windows. Then, 3-sec encoding power segments were z-scored on the 300-msec pre-stimulus baseline (450-150 msec prior to scene onset) using a statistical bootstrapping procedure. We found that HFB increases in PFC were timed to the presentation and/or judgement of each scene, providing initial evidence that the developing PFC is involved immediately and dynamically during memory formation. These increases were observed in all subjects with single-trial reliability ($p < 0.05$) - with the most robust effects focused in middle frontal and precentral gyri, two regions that have been implicated in subsequent memory in adults. Furthermore, analysis of subsequently remembered versus forgotten scenes evidenced a partially overlapping and similarly diverse pattern of effects (all $p < 0.05$, permutation-corrected). We show that PFC exhibits spatially distributed, rapidly shifting, and behaviorally relevant patterns of activity during memory formation, even in young children. These findings provide novel evidence that challenges prevailing theories on the role of PFC in memory development.

**Title:** Visual cortices assume distinct cognitive functions in congenital and adult-onset blindness

**Authors: *R. PANT**[1], S. KANJLIA[1], C. LANE[2], M. BEDNY[2]
[1]Psychological and Brain Sci., [2]Johns Hopkins Univ., Baltimore, MD

**Abstract:** How does the potential for cortical plasticity change over the lifespan? In blindness, the visual cortices respond to somatosensory and auditory stimuli (Sadato et al., 1996, Nature; Collignon et al., 2011, PNAS). These responses are observed not only in congenital blindness, but also in adult-onset blindness (Collignon et al., 2013, Brain). Surprisingly, in congenitally blind individuals the visual cortices also become involved in higher-cognitive functions, such as language (Roder et al., 2002, European JoN.; Amedi et al., 2004, Nat Neuro; Bedny et al., 2011, PNAS). Do visual cortices also take on higher-cognitive functions in adult-onset blindness? More generally, do visual cortices perform similar cognitive functions in those who are blind from birth as opposed to those who become blind in adulthood?
In a previous study we showed visual cortices of congenitally blind people are more active during sentence processing than in a working memory control task with non-words. Furthermore, in congenitally blind but not sighted individuals, activity in the visual cortex increases with the grammatical complexity of sentences (Lane et al., 2015, JoN).
In the current study we used the same task to ask whether the visual cortices of adult-onset blind individuals show a similar or different functional profile. 18 congenitally blind, 11 adult blind (blindness onset after age 17) and 17 sighted participants were scanned while listening to sentences and performing a working memory task. Each sentence was followed by a yes/no question. Questions required participants to judge who did what to whom. Half the sentences were grammatically complex, i.e. contained syntactic movement. In the control task, participants decided whether the order of non-words in a probe stimulus matched the order of the same non-words in the target stimulus.
The visual cortex of adult-onset blind participants responded to sentences more than non-words when compared to the sighted participants, but this effect was much smaller than in the congenitally blind ($P < 0.05$). Unlike in the congenitally blind, the degree of response to sentences correlated with the duration of blindness in the visual cortex of the adult-onset blind ($r = 0.73$, $P < 0.05$), suggesting a different mechanism of plasticity. Crucially, unlike the visual cortex of the congenitally blind, the visual cortex of adult-onset blind participants did not respond to grammatical complexity (group-by-condition interaction $P < 0.05$). These findings suggest that visual cortices assume distinct cognitive functions in congenital and adult-onset blindness and suggest greater potential for functional repurposing of the cortex in childhood.

**Abstract: Background:**
Cortical regions participating in functional networks at rest exhibit highly correlated levels of gene expression. Yet, the relation between gene expression and cognition is unknown. We assessed whether correlated gene expression is elevated between regions engaged in similar task-related cognitive processes.
**Methods:**
Microarray data from postmortem tissue samples of 6 adults (Allen Institute Human Transcriptional Atlas) provided expression levels of 16,906 genes across 1,193 neocortical regions. Each region was assigned to 1 or more (of 12 total) cognitive processes, estimated from a hierarchical Bayesian model applied to 10,449 experimental contrasts in the BrainMap database. We assessed relations between gene co-expression (Pearson correlation across detrended expression levels) and cognitive process overlap (presence or absence of a shared cognitive process) among all cortical region pairs, while controlling for spatial proximity, tissue class similarity, and between-subject variance. Additionally, we performed enrichment analyses (GOrilla; $P<10e^{-4}$) on genes ranked by differential co-expression between regions with or without cognitive process overlap.
**Results:**
Overlapping cognitive processes characterized 29% of interregional connections. Gene co-expression was greater for connections with ($0.018 \pm 0.129$) versus without ($-0.009 \pm 0.125$) cognitive process overlap ($\chi^2=177.5$, $P<2.2e^{-16}$; **Fig. 1**). Genes that were preferentially co-expressed between regions with cognitive process overlap were enriched for 40 cell component and 94 biological process terms relating largely to activity and maintenance of synapses. In contrast, no gene ontology term was enriched among genes preferentially co-expressed between regions without cognitive process overlap.
**Conclusion:**
Gene co-expression is elevated between regions engaged in similar cognitive processes, due in part to coupled expression of genes involved in synaptic communication. This result suggests a molecular basis for the organization of human neocortex into task-related networks.

**Abstract:** Statistical learning, the ability to extract regularities in our environment, may be fundamental for social behavior. We tested 124 young children (ages 2-8 years), 56 children with autism compared to 68 typically developing children on a novel, flexible visual statistical learning task to determine whether individual variability in statistical learning was associated with autism symptoms. On average, as a group, children with autism appeared to demonstrate no learning on the task compared to typically developing children. However, Bayes classification probabilities, which measured how likely an individual child's pattern of learning was similar to that of a typically developing child, demonstrated that there was significant overlap in learning patterns between a subset of children with autism and typically developing children. Children with autism who demonstrated clear learning on the task had less severe autism symptoms. Children with autism and typically developing children with higher verbal abilities demonstrated superior statistical learning abilities. Together, findings suggest that averaging data in young children with autism may mask heterogeneity. Individual variability in statistical learning may help to understand differences in symptoms across individuals with autism. The results have significant clinical implications for identifying distinct learning patterns in young children with autism that could be used to tailor and inform treatment decisions. Behavioral findings will be the foundation for future research during functional Magnetic Resonance Imaging to understand the neural underpinnings of individual variability in statistical learning in autism.

**Title:** Cognitive control training supports the functional integration of control networks in adolescence

**Authors: R. LEE**[1], S. KWAK[2], D. LEE[2], *J. CHEY[2,1]
[1]Interdisciplinary Program in Brain Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Psychology, Seoul Natl. Univ., Seoul, Korea, Republic of

**Abstract:** Cognitive control continues to mature throughout adolescence, and lower cognitive control at this time is linked to various clinical outcomes such as risk-taking behavior, substance abuse, and mental disorders. Although some research examined behavioral effects of cognitive control training in adolescents, no studies have explored the neural basis of these training effects. In this study, we investigated resting-state connectivity (rsFC) using functional magnetic resonance imaging (fMRI) before and after 6 weeks of cognitive control training in 51 adolescents (mean age 13.2 years). A seed-based functional connectivity analysis was conducted, with the seed regions identified through an automated meta-analysis to be implicated in cognitive control. The trained group showed increased rsFC between right anterior insula/frontal operculum (aI/FO) and cerebellum compared with the control group. This result can be interpreted in the context of developmental change, which implies that the development of positive functional connections between cerebellar network and other cognitive control networks in adolescence was promoted by cognitive control training. In other words, given that previously isolated regions of the cerebellar network have been reported to coalesce into two other control networks (fronto-parietal and cingulo-opercular networks) at this age, our result suggests this functional integration of control networks over development was accelerated by intensive training. Using well-established cognitive control networks as regions of interest (ROIs), a follow-up analysis revealed that rsFC between cingulo-opercular and cerebellar networks was strengthened in the trained group compared with the control group. Furthermore, increased strength of connectivity was associated with improvement in Block Design test, with the magnitude of these connectivity changes being reflected by individual gains in cognitive control performance. These findings emphasize the supportive role of cognitive control training in enhancing functional integration of control networks that may drive cognitive control improvement in adolescence.

**Authors: *D. P. PANFILI**[1], K. Z. OSIPOWICZ[2]
[1]Drexel Univ., Chesterfield, NJ; [2]Psychology, Drexel Univ., Philadelphia, PA

**Abstract:** Autism spectrum disorder (ASD) is a common but heterogeneous spectrum of developmental disorders. The nociferous effects of ASD have been demonstrated on cognitive, functional, and structural levels. All of these previous studies support the view that ASD is a

network disease, affecting function and structure of cortical and subcortical regions throughout the brain. Though all of these effects are well established, previous investigations into network disruption caused by ASD have been hypothesis driven. Hypothesis driven analyses of network effects are insightful, but limited in that they do not allow untethered exploration of network disruption. Here, we analyzed network differences between 531 ASD patients and 571 age matched controls utilizing a support vector machine multi-voxel pattern analysis of resting state functional connectivity data. Additionally, utilizing a similar analytic approach, we analyzed network disruptions occurring differentially between ASD severity, as determined by ASD DSM-V severity level and ADOS score. Our findings confirm that ASD causes wide ranging network disruptions, and that functional connectivity evidence of these disruptions is a distinguishing feature of ASD, and that there are a number of distinguishing features of severity level classification. These findings confirm and replicate a number of previous effects, and extend the understanding of ASD as a network disorder affecting multiple functional domains.

**Abstract:** Much of what we know about learning and memory in the human brain comes from adults. However, the greatest period of learning in life happens early in development as infants and toddlers acquire language, gain knowledge about the world, build motor and social skills, etc. This poses a challenge for theories of learning and memory because many of the brain systems involved in adults may not be fully functional in infancy. For example, complementary learning systems theory posits that the medial temporal lobe (more specifically, the hippocampus) is needed to represent individual episodes in memory. However, the hippocampus has a protracted developmental trajectory, with critical subregions only coming online after infancy and possibly not until adolescence. Thus, episodic memory in infants may be implemented in a different way. Likewise, an updated version of the same theory posits that the hippocampus is also needed for statistical learning, our ability to extract regularities across episodes, and yet there is considerable behavioral evidence of statistical learning in infants and even newborns. These tensions highlight the critical need for more data on brain function in

awake, behaving infants. The most common neuroscience methods for this population, such as EEG and NIRS, are surface based and thus cannot resolve deep structures like the hippocampus. Therefore we have been exploring the viability of conducting fMRI studies in infants and toddlers while they perform tasks designed to test episodic memory and statistical learning. Here we will present initial findings from these investigations as well as broader considerations associated with studying learning and memory in early development. One possible outcome is that the hippocampus is not involved in either episodic memory or statistical learning at this age. Alternatively, the hippocampus may be at least partly functional early on and already supportive of both behaviors, as in adults. Finally, a middle ground is that episodic memory and statistical learning may depend on different pathways within the hippocampus that develop at different rates, thus hippocampal activation may emerge earlier in one task than the other. Specifically, statistical learning is supported by the monosynaptic pathway to CA1, which develops earlier in non-human primates than the trisynaptic pathway, which passes through dentate gyrus and CA3, and supports episodic memory. Findings from these studies will help reveal the organization of the developing mind and inform existing theories about mechanisms in the brain that are critical for learning and memory.

**Abstract:** There have been thousands of fMRI studies over the past two decades, and they have provided important insights about how the adult mind and brain work. In light of this success, it is striking that only a small handful of fMRI studies have tested infants in the same way. This is not for a lack of interesting and deep questions about cognitive development — indeed, such a rich dependent measure could open up exciting new questions and opportunities for studying preverbal infants. Rather, the dearth of studies likely reflects the technical and experimental challenges of conducting fMRI studies in this population, including head motion, attention span and fussiness, an ability to understand or follow instructions, acoustic noise, a scanning

apparatus that is typically designed for adults, and analyses optimized for adult data. Some labs have successfully scanned infants, particularly when they are sleeping or sedated, but there have been few attempts to translate paradigms from infant cognition to the scanning environment. Here we report on our efforts over the past two years to re-imagine task-based fMRI procedures for early development. Our approach has benefitted from recent progress in cognitive neuroscience in the acquisition and analysis of adult fMRI data, and from the methodological and theoretical groundwork laid by developmental psychologists. We have devised several novel procedures that increase the likelihood of successfully scanning awake, behaving infants, maximizing the amount of useful brain data collected per session, while also collecting behavioral eye-tracking data. First, we changed the scanning environment to increase infant comfort, including using vacuum pillows to reduce movement, supplying redundant hearing protection, and involving parents in the scans. Second, we altered experimental designs and equipment, including presenting stimuli panoramically on the ceiling of the scanner bore, importing successful stimuli and tasks from the infant cognition literature, and building flexible code for running experiments in short modules. Third, we composed a novel analysis pipeline that incorporates cutting-edge tools from several packages to assess data quality, identify and scrub motion artifacts, and, when possible, functionally align brains longitudinally within participant and cross-sectionally across participants. With these procedures, we have thus far obtained usable data from 11 out of 15 participants under the age of 18 months. Although this endeavor continues to be challenging, our hope is that these methodological insights will eventually increase the prevalence of early developmental fMRI.

**Title:** Local functional connectivity development in early childhood: Associations with socioeconomic status

**Authors: *U. A. TOOLEY**[1], A. P. MACKEY[2]
[2]Psychology, [1]Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Over the course of development, children undergo large changes in functional brain organization, and these changes have been shown to be sensitive to early experiences.

Many studies have characterized developmental changes in the resting state functional connectivity of specific brain structures and networks. However, no studies have investigated changes in patterns of local connectivity across the brain in early childhood. Regional homogeneity (ReHo) is an analytical approach that compares each voxel's blood oxygen time course at rest to its neighboring voxels. In adults, ReHo is highest in sensory regions and the default mode network (Lopez-Larson et al., 2011), a result that is consistent with high local connectivity in these regions (Sepulcre et al., 2010).
In this study, we conducted whole-brain ReHo analyses in a sample of children ages 3-10 from the Pediatric Imaging Neurocognition and Genetics (PING) dataset ($n$=64). All analyses controlled for motion, site of data acquisition, and sex, and were corrected for multiple comparisons using permutation testing (FSL's randomise) at $p < .05$. We found that ReHo was highest in sensory and motor cortices. ReHo decreased with age in sensory and motor cortices and in subcortical structures. ReHo increased with age in regions of the default mode network (as defined by Yeo et al., 2011), including posterior cingulate, precuneus, and left inferior frontal gyrus (IFG). Additionally, there was a positive correlation between socioeconomic status (SES), and ReHo in an area of right IFG at the intersection of three networks: default mode, frontoparietal, and ventral attention.
In sum, we found that, as in adults, sensory and motor cortices have relatively high local connectivity, and that local connectivity decreases with age in these regions. In contrast, default mode areas show increases in local connectivity with age. Further, our findings suggest that SES may have an impact on the development of local connectivity at the junction of networks in prefrontal cortex. Future analyses will examine the associations between the development of local connectivity, SES, and cognition.

**Title:** Task control network brain activity before intervention relates to future reading gain in struggling readers

**Authors: *T. NUGIEL**[1], M. ROE[1], W. TAYLOR[2], J. M. FLETCHER[2], J. J. JURANEK[3], J. A. CHURCH[1]
[1]Psychology, Univ. of Texas At Austin, Austin, TX; [2]Univ. of Houston, Houston, TX; [3]Univ. of Texas at Houston, Houston, TX

**Abstract:** Reading is a fundamental life skill, but many children have reading difficulties, with nearly one in three children reading below a basic level in 4th grade (NEAP, 2015). Responses to reading interventions can vary and behavioral measures cannot always predict whether a struggling reader will respond to a given intervention. At the same time, the role of task control processes in reading provides an important less-explored angle on reading development. This study tested for brain activity differences in reading and control regions both within a group of struggling readers and between struggling and typical readers based on whether the struggling readers went on to show substantial reading gains at the end of the school year.
We used functional magnetic resonance imaging (fMRI) data in 4th grade children to measure activity in reading and task control regions of interest (ROIs) related to reading outcomes. 46 struggling readers (26 males) and 31 age-matched typical readers (15 males) performed an in-scanner sentence comprehension task as well as an out-of-scanner battery of neuropsychological and reading measures. Struggling readers also repeated both in and out of scanner measures in the spring after remedial instruction. Whole brain analyses for the correct response > baseline contrast and the mean percent signal change extracted from literature-derived ROIs were used to test for reader group differences. Gains in reading measures calculated from pre-post (fall-spring) test score changes were used to sort struggling readers at the pre-intervention scan (fall) into future improver and future non-improver groups. Importantly, there were no differences in reading ability or IQ between future improvers and future non-improvers before instruction (all *p's* >0.10).
We saw whole brain differences in activation between future improvers and future non-improvers in bilateral ventral fusiform, as well as ROI differences in a right frontal task control region ($t(34.92) = 2.28$, $p = 0.03$). Differences in activation between future improvers and typical readers were seen in task control and default network regions at the whole brain level, as well as in left inferior parietal ($t(50.27) = -2.05$, $p = 0.04$) and left inferior frontal gyrus ($t(46.23) = 2.06$, $p = 0.04$) ROIs. Taken together, these findings suggest that recruitment of task control brain regions, in addition to reading regions, may be important predecessors for subsequent reading gain in 4th grade struggling readers.

**Title:** Higher responsiveness to familiar scenes in the retrosplenial cortex develops in late childhood

**Authors: *T. W. MEISSNER**, S. WEIGELT
Developmental Neuropsychology, Ruhr-Universität Bochum, Bochum, Germany

**Abstract:** *Introduction:* Our ability to recognize a current visual scene as familiar or unfamiliar is a key necessity for a good sense of orientation and enables us to successfully navigate our environment. Younger children (< 10 years) display a notably lower proficiency in recognizing scenes as familiar vs. unfamiliar, while older children (10-12 years) perform as well as adults. An underdeveloped functioning of the visual cortical scene processing network (parahippocampal place area (PPA), retrosplenial cortex (RSC), transverse occipital sulcus (TOS, also named occipital place area, OPA)) in younger children might be an underlying factor for their lower capability to efficiently recognize scenes as familiar or unfamiliar. Studies in adults suggest that especially the RSC is highly responsive to the familiarity of scenes, while a familiarity effect in the PPA and the TOS is rather unreliable. So far, studies on the functional development of the scene processing network almost exclusively focused on the PPA. Moreover, the emergence of a responsiveness towards familiarity has not been investigated in pediatric samples. *Method:* Here, we investigated the development of the scene processing network's response to familiar scenes in contrast to new scenes. We analyzed BOLD amplitudes with regard to stimulus category (familiar scene, unfamiliar scene) in three age groups (7-8-year-olds, 11-12-year-olds, adults) in a mixed ANOVA for scene-selective regions (PPA, RSC, TOS, subject-specifically defined using a separate scene localizer). *Results:* Preliminary analysis of 27 participants so far reveled a higher response to familiar vs. unfamiliar scenes in all regions of interest across age groups. Moreover, our results suggest an RSC-specific development of familiarity responsiveness in late childhood: Both younger and older children did barely differ between responses to familiar vs. unfamiliar scenes. In comparison, adults developed a larger response to familiar scenes while their response to unfamiliar scenes stayed constant. We found the same pattern for the rRSC, albeit as a nonsignificant trend. Familiarity x age group interactions were not evident in PPA or TOS. *Discussion:* These results indicate that while the behavioral development of scene recognition in concluded early (up to age 12), functionality in the scene-selective RSC continues to develop beyond the age of 12 years of in terms of a familiarity effect. This provides evidence for further neuronal maturation processes in the scene network that do not have a behaviorally measurable equivalent in navigation or sense of orientation tasks.

**Title:** A sensitive period for higher-cognitive repurposing of visual cortex in blindness

**Authors: *S. KANJLIA**, L. FEIGENSON, M. BEDNY
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Recent evidence suggests that visual cortices not only respond to auditory and somatosensory input, but are repurposed for higher cognitive functions, such as language and mathematical reasoning in congenital blindness (Kanjlia et al., 2016, PNAS). In addition, resting-state activity of visual cortices becomes more correlated with fronto-parietal networks (Deen, et al., 2015, JoCN). Is such dramatic functional reorganization restricted to a sensitive period early in development? To address this question, we compared visual cortex function and connectivity across congenitally blind, adult-onset blind and sighted individuals.
While undergoing fMRI, 12 adult-onset blind (AB; vision loss after age 17), 20 congenitally blind (CB) and 19 blind-folded sighted adults performed an auditory math task in which they decided whether the value of an unknown variable across two math equations was the same. Math equation difficulty was manipulated by increasing digit-number (e.g. 7-2=x vs. 27-12=x) and by moving the x variable (e.g. 7-2=x vs. x-2=7). In a language control task, participants decided if pairs of sentences had the same meaning. Participants (11 AB, 23 CB, 38 S) took part in 1-4 8-minute resting state scans to evaluate visual cortex functional connectivity with fronto-parietal language and number networks.
All groups recruited a classic fronto-parietal number network, including the intraparietal sulcus, during the math task. However, unlike congenitally blind individuals, adult-onset blind individuals did not recruit visual cortices selectively during the math task (whole-cortex, math>lang, $p<0.05$, cluster-correct.). Although visual cortices of adult-onset blind individuals demonstrated an indiscriminately larger response to auditory stimuli compared to sighted individuals, activity was not modulated by task (math vs. lang) or by equation difficulty, as observed in congenitally blind individuals (digit-number by group (CB vs. LB) interaction: $F(1,30)=4.11$, $p=0.05$). Thus, a subset of visual regions only assumes mathematical functions in congenital blindness. Interestingly, resting state data revealed an intermediate connectivity pattern in the adult-onset blind group, relative to the sighted and congenitally blind participants. Similar to the congenitally blind group, the adult-onset blind group showed network-specific

increases in resting-state functional connectivity between visual and prefrontal cortices. These results suggest that changes in functional connectivity in blindness lead to visual cortex plasticity for higher cognitive functions, but only during a sensitive period early in development.

**Title:** White matter integrity is related to cognitive ability in early life

**Authors:** ***J. N. BULLINS**[1], E. CORNEA[1], B. D. GOLDMAN[2], R. C. KNICKMEYER[1], M. STYNER[1,3], J. H. GILMORE[1]
[1]Psychiatry, [2]Psychology & Neurosci., [3]Computer Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract: Background:** Mounting evidence reveals white matter (WM) integrity as an indicator of cognitive ability in children and adults. However, it is unknown how WM fibers support cognitive development in early life. This study explores relationships between *in-vivo* WM microstructural properties and cognitive ability in the first 2 years of life.
**Methods:** Tract-based diffusion properties (FA, RD, AD) were computed using diffusion tensor images from healthy neonates (n=332), 1-year-olds (n=255), and 2-year-olds (n = 181). Cognitive measures at ages 1 and 2 (ELC1, ELC2) were collected using the Mullen Scales of Early Learning. Data were analyzed using raw and partial correlations and mixed effects models comparing global tract-average properties at birth, age 1, and age 2 to ELC1 and ELC2. All results were corrected for multiple comparisons using false discovery rate (FDR).
**Results:** Unadjusted Pearson's correlations revealed widespread significant correlations between individual tract FA ($0.13 \leq r \leq 0.22$; $p<0.05$), AD ($-0.23 \leq r \leq -0.13$; $p<0.05$), RD ($-0.25 \leq r \leq -0.14$; $p <0.02$) and ELC2. However, FA, RD, and AD are significantly correlated with

gestational age at birth (FA: $0.11 \leq r \leq 0.44$, $p < 0.003$; AD: $-0.48 \leq r \leq -0.29$, $p < 0.0001$; RD: $-0.49 \leq r \leq -0.31$, $p < 0.0001$) and gestation number (FA: $-0.30 \leq r \leq -0.12$, $p < 0.004$; AD: $0.22 \leq r \leq 0.39$, $p \leq 0.0002$; RD: $0.24 \leq r \leq 0.38$, $p < 0.0001$), and controlling for these covariates in partial correlations revealed no significant relationships between WM at birth and ELC2. Gestational age ($r = 0.34$, $p < 0.0001$), gestation number ($r = -0.35$, $p < 0.0001$), and maternal education ($r = 0.41$, $p < 0.0001$) were also directly related to ELC2; these factors were not related to ELC1. At age 1, widespread correlations were found between tract RD, AD and ELC1, mainly in projection tracts from the brainstem and thalamus to cortex, and also in arcuate and superior longitudinal fasciculi (SLF; all results: $-0.21 \leq r \leq -0.14$, $p < 0.05$). The left SLF at age 2 was related to ELC2 ($p<0.05$); no other brain-cognition relationships at this age survived FDR. **Conclusions:** More mature microstructural properties along WM bundles at birth and 1-year is related to future and present cognitive ability. WM integrity at birth is related to gestational characteristics, and these gestational characteristics along with maternal education are important sociodemographic predictors of cognition at age 2. Tracts detected as markers of early ability are important for primary sensory, sensory integration, and higher-order cognitive functions. Results suggest WM integrity in early life, particularly across the first postnatal year, is important for emerging cognition and deserves further study.

**Abstract: Introduction:** We present converging evidence from MRI cortical morphometry and ERPs studies that a pattern of connectivity of cortical nodes within two attentional networks - the *Dorsal Visual Network* (**DVN**; visual-spatial w. frontal dorsal-parietal nodes) and *Ventral Visual Network* (**VVN**; object categorization w. frontal ventral-temporal nodes) demonstrates an earlier track of maturation for DVN than VVN. **Methods:** Thirty typically developing children rigorously selected using neuropsychological tests (**TD**; age 6-15) and thirty young adults (**A.;** 21-40) participated in studies. 3D MRI scans were used to construct individual cortical surfaces yielding a gray/white matter/pial boundry model. MRI Cortical Thickness (**CTh**) was mapped to the inflated surface. The development of *structural connectivity* was defined as the age-dependent thinning of the cortex, where two cortical nodes, highly connected, showed a significant pair-wise correlative relationship (significant network edge). Stop-Response Task-related Event-Related Potentials (ERPs) were analyzed. The ERPs cortical *functional connectivity*, as measured by P200-N200 peak amplitude and latency in frontal and posterior nodes, respectively, were submitted to correlative analysis within the DVN and VVN cortical nodes. **Results:** Between-group contrasts t-statistics (Cohen's D) and within-group Pearson's r for linear relationship between variables (N200, P200 amplitudes, latencies) showed no significant differences TD vs. A for DVN in cortical thickness (except Frontal Premotor) and in ERPs amplitude or latency measures. The correlative computations showed significantly less connectivity between long-range nodes in TD than A, for both CTh and ERPs P200/N200 amplitudes, with a statistically significant group discrepancy for measures in VVN. The peak latency was persistently prolonged in TD. Long-range VVN network frontal-temporal nodes connectivity, displayed in A was significantly lower or nonexistent in young TD children (e.g. prefrontal ventral to fusiform gyrus). **Conclusion:** The MRI CTh morphometry and ERPs P200/N200 reflect a tight cohesiveness in displaying less child-adult differences in structural and functional connectivity between nodes of the DVN but more statistically significant group differences for VVN, thus suggesting an earlier maturational course for DVN. This finding, consistent with a proposed earlier hypothesis of specific DVN susceptibility to pathology in disorders of early childhood (Atkinson et al., 1999; Braddick et al., 2011), is of high importance for early clinical diagnosis and prevention, and for understanding chronometry of typical development.

**Title:** Early educational intervention for poor children modifies brain structure in adulthood

**Authors: *M. J. FARAH**[1], J. T. DUDA[2], T. A. NICHOLS[3], S. L. RAMEY[4], P. R. MONTAGUE[5], T. M. LOHRENZ[4], C. T. RAMEY[4]

**Abstract:** The Abecedarian project was an experimental early childhood intervention for poor children, which provided comprehensive cognitive and social enrichment in a daycare setting for 6–8 hours a day, five days a week, starting in infancy and continuing through age 5. Activities emphasized language and play-based learning. A control group received nutritional support, health care, and social services, as did the intervention group, so that outcome differences would not be attributable to these factors. Over the ensuing decades participants were evaluated on their functioning in various important spheres of life including educational, occupational, economic, and health outcomes, with significant positive impacts of the intervention apparent by several measures. Now in their late 30's and early 40's, the participants were imaged with MRI of the brain to examine whether those who experienced an enriched early education had measurable differences in brain structure. Forty-seven participants could be successfully scanned; 29 of these (15 males, 14 females) were in the early educational intervention group and 18 (9 males, 9 females) were in the control group. Covarying sex and age, initial findings were (here and throughout, standardized regression coefficients and 2-tailed significance levels): Larger overall cortical grey volume ($\beta$=.23, p=0.035) and borderline significant larger white matter volume ($\beta$=.21, p=0.084), with no difference in overall deep grey matter volume. Five a priori regions of interest were selected to assess the effects of the intervention on areas related to language (L inferior frontal gyrus, L superior temporal gyrus) and cognitive control (L and R anterior cingulate cortex and R inferior frontal gyrus) covarying whole brain volume as well as the earlier covariates. Of these 5 regions, two showed significant positive effects of intervention, L IFG ($\beta$=.38, p=0.005) and R IFG ($\beta$=.37, p=0.006) and one showed a borderline significant effect, L ACC ($\beta$=.27, p=0.08). In sum, children from poor families who experienced an intensive language and play-based educational intervention starting early in life had more cortical grey matter and, in a preliminary examination of specific regions, larger IFG volumes bilaterally in middle adulthood.

**Abstract:** Spatial representations underlie many cognitive tasks, including memory for spatial configurations and mental rotation. The literature has tended to attribute spatial abilities to the right hemisphere (RH) parietal areas of the brain, but even the classic task of mental rotation appears to activate bilateral parietal regions. Recently, we adapted a widely used visual-spatial construction task to examine neural patterns in adults, and found strong bilateral activation. In the present research, we ask whether this is also shown in young children, or alternatively, whether a pattern of RH lateralization precedes the mature pattern of bilateral activation.
fMRI activity was measured in typically developing children ages 5–11 years (n = 22, mean age = 8.03 years) while they performed a visual-spatial construction task. The task engages several aspects of spatial ability, including representation of object shape and orientation as well as mental translation and rotation. In the Spatial condition, participants indicated whether two separated puzzle pieces could be fit together to form a square. In the Color (control) condition they indicated whether gray squares on the pieces were the same color.
Children obtained high levels of task accuracy ($M$ = 90%, $SD$ = 9%), which was positively correlated with age. Analyses of neural activity at the individual level showed significant clusters of activation in bilateral superior and inferior parietal areas of all participants (Spatial > Control condition, $p < .001$, $k < .05$). The number of active voxels was positively correlated with age, with older children showing a greater number of significantly active voxels. Hierarchical linear regression confirmed that this relationship remained unchanged when controlling for accuracy. This age-related increase in spatial extent (number of voxels) reflects the expanding involvement of parietal regions.
No correlations were found among the variables of response time, IQ (WASI-II), or motion parameters. Functional cluster parietal ROIs were defined by a GLM (contiguous supra-threshold voxels) and BOLD response amplitudes of these ROIs were calculated. These did not show a

correlation with either age or number of active voxels. There were no differences between the RH and LH in terms of either voxel counts or response amplitudes. This reveals a strong and consistent bilateral activation pattern. Across development and into adulthood, both the RH and LH contribute to the complex computations underlying visual-spatial construction.

**Title:** Adolescents are sensitive to peer influence, but only for so long

**Authors: *J. M. RODRIGUEZ BURITICA**[1], H. R. HEEKEREN[2], W. VAN DEN BOS[3]
[1]Dept. of Educ. Sci. and Psychology, Freie Universität,, Berlin, Germany; [2]Freie Univ. Berlin, Berlin, Germany; [3]Max-Planck-Institute for Human Develop., Berlin, Germany

**Abstract:** Adolescents have the reputation to be fickle and easily influenced by their peers, particularly to do things that may not be in their best interest. Indeed several studies have shown that specifically teenagers show increased levels of risk taking in the presence of peers (Albert et al., 2013). Yet a recent study also suggest that adolescents, compared to adults, may be less influenced by prior instructions and put relative more weight on their own experience (Decker et al., 2015). Thus at this point it is not clear how these findings can be resolved and whether adolescents are more sensitive to prior social advice, particularly of their own peers, or weight their own experience more heavily. Here we present an age-comparative study (in 8-10, 13-15 and 18-22 year olds) study that investigates the mechanisms of learning from social and individual information. Using computational models we are able to test the interaction between different (social) learning mechanisms, and track how they change with age. Our results suggest that there are two mechanisms that facilitate social learning: 1) setting initial expectations (priors) and 2) a constant bonus for the advised option. More importantly, our results show that adolescents are indeed initially the most sensitive to their peer's advice (sets a strong prior), but that this is quickly updated by their own experience. On the other hand, adults show the long lasting bias towards the advised option. Finally, we also find that the younger participants are in general more exploratory, and this helps adolescents even to find out more advantageous information. Our results provide novel insights in the dynamic interaction between social and individual learning and also provide a framework for understanding previous (seemingly conflicting) results.

**Title:** Casual prefrontal cortex neuromodulation of reinforced skill learning

**Authors: *J. HERSZAGE**[1], E. DAYAN[2], R. LAOR MAAYANY[1], N. CENSOR[1]
[1]Sch. of Psychological Sciences, Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract:** Procedural motor skill learning is mediated by reinforcement, whether in the form of reward or by punishment (Abe et al., 2011; Dayan et al., 2014b; Galea et al., 2015). However, a mechanistic account identifying the neural substrates underlying reward based motor skill learning is incomplete. The lateral prefrontal cortex (lPFC) is densely connected with motor (Cieslik et al., 2012; Hasan et al., 2013), declarative/hippocampal (Preston and Eichenbaum, 2013) and reward systems (Haber, 2011; Jarbo and Verstynen, 2015). We thus hypothesized that due to the system interactions of lPFC with procedural, declarative and reward networks, it plays a crucial role in reinforcement-based skill learning and memory formation. To explore the causal role of the human lPFC in reinforced skill learning, participants (n=20) in the current study performed the motor skill learning task (Karni et al., 1995), in a rewarded or non-rewarded paradigm, after undergoing non-invasive brain stimulation (TMS). Baseline performance levels were comparable between the two counterbalanced sessions ($t_{19}$=1.836, ns). In comparison to control vertex stimulation, inhibitory 1Hz rTMS over the lPFC diminished learning gains, relative to baseline performance ($F_{1,19}$=4.57, $p<0.05$). In addition, correlation between task-free functional connectivity of distinct memory systems and the behavioral motor skill formation, are measured. The results reveal a unique role for the lPFC underlying reinforced acquisition of complex skills, and may suggest that it mediates systems-wide interactions across memory and reward networks.

**Title:** Enhancing cortical targeting for non-invasive brain stimulation in order to modulate the consolidation of motor sequence memory

**Authors: *M. A. GANN**[1], B. R. KING[1], D. MANTINI[1], M. DAVARE[1], S. SWINNEN[1], E. M. ROBERTSON[2], G. ALBOUY[1]
[1]Dept. of Kinesiology- Motor Control and Neural Plasticity Res. Group, KU Leuven, Leuven, Belgium; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

**Abstract:** Motor sequence memory consolidation is supported by dynamical interaction between striato- and hippocampo-cortical networks (Albouy et al., 2013). However, it remains unknown whether activity within these networks can be modulated in order to influence the consolidation process. The aim of the present study is to use resting-state (RS) functional connectivity to identify potential cortical areas that can be subsequently targeted with non-invasive brain stimulation (NIBS) in order to modulate the interaction between these two brain networks, ultimately influencing motor memory consolidation.
RS fMRI data were recorded on 26 young healthy subjects (mean age: 25.4 y.o.) with EPI sequences (TR=2.5s, voxel size=2.5x2.5x2.5mm$^3$) in a 3T MRI scanner. Whole-brain functional RS connectivity maps using the hippocampus and the caudate nucleus as seeds (defined anatomically bilaterally according to the AAL brain atlas) were computed with procedures similar to Solesio-Jofre et al. (2014). Conjunction analyses between the resulting hippocampal and striatal RS connectivity maps were performed in order to identify cortical nodes connected to both seed regions. Results indicate that the left DLPFC (-26 18 52mm) was significantly commonly connected to the hippocampus ($z$=2.30, $p_{FDR}$<.05) and the caudate nucleus ($z$=2.44, $p_{FDR}$<.05). Additional clusters in the conjunction map were also present in midline default mode network regions (e.g., MPFC, cingulum) as well as in the cerebellum and thalamus. In order to confirm that the identified DLPFC region is relevant for motor sequence learning, we analyzed an independent sample of task-related fMRI data obtained from 55 young healthy participants (mean age: 23 y.o.) with EPI sequences (TR=2.65s, voxel size=3.4x3.4x3 mm$^3$) in a 3T scanner. Whole-brain Psycho-Physiological Interaction analyses were conducted using the above-mentioned left DLPFC as a seed region. Results indicate that task-related functional connectivity between the DLPFC and the left parahippocampus (-32 -46 -12mm, $z$=3.54, $p_{FWEsvc}$<.05) as well as the left putamen (-28 -10 -6mm, $z$=3.38, $p_{FWEsvc}$<.05) was modulated by performance on the

motor task.
Altogether, our results suggest that the DLPFC is a critical cortical node orchestrating functional interactions between hippocampal and striatal networks involved in motor memory processes. Future research will use the identified DLPFC cluster as a cortical target for NIBS in order to modulate activity in the hippocampal and striatal networks and ultimately influence motor memory consolidation.

**Title:** The evolution of whole-brain community structure during sensorimotor adaptation

**Authors: *D. STANDAGE**, J. Y. NASHED, J. R. FLANAGAN, J. P. GALLIVAN
Queen's Univ., Kingston, ON, Canada

**Abstract:** Traditionally, sensorimotor adaptation was believed to be solely driven by an implicit learning process, characterized by a slow, automated reduction in sensory prediction errors. However, recent behavioral evidence suggests that explicit cognitive strategies also play an important role in adaptation, supporting faster learning and re-learning when encountering the task a second time (savings). While previous behavioral work has proven invaluable in characterizing the distinct computations supporting sensorimotor learning, its underlying neural bases remain poorly understood. To date, neural studies of adaptation learning have largely focused on changes in the activity of single brain regions or the interactions between several such regions, failing to fully capture the widely accepted notion that learning reflects a whole-brain process, involving the coordination of brain regions over a broad range of spatial and temporal scales. Moreover, it remains unclear which features of functional brain network organization underlie well known differences across participants in their capacities for learning and their expression of savings. Here, we used functional magnetic resonance imaging (fMRI) to investigate the whole-brain, large-scale temporal networks that govern visuomotor rotation learning and re-learning. Participants performed two separate MRI sessions, separated by 24 hours. On each trial, they moved a centrally located virtual cursor, via the hand, to contact one of

eight possible targets. On each testing day, following baseline trials, we introduced an instantaneous 45 degree rotation of the hand cursor with respect to the hand and tracked participant learning during continuous MRI acquisition. Following earlier studies (Bassett et al, PNAS, 2011; Bassett et al, Nat Neurosci, 2015), we used time-resolved clustering methods to determine the community structure of multi-layer networks collated across sliding time windows during rotation learning on each day. We quantified the modularity of network structure, the extent to which brain regions changed community affiliation, and the probability that any two brain regions were assigned to the same community. We show that participants who exhibit the behavioral signatures of explicit, cognitive strategies during learning also exhibit greater flexibility in their network community structure, particularly in frontal and ventrotemporal brain areas. Our results suggest that individual differences in sensorimotor adaptation are linked to the adaptability of large-scale network structure.

**Abstract:** Learning new motor skills and re-learning motor skills during rehabilitation from an injury are abilities needed throughout the lifespan. In this study, we examined the age-related changes in brain activation during visuomotor skill acquisition and retention. Healthy young (n = 17, 10F, age mean 25.5 years) and older adults (n = 16, 7F, mean age 62.6 years) performed a visuomotor tracking task, using flexion and extension of the right-dominant wrist, while lying in an MRI scanner. On Day 1, participants performed a pre-test, a training session and a post-test. On Day 2 (24h later) participants performed a retention test. Testing consisted of 6 blocks of 5 trials of both the experimental (zig-zagged template) and control task (monotonically increasing or decreasing line) with each trial being 4, 5 or 6 s. The training session consisted of 120 trials of

the experimental task, inside the MRI scanner. FMRI acquisition only took place during the test sessions (Siemens Allegra, 3T, 279 volumes per test). Old (error: 14.5°) compared with young adults (error: 9.7°) performed more poorly at the pre-test on the visuomotor tracking task but practice improved both age-groups' performance to a similar extent (young: 26%, old: 31%). Performance of both age groups remained stable at retention. Preliminary fMRI data analysis in 15 young and 12 old adults showed a main effect of Time on activation in the right middle occipital gyrus, while there was no main effect of Age on brain activation. There was an Age*Time interaction in bilateral precuneus activation, with increases in activation in this area from pre- to post-test in young but not in old adults. However, in old adults, activation decreased from pre- to post-test in a more superiorly located part of the precuneus. At retention, the activation in the precuneus returned to pre-test levels in both age groups. These results suggest that the precuneus is differently activated in young and old adults during the acquisition and retention of a visuomotor skill.

**Title:** tACS-applied slow-wave oscillations enhance repeated plasticity paradigm effects

**Authors: *C. BRADLEY**[1], G. KIESEKER[1], J. B. MATTINGLEY[1,2], G. TONONI[4], M. V. SALE[3]
[1]Queensland Brain Inst., [2]Sch. of Psychology, [3]Sch. of Hlth. and Rehabil. Sci., The Univ. of Queensland, St Lucia, Australia; [4]Univ. of Wisconsin Madison, Madison, WI

**Abstract:** If two plasticity paradigms are applied in close succession, response to the second paradigm is reduced compared with when it is administered on its own. This effect is thought to arise from saturation of synaptic connections by the preceding plasticity event. Slow-wave sleep has been hypothesized to "unload" synapses, allowing greater plasticity to occur with subsequent plasticity paradigms. Here we examined whether this unloading effect could be mimicked using non-invasive electrical brain stimulation. Specifically, we ask whether artificial induction of slow waves in awake humans allows successive plasticity protocols to exert their full effects. Thirty healthy adult participants underwent two successive plasticity protocols: (1) a motor training task (30 min ballistic thumb abduction, 0.5Hz), and (2) a paired associative stimulation

(PAS), “excitatory” paradigm involving near-synchronous stimulation of the median nerve and primary motor cortex (M1; 133 stimuli at 0.2Hz). Plasticity within the corticospinal motor tract was quantified indirectly by measuring motor evoked potential (MEP) amplitude elicited by single pulses of transcranial magnetic stimulation (TMS) over left M1. In between the two plasticity paradigms, participants received transcranial alternating current stimulation (tACS, 1mA, 3 x 6-minute exposures, 1 min break intervals) targeting left M1. Crucially, tACS was delivered at a slow wave frequency (0.75Hz), under active or sham (no stimulation) conditions. Each participant underwent two separate sessions, in a double-blind, randomised cross-over design. As expected, motor training significantly increased MEPs in the target muscle (~165% of baseline amplitude, $p<0.01$) by a similar amount for both the active and sham tACS sessions. Importantly, MEP amplitude was modulated differently following sham versus active tACS (ANOVA interaction, $p=0.01$). Specifically, MEPs were significantly larger after sham than after active tACS ($p=0.04$). Consistent with existing literature, the PAS plasticity protocol following motor training did not result in further modulation of MEPs in the sham session, suggesting a saturation of targeted synapses. In contrast, when active tACS was applied after motor training, PAS had a significant facilitatory effect on MEPs ($p=0.02$). These results provide evidence for modulation of motor cortex plasticity by low-frequency, slow-wave-like non-invasive electrical stimulation in the awake human. We speculate that slow-wave tACS plays a similar role to slow-wave sleep by re-setting synaptic connections that have been potentiated, permitting them to respond to successive plasticity paradigms.

**Title:** Individual differences in implicit probabilistic sequence learning

**Authors: *S. A. KISER**[1], P. KHOSRAVI[2], N. E. ADLEMAN[2]
[1]Physical Med. and Rehabil., DC VA Med. Ctr., Washington, DC; [2]Psychology Dept., The Catholic Univ. of America, Washington, DC

**Abstract:** Emotion regulation, mood, and attention have been shown to influence learning and memory. However, their effect on implicit probabilistic sequence learning (IPSL) has yet to be determined. IPSL is fundamental to adaptive behavior and results from knowledge gained from the probabilistic structure of events. Many skills, such as written and spoken language, driving, cooking, and performing sports or music comprise such ordered regularities. Therefore, it is

important to understand the interaction between IPSL and other cognitive processes. The current study aimed to investigate the role emotion regulation, mood, and attention play in probabilistic sequence learning in a Triplets Learning Task (TLT). Specifically, we investigate: 1.) the relationship between IPSL and self-reported emotion regulation, mood, and attention, and 2.) whether attention control mediates these relationships.
Twenty-one healthy college-aged (20.76±1.34) students (12 female) completed questionnaires related to Mood Regulation (MR), Depression & Anxiety (DA) symptoms, Attention & Impulsivity (AI), and were administered a TLT via a touch-screen tablet.
Results from the TLT revealed that subjects learned to predict high probability events. Overall response times improved with practice ($F(1.67,31.67)=16.54$, $p<0.001$), were fastest for high probability events ($F(1,19)=24.54$ $p<0.001$), and a trend interaction between event frequency and practice ($F(5,95)=2.13$, $p=0.069$) showed responses to high probability events improved most with practice. A recognition test showed no subjects were aware of event frequencies.
Correlation analyses returned no significant relations between TLT learning scores (LS) and self-reported medical, neurological, or attention deficit diagnoses. However, regression analyses revealed a significant relationship between Depression & Anxiety measures and LS ($F(2,17)=3.88$, $R^2=0.313$, $p=0.041$). Measures of MR and AI failed to predict LS.
Mediation analyses were performed to determine if Attention Control (AC) using the Attention Control Scale mediated the relationship between Depression & Anxiety and Learning Scores. Results revealed a trend where DA predicted AC ($F(2, 17)=2.99$, $R^2=0.26$, $p=0.077$); however, AC was not a mediator of DA and LS. Three explanations could account for these findings: 1) N not sufficient to power the analysis, 2) range of scores were too limited, 3) DA could affect both AC and LS.
In conclusion, DA appears to predict IPSL performance, yet our results do not implicate attention as mediator. Future studies should be aware that mood could influence IPSL, which could affect learning new skills and engaging in adaptive behaviors.

[2]Psychology, [3]Mechanical Engin., [1]Lafayette Col., Easton, PA

**Abstract: Purpose:** Marksmanship and competitive shooting tasks require active engagement and demand high levels of hand-eye coordination. Training can improve performance, but how? Gaze control learning has improved performance in sporting events that employ Quiet Eye, a form of gaze fixation where the object is fixed, such as in basketball (Harle & Vickers, 2001), darts (Vickers, Rodrigues & Edworthy, 2000), and shotgun shooting (Causer et al., 2010). Gaze control training has not yet been shown for Smooth Pursuit Eye Movements (SPEM), or for unpredictable ballistic target motion. Furthermore, the purpose of the present study was to provide insight into which strategy participants used to track targets: chasing, one in which humans follow the trajectory of the target (Hoffman, 1991), or ambushing, when humans anticipate where the target will be in the future and wait there (Tresilian, 2005).
**Method:** This study used a simulated 3-Gun competitive shooting event (Brown, 2016) involving what is colloquially known as the *Death Star*. The Death Star requires individuals to hit five steel plates that rotate and swing on a double-hinged target. The simulation used non linear equations that mimic the actual event and it was sensitive to internal conditions; the timing and location in which a plate is hit influences its path. As such, no two trials are alike. The star's swift and unpredictable movements makes this event engaging and it requires one's full attention to learn the task. Twenty two naïve participants attempted 20 trials over 6 training days. Half of them received gaze control training while the others did not. Participants stood three meters away and shot the targets with a plastic pistol outfitted with a laser pointer and wore a head mounted eye tracking system. Participants also played a round of Darts before and after the study to investigate if ability was transferred between tasks.
**Results:** The present study found evidence for both chasing and ambushing strategies. Both strategies efficiently tackled the complexity of the Death Star task under our experimental conditions. The present study is also the first demonstrate that two-dimensional, unpredictable target tracking can be improved through gaze control training. Additionally, we found that this skill was transferable between a dynamic and stationary target tracking task.

**Title:** Discovery-based learning affords neural facilitation enhancing generalization to a novel motor task

**Authors: *R. LAWSON**[1], J. JOHNSON[2], L. WHEATON[2]
[1]Applied Physiol., [2]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

**Abstract:** Prior studies have shown that the presence of explicit awareness in motor learning is detrimental to generalization, a key aspect for flexibility in motor skill acquisition. However, as most of these studies have utilized an intentional paradigm to elicit awareness, it is unclear if awareness developed incidentally results in the same detrimental effects on generalization. A recent study by our lab demonstrated the presence of a facilitative network for subjects demonstrating explicit awareness during a motor learning task. This network may provide individuals with improved neural connections which enhance the ability to quickly identify efficient motor heuristics in a novel environment. The purpose of our study was to examine the effect of priming subjects to a level of incidental explicit awareness on the ability to transfer to a novel, more complex motor task. To this end, subjects assigned to a priming condition experienced a 7-element serial reaction time task and then transferred to a 10-element sequence. Subjects in the control condition (CONTROL) experienced just the 10-element sequence without priming. Utilizing our behavioral indicator for the presence of incidentally developed explicit awareness, primed subjects were classified as explicit (EXP) or non-explicit (NOEXP) to the order of the 7-element sequence. Results show that over 50% of the EXP subjects developed explicit awareness of the 10-element sequence, as compared to less than 10% of the NOEXP or CONTROL subjects. EEG data analysis demonstrates a neural shift for both the EXP and NOEXP subjects in the 10-element sequence as compared to the CONTROL group, demonstrating neural changes associated with the priming effect of the initial 7-element sequence. Primed subjects failing to develop awareness on the 10-element sequence significantly differed from the EXP and CONTROL group in neural patterns suggesting that successful transfer may require a balance of sensory and motor processing afforded by the facilitative network utilized in the initial discovery learning. The current results reveal the beneficial effects of explicit awareness developed in a discovery-based paradigm on generalization.

**Title:** Implicit & explicit knowledge in visual statistical learning

**Authors: *K. HIMBERGER**[1], A. S. FINN[2], C. J. HONEY[1]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Toronto, Toronto, ON, Canada

**Abstract:** *Background*: Statistical learning, the process of extracting regularities from the environment, is believed to produce both "implicit" and "explicit" knowledge (Batterink et al, 2015; Turk-Browne et al, 2005). Implicit knowledge is revealed indirectly, as in facilitation of the reaction time (RT) for predictable elements in a target detection stream (Schacter, 1992). Explicit knowledge is directly measured, and may also be the dominant influence in the two-alternative forced choice (2AFC) recognition procedure that is widely used to assess statistical learning (Batterink et al, 2015). In light of proposed connections between statistical learning and implicit learning (Perruchet & Pacton, 2006), it is important to understand which kinds of knowledge contribute to which tests. Therefore, we asked: (i) is 2AFC recognition performance driven by explicit knowledge even for visual sequence learning that occurs incidentally during a cover task?; and (ii) how are the contributions of implicit and explicit knowledge altered when the timing of stimulus presentation changes?
*Methods*: We conducted a series of online experiments in which participants viewed visual streams composed of four sets of image triplets (5-12 minutes of exposure), while performing a "jiggle detection" task (Turk-Browne et al, 2009). Participants then completed three tests: (1) target detection; (2) 2AFC familiarity; (3), explicit triplet creation. Stimuli were presented either speeded (200ms duration; 40ms ISI) or unspeeded (800ms duration; 200ms ISI).
*Results*: Mean 2AFC performance varied between 54 and 56% across conditions. There was substantial individual variability in both RT facilitation and 2AFC performance within each condition. Across all conditions, 2AFC performance was correlated with the ability to subsequently "create" parts of triplets or entire triplets. Conversely, the more implicit measure of learning (RT facilitation) was not correlated with the ability to create triplets. Preliminarily, speeded stimulus presentation and testing appeared to decrease 2AFC performance and increase RT facilitation.
*Conclusions*: Our results are broadly consistent with those of Batterink et al. (2015), who argued for dissociable contributions of explicit and implicit knowledge on 2AFC performance and RT facilitation. We extend these findings to visual stimuli presented under a cover task, and find tentative evidence that speeding the stimuli during test leads to a greater contribution of implicit knowledge. Future work will explore stimulus timing (independently varying stimulus duration and ISI) and the possible effects of acquiring explicit knowledge during testing.

**Title:** tACS-applied slow wave oscillations promote consolidation of motor cortical plasticity in the awake human brain

**Authors: *M. V. SALE**[1], N. BLAND[2], C. BRADLEY[3], G. TONONI[4], J. B. MATTINGLEY[3]
[1]Univ. of Queensland, St Lucia, Australia; [2]Queensland Brain Inst., [3]The Univ. of Queensland, St Lucia, Australia; [4]Univ. of Wisconsin Madison, Madison, WI

**Abstract:** Slow wave sleep is thought to play an important role in consolidating plastic changes (e.g., memories, learnt skills) that arose during the preceding period of wakefulness. These processes for consolidating plastic change are believed to manifest from the high amplitude, low frequency oscillations in cortical excitability that are present during slow wave sleep. Non-invasive brain stimulation (transcranial alternating current stimulation; tACS) has been shown to mimic these slow oscillations, and can affect learning in the *awake* state. This suggests that induced slow oscillations can affect plasticity without the need to sleep. Here, participants (n = 20) received slow (0.75Hz) oscillatory active tACS to left motor cortex for 15 minutes, or sham stimulation, in separate sessions. Prior to tACS, participants received a repetitive transcranial magnetic stimulation (rTMS) paradigm to induce a long-term potentiation-like change in synaptic efficacy to motor cortex. Plasticity was quantified indirectly by measuring the amplitude of motor evoked potentials (MEPs) from single-pulse TMS at several time-points: before rTMS, after rTMS (before tACS), and then every 5 minutes for 30 minutes after tACS. As expected, MEP amplitude increased significantly and to an equivalent level following rTMS in both active and sham conditions. Following sham tACS, however, MEP amplitude returned to baseline levels. Critically, MEPs following active tACS remained elevated at least 30 minutes after stimulation ceased. This suggests that slow oscillatory tACS can consolidate the plasticity induced in human motor cortex, and mimics the effects of slow wave sleep, without the need for sleep. These findings have important implications for our understanding of the physiological basis of slow wave sleep, and could have translational value for neurological rehabilitation. For example, it may be possible to promote consolidation of learnt skills etc. by applying slow oscillatory tACS to improve motor recovery after stroke, or in patients with cognitive deficits.

**Title:** Static magnetic field stimulation alters motor learning in humans

**Authors: *A. LACROIX**[1], L. PROULX-BÉGIN[2], F. MORIN-PARENT[1], J.-F. LEPAGE[1]
[1]Pediatrics, Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Psychology, Univ. Du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

**Abstract:** An increasing number of studies show that static magnetic fields (SMF) can modify brain activity by reducing neuronal excitability. Evidence for this comes mainly from neuroimaging studies, but data showing the ability of SMF to alter human behaviour is scarce. Here, we used the serial reaction time task (SRTT), a task known to be sensitive to common non-invasive neuromodulatory tools, to assess the efficacy of SMF to modulate sequence motor learning. Twenty right-handed adults performed the SRTT while a 50mm neodymium magnet (N42) or a placebo was applied to the primary motor cortex of the left hemisphere. Results show a marked decrease in learning rate for participants in the real-magnet condition, affecting reaction time in sequence blocks ($p<0.001$) without altering reaction time for random blocks ($p > 0.1$). These results show that SMF applied to the motor cortex can potently alter the neurophysiological processes involved in motor learning, validating the utility of SMF stimulation for cognitive studies in humans.

**Abstract:** Statistical learning is crucial for obtaining motor, cognitive, and social skills. Accumulating evidence suggests that the spontaneous intrinsic (resting state) functional connectivity (FC) between regions of the brain may contribute to the capacity of the nervous system for acquiring probabilistic knowledge. The present study aimed to investigate resting-state FC and its relationship with statistical learning performance on a widely used probabilistic learning task (the Alternating Serial Reaction Time, ASRT) task. It was hypothesized that intrinsic FC of the frontal and temporal brain regions exclusively in the theta rhythm (4-7 Hz) promote the individual's learning capabilities. 64-channel EEG was recorded for 5 minutes during a resting period (eyes-opened) before the participants performed the ASRT task. FC between 62 source reconstructed cortical regions was measured by phase synchronization index (PLI) within theta band. Significant positive linear correlation was evident between the FC of the medial frontal gyrus and a statistical learning index, suggesting that increased frontal connectivity in theta band during the pre-learning period predicts better performance in statistical learning. The present results further emphasize the role of trait characteristics function of the fronto-parietal network in the extracting regularities from the environment.

**Abstract:** Motor adaptation involves contributions from multiple cortical and subcortical regions of the human brain, organized in widespread networks. In this learning process, cerebellum seems to play a major coordinating role, synchronizing large-scale interregional systems. We report a study where 18 participants carried out a visuo-motor task under the impact of cerebellar Transcranial Alternating Current Stimulation (tACS) using 20 Hz, 50 Hz or sham tACS delivered at 2mA for ~12 minutes. Participants must perform a reaching task with the right arm to bring a central dot towards a target distributed across eight eccentric locations. In parallel, participant's motor responses had to compensate a 45° counter-clockwise distortion of the screen's visual feedback on online target location, while being under the effects of one of the tACS conditions. Kinematic analysis of individual trials allowed the identification of two sub-groups of ballistic arm responses: *accurate responses* (i.e., movements that reached the target in time) and *erratic responses* (i.e., responses in which the target was undershot or overshot at the end of response window). Analysis of *erratic responses* across tACS conditions revealed for the 50 Hz tACS a significant decrease of the kinematic error, and a faster adaptation process to visual distortions across trials. Such effect proved specific for reaching movements towards targets displayed in the upper left and upper right side of the screen (but not for those displayed in the lower left and right-sided locations). No significant effect of tACS condition was found for any of the tested metrics indexing motor adaptation for *accurate responses*. Our results provide support to the notion of a direct modulatory enhance of error processing conducted by the cerebellum, likely induced by a local entrainment of frequency specific rhythmic activity at 50 Hz. Moreover, our data support future promise for cerebellar tACS for the modulation of motor adaptation in healthy participants and also neurological patients with impaired motor learning abilities.

**Title:** Investigating the role of the cerebellum in motor, linguistic, and social prediction: A tDCS-fMRI study

**Authors: *C. J. STOODLEY**[1], S. E. MARTIN[2], B. C. DRURY[2], A. M. D'MELLO[1]
[1]Psychology, [2]Neurosci., American Univ., Washington, DC

**Abstract:** Clinical, neuroanatomical, and neuroimaging data suggest that the human cerebellum is involved in cognitive and social processing as well as motor control. However, the precise contribution of the cerebellum to cognitive and social processes has yet to be established. Based on the motor literature, we hypothesize that the cerebellum builds internal models that are used to optimize performance and predict upcoming stimuli, leading to improved accuracy and faster response times. Here, we combine transcranial direct current stimulation (tDCS) and functional neuroimaging (fMRI) to investigate the role of the right posterolateral cerebellum in predictive processing in motor, linguistic, and social domains. Healthy young adults (all male; mean age 21.6±2.3 years) completed three tDCS-fMRI sessions. In each session, participants received 20min of 1.5mA anodal, cathodal, or sham tDCS over the right posterolateral cerebellum (1cm down and 4cm to the right of the inion). Then, participants completed three task paradigms, each with both non-predictive and predictive components: a serial response time task (SRTT), a sentence completion task, and a social ball-playing task. Task and modulation conditions were counterbalanced within and between participants, and repeated-measures analyses were conducted. We hypothesized that cerebellar tDCS would specifically impact performance on trials requiring implicit predictive processing (i.e. sequence learning blocks during the SRTT, highly predictive sentences during the sentence completion task, and learning which player had the highest probability of being a good partner on the social ball-playing task). Results suggest that cerebellar tDCS affected performance on trials in which prediction was necessary (e.g. sequence but not random trials on SRTT). Initial imaging results indicate that cerebellar tDCS had anticipated effects on BOLD signal based on tDCS polarity, with anodal tDCS and sham conditions showing increased right posterolateral cerebellar activation relative to cathodal tDCS (e.g. language task; $p<0.001$, FDR 0.05). There was also increased basal ganglia and primary motor cortex engagement during the SRTT when cerebellar activation was modulated ($p<0.001$, FDR 0.05), indicating a potential compensatory effect to maintain task performance. These findings support the hypothesis that the cerebellum is involved in implicit predictive processing across a range of tasks.

**Abstract: Background.** There is evidence that motor sequence learning (MSL) is related to working memory (WM) abilities. However, a potential interaction between WM and MSL trainings has not been investigated so far. **Aim.** We aimed at evaluating the differences in brain functional connectivity (FC) induced by two sequential training programs (WM + MSL and MSL + WM) and a combined program (WM and MSL in the same session). In the first setting the purpose was to quantify the additive effects. In the second case we analysed the interaction effects. **Methods.** Fifty-four healthy subjects (27 women; mean age: 30.2±8.6) were pseudo-randomly assigned to the three training programs. In total all subjects had four MRIs. Two MRIs were done prior to the trainings, a third MRI after three weeks and a fourth after six weeks of training. Each participant conducted all 24 training sessions at home using touch-screen devices. The MRI protocol included a 3D T1-weighted (MPRAGE, voxel size=0.7x07x07mm), and a multi-band EPI sequence (voxel size=2x2x2mm, TR=768 ms with 1160 repetitions) acquired on a 3T scanner. The FC matrices were generated by parcellating the brain in 234 regions and computing the cross-correlations among the resting-state fMRI signal in all regions. Differences in the strength of FC between sessions were computed in the whole sample by using the network-based statistic (NBS) algorithm. Differences among subgroups were investigated by computing the effect size (Cohen's *d*) between each pair of nodes of the network identified in the whole sample analysis. **Results**. The comparisons performed on the whole sample between the first and fourth MRI showed increased FC after the training in the parieto-fronto-temporal network. Within this network, the right inferior parietal gyrus showed increased FC with the right middle temporal gyrus, the right orbitofrontal gyrus and the right hippocampus. The left posterior-superior temporal and the precentral gyri showed increased FC with the right superior parietal and the supramarginal gyri and the right insula. No differences were observed between the two pre-training MRIs. The analysis of the effect size showed higher FC changes between

left temporal and right parietal regions for the combined program, between left temporal and bilateral parietal regions for the WM + MSL program and between right fronto-parietal regions for MSL + WM program. **Conclusion**. Sequential and combined training programs produced distinct patterns of FC modulation suggesting a relevance of the order in which trainings are performed. These observations provide new insight to plan effective training/rehabilitation programs.

**Abstract:** Probabilistic sequence learning enables the sensitivity to and the extraction of statistical regularities embedded in the environment; therefore, it plays a crucial role in the acquisition of automatic behaviors, such as skills and habits. Although several processes contribute to the overall learning performance that can be measured with overt behavioral responses in skill learning tasks, the temporal dynamics of neural mechanisms underlying these different learning processes have remained unclear. Therefore, we investigated whether two prominent learning processes - statistical learning and the learning of sequential structures - can

be distinguished using event-related brain potentials (ERPs) during probabilistic sequence learning. Healthy young adults (N = 40) performed the Alternating Serial Reaction Time (ASRT) task while EEG was recorded with 64 electrodes. The ASRT task is a unique tool to investigate the learning of raw statistical probabilities as well as more complex sequential structures within the same experimental design. We measured RTs and ERPs time-locked to the onset of the stimulus. At the behavioral level, while raw statistical probabilities were acquired rapidly, the learning of sequential structures developed gradually during the task. ERPs also reflected the distinct trajectory of these two mechanisms. Although the N2 component showed rapid, automatic detection of raw statistical probabilities, it gradually changed as participants acquired the sequential structures. ERP modulation related to the processing of raw statistical probabilities and sequential structures was also observed at the early stage of perceptual processing as the P1 component was sensitive to both mechanisms and this sensitivity did not change with practice. Overall, the N2 was elicited when the actual stimulus deviated from the predicted one that followed from the previously established representation of statistical contingencies experienced in the given environment. In addition, exposure to probabilistic regularities altered selective attention and thereby early visual processing of stimuli. In sum, our results indicate that statistical learning and the learning of sequential structures develop differently at the neural level. These findings could be interpreted in the broader framework of predictive theories and might provide insight to the dynamic change of multiple processes that occur during sequential memory formation.

**Abstract: Aim:** To verify the effects of transcranial direct current stimulation (TDCS) on the learning, retention and generalization of a new motor skill involving finger opposition sequence movements in healthy adults **Methods:** The present study compared the motor performance in terms of speed and accuracy, on two sequences of 5 opposing finger movements, where one sequence was trained (TS) and the other was not (NTS). Comparisons were made before (BT), 5 minutes (AT), 48 hours (48AT) and 7 (7DT) and 28 (28DT) days after a single training session, split into 4 blocks of 600 movements, in 20 healthy subjects with mean age of 20.8 years (SD=2.1), randomly allocated in an experimental group, which received 20 minutes of TDCS (2ma), concomitantly the training, and a control group, which received a placebo TDCS, concomitantly the training too. After the end of training, the performance was assessed under exactly the same conditions used in the previous assessments. The results were analyzed by RM ANOVA using as factors 2 groups (EG;CG) X 2 sequences (TS;NTS) X 5 assessment points (BT; AT; 48AT; 7AT; 28AT), which the two last were considered as repetitive measure **Results:** The analysis of performance, in terms of number of correct sequences showed a significant interaction amongst group, assessment and sequence ($F(15,18) = 2.58$, $p < .001$, ES=.90). **Conclusion:** The TDCS applied concomitantly the motor training improve the motor learning even in healthy adults, suggest that the increased cortical excitability mediate by TDCS can facilitate the mechanisms of synaptic reorganization associated to the learning process

**Title:** Impact of error magnitude on sensorimotor skill performance changes before and after consolidation

**Authors: *B. JOHNSON**, K. P. WESTLAKE
Dept. of Physical Therapy & Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD

**Abstract:** The period following sensorimotor skill acquisition, known as consolidation, is a necessary aspect of skill learning in health and disease. However, multiple practice sessions are often required for sensorimotor skill mastery and error reduction. While the adaptation to errors in skill performance is important to improve performance and learning, little is known about how error impacts performance before versus after the occurrence of consolidation. The objective of

this study was to determine differences in the impact of error during sensorimotor skill performance before and after a period of consolidation. Fifteen healthy right handed young adults (18-35 yrs) participated. The training protocol involves repetitive throwing of a small ball using the non-dominant upper extremity to five unique visuospatial targets while seated. Testing blocks consist of a random presentation order of the targets (e.g. target 1, 5, 3, 2, 4), whereas training blocks consist of blocked presentation order of the targets (e.g. target 2, 2, 2, 2, 2). Spatial metrics of throwing accuracy during testing blocks were collected at four time points (baseline, post initial training session, post one hour interval, and post second training session). Results show that, after normalizing training block throwing error distance and testing block change scores to baseline performance, the magnitude of error during training was significantly negatively correlated with within-initial training session performance change score ($r = 0.704$, $p = 0.005$). However, following the 1 hr consolidation period, the magnitude of error during training was less negatively correlated with within-second training session performance change score ratios ($r = 0.459$, $p = 0.085$). These findings suggest that error during sensorimotor performance may become more useful for fine-tuning skill performance over time following consolidation. A larger study with increased subjects is now underway. Future research will investigate the impact of various activities performed during the consolidation phase on the subsequent importance of error to sensorimotor skill performance.

**Abstract:** In today's web-based society, information on 'how something is done' can be found easily and quickly: Platforms like YouTube offer the possibility for everyone to upload self-made instructive videos which anybody interested can watch and thus learn by observing and imitating the seen content. Here we investigated this media-based approach of human observational learning using fMRI: a highly trained instructor folded an origami inside the MRI

scanner while being videotaped. We took care that the content of the video was instructive by making sure all steps were well visible and the folding was performed at a moderate pace. In the scanner, the instructor performed the origami without vision while being blindfolded. As a control, the instructor folded similar but partly repetitive folds while being videotaped and scanned.
For the preliminary results reported here, 19 subjects viewed the instructive video three times inside the MRI with the task to memorize the steps leading to the final origami. Right after each video, they had to reproduce the origami as far as they could. While watching the control video of the repetitive folds, subjects had to count the number of folds being made to ensure cognitive load and attentiveness. We assessed similarity using the intersubject-correlation method (Hasson et al. 2004) and the intersubject-correlation toolbox (Kauppi et al. 2014).
We found similar activity between the blindfolded instructor and the mean action observer in the action observation network in all conditions. This highlights similar activity when performing a complex naturalistic task and when observing it, even though similarity due to visual feedback can be ruled out, since it was not available for the instructor. (Out of the 19 subjects, only one detected the blindfold, which ensures that the naturalistic context was kept.)
The action observation network was also involved in all viewings when comparing between-observer similarity. However, average between-subjects correlations were significantly higher in the action observation network for the 'learning' conditions than the 'count folds' condition. This was the case also for the third repetition of watching the video, even though reported attentiveness was on average smaller than in the 'count folds' condition. This demonstrates a new facet of action observation network engagement: similarity of activity while learning a bimanual naturalistic task, with higher similarity of activity than during a task of visual-spatial processing and action identification.

**Abstract:** Older adults frequently experience declines in memory for personally experienced events, or episodic memory. However, the degree of memory decline varies considerably across individuals, even among putatively healthy older adults who do not meet clinical criteria for cognitive impairment. The present study seeks to investigate how hippocampal and cortical mechanisms supporting episodic memory relate to variation in memory performance among healthy older adults (60-90 yrs). This multi-modal study included the following measures: neuropsychological testing, high-resolution whole-brain 3T functional MRI with hippocampal subfield segmentation, hippocampal microstructure defined by ultra-high resolution 7T MRI, as well as genetic (APOE ε4) and molecular (CSF tau, beta-amyloid) biomarkers of Alzheimer's disease (AD). In the high-resolution fMRI study, participants were scanned during encoding and retrieval phases of an associative memory task. During encoding, participants were presented with a series of word-picture associations. During retrieval, participants were presented with studied words intermixed with new words, and asked to recall the specific picture paired with each word. The memory test included measures of both associative (source) and item memory: participants indicated the category of the paired associate (face or scene) if they could recall it successfully or, if they failed to remember the associate, had the option to classify the word as "old" (item memory only), or "new". Preliminary analyses (N = 31) targeted cortical reinstatement in ventral occipitotemporal cortex (VOTC; parahippocampal, fusiform, and inferior temporal cortex) during correct source memory retrieval. A logistic regression classifier was trained to discriminate between face and scene multi-voxel patterns in VOTC during encoding. The trained classifier was then tested on recall data; classifier performance at recall was treated as a measure of cortical reinstatement. Individual differences in source memory accuracy were partially accounted for by differences in cortical reinstatement (R-squared = .34; $t(29) = 3.82$; $p = .001$), even after controlling for the effects of age (R-squared-change = 0.31; $t(28) = 3.61$, $p = .001$). These preliminary findings suggest that individual differences in associative memory performance are linked to differences in cortical reinstatement during memory retrieval. Ongoing analyses will integrate multi-modal measures of medial temporal lobe structure, function, and AD biomarkers to explain the mechanisms underlying individual differences in episodic memory performance in older adults.

**Title:** Playing 3D video games can improve memory and hippocampal structure in older adults

**Authors: *G. D. CLEMENSON**, C. E. STARK
Univ. of California Irvine, Irvine, CA

**Abstract:** It is well understood that simply exposing rodents to a larger and more stimulating environment can have a positive impact on hippocampal neuroplasticity and function. This manipulation, known as environmental enrichment, has been shown to ameliorate and even rescue deficits in the hippocampus associated with aging. We are interested in whether this environmental enrichment manipulation has relevance to humans and can improve the structure and function of the hippocampus within an aging population of humans. Previously, we showed that playing 3D video games (Super Mario 3D World) can enhance hippocampus-associated behaviors in young adults and may act as a human correlate of environmental enrichment. Here, we further investigate the potential of video games as an intervention to mitigate cognitive and structural decline associated with aging in the hippocampus of older adults. We train an older population of naïve gamers in the video game Super Mario 3D World for one month. Participants are subject to pre- and post- testing sessions including a neuropsychological battery, high resolution structural and diffusion imaging brain scans, and a hippocampal-dependent mnemonic discrimination task. Preliminary results show that participants who played Super Mario 3D world demonstrated an enhancement in their mnemonic discrimination ability and this improvement was positively correlated with volumetric changes in hippocampal gray matter from pre-test to post-test with the dentate gyrus showing the most reliable changes. These data suggest that playing specific types of modern video games may have a meaningful impact on hippocampal deficits associated with aging.

**Title:** The relationships between global cortical thickness, intra-scan motion and recognition memory performance as a function of age

**Authors: *M. A. DE CHASTELAINE**[1], D. D. R. KING[2], B. E. DONLEY[2], K. M. KENNEDY[2], M. D. RUGG[3]
[1]The Ctr. for Vital Longevity and Behavioral and Brain Sci., Univ. of Texas At Dallas, Dallas, TX; [2]Ctr. for Vital Longevity and the Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX; [3]Ctr. for Vital Longevity and the Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas Ctr. for Vital Longevity, Dallas, TX

**Abstract:** The relationship between global cortical thickness and cognitive performance is moderated, non-monotonically, by age. Moreover, it has recently been reported that head motion during MR scanning can systematically underestimate measures of cortical thickness. Here, we investigated the effects of head motion on estimates of global cortical thickness and the relationship between cortical thickness and memory performance (controlling for motion) on associative recognition performance in three age groups encompassing much of the adult lifespan (young, middle-aged and older adults; total n = 133). Measures of global cortical thickness were obtained using a semi-automated method, and an index of mean head motion obtained during functional scanning was employed as a proxy for head motion during the structural scan. In addition to decreased memory performance, older age was associated with increased motion and cortical thinning (both before and after controlling for head motion). Amount of head motion was negatively associated with memory performance in young and middle-aged, but not older, participants, while cortical thickness was negatively associated with memory performance in the young, and positively correlated with memory performance in older participants, both before and after controlling for head motion. Thus, in regard to the relationships between cortical thickness, age and cognitive performance, our results are consistent with previous findings, and were not altered by controlling for head motion. The current study further demonstrated an age-dependent relationship between head motion and memory performance, which was reliable in the two younger groups only. We conjecture that the latter correlation is mediated by factors, such as cognitive control, that relates to both a propensity for movement in the scanner as well as poorer memory performance. In the older participants, we suggest that such a relationship may have been diluted by non-cognitive factors that also influenced amount of motion.

**Title:** Age differences in pre-stimulus subsequent memory effects: A time-frequency analysis

**Authors:** ***N. HAUCK**, J. KOEN, E. HORNE, M. RUGG
Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX

**Abstract:** Pre-stimulus subsequent memory effects (preSMEs) - differences in neuronal activity immediately preceding the onset of subsequently remembered and forgotten events during encoding - are thought to reflect proactive processes that benefit memory encoding. A recent study from our lab found differences between young and older adults in preSMEs assessed with event-related potentials (ERPs). Specifically, young adults showed preSMEs during the second or so prior to the onset of a to-be-remember stimulus, whereas older adults did not. The purpose of the current study was to examine if there are age differences in preSMEs using time frequency analysis of these EEG data. In this study, 24 healthy young and older adults studied words for a subsequent memory test. A task cue, that onset 2000 ms before each word, signaled one of two semantic judgments (shoebox or manmade) to perform on the word. Participants were then presented with the word for either a short (300 ms) or long (1000 ms) duration. The goal of this manipulation was to place differential demands on preparatory processes initiated by the onset of the task cue. Memory for the words was tested some 10 minutes after the study phase. EEG data from the pre-stimulus period (locked to the onset of the task cue) was subjected to time frequency analysis using Morlet wavelets from 4-20 Hz (7 cycles per wavelet), and the present analysis focused on three frequency bands: theta (4-7 Hz), alpha (8-12 Hz), and low beta (13-20 Hz). In the young adults, power increases in theta were associated with successful subsequent memory performance in the short encoding condition only, whereas theta was not modulated by subsequent memory in older adults or in the long encoding condition in young adults. Additionally, power in the low beta frequency range differed according to the accuracy of a subsequent source memory judgment undertaken on the words. This effect occurred quite early in the pre-stimulus epoch and was age-invariant. These results largely mirror those from the ERP

analyses, and suggest that young and older adults differ, at least in some respects, in how they engage preparatory processes to benefit memory encoding.

**Title:** Can spontaneous EEG activity predict spatial working memory performance during normal aging in humans?

**Authors: *G. KLENCKLEN**, A. JABÈS, P. BANTA LAVENEX, P. LAVENEX
Inst. of Psychology, Lausanne, Switzerland

**Abstract:** Normal aging is associated with numerous cognitive changes, including an overall decline in working memory performance. Whereas some neuropsychological evaluations have suggested that visuo-spatial working memory may exhibit a greater age-related decline than verbal working memory, we have previously shown that age-related declines in working memory performance may be most influenced by the representational demands of the task and its dependence on hippocampal function, and not by the type of information to be remembered. Here, we aimed to determine whether spontaneous brain activity may correlate with, and thus be used to predict, working memory performance during normal aging. We first recorded eyes-closed spontaneous electroencephalographic (EEG) activity in young (20-30 years) and older (65-75 years) healthy adults. We then tested the same subjects in a real-world laboratory memory task to assess their allocentric spatial working memory performance. We found that about 50% of older individuals performed as well as young adults, whereas 50% of older individuals exhibited decreased spatial working memory performance. Preliminary analyses of spontaneous EEG activity revealed some age-related changes consistent with previous findings reported in the literature, in particular a decrease in alpha averaged peak frequencies with age. In addition, spontaneous alpha averaged peak frequencies correlated with spatial working memory performance across age groups. We will present the results of more detailed analyses, including microstates analyses, and discuss whether specific patterns of spontaneous EEG activity may serve as a biomarker associated with memory performance during normal aging.

**Title:** Age-related changes in resolving proactive interference in associative memory

**Authors: *B. CORBETT**[1], S. M. POLYN[2], A. DUARTE[1]
[1]Psychology, Georgia Tech., Atlanta, GA; [2]Dept Psychol, Vanderbilt Univ., Nashville, TN

**Abstract:** Proactive interference can impair our memory in daily tasks such as retrieving a recently updated email password or the updated dosage of a medication. Existing evidence is mixed with regard to whether older adults are less able to overcome proactive interference in associative memory than younger adults. In the current study, we investigated the effect of varying levels of proactive interference on the degree of episodic precision during associative memory retrieval in young and older adults. In an fMRI paradigm, participants were asked to remember which associate (face or scene) objects were paired with most recently under conditions of high, low or no interference. Following scanning, we tested participants' memory for varying levels of episodic detail about the pairings (i.e. face category vs. gender vs. specific face). Behavioral results show that as proactive interference increased, associative memory performance worsened similarly across groups. Importantly, proactive interference disproportionately impaired older adults' memory for specific, but not general, details about pairs. Imaging results demonstrate that separate PFC processes along the caudal-rostral axis support interference resolution during associative memory retrieval. These results shed light on the conditions under which older adults' associative memory performance will be most impaired and the cognitive control operations that are needed to overcome them.

**Title:** Differences in prefrontal and hippocampal functional connectivity related to spatial memory performance across the adult lifespan

**Authors: *E. ANKUDOWICH**[1,3], S. PASVANIS[3], M. N. RAJAH[2,3]
[1]Integrated Program in Neurosci., [2]Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Brain Imaging Ctr., Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

**Abstract:** Reductions in memory for the contextual details of items or events (i.e., context memory) have been found to occur across the adult lifespan from midlife into older adulthood. These context memory deficits are thought to be due, in part, to age-related differences in lateral prefrontal (PFC) and medial temporal (MTL) cortical function. However, there is growing consensus that cognitive abilities such as context memory are mediated by interactive, dynamic functional connections between specialized brain regions. It is therefore possible that age-related differences in the functional connectivity of PFC and MTL regions impact successful context memory and contribute to declines in performance observed with advancing age. The current study aimed to investigate differences in patterns of lateral prefrontal and hippocampal connectivity related to context memory accuracy across the adult lifespan. Using functional magnetic resonance imaging (fMRI), we tested young (20-35; n=44), middle-aged (40-58; n=38), and older (60-76; n=44) adults on memory for the spatial details of photographs of faces. Participants completed both easy (6 faces encoded) and difficult (12 faces encoded) versions of the task. Behaviorally, a Difficulty (easy, hard) x Group (young, middle-aged, older) ANOVA yielded a significant Difficulty x Group interaction on retrieval accuracy ($p<.05$). Although young adults outperformed older adults on both the easy and hard levels of task difficulty, they only outperformed middle-aged adults on the harder task. In addition, middle-aged adults performed no differently from older adults on either level of task difficulty. To assess PFC and MTL connectivity, we used multivariate seed-based partial least squares (seed PLS) to analyze the fMRI data. Extracted activation from a voxel in right dorsolateral PFC and from a voxel in left hippocampus was entered, along with retrieval accuracy, into the PLS analysis to identify whole-brain patterns of correlated fMRI activity in young, middle-aged, and older groups. We found that dorsolateral PFC and hippocampal correlations differentially associated with spatial memory accuracy in young adults relative to middle-aged and older adults. We also found that this pattern interacted with task difficulty. Our results suggest that differences in prefrontal and hippocampal functional connections that contribute to context memory performance may be evident by midlife.

**Title:** Aging effects on object and scene mnemonic discrimination in a large-scale adult lifespan approach

**Authors: *J. GÜSTEN**, D. BERRON, E. DUZEL
Inst. Cognitive Neurol. and Dementia Res., Magdeburg, Germany

**Abstract:** There are distinct neural pathways subserving memory-guided behavior, such as mnemonic discrimination, with item/object memory depending more strongly on perirhinal cortex (PRC) and lateral entorhinal cortex (LEC), while scene/context memory mainly involves a network of parahippocampal cortex (PHC), medial entorhinal cortex (MEC) and retrosplenial cortex (RSC)(Ranganath&Ritchey, 2012). Aging affects these domain-specific pathways in a differential fashion but it remains unclear whether that results in differential and domain-specific memory impairments across the adult lifespan. In this study, we investigate ageing effects on object vs. scene mnemonic discrimination across the entire adult lifespan. 2000 adult participants (age range 18-79 years) performed a computerized object-scene mnemonic discrimination task (Berron et al., in preparation). Participants were recruited online via the crowdsourcing platform Amazon Mechanical Turk (AMT), which has shown to be a promising and increasingly used tool for behavioral psychological research (Crump et al., 2013). Each participant was tested for 25 minutes on a subset of 1194 stimulus pairs, consisting of 610 object pairs and 584 scene pairs. Object and scene pairs were presented in a 2-back task design. Participants had to indicate whether a stimulus was repeated identically (repeat) or presented in a similar version (lure) via button presses. We found evidence that ageing affects memory for objects and scenes differentially across the adult lifespan and that object and scene performance become more independent from each other with age. These results are important for future research to better understand how these distinct memory processes are affected in ageing and disease, and to apply behavioral paradigms as non-invasive tools to detect early changes in cognitive functioning.

**Title:** Age-related deficits in the mnemonic similarity task for objects and scenes

**Authors: *S. M. STARK**[1], C. E. STARK[2]
[1]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [2]Univ. of California Irvine, Irvine, CA

**Abstract:** Using the Mnemonic Similarity Task (MST), we have demonstrated an age-related impairment in lure discrimination, or the ability to recognize an item as distinct from one that was similar, but not identical to one viewed earlier. A growing body of evidence links these behavioral changes to age-related alterations in the hippocampus. In this study, we sought to evaluate a novel version of this task, utilizing scenes that might emphasize the role of the hippocampus in contextual and spatial processing. In addition, we evaluated differential contributions to these tasks by relating performance on objects versus scenes to volumes of the hippocampus and surrounding medial temporal lobe structure. We collected behavioral data on the objects and scenes task in a group of 26 younger (ages 21-38 years old) and 28 older (59-84 years old) adults, in addition to structural MRI scans. We found that while there was an age-related impairment in lure discrimination for both objects and scenes, relationships to brain volumes and other measure of memory performance were stronger when using objects. In particular, lure discrimination performance for objects showed a positive relationship with the volume of the hippocampus, specifically the combined dentate gyrus and CA3 subfields and the subiculum. Further, we found that four measures of memory performance (MST-Objects LDI, MST-Scenes LDI, RAVLT delay, and Rey-O delay) were strongly related and dependent on the hippocampus and surrounding MTL cortices, relationships that were maintained even when age was regressed out of the relationships. In conclusion, we found little evidence to support a benefit to using scenes over objects in the MST. While both tasks resulted in an age-related decline in lure discrimination performance, relationships with hippocampal and MTL volumes were much stronger for MST-Objects. Likewise, Objects LDI showed a stronger relationship with standardized measures of memory (RAVLT and Rey-O delayed recall). Our data also suggests that the Rey-O may be a stronger measure of memory and possibly less prone to non-memory strategy that would alter performance, though that is partly speculation on our part. In conclusion, these findings emphasize the utility of MST-Object lure discrimination in revealing age-related memory changes and the relationship to hippocampal circuit alterations.

**Title:** Establishing a new skill learning model, "pot-jumping" in rats

**Authors: *A. J. ERNYEI**[1,2], T. GROHMANN PEREIRA[1], K. KOZMA[1,2], F. KASSAI[1,2], I. GYERTYÁN[1,2]
[1]MTA-SE NAP B Cognitive Translational Behavioural Pharmacol. Group, Semmelweis University, Dept. of Pharmacol., Budapest, Hungary; [2]Inst. of Cognitive Neurosci. and Psychology, Res. Ctr. for Natural Sci. - MTA, Budapest, Hungary

**Abstract:** Impairment of procedural memory is a frequent and severe symptom in many neurological and psychiatric diseases as well as during aging. Our aim was to establish an assay in rats in which procedural learning and changes in performance can be studied on long-term. The work was done in the frame of a larger project aiming to establish a complex cognitive animal test battery of high translational value.
Subjects of the study were 36-36 male 5 months old Lister-Hooded (LH) and Long-Evans (LE) rats kept on reversed light-dark cycle and restricted food-access. Parallel to the pot-jumping training the animals participated in various other cognitive tasks. The equipment was a 190 cm diameter circular open arena with 60 cm high walls where 12 flower pots (16 cm high, 10 and 17.5 cm wide at base and top, respectively) were placed upside down in a circle form with increasing distances (18-46 cm) between them. The arena was filled 6 cm deep with cold water to make the rats refrain from descending from the pots. An animal was put onto the start pot (the one within the shortest distance to the next) and allowed to move on the pots for 3 min. Training sessions were held at least once a month. Movement of the animals were video-recorded.
Motor skill development was characterized by the longest distance successfully spanned by the rats across all the trials. They were able to step over from one pot to the other until 26 cm distance, but had to jump beyond 26 cm. The distribution of the “personal best” values of LE animals showed a more or less Gaussian curve between distances of 24 and 40 cm with a mode of 34 cm (11 rats). In contrast, the distribution of LH rats was uniform spreading from 24 to 46 cm. There were 4 LE and 8 LH animals which did not move longer than 26 cm. The “record” of LE rats was 40 cm jumped by 4 animals, while 7 LH rats could reach the 44 cm range, and the recorder jumped even 46 cm. A relatively flat bell-shaped age-dependence was observed; the

mean longest distance peaked around the age of one year both in LE and LH rats (32.8 and 37.0 cm, respectively).
Animals were obviously motivated to move around on the pots, however, the distance which required jumping meant a barrier for some of them. The LH group involved more courageous as well as more anxious rats than the LE cohort. A slow decline in performance could be observed after the age of 2 years which might be connected to decreased motivation and/or motor coordination ability.
The study was funded by the Hungarian National Brain Research Program (NAP), contract# KTIA_NAP_13-2014-0015.

**Title:** White matter tracts mediate age-related cognitive inhibition decline in Stroop interference

**Authors: *P. LI**, Y. GAZES
Col. of Physician and Surgeon, Neurol., Columbia Univ. Med. Ctr., New York, NY

**Abstract:** One potential source of the age-related decline in cognitive inhibition is the integrity of the underlying white matter. Previous DTI studies have found associations between white matter integrity and performance on the Stroop test. The current study aimed to add to these studies of cognitive inhibition by investigating how the differences in age and in white matter integrity relate to Stroop performance, and to examine whether the effect of age on Stroop performance is mediated by white matter integrity. Method:179 healthy adults from 20-80 years old were recruited in the study. DTI data were processed through TRACULA and the mean fractional anisotropy (FA) of 18 major white matter tracts were extracted and used for statistical analysis. Correlation analysis was performed to examine the relationship between age and the Stroop interference score (IG). Simple linear regressions were performed between the mean FA and age to investigate if age is a predictor of FA, and between FA and IG to examine if FA is a predictor of IG. For significant results exceeding the multiple comparison correction, a moderation analysis was performed to examine if there is an interaction effect of age and FA on IG. Finally, for those that we did not find a moderation effect, we investigated if FA mediated the effect of age on IG. Results: Correlation analysis showed a strong negative relationship

between age and IG. Higher IG indicated better cognitive inhibition. Simple linear regression analyses indicated that most of the tracts showed negative relationships with age, and positive relationships with IG. Moderation effect of age on the relationship between FA and IG was tested on tracts that significantly predicted IG after multiple comparison corrections, but none of these moderations were significant. Then we tested if these tracts mediated the effect of age on IG and found significant indirect effects of age on IG through the FA of the left corticospinal tract and through the right inferior longitudinal fasciculus. In both mediation results, age was negatively associated with FA, consistent with the decline in white mater integrity in older age, and the FA was positively associated with IG,demonstrating better inhibitory performance with more intact white matter integrity.Conclusions: Our results highlight the role of a number of major white matter tracts in the processes supporting the Stroop inhibitory performance and further pinpointed the lower white matter integrity of the inferior longitudinal fasciculus and the corticospinal tract as contributors to the decrease in inhibitory ability associated with the Stroop test in older age.

**Title:** Age and education have fundamentally different multimodal neural substrates than verbal intelligence across the life span

**Authors: *C. G. HABECK**[1], Q. R. RAZLIGHI[2], Y. GAZES[1], Y. STERN[3]
[1]Taub Inst., [2]Neurol., Columbia Univ., New York, NY; [3]Cognitive Neurosience Division, Columbia Univ., New York, NY

**Abstract:** We conducted a multimodal investigation to what extent the formative factors education and biological age influence people’s structural and functional brains, and lead to different neural correlates from the reflective factor verbal intelligence, operationalized as NARTIQ. We analyzed a cross-sectional multi-modal data set which consisted of (1) structural data (=cortical thickness in 68 ROIs) and (2) resting-state functional-connectivity data (=264 x 264 temporal correlation matrices) for 451 participants, and (3) fMRI-activation data from 12 cognitive tasks for 255 participants. To assess the influence of age, education and verbal

intelligence, we picked all possible pairs of participants who differed in all three factors by less than the pre-specified upper bounds ΔEducation, ΔAge and ΔNARTIQ. The stringency of the matching requirement was varied systematically to verify that the results of the performed analyses behaved in a consistent manner. We computed pair-wise similarities for all neuroimaging data modalities, i.e. for any participant-pair conforming to the matching requirements we computed the topographic correlation between the neural data from both participants in the pair. For cortical thickness, this entailed a correlation across all 68 ROIs between both participants' thickness data. For resting-state connectivity, it entailed a correlation between all off-diagonal elements of the 264 x 264 connectivity matrices of both participants. Lastly, for functional activation, it entailed the correlation across all voxels between both participants' functional-activation maps. The correlations were Fisher-Z transformed and then served as dependent variables in a linear regression, where the average values of age, education and NARTIQ of the corresponding participant pairs were used as simultaneous independent variables. Despite variations in statistical significance, a consistent finding emerged for all modalities: similarity of thickness, resting connectivity and functional activation between two participants was associated *negatively* with age and education, but *positively* with NARTIQ. Age and education, when carefully matched, might induce changes in participants' brains that become greater with the level of age or education. NARTIQ, on the other hand, seems to capture latent and innate neural factors that cause participants' brains to be more similar with higher levels. These findings point to fundamental differences in the neural substrates of formative and reflective subject variables, and caution against combining such variables into composites for the purpose of mapping unidimensional neural substrates.

**Title:** Application of awFC, a technique combining functional and structural connectivity, in the context of aging and a reasoning task performance

**Authors: *Y. GAZES**[1], D. F. DRAKE[2], F. D. BOWMAN[2]
[1]Taub Inst., [2]Columbia Univ., New York, NY

**Abstract:** Both functional and structural connectivity in brain networks are predictive of cognitive decline in aging, but more robust networks can be identified if structural connectivity

information is incorporated into the network analysis. Our study used the Anatomically Weighted Functional Connectivity analysis (awFC) (Bowman, 2012) to identify brain networks involved in performing a reasoning task called the Letter Set task, a reasoning task, in a group of 78 older adults (mean age=69.2±5.54 years old). Functional Magnetic Resonance Imaging (fMRI) data were collected during the performance of the Letter Set task and was analyzed in FSL to get the set of regions associated with task performance. Tractography was performed on Diffusion Tensor Imaging (DTI) data also using FSL for 90 regions of interest from the AAL templates, from which structural connectivity was calculated and used as weights for evaluating functional connectivity among the ROIs. Results: Mean task accuracy was .689±.224 and the median RT was 15.9±6.7 s. All age effects were negative such that older age was associated with lower connectivity strength and the strongest Age effect was observed in the connections between the right calcarine and the right inferior temporal gyrus ($z = -3.1$, $p=.0017$). For task accuracy, both positive and negative relationships were observed, suggesting that stronger connection between some regions pairs are beneficial for task performance while others are detrimental to task performance. The strongest positive relationship was observed between the right inferior parietal lobule and the left angular gyrus ($z=3.05$, $p=.002$), whereas the strongest negative relationship was observed between the right postcentral gyrus and the left paracentral lobule ($z=-3.3$, $p=.0009$). A positive Age by Task accuracy interaction was also found such that the older and higher performance subjects showed stronger connections between region pairs. The region pair with the stronger interaction effect was between the left middle occipital gyrus and the left inferior temporal lobule ($z = 3.2$, $p = .0015$). The results are consistent with the theory that cognitive decline in aging is associated with disconnected brain regions. Furthermore, high performers among older adults showed stronger connections among region pairs.

**Abstract:** Diffusion tensor imaging (DTI), a non-invasive method for characterizing microstructural white matter, has been used to evaluate white matter differences in aging. Previous studies have primarily applied univariate approaches for evaluating relations between age and DTI metrics of white matter integrity, with prominent results showing associations between advancing age and decreases in fractional anisotropy (FA) and increases in mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD). We applied a multivariate method, the Scaled Subprofile Model (SSM; Alexander & Moeller, 1994), to identify separate white matter regional network patterns for each diffusivity measure that optimally predicted age in a sample of 196 neurologically healthy community-dwelling older adults, ages 50-89. Additionally, we assessed the contributions of common vascular risk factors, including white matter hyperintensities (WMH), hypertension, and homocysteine, to each covariance pattern. We used TRACULA for automated probabilistic tractography to reconstruct 18 major white matter pathways and to generate estimates of FA, MD, RD, and AD. We used a multivariate model of regional network covariance, SSM, to identify regional patterns of white matter integrity associated with aging. We found distinct age-related regional patterns of white matter tracts for each diffusivity metric ($5.3E\text{-}9 \leq p \leq 0.001$). Additionally, there were no interactive effects of vascular risk factors and age on the covariance patterns. Only WMH volume showed an additive effect on the white matter integrity network patterns for FA, MD, and AD ($0.019 \leq p \leq 0.029$), whereas hypertension and homocysteine did not show contributory effects. Together, these findings suggest that in the context of healthy aging, damage to white matter microstructural tracts may differentially predict advancing age through region-specific effects and may be further influenced by macrostructural white matter lesion load.

**Abstract:** Healthy aging preferentially affects selected gray matter (GM) and white matter (WM) brain regions and has been widely studied using univariate analysis methods. Multivariate network analysis of multimodal magnetic resonance imaging (MRI) data may potentially improve regional characterization of age-related differences by combining information from complementary imaging modalities. Here we use this framework to investigate how differences in global WM microstructural integrity relate to regional network covariance of subcortical grey matter (SGM) volumes, including the hippocampus, amygdala, thalamus, pallidum, putamen, caudate and nucleus accumbens, and further assess how this pattern is related to age and regional white matter hyperintensity (WMH) load. T1-weighted volumetric, diffusion weighted imaging (DWI), and T2 FLAIR 3T MRI scans were obtained in 196 healthy community dwelling older adults, 50 - 89 years of age (mean±sd age = 69.8 ± 10.6; 95F/101M). Freesurfer v5.3 was used for segmenting T1 scans and extracting SGM volumes. DWI scans were processed with TRACULA and global fractional anisotropy (FA) and mean diffusivity (MD) were computed as the average of 18 major WM tracts. WMH maps were produced by automated multispectral

segmentation using SPM12's Lesion Segmentation Toolbox. A lobar atlas template was used to obtain regional WMH volumes from the four major lobes. The Scaled Subprofile Model was applied to the SGM volumes to derive their regional covariance networks in relation to global mean FA and MD. The FA-related SGM network pattern accounted for 9.8% of the variance in FA, included relative reductions in bilateral thalamus with preservation of the right caudate, but was not related to age ($p = 0.73$). The MD-related SGM network pattern accounted for 18.6% of the variance in MD, exhibited volume reductions bilaterally in hippocampus and putamen with relative preservation of left caudate and right pallidum, and was positively related to age ($r^2 = 0.29$, $p = 1.1E-16$). After adjusting for age, gender, years of education and hypertension status, the FA-SGM pattern was not related to regional WMH (FDR $p > 0.14$), while the MD-SGM pattern was positively related to WMH load in the frontal ($r^2 = 0.078$, FDR $p = 9.0E-6$), temporal ($r^2 = 0.06$, FDR $p = 7.5E-5$) and parietal ($r^2 = 0.045$, FDR $p = 4.9E-4$) lobes. Together, these findings demonstrate the regionally varying impacts of differential aspects of WM integrity on subcortical GM in the context of healthy aging, providing further support for using multimodal, multivariate network analyses to more fully characterize the regionally distributed effects of brain aging.

**Abstract:** It is well established that healthy aging is associated with regional brain atrophy, which may be exacerbated by an increased risk for Alzheimer's disease (AD) with the apolipoprotein E (APOE) ε4 allele. We have previously reported regionally distributed network patterns of gray matter volume throughout the brain associated with healthy aging and APOE risk for AD (Alexander et al., 2006, 2012; Bergfield et al., 2010) using magnetic resonance imaging (MRI) and a multivariate model of regional covariance, the Scaled Subprofile Model (SSM; Alexander and Moeller, 1994). In this study, we sought to evaluate the effect of aging on the SSM network pattern of hippocampal subfield volumes in a cohort of healthy, community-dwelling middle-aged to older adults, who were screened to exclude common medical conditions of aging, including hypertension and diabetes. T1-weighted 3T volumetric MRIs were obtained in 81 healthy adults (45F/36M, mean±sd age = 66.2±10.1, mean±sd Mini-Mental State Exam = 29.2±0.9, APOE ε4 status = 22 carriers/59 non-carriers), 50 to 89 years of age. Image processing was performed using Freesurfer (v6.0) software to obtain bilateral hippocampal sub-region volumes of CA1, CA3, CA4, dentate gyrus granule cells (DG-GC), molecular layer, subiculum, presubiculum, and hippocampal tail. Total intracranial volume (TIV) was computed for each participant's native scan using SPM12. Regional network analysis was performed with SSM bootstrap re-sampling and 10,000 iterations on the TIV-adjusted hippocampal subfield volumes using the Akaike information criterion. A linear combination of the first eight SSM components was associated with increasing age in the sample ($R^2 = 0.27$, $p \leq 2.49E\text{-}3$). This regional pattern was characterized by volume reductions in bilateral DG-GC and molecular layer sub-regions with relative increases in bilateral CA3. Univariate regional analyses showed that each of the bilateral DG-GC and molecular layer sub-regions were inversely correlated with age ($p's \leq 2.86E\text{-}5$), whereas CA3 regions did not reach significance ($p's \geq 0.07$). After we controlled for age and gender, expression of the SSM pattern was greater in the APOE ε4 carriers than non-carriers ($p \leq 0.004$). The results indicate a regionally specific pattern of hippocampal subfield volumes with reductions in the vicinity of the dentate gyrus and relative preservation in the region of CA3 that is associated with healthy aging, and is further expressed to a greater extent in APOE ε4 carriers. Together, these findings support selective regional vulnerability of the dentate gyrus in the context of healthy aging and in relation to genetic risk for late onset AD.

**Title:** Relation of physical sport activity to regional white matter integrity in older adults

**Authors: *M. FRANCHETTI**[1,8,9], P. K. BHARADWAJ[1,8,9], L. A. NGUYEN[1,8,9], Y. C. KLIMENTIDIS[2], K. A. HAWS[1,8,9], M. C. FITZHUGH[1,8,9], G. A. HISHAW[3], T. P. TROUARD[4], D. A. RAICHLEN[5], G. E. ALEXANDER[1,6,7,8,9]
[1]Dept. of Psychology, [2]Epidemiology and Biostatistics, [3]Dept. of Neurol., [4]Biomed. Engin., [5]Sch. of Anthrop., [6]Neurosci. & Physiological Sci. Grad. Interdisciplinary Program, [7]Psychiatry, Univ. of Arizona, Tucson, AZ; [8]Evelyn F. McKnight Brain Inst., Tucson, AZ; [9]Arizona Alzheimer's Consortium, Phoenix, AZ

**Abstract:** Physical activity (PA) may have an important role in maintaining cerebral white matter (WM) integrity in healthy aging. We sought to determine whether high levels of self-reported physical sport activity are associated with better WM integrity. Self-report ratings of physical sport activity were obtained from 210 healthy older adults (M ± SD age = 70.0 ± 10.4 yrs). Participants reporting high sport activity (n=38) were compared to those with low sport activity (n=172). T1 and diffusion weighted 3T MRIs were processed using Freesurfer v5.3 and TRACULA for tractography to compute fractional anisotropy (FA) and mean (MD), radial (RD), and axial (AD) diffusivity for 18 WM tracts. ANCOVA tested age group (young-old group (YO) = 50-69 yrs; old-old group (OO) = 70-89 yrs), PA group, and interaction effects after controlling for hypertension status. No main effects for PA group ($p$'s > 0.05) were observed across all four diffusion metrics. For FA, results revealed main effects for age group for three WM tracts ($0.003 \leq p \leq 0.006$) such that, for two tracts, the OO had lower values. All age group effects for MD, RD, and AD revealed that the OO had higher diffusion than the YO. For MD, we found age effects for all but one bilateral WM tract ($2.0E\text{-}5 \leq p \leq 0.039$). For RD, we found age effects for all but one bilateral and two individual WM tracts ($0.002 \leq p \leq 0.048$). For AD, effects for all but two bilateral and two individual WM tracts ($4.0E\text{-}7 \leq p \leq 0.047$) were observed. We found age

by PA interactions for two tracts for FA, left inf. longitudinal fasciculus (ILF; $p = 0.045$) and right uncinate (UNC; $p = 0.025$). Interactions were observed for the same three tracts, ant. thalamic radiation (ATR), sup. longitudinal fasciculus-parietal (SLFP), and temporal (SLFT) bundles, bilaterally for MD ($0.016 \leq p \leq 0.04$) and in left tracts of AD ($0.007 \leq p \leq 0.037$). An interaction was observed for left ILF for MD ($p = 0.011$) and right cingulum cingulate gyrus (CCG) for AD ($p = 0.035$). For RD, interactions were observed for bilateral SLFT, left ILF, right ATR, SLFP, and UNC ($0.007 \leq p$'s $\leq 0.043$). Simple effect analyses showed that within the OO, those with lower PA had lower FA for the ILF tract ($p = 0.011$). For the UNC tract, among those with low PA, the OO had lower FA ($p = 0.012$). Effects for MD, RD, and AD showed that among those with low PA, the OO had higher diffusion ($p \leq 0.002$). In the OO, those with low PA had higher diffusion in all but one tract for MD and RD and two tracts for AD ($0.002 \leq p$'s $\leq 0.043$). After adding gender as an additional covariate for main and interaction effects, the regional findings were consistent. These findings suggest that high levels of PA may be an important lifestyle factor that can help to maintain WM integrity in old age.

**Title:** The role of anxiety on the cognitive control of gait in older adults

**Authors: *M. E. HERNANDEZ**, M. E. KERSH, G. CHAPARRO
Kinesiology and Community Hlth., UIUC, Urbana, IL

**Abstract:** Falls are a prevalent and significant problem in older adults. Fear of falling in older adults has been associated with an increased fall risk and decreased quality of life and active participation. Based on the attentional control theory, anxiety is posited to impair processing efficiency to a greater extent than performance on tasks that involve the central executive. Given the importance of attention on the cognitive control of gait in older adults, we hypothesize that increasing anxiety due to walking on a virtual beam, will result in a decreased efficiency of activation of the prefrontal cortex (PFC) in older adults. Using a combination of functional near-infrared spectroscopy (fNIRS) with virtual reality, we examine changes in PFC activity while walking in healthy young (HYA, n=10) and older adults (HOA, n=12). Participants were asked to walk at a comfortable pace on an instrumented treadmill. While walking, simultaneous fNIRS and force plate data from the instrumented treadmill was collected. Using a self-paced gait,

participants were presented with either no visual stimuli (NW = normal walking) or with a narrow virtual reality beam (BW = virtual beam walking), so as to elevate anxiety. In all conditions, participants walked for 75 seconds, with 30 seconds to warm-up, 30 seconds for steady state walking, and 15 seconds to cool-down. Prior to each task, a 10 second baseline was collected for data analysis. Measures collected included spatiotemporal gait parameters (i.e., stride length and stride time) and PFC activation levels, evaluated by oxygenated hemoglobin (HbO2) levels. The effect of group (HYA vs. HOA) and task (NW vs. BW) on outcome measures was evaluated using linear mixed models, with intercepts for individuals modeled as a random effect. Significance was set at $p = .05$, using R 3.1.1. Overall, a significant interaction between age and task ($p < .05$) was observed on stride length and stride time. In addition, the task resulted in significant changes in stride length and stride time ($p < .05$). In older adults, a significant increase in PFC oxygenation levels was observed in BW relative to NW ($p < .05$). The increases in HbO2 levels observed from NW to BW suggest that increased attention is necessary for walking on a virtual beam relative to normal walking, consistent with the attentional control theory. Future studies should examine a larger sample of individuals with and without fall-related anxiety and explore the relationship between anxiety, attention, and cognitive control of gait in older adults.

**Title:** Default to executive coupling is associated with divergent thinking in older adulthood

**Authors: *A. ADNAN**[1], R. BEATY[3], P. SILVIA[4], N. SPRENG[5], G. R. TURNER[2]
[1]York Univ., North York, ON, Canada; [2]York Univ., Toronto, ON, Canada; [3]Dept. of Psychology, Harvard Univ., Cambridge, MA; [4]Dept. of Psychology, Univ. of North Carolina at Greensboro, Greensboro, NC; [5]Montreal Neurolog. Inst., Montreal, QC, Canada

**Abstract: Introduction:** The default – executive coupling hypothesis of aging (DECHA) posits that increased functional coupling between the default network (DN) and executive control regions occurs in response to increased cognitive control demands in older adulthood (Turner and Spreng, 2015). A similar pattern of network coupling has been associated with divergent

thinking (DT) and creativity in young adults, possibly reflecting flexible engagement of control and associative processes (Beaty et al., 2015). Divergent thinking and creative ability remains constant across the adult lifespan (e.g. Addis et al., 2016; Palmiero et al., 2014; Roscos-Ewoldson et al., 2008). This suggests that default – executive coupling may support divergent thinking in the context of declining cognitive control capacity in later life. However, this has not been directly investigated.
**Methods:** Young (N=30) and Old (N=25) adults completed a divergent thinking (alternate uses) task while undergoing fMRI scanning. Functional connectivity analyses were conducted using the Conn Toolbox. DMN and executive control regions were defined a priori from a functional cortical parcellation scheme (Gordon et al., 2014). Age-related differences in functional connectivity within the DN, and between default and executive control regions, were contrasted across the Control and DT conditions. **Results:** Age-related increases in functional connectivity within the DN were observed during the DT but not the Control condition. Specifically, increased functional connectivity was observed between left posterior superior temporal gyrus and right medial PFC, right medial superior frontal gyrus and the posterior cingulate cortex and anterior medial PFC. Consistent with the DECHA, age-related increases in functional connectivity during DT was observed between left dorsolateral PFC and the DN (left posterior cingulate cortex, anterior medial PFC and angular gyrus).
**Conclusions:** Our results provide early evidence for age-related increases in connectivity within the DN and between default and executive control regions during creative thought, consistent with DECHA. While speculative, this may reflect greater reliance on associative processing (mediated by DN regions) in the context of declining cognitive control in older age. DECHA has been associated with age-related decline in fluid reasoning ability (e.g. Rieck et al., 2017). However, in the domain of creative thought, where past knowledge and experience may provide access to a larger solution space, such brain changes may be adaptive. These data identify DECHA as putative neural mechanism supporting creative thinking across the adult lifespan.

**Abstract:** Introduction: Daytime Sleepiness (DS) may be considered a symptom or risk factor associated with sleep disorders and physical or mental illness, and is frequently evaluated using the Epworth Sleepiness Scale (ESS). In older adults, changes are observed in the circadian cycle of sleep and wakefulness, including phase advance and decrease in total sleep time. Objective: The objective of this study was to determine the presence of DS in a sample of older adults and its association with demographic and health variables, substance use, and daytime and nocturnal symptoms. Method: Observational, retrospective chart review of patients 60 years and older during 2009-2013 at the Sleep Disorder Clinic of the Faculty of Medicine, National Autonomous University of Mexico. The measures of association used were chi-squared and odds ratios. A multivariate logistic regression was also performed. Results: 53.4% of the population showed DS, and 83% Obstructive Sleep Apnea Syndrome (OSAS). Using odds ratios, a positive association was found between DS and OSAS, nighttime breathing problems, snoring interrupted by silence, use of alcohol to sleep, perceived sleep latency <30 minutes, and napping. A negative association was found between DS and the use of drugs to fall asleep and wake up earlier. The multivariate logistic regression showed a positive association with naps, self-reported somnolence, and OSAS diagnosis. Conclusion: The ESS is a valuable tool for the preliminary diagnosis of OSAS in older adults. Together with other measures, such as body mass index (BMI) and interrupted snoring, it can aid in the timely referral of such patients to confirmatory polysomnography.

**Title:** Modified stroop task-set switching test: Brief screening for executive functioning across the life span

**Authors: M. BELGHALI**[1], C. CHESNEAU[2], D. DAVENNE[1], *L. M. DECKER[3]
[1]UMR-S 1075 Inserm/Université de Caen Normandie, Caen Cedex 5, France; [2]LMNO, Univ. de

Caen, Campus 2, Caen, France; [3]UMR-S 1075 Inserm/Université De Caen Normandie, Caen Cedex 5, France

**Abstract: Background**. The relationship between executive functioning (EF; high-level processes involved in monitoring and controlling goal-directed behavior) and age has shown contradictory findings. Some studies have reported an age-related change in certain EF across the life span whereas others did not. This may result from the lack of neuropsychological tests of EF that are applicable across all life stages. This study sought to address this issue by developing a new neuropsychological test (i.e., Modified Stroop Task-Set Switching; MSTSS) designed to assess four components of EF, namely flexibility, inhibition, working memory updating, and planning. **Objective**: This study aimed at examining the utility of MSTSS in the assessment of EF from childhood to old age, in order to identify the most sensitive measures of early EF decline. **Methods:** A sample of 129 participants ranging in age from 9 to 75 years completed: i) standardized neuropsychological tests (SNT) evaluating flexibility (Trail Making Test), inhibition (Stroop Test), working memory updating (Forward and Backward Digit Span), and planning (Rey Complex Figure), and ii) MSTSS. Principal component analysis and multiple regression analysis were used to demonstrate the utility of MSTSS (i.e., response time and the number of errors in flexibility, inhibition, working memory updating, and planning, respectively) for early detection of age-related EF decline. **Results and discussion:** A U-shaped relationship was found between age and EF, as assessed by both SNT and MSTSS, with larger costs in response time (i.e., time of completion in each test) for children (mean±SD: 10±1 years), middle-aged (50±5 years) and older (66±4 years) adults. Most interestingly, principal component analysis revealed that the response time and the number of errors in MSTSS are more correlated with age than measures from SNT. Specifically, only the number of errors in inhibition (as assessed by MSTSS) was selectively increased in older adults, demonstrating that this measure is more sensitive to age-related change in EF as compared with measures from SNT. Moreover, multiple linear regression showed that measures from SNT could predict response time in MSTSS, suggesting that the latter could be used as a global measure of EF efficiency across the life span. **Conclusions**: The findings demonstrated that MSTSS, and more specifically the number of errors in inhibition, is more sensitive to aging than SNT.

**Title:** Structural integrity of the dorsal striatum correlates with learning rate in a valenced go/no-go task

**Authors: *V. PEROSA**[1,2], M. BETTS[1], M. GUITAT-MASIP[3], G. ZIEGLER[1], E. DUEZEL[1,4]
[1]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany; [2]Dept. of Neurology,, Otto-von-Guericke University,, Magdeburg, Germany; [3]Ageing Res. Ctr. Karolinska Inst., Stockholm, Sweden; [4]Inst. of Cognitive Neurol. and Dementia Res., Mageburg, Germany

**Abstract: Background:** Evidence exists showing an association between instrumental learning and the dorsal striatum. In this study we used voxel based morphometry (VBM) to investigate the role of the dorsal striatum in instrumental learning in the healthy ageing brain, using ultra-high resolution magnetic resonance imaging (MRI) at 7 Tesla. **Methods:** We performed a VBM-analysis on T1-weigthed MPRAGE images (0.8 mm iso) using CAT12 (Gaser and Dahnke, 2012) to investigate, whether changes in grey matter (GM) volume in the striatum influenced learning in the ageing brain. We tested 25 young adults (mean age = 24.1, 12 females and 13 males) and 30 community-dwelling elderly adults (mean age = 68.58, 19 females and 12 males). Participants completed a go/no-go behavioral task, which orthogonalizes action (performing an active response or withholding it) and valence outcome (reward or punishment) (Guitart-Masip et al., 2011). A task-specific computational reinforcement learning model was applied to our results and its parameters were implemented in the VBM analysis. **Results:** Behavioral data showed how participants had more difficulties to avoid losing by performing an action and obtaining reward by withholding it, as already descripted in previous studies (Chowdhury et al., 2013; Guitart-masip et al., 2012). Furthermore, performance and learning in older adults was overall poorer, especially in the no-go conditions. After calculating the modelling parameters, an age-related difference was observed in learning rate, reward and punishment sensitivity, which were then included in the VBM-analysis. In a group comparison, we found learning rate in older adults positively correlated with GM volume in bilateral caudate nucleus. An additional multiple regression analysis to assess individual variability in older adults also revealed a positive correlation with learning and bilateral caudate nucleus. **Discussion:** Our results suggest that age-related structural changes in the caudate nucleus can explain individual variability in learning rate in older adults. This conclusion is consistent with other studies, showing a contribution of the dorsomedial striatum to goal-directed behavior.

**Title:** Neural network properties as a function of age and apoE genotype

**Authors: *L. JAMES**[1], A. C. LEUTHOLD[2], A. P. GEORGOPOULOS[3]
[1]Brain Scienes Ctr., Univ. of Minnesota/Minneapolis VAHCS, Minneapolis, MN; [2]Dept Neurosci, VA Med. Ctr., Minneapolis, MN; [3]Neurosci, Univ. Minnesota, Minneapolis, MN

**Abstract:** Apolipoprotein E (apoE) is a plasma apolipoprotein implicated in various functions related to brain health and disease. In humans, apoE exists in three primary isoforms - E2, E3, and E4 - that differ in terms of structure and function and, consequently, promotion of risk or resilience for various insults and diseases. The E2 and E3 alleles are thought to confer relative superiority over E4 in terms of brain structure and function. In the present study, we evaluated brain function derived from resting state MEG in 165 cognitively healthy (MoCA $\geq$ 26) participants of age range 28-99 y old according to apoE genotype. We analyzed properties of the neural network, including the flexibility and variability of interactions between MEG sensor pairs. Results demonstrated that network flexibility increased from E4 to E2 genotype whereas network variability decreased from E4 to E2 genotype. Plotting network properties by decade and genotype revealed that both network properties were relatively stable up to the 7th decade of life. After that, the network properties differed substantially according to genotype with E2 carriers evidencing healthier network properties than E4 carriers. Results of this study highlight that the effects of apoE on network functions are manifested more clearly with increasing age, even among cognitively healthy individuals.

**Title:** Peripheral visual perception and motor performance in younger and older adults: A MoBI-study

**Authors: *J. PROTZAK**[1], K. GRAMANN[2]
[1]Dept. of Psychology and Ergonomics, Junior research group FANS, [2]Dept. of Psychology and Ergonomics, Biol. Psychology and Neuroergonomics, TU Berlin, Berlin, Germany

**Abstract:** Human experiences and activities are rarely restricted to a single task and therefore associated with several ongoing perceptual and cognitive processes. Especially in older adults effective resource allocations to these parallel processes are crucial as aging is often associated with interdependent compensation mechanisms of age-related cognitive and sensory declines. Everyday tasks like the maintenance of a stable and secure gait can require increased cognitive control leaving fewer resources for concurrent tasks such as scanning the traffic for peripheral approaching cars or the environment for obstacles. Although techniques to record neurophysiological data during realistic locomotion are nowadays possible using Mobile Brain-Body Imaging (MoBI) approaches, the interplay of visual perception and motor performance and the underlying brain dynamics are not yet understood in detail. Therefore, the present study aimed at investigating peripheral visual perception and motor task performance in a dual-task scenario in older and younger adults. Furthermore, the potential of vibro-tactile warning cues to improve the perception of peripheral stimuli in older participants will be evaluated.
A study set-up was realized that allowes for dynamic presentations of visual stimuli at different eccentricities dependent on participants current heading while standing or walking up and down a hallway of ten meter in length. In addition, a device that delivered short vibro-tactile warning cues to the upper arm prior to the visual stimulation was integrated for further assessments. The data recording protocol comprised synchronized recordings of behavioral data, gait and posture parameter and continuous EEG-data by a 64-channel mobile set-up. EEG-, behavioral as well as gait and posture data were yet collected from 15 younger (< 35 years) and 15 older (> 65 years) adults.
The present study results replicate previous findings of dual-task effects on performance measures (response time, errors, misses), as well as posture and gait parameter. Importantly, the EEG data reveal significant differences in stimulus-locked event-related potentials (ERP) between younger and older participants. The study demonstrates the feasibility of MoBI in understanding dual-task effects in young and older adults during naturalistic behavior. The results can be used to design assistance systems for older users in complex traffic situations.

**Title:** Socioemotional and neural correlates of off-task thinking in young and old adults

**Authors: *J. R. ANDREWS-HANNA**[1], C. K. GARDINER[2], M. T. BANICH[3], A. D. BRYAN[2]
[1]Dept. of Psychology, Univ. of Arizona, Tucson, AZ; [2]Psychology and Neurosci., [3]Psychology and Neuroscience; Inst. of Cognitive Sci., Univ. of Colorado Boulder, Boulder, CO

**Abstract:** Recent years have brought a growing appreciation that the human mind has a propensity to wander away from the task at hand. Adults spend upwards of half their waking day cognitively disengaged from the here-and-now, yet despite this high frequency, the correlates and consequences of off-task thought are poorly understood. Off-task thought may facilitate problem solving and contribute to one's sense of self-identity, but it can also fuel unhappiness and be associated with psychiatric disorders. Further, little is known about how on- and off-task thoughts change in aging. Despite the well-established cognitive "positivity effect" in old age, the elderly are highly vulnerable to depression and social isolation. These gaps call for a deeper understanding of influences on cognitive and socioemotional well-being across the lifespan. Toward this end, we explored the frequency, content, and correlates of on- and off-task thought in young (N = 42, ages 25-35, mean = 28.5) and older adults (N= 115, ages 60 - 88, mean = 70) across two contexts. First, we developed a trait questionnaire to estimate thought patterns in daily life. Second, we developed a retrospective self-report questionnaire to assess thought content during a 5 minute resting state paradigm while acquiring fMRI data to explore neural correlates of cognitive changes. Results reveal numerous differences between young and older adults, with broad consistency across the two contexts outlined above. Older adults reported less frequent internally-focused off-task thoughts (i.e., mind-wandering), but greater focus on the fixation crosshair and distraction by irrelevant external stimuli. They also displayed greater present-focused and reduced past-focused content, as well as biases toward positive and other-focused thoughts. Among older adults, better well-being was associated with fewer internally-focused off-task thoughts (especially negative thoughts), fewer external distractions, and more goal-oriented content and imagery. Importantly, resting state functional connectivity analyses revealed group differences in default and frontoparietal control networks, which have been implicated in off-task thought in young adults. Overall, these findings shed light on the content, mental health correlates, and neural underpinnings of off-task thinking in young and older adults.

**Abstract:** Extant theories of neurocognitive aging are largely based on age differences in blood-oxygen-level-dependent signal (BOLD) as measured with functional magnetic resonance imaging (fMRI). Straightforward interpretation of age-related changes in BOLD as an index of age-related changes in neural activity depends upon the assumption that BOLD increases monotonically with increasing task demand. We sought to test this assumption across age groups by disentangling two physiologic factors underlying BOLD: (1) Cerebral blood flow (CBF), known to change with age, quantifies oxygen delivery to neurons undergoing changes in (2) cerebral metabolic rate of oxygen ($CMRO_2$). Taken together, these two factors reflect the integrity of the neural-vascular coupling mechanism. Sixteen healthy younger (mean age = 23.6, SD = 3.4, 10 F) and eighteen healthy older (mean age = 58.9, SD = 4.6, 11 F) right-handed adults performed block-designed visual and motor tasks while undergoing calibrated fMRI scanning. Participants were screened for any potential cardiologic, respiratory, pulmonary, or vascular conditions. During the visual task, participants responded via bilateral button-press whenever a fixation cross at center-screen changed in luminance; during stimulation blocks, flickering checkerboards were presented at varying frequencies (2 Hz, 4 Hz, and 8 Hz). During the motor task, participants pressed buttons bilaterally in rhythm with an auditory cue (1 Hz, 2 Hz, and 3 Hz). To estimate maximum possible BOLD, participants completed a hypercapnia challenge, in which they breathed room air for 4 minutes and then a gas containing 5% CO2 21% O2, and 74% N2 for 6 minutes while being scanned at rest. During all functional scans, BOLD and CBF were collected in separate echoes using a novel pCASL-based sequence (parameters TE1/TE2=11/30 ms, TR = 4 s, 22 6-mm axial slices, no gap, in-plane=3.4×3.4 $mm^2$). In visual cortex, during visual stimulation, younger participants exhibited monotonic increases in both BOLD and CBF with increasing task demand. Older participants exhibited decreases in BOLD with increasing task demand. CBF for older participants plateaued at higher task demand. Similar results were observed in motor cortex during motor task performance. Non-equivalence of BOLD-signal monotonicity with task demand between age groups does not support the assumption that BOLD is proportional to local neural activity in older adults as it is in younger adults. Apparent BOLD decreases with increasing task demand, irrespective of cognitive demand, in older participants might be a result of inability to sustain neural-vascular coupling in the face of increasing task demand.

**Title:** Modulation of alpha oscillations in humans during allocation of internal resources in relation to sub-regions of the striatum: Effects of aging

**Authors:** ***S. AURTENETXE**[1], E. VAN BIJNEN[1], R. KESSELS[2], A. NOBRE[3], O. JENSEN[4]
[1]Donders Ctr. For Cognitive Neuroimaging, Nijmegen, Netherlands; [2]Donders Inst. for Brain Cognition and Behaviour, Nijmegen, Netherlands; [3]Oxford Univ., Oxford OX1 3UD, United Kingdom; [4]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

**Abstract:** Spatial attention to external information modulates neural oscillatory activity of the human brain. Processing relevant information is believed to be supported by oscillations at higher frequencies (gamma range, >30 Hz), whereas inhibition of task-irrelevant information is believed to be supported by oscillations at low frequencies (alpha range, 8-13 Hz). In a similar manner, directing attention to internal representations (as revealed in retro-cue paradigms), has been shown to be supported by analogous mechanisms. It is well established that attention and working memory (WM) functions decline with age. This decline is possibly explained by altered top-down control or compensatory mechanism involving the fronto-striatal network. The aim of this project is to identify striatal regions relating to the reduced ability to modulate posterior oscillations in the elderly. In the current study, 30 young and 30 older participants (18-30 and 58-70 years old respectively and matched on education) performed a retro-cue task while their respective neural activity was recorded with magnetoencephalography (MEG). In addition, each participant underwent structural brain image scanning and neuropsychological assessment. Centrally presented retro-cues induced lateralized patterns of alpha power in occipital sensors depending on whether the relevant stimuli were located left or right during the encoding. This lateralization was reduced in the older adults. From the structural brain scans we identified the volume of the subregions of the basal ganglia using FSL-FIRST. We correlated the hemispheric asymmetry in these subregions with the ability to modulate alpha in response to the retro-cue. Importantly, those elderly who showed a left hemispheric bias in their ability to modulate alpha power also showed reduced volume of the globus pallidus (GP) in the right hemisphere.Our findings demonstrate a role for alpha oscillations when directing attention towards internal representations. The ability to modulate alpha oscillations when orienting to internal

representation is diminished in the elderly. Importantly, the current preliminary results point that structural changes in the GP in the elderly are associated with a reduced ability to modulate alpha oscillations. In future work we aim to elucidate if these structural changes are compensatory or directly involved in the top-down control.

**Title:** Anatomical substrates of cognitive fatigue and fatigability in aging

**Authors: *S. E. BURKE**[1], I. B. H. SAMUEL[2], Q. ZHOU[2,3], C. PRICE[2], B. KLUGER[3], M. DING[1]
[2]Biomed. Engineeering, [1]Univ. of Florida, Gainesville, FL; [3]Neurol., Univ. of Colorado Denver, Denver, CO

**Abstract:** Cognitive fatigue is a disorder of extreme unrelenting mental exhaustion. It can result in severe disability, diminished quality of life, and even increased mortality. Cognitive fatigue affects an estimated 38% of the healthy aged population. However, this number does not include the many individuals that suffer from fatigue as a comorbidity of age-related diseases. The state level perception of cognitive fatigue is widely assessed by the Fatigue Severity Scale (FSS). There is, however, no effective instrument to measure an individual's susceptibility to develop fatigue for a given workload, referred to as fatigability. In addition, the neural substrate of cognitive fatigue and fatigability remains unknown. To address these gaps in knowledge, we recruited 37 older fatigued adults to undergo cognitive behavioral testing and MRI scanning. To test performance fatigability, we conducted a 2.5 hour cognitively demanding task, the Stroop Task. Behavioral measures (e.g., reaction times) were collected simultaneously with physiological measures (pupillometry). Further, subjective assessments were collected as participants rated their fatigue level every 20 minutes throughout the task. On a separate visit, participants will undergo structural and diffusion imaging to evaluate gray matter and white matter integrity. Through the analysis of fatigue and fatigability measures, we intend to show that an objective performance fatigability index can derived from behavioral performance. This

index will be validated via simultaneous subjective and physiological assessments. A priori regions of interest, the anterior cingulate cortex (ACC) and the dorsolateral prefrontal cortex (DLPFC), will be analyzed via structural and diffusion MRI scans. These regions are both vulnerable to aging and have crucial roles in cognitive control functions that are related to fatigue and fatigability. Specifically, the DLPFC is responsible for behavioral action and the ACC is related to perception. Therefore, we will test the hypothesis that perceived fatigue is related to atrophy in the ACC and that performance fatigability is related to network disruption within DLPFC.

**Abstract:** Tissue composition impacts metabolite quantification. The goal of applying tissue correction is to decrease the dependency of metabolite concentrations on the underlying voxel tissue composition. Different tissue correction strategies have different underlying assumptions

and account for different aspects of the voxel tissue fraction. The most common tissue correction is the CSF-correction, which aims to account for the CSF fraction in the voxel in which it is assumed there are no metabolites. More recently, the α-correction was introduced to account for the different concentration of GABA in grey matter compared to white matter. In this paper, using a healthy aging cohort, we show that the selection of tissue correction strategy can alter the interpretation. In a frontal voxel, we show an age-related decline in GABA when no tissue correction ($R2= 0.25$, $p < 0.001$) or the CSF-correction is applied ($R2= 0.08$, $p < 0.01$). However, when applying the α-correction, there is no relationship between age and GABA ($R2= 0.02$, $p = 0.15$). This indicates that the selection of tissue correction can significantly impact the interpretation of MRS results. Furthermore, this data shows that in healthy aging, while there is normal atrophy, the GABA concentration in the remaining tissue is not decreasing.

**Abstract:** Previous functional magnetic resonance imaging (fMRI) work in humans has demonstrated that neural activity associated with different visual stimulus categories (e.g., faces and houses) becomes less distinguishable with age. Furthermore, this decline in neural distinctiveness predicts age-related declines in fluid processing ability. One hypothesis about why neural distinctiveness declines with age is based on changes in gamma-aminobutyric acid (GABA) concentrations. Studies in nonhuman primates have found that GABA levels decline with age, and increasing GABA levels experimentally increases the selectivity of receptive fields in visual neurons of older macaques. In this study, we investigated whether individual differences in GABA levels in ventral visual cortex predict individual differences in neural

distinctiveness in human beings. Older and younger adults completed a six-minute fMRI task in which they passively viewed greyscale images of faces and houses, and responded to occasional target images. Multi-voxel pattern analysis (MVPA) of activation patterns in the bilateral fusiform gyrus and parahippocampal gyrus was used to estimate the neural distinctiveness of face and house representations. Magnetic resonance spectroscopy (MRS) was used to estimate GABA concentrations in ventral visual areas that were activated by the fMRI tasks. Multiple regression analysis was conducted to examine changes in neural distinctiveness and GABA concentrations with age, as well as the relationship between neural distinctiveness and GABA level. While data collection is ongoing, neural distinctiveness and GABA concentrations declined with increasing age in 9 younger and 9 older adults. Additionally, GABA concentrations in right ventral visual cortex significantly predicted neural distinctiveness, and a backward elimination stepwise regression demonstrated that GABA concentration was a better predictor of distinctiveness than age group. These findings indicate a relationship between neural distinctiveness and GABA concentrations in the ventral visual cortex, and support the hypothesis that age-related reductions in GABA concentrations contribute to age-related declines in neural distinctiveness.

**Title:** Facilitating scalable cognitive science research through the human cognition project

**Authors: *E. CORDELL**, K. KERLAN, N. NG, B. SCHAFER
Res., Lumos Labs, San Francisco, CA

**Abstract:** Advancements in our understanding of human cognition have been tempered by the methodological constraints that characterize the domain of cognitive science research. At present day, investigators tackle individual research hypotheses by conducting discrete, small-scale studies of cognition with insufficient sample sizes, low power, and incomparable task designs. The result is an unsystematic and fragmented body of cognitive research literature, comprised of studies that are time consuming, costly, and difficult to replicate.
The Human Cognition Project (HCP) is an online platform created to facilitate large-scale, collaborative research studies, led by independent academicians and clinicians. The goal of the HCP is to advance our understanding of human cognition by supporting research collaborators

world-wide in their pursuit of efficiently conducting well-powered research initiatives. Inspired by Lumosity's web-based cognitive training platform, qualified research collaborators are granted fully-customized access to a suite of online cognitive training tasks, neuropsychological assessments, surveys, tracking metrics, and other research tools. Additionally, research collaborators have access to the largest database of human cognitive performance, with data from over 80 million individuals to date.
The HCP is guided by the hypothesis that bringing together a broad network of academic scientists and clinicians will accelerate our understanding of normal and disordered cognitive performance across the lifespan, thereby advancing the field of human cognition. Since the project formally began in 2011, HCP has resulted in twelve peer-reviewed publications. Here we will present an overview of the HCP platform as well as several primary findings from published studies that have resulted from the project.

**Title:** Effects of dietary habits and genotype on neural network properties

**Authors: *S. DOLAN**[1], L. JAMES[2], A. C. LEUTHOLD[3], A. P. GEORGOPOULOS[4]
[1]Brain Sci., Minneapolis VA Hlth. Care Syst., Minneapolis, MN; [2]Brain Scienes Ctr., Univ. of Minnesota/Minneapolis VAHCS, Minneapolis, MN; [3]Dept Neurosci, VA Med. Ctr., Minneapolis, MN; [4]Neurosci, Univ. Minnesota, Minneapolis, MN

**Abstract:** Genetics and lifestyle play important roles in healthy aging. For instance, apolipoprotein E (apoE) is widely known to be associated with age-related cognitive changes, and dietary habits are well known to be linked to overall health. Here we evaluated brain health as it relates to apoE genotype and dietary habits in cognitively healthy (MoCA $\geq$ 26) participants.

Participants record food and beverage intake for three days, two weekdays and one weekend day. The items are then entered into Nutritionist Pro Version 6 to quantify over 100 macro- and micro-nutrients, including amino acids, trace minerals, and lipids. Participants also provide a blood sample for apoE genotyping and undergo a MEG scan. We analyzed properties of the neural network, including the flexibility and variability of interactions between MEG sensor pairs as it relates to genotype and dietary habits. Results demonstrated that network properties varied by genotype and were moderated to some extent by dietary habits. These findings highlight the importance of lifestyle factors in moderating brain health, particularly in those with at-risk genotypes.

**Title:** Changes in cognitive pupil responses across the lifespan

**Authors: *J. HUANG**, M. L. SMORENBURG, B. C. COE, C.-A. WANG, D. P. MUNOZ
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

**Abstract:** Change in cognitive functions occurs as a result of natural development and aging, with maturation processes in childhood and deterioration in old age. Pupil size is an easy-to-measure index that is increasingly used to assess cognitive function. Neurophysiological experiments have shown that pupil size is modulated by converging inputs from both bottom-up sensory and top-down cognitive signals. In order to use pupil responses as potential biomarker of diseases, we must first understand changes in pupil response across the lifespan. Here, we examined pupil dynamics in different ages across the healthy lifespan, and hypothesized that modulation of pupil response by top-down signals should change with age, due to delayed frontal maturation in children and cognitive decline in the aging population. Pupil size was recorded in healthy subjects (age 5-85) while performing the interleaved pro- and anti-saccade task. Subjects were instructed via the colour of a fixation cue to generate either an automatic eye movement toward a peripheral stimulus (pro-saccade) or a voluntary eye movement in the opposite direction (anti-saccade). The pupil response consisted of an initial constriction shortly after the presentation of a fixation cue, followed by pupil dilation. Analysis showed age-related effects in each component of pupil response: baseline pupil size decreased with age, and the latency of

peak constriction was longer with increased age. Pupil dilation velocity also decreased with age, and the modulation of pupil dilation by saccade preparation showed age-related decrease that may link to changes of different brain regions in development and aging. The results demonstrated changes in pupil dynamics linked with development and aging, providing the baseline with which abnormal pupil responses due to neurological deficits can be studied.

**Abstract:** To provide feasible and rapid assessment tools to assist in cognitive diagnosis in research and clinical practice, as well as to establish thresholds for cognitive impairment, adapted to the Portuguese context, the applicability of rapid cognitive screening (TICSM-PT) through technology was explored. Results indicated that the TICSM-PT presents associations not only with global cognitive measures, but also with a number of cognitive and psychological instruments performed in-person. Moreover, it demonstrated to be a practical tool for rapid cognitive assessment, and a valid method of screening cognition by telephone. Using a different technological approach, but the same instrument, it was further demonstrated that is possible to carry out accurate and reliable cognitive assessments using videoconference with individuals from different settings with a diagnostic cognitive spectrum from normal to dementia. Findings indicate that the videoconference administration method yields comparable results to the traditional face-to-face administration. The participants also demonstrated to be "at ease" throughout the videoconference test administration and that there was no significant difference in approaches between locales. The findings of this study indicate that cognitive test assessment via

videoconferencing is a tool for consideration by the health professionals to reliably follow-up their patients who live in different settings. In order to make the study more robust and disseminate the practice of telemedicine, more evaluations are ongoing. From a clinical and research point of view, the implementation of home-based technologies for cognitive test administration both enables a cut with the burden of travelling to the hospital and, also, a close patient follow-up of individuals living anywhere.

**Title:** A 16-week visuomotor exercise program improves overall cognition and functional abilities in older adults with cognitive impairment

**Authors: *C. DE BOER**[1], A. ROGOJIN[2], B.-R. BALTARETU[3], H. ECHLIN[4], L. E. SERGIO[5]
[1]Ctr. for Vision Research, Sch. of Kinesiology & Hlth. Sci., York Univ., Toronto, ON, Canada; [2]Kinesiology and Hlth. Sci., York Univ., Thornhill, ON, Canada; [3]York Univ., North York, ON, Canada; [4]Neurosci., [5]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto, ON, Canada

**Abstract:** To efficiently interact with the environment, our brain continuously has to make accurate visuomotor transformations. This process requires well-functioning large cortical-subcortical neural networks, particularly during cognitively challenging tasks, e.g. when vision and motor action are dissociated. In recent years, evidence has emerged that large neural networks, such as those involved in visuomotor transformations, are particularly vulnerable to the early-stage neurodegenerative effects of dementia. This implies that preservation of neural network integrity and functioning is an important target for early-stage intervention strategies. Here, we present behavioural data on the effects of a tablet-based visuomotor exercise program in older adults with various degrees of cognitive impairment. The overall goal of this study is to assess whether such exercises may maintain neural network integrity and its functional counterparts in this population. A 16-week visuomotor training program (1 session/week, 30 min/session) was completed by 39 elderly (13 controls, 8 sub-average cognition, 8 mild cognitive deficits, 10 severe cognitive deficits). Visuomotor exercises involved making goal-directed finger sliding movements on a tablet by playing the videogame Fruit Ninja®. Several variations designed to integrate cognition and motor action were implemented, including visual

plane dissociation and proprioceptive feedback reversal. Pre-and post training, all participants completed a test battery to measure their level of cognition, functional independence in daily life (caregiver rated), and visuomotor functioning. All subgroups significantly improved their game scores at all difficulty levels after training. Older adults that completed the program showed mildly improved cognitive scores (Dementia Rating Scale: mean increase 3.3 points, Montreal Cognitive Assessment: mean increase 1.4 points). Functionally, those elderly with cognitive impairment showed signs of improved visuomotor functioning, displaying faster response times, faster movement times, and better movement accuracy ($p<0.05$). This coincided with a stabilization of caregiver reported scores of functional independence. These results provide behavioral evidence that (1) improving visuomotor functioning in elderly with cognitive impairment can transfer to improved cognition and functional skills, and (2) neural networks in these elderly may still possess a degree of neuroplasticity. We are currently testing this latter idea by assessing possible exercise related changes in neural network integrity through MRI imaging.

**Title:** Associations between cardiovascular risk factors and cognition in aging Hispanics compared to Non-Hispanic Whites

**Authors: *A. STICKEL**[1], L. RYAN[2]
[1]Psychology, [2]Evelyn F. McKnight Brain Inst., Univ. of Arizona, Tucson, AZ

**Abstract:** The presence of one or more cardiovascular risk factors is associated with poorer cognitive abilities (e.g., processing speed, executive functions). In cohorts of Hispanics and non-Hispanic Whites with cardiovascular risk factors, Hispanics tended to live longer than Whites. This finding, known as the Hispanic paradox, is robust. However, it is unclear whether the Hispanic paradox confers protection on cognitive processes. The present study compared relationships between cardiovascular risk and cognition in late-middle age and older Hispanics (n = 67) and non-Hispanic Whites (n = 67) selected from the National Alzheimer's Coordinating Center (NACC)* database. Participants included healthy controls (n = 90) and individuals with mild cognitive impairment (n = 44). Hispanics and non-Hispanic Whites were matched on age (50-94 years, mean age = 72 years), gender, cognitive status (i.e., cognitively healthy versus

MCI), hypertension, and apolipoprotein e4 status. Hispanics had higher body mass index (BMI) and fewer years of education, on average, than Non-Hispanic Whites. A neuropsychological battery of tests was administered to all participants. Tests of interest were Forward Digit Span, Backward Digit Span, Logical Memory Long Delay Recall, phonemic fluency (F-A-S), semantic fluency (Animals), and the Boston Naming Test. In SPSS, the general linear models tested if cardiovascular risk factors influenced cognition differentially for Hispanics compared to Non-Hispanic Whites, controlling for age and education. Associations between cardiovascular risk and cognition differed between Hispanics and Non-Hispanic Whites. These risk factors predicted poorer cognition in Hispanic individuals but not Non-Hispanic Whites, particularly on measures of executive functions, including working memory (Backward Digit Span) as well as semantic fluency (Animals). No main effects of hypertension or BMI were detected. Taken together, cardiovascular health influenced cognition among Hispanics to a greater degree than non-Hispanic Whites. This finding is contrary to the notion of a Hispanic Paradox-like protection on cognitive processes.

**Title:** SUVN-502 (pure 5-$HT_6$ antagonist): A promising therapeutic potential for menopause associated dementia

**Authors: V. GRANDHI**, J. TADIPARTHI, N. GANUGA, R. MEDAPATI, *P. JAYARAJAN, R. NIROGI
Suven Life Sci. Ltd, Hyderabad, India

**Abstract:** Human life expectancy has increased from 75 to 83 years in developed countries over the last century. However, the age at which women encounters major hormonal change, i.e. menopause transition has essentially remained constant at around 50 years. Women spend over one-third of their life time in post menopausal state with chronic decline in circulating hormones, making women prone to degenerative changes and disability. Evidence shows that post-menopausal women are highly susceptible to dementia and Alzheimer's Disease (AD) which has negative impact on quality of life. Although donepezil or hormonal therapy (HT) were tried clinically, the outcome was not satisfactory. Moreover, there could be increased risk of coronary heart disease, pulmonary embolism, ovarian and breast cancers with HT. No effective and alternative intervention is available or approved till date for cognitive deficits associated with

menopause. SUVN-502, a pure 5-$HT_6$ receptor antagonist was evaluated for its potential to alleviate menopause related dementia in a neuro-cognitive animal model of surgical menopause. Bilateral ovariectomy was conducted in female Wistar rats to induce surgical menopause state. Following the recovery period (4-weeks), animals were evaluated for episodic memory, i.e. novel object recognition task (NORT). SUVN-502 was evaluated in two different experiments based on either acute (2-days) or sub-acute (17-days) treatment at 1, 3 and 10 mg/kg, *p.o.* Donepezil (1 mg/kg, *i.p.*) group was included in both models. Object exploration time and discriminative index were assessed. Acute treatment with SUVN-502 dose dependently reversed surgical menopause-induced object memory deficits. A significant improvement in discriminative index was observed in SUVN-502 10 mg/kg, *p.o.* treatment group when compared to vehicle and donepezil treated groups. Sub-acute treatment (17-days) with SUVN-502 further enhanced object recognition memory dose dependently. Vehicle treated rats did not discriminate between the objects, whereas rats treated with SUVN-502 spent significantly more time exploring novel object as compared to familiar one. Significant improvement in discriminative index was observed for groups treated with SUVN-502 at 3 and 10 mg/kg, *p.o.* when compared to vehicle or donepezil groups. Donepezil did not reverse deficits in both the experiments, which is in accord with the clinical outcome. These results indicate that SUVN-502 could be a promising therapeutic strategy in post-menopause associated dementia and AD.

**Authors: *G. M. LERMAN**[1], J. V. GILL[2], D. RINBERG[3], S. SHOHAM[4,3]
[1]Neurosci., New York Univ. Sch. of Med., New York, NY; [2]Ctr. for Neural Sci., [3]New York Univ., New York, NY; [4]Technion, Haifa, Israel

**Abstract:** Holographic optogenetics is an emerging tool for distributed control of spatiotemporal neuronal activity. Establishing causality between specific sequences of neuronal activity and behavior requires manipulating this code at the level of individual neurons while recording neural responses and behavioral readout. However, traditional methods of optogenetic perturbation lack the ability to emulate natural patterns of neural activity, or to rapidly alter the activity of specific neurons deep in the brain. To address the goal of producing behaviorally relevant sequences of neural activity, we have developed an all-optical, rapid two-photon optogenetic stimulation and imaging system with cellular resolution and 5 ms temporal precision. Using an amplified laser with high peak pulse power, together with wavefront shaping methods using a fast spatial light modulator (3 ms switching time), we were able to stimulate dozens of neurons deep in the olfactory bulb (>350 μm) at a high rate (>100 Hz) with cellular resolution. We optimized the system parameters to enable efficient excitation with a low power budget, to enable the simultaneous stimulation of many cells (~60). We then demonstrated stimulation of mitral and tufted cells, the projection neurons of the olfactory bulb, at a high rate, generating artificial odor-evoked responses. We will present the system characteristics and discuss its potential applications for manipulating and reading neuronal activity on a behaviorally relevant spatiotemporal scale to dissect the activity codes that guide behavior across different modalities.

**Title:** Effects of wireless optogenetic stimulation of medial prefrontal pyramidal neurons on within-session habituation of locomotor activity in freely moving rats

**Authors: *K. ISHIWARI**, A. M. GEORGE, C. D. MARTIN, R. Y. SHEN, S. HAJ-DAHMANE, J. B. RICHARDS
Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY

**Abstract:** In rodents, exploratory locomotor activity in a novel environment diminishes over time and with repeated exposures and displays behavioral characteristics of habituation, such as spontaneous recovery and dishabituation. However, little is known about the brain circuitry involved in locomotor habituation. The present study examined effects of optical stimulation of

pyramidal neurons in the medial prefrontal cortex (mPFC) on intra-session habituation of locomotor activity in freely moving rats using a wireless optogenetic system. Adult male Sprague Dawley rats were randomly assigned to two groups. One group was unilaterally injected with an adeno-associated viral vector encoding channelrhodopsin-2 (ChR2) under the control of CaMKIIα promoter (AAV9.CaMKIIα.hChR2(H134R)-eYFP) into the mPFC, while a second group received a control vector encoding only a fluorescent protein (GFP). Both groups were implanted unilaterally with a semi-rigid shank (8 mm in length, 0.55 mm in width, and 0.035 mm in thickness) with an LED (0.32 mm × 0.24 mm × 0.14 mm, $\lambda = 465$ nm) at the site of virus injection. Four weeks after virus injection, rats were tested for locomotor activity in a dark plastic test chamber (42.5 cm × 22.5 cm × 19.5 cm) equipped with an infrared motion-sensor system and located in a sound- and light-attenuating enclosure in two 30-min sessions. Rats were tested twice to ensure the reproducibility of the results. The two sessions were conducted in different chambers and separated by a minimum of four days to allow for spontaneous recovery and minimize inter-session habituation. In both sessions, rats were allowed to explore and habituate for 18 min, and then blue light pulse trains (10 ms, 20 Hz, 13 mW, 15 s on and 15 s off for 6 cycles) were delivered wirelessly for 3 min. The GFP group underwent the same light stimulation procedure as the ChR2 group, providing a control for the effects of light alone. The results showed significant increases in activity and distance traveled in the 3-min period in which stimulation was delivered in the ChR2 group, while no such increases were observed in the control group. Thus, with the stimulation parameters used, optical stimulation of mPFC pyramidal neurons had dishabituating effects on locomotor activity. Future research needs to further elucidate the circuitry involved in locomotor habituation. The present results demonstrate the feasibility of using a wireless optogenetic system in freely moving rats.

**Authors: I. P. CLEMENTS**, D. C. MILLARD, M. CLEMENTS, A. M. NICOLINI, S. A. CHVATAL, *H. B. HAYES, J. D. ROSS
Axion Biosystems, Atlanta, GA

**Abstract:** Optical stimulation techniques including optogenetics methodologies enable control over cultured cells, tissues, and small organisms. Patterns of neural activity, gene expression, protein localization, and iPSC-derived maturation or network development, can all be influenced with specificity and precision via non-invasive optical stimulation. Here, we describe a system for high-throughput light delivery to multiwell microplates for a wide range of applications in neuroscience. Light of up to four wavelengths is delivered to each well of a multiwell (*e.g.* 24, 48, 96) microplate with flexible and precise control over intensity and timing for each wavelength and well. Optical specializations enable high maximum irradiance, even light delivery across the culture substrate, and elimination of light bleed-through between wells. These capabilities are achieved with a top-side light delivery format, leaving the bottom of the microplate open for optional simultaneous imaging, electrophysiology, temperature control, or other interfacing modalities. Provisions for environmental control enable long-term light delivery experiments, such as optical modulation of activity, gene expression, or intracellular pathways during development/maturation. Proof-of-concept applications are given to demonstrate the utility of this system to enable scalable, high throughput control of critical biological parameters, with the additional capability to pair with complementary technologies such as electrophysiology or imaging.

**Authors: *J. C. MORIZIO**, V. GO, D. PEREZ
Triangle Biosystems, Inc, Durham, NC

**Abstract:** Over the last decade, wireless technology advancements for neural recording and stimulation continue to improve with respect to data rates, power consumption, weight and size

thus inspiring new experiments for in vivo electrophysiology research on freely moving rodents. In this presentation, we present the latest technology enhancements to a neural recording system using telemetric implantable capsules that can record from 5 to 128 channels of EEG, EMG, ECG, and single units or spikes signals simultaneously in real time. In addition, we present an implantable neural stimulation system which includes full duplex digital transceiver capsules that can stimulate 2 channel or 16 channel constant current bipolar pulses or 2 channel optogenetic stimulation. Key design challenges and trade-offs of these implantable wireless technologies will be explained. Sub-system components and accessories will also be described that include electrodes and neural interfaces, as well as low noise integrated CMOS electronics, RF transceiver circuitry, 90-day packaging, coating processes and inductive powering technologies. Test data from rat, pigs and NHP with electrical specifications for each of the implantable technologies will also be presented. DAQ analysis software used for neural recording and stimulation for pattern definition and triggering will conclude the presentation.

**Abstract:** Integrative brain functions depend on widely distributed, rhythmically coordinated computations. Through its long-ranging connections with cortex and most senses, the thalamus orchestrates the flow of cognitive and sensory information. Essential in this process, the nucleus reticularis thalami (nRT) gates different information streams through its extensive inhibition onto other thalamic nuclei; however, we lack an understanding of how different inhibitory neuron subpopulations in nRT function as gatekeepers. We dissociated the connectivity, physiology, and circuit functions of neurons within rodent nRT, based on parvalbumin (PV) and somatostatin (SOM) expression, and validated the existence of such populations in human nRT. We found that PV but not SOM cells are rhythmogenic, and that PV and SOM neurons are connected to and modulate distinct thalamocortical circuits. Notably, PV but not SOM neurons modulate somatosensory behavior and disrupt seizures. These results provide a conceptual framework for how nRT may gate incoming information to modulate brainwide rhythms

**Title:** An open-source PCIe based electrophysiology system for high data rate, low-latency closed-loop experiments

**Authors: *J. P. NEWMAN**[1], J. ZHANG[2], J. VOIGTS[3], A. CUEVAS LOPEZ[5], M. A. WILSON[4]
[1]Dept. of Brain and Cognitive Sci., [2]BCS, [4]Picower Inst. Learn/Memory, [3]MIT, Cambridge, MA; [5]Dept. de Ingeniería Electrónica, Univ. Politècnica De València, Valencia, Spain

**Abstract:** Testing increasingly specific hypotheses about the necessity and sufficiency of the neural codes for behaviors requires closed-loop experiments that can execute complex control algorithms on fast timescales. While many existing solutions can cope with high data rates or low latencies, it is still technically challenging to develop and perform such experiments, and few standards exist that ensure interoperability of hardware and software components and that would allow researchers to share methods and replicate experiments.
We have developed an electrophysiology system that implements a full bi-directional data pipeline between headstages and software at sufficiently low latencies to implement closed-loop control algorithms entirely in software on a commodity PC. The system has two main hardware components. First is a 256-channel headstage (using neural amplifier chips from Intan Technologies) for use with behaving rats, with integrated FPGA, high-bandwidth data serializer, 9-axis IMU, and 32-channel LED driver. Second is an galvanically-isolated PC-housed acquisition board containing headstage deserialization circuitry, multi logical-level GPIO, and FMC interfacing circuitry. PCIe communication is provided by a commodity, and easily upgradable, FPGA development board (Xilinx KC705). Communication and power between the headstage and acquisition board board is provided by a single coaxial tether, which is easily commutated.
The acquisition system makes full use of the high bandwidth and low latency of the PCIe bus and is capable of recording and reacting to over 1000 channels of electrophysiology in significantly under 1ms round-trip latency. The system is based on a commodity FPGA evaluation board and industry standard FMC interconnects and can easily be extended to use other data sources. Similarly, the system can be integrated into new software easily through a common API. This library facilitates parallelized acquisition and processing of data streams in (potentially multiple) userland applications. Using this API, we have created a plugin for the Open Ephys GUI. All hardware and software designs are publically available along with detailed documentations concerning hardware acquisition, system setup and usage.

**Title:** Dissecting the functional structure of CA1 assemblies with light

**Authors: *T. TRESSARD**[1], E. RONZITTI[2], A. MALVACHE[1], E. PAPAGIAKOUMOU[2], V. EMILIANI[2], R. COSSART[1]
[1]INMED, INSERM U-901, Marseille, France; [2]Neurophotonics Lab., Paris, France

**Abstract:** The CA1 region of the hippocampus has been recently shown to be functionally organized in neural assemblies which are successively recruited during experience and independently recalled during replay events (Malvache Science 2016). Such functional topology could either be shaped by common inputs from upstream regions or arise from local inhibitory circuits. In the latter case, CA1 assemblies would be shaped by the local activity of pyramidal neurons. In order to test this hypothesis, we use an all-optical approach in the hippocampus taking advantage of the fast opsin Chronos (Klapoetke Nat Methods 2014, Ronzitti bioRxiv 2016). First, we have optimized the expression of Chronos-Td-Tomato and GCamp6s in the dorsal hippocampus of mice using multi-site viral infections for a large spreading and an efficient co-expression. Quantification was made using histology to confirm the compatibility for large scale in vivo two photon imaging. We compared the level of neuronal activity reported by calcium imaging in double labeling conditions and in the absence of opsin expression. Second, we have tested the in vitro photo-stimulation of CA1 pyramidal cells using electrophysiological patch clamp recordings as a readout. This gave us an estimation of the power required to induce enough photocurrents to trigger spikes and confirmed the high expression of opsins in the CA1 pyramidal cells layer. We also quantified the probability for a given Td-Tomato-expressing cell to express a sufficient amount of opsin to be stimulated. Finally, in order to evaluate how spontaneous activity levels in Chronos-expressing neurons are affected by the imaging laser beam, we quantified the depolarization induced with respect to laser power in the raster scanning conditions used for in vivo calcium imaging.Last, in vivo large-scale calcium imaging (GCamp6s) and photo-stimulation will be combined, in the pyramidal cell layer of the CA1 dorsal hippocampus, to probe the organization of cell assemblies when stimulating a subset of cells.

**Abstract:** The development of fiber photometry added an important building block to optogenetic methods, allowing the detection of neural signaling from genetically targeted cellular populations with simple optical fibers. In its standard implementation, an optical fiber stub is implanted into the mouse brain and used to collect luminescence from fluorescent dyes whose emission intensity is proportional to neural activity. However, although fiber photometry is rapidly diffusing among neuroscientists, there is still a considerable lack of knowledge on light collection performances of the different tools available for fiber optic neural interfaces.
We present an easy-to-implement and multipurpose method to measure collection diagrams of fiber photometry devices. It is based on the optical path in Fig.1. A 2-photon microscope generates fluorescence within a fluorescein droplet in which the device is inserted. The excited fluorescence simulates an omnidirectional point source in the sensitive area of the device. Emitted light is collected by a photomultiplier tube (fiber PMT) at the distal facet of the fiber, and by the microscope PMT to identify the position of the fluorescent spot. The signal from the fiber PMT is synchronized with a galvo scan-head moving the beam in the xy plane, resulting in a direct measurement of the collection diagram of the fiber optic. The potential of this approach relies on the fact that it can be used to evaluate light collection properties of most fiber optic devices already diffused for optogenetics. An example is given in Fig. 1B-C, displaying collection diagrams for flat-cleaved fibers and tapered optical fibers (TF) [Bioarxiv 094524], showing that TFs potentially allow for light collection from a 2mm-long segment of the taper.

Although we here discuss 2D images in a fluorescent solution, moving the microscope objective along z allows for measuring collection diagrams in 3D. Importantly, the described approach has the potential to work well also in brain slices, allowing an evaluation of the influence of tissue absorption and scattering on light collection.

**Title:** Frequency-agile, low-intensity, broadband ultrasonic array as a brain computer interface technology for improving neurological health

**Authors: S. W. LANI**, A. P. ROSENBERG, S. F. MAGRUDER, *G. M. HWANG
Johns Hopkins Univ. Applied Physics Lab., Laurel, MD

**Abstract: Background**: The skull is a complex medium that causes phase aberrations in transcranial ultrasound which can limit the focusing resolution of low-intensity

ultrasound.**Objective**: Determine whether time-reversal broadband ultrasonic transducer arrays can focus ultrasound through high-fidelity skull diploe layer adaptively with frequency selectivity between 0.5 and 10 MHz. **Methods**: Analytic methods were used to validate simulation results from k-Wave pseudo spectral time domain (PSTD) solver. A three-layer skull was modeled at three different diploe widths including 1.8, 4.6, and 2 mm. Time-reversal focusing was implemented for simulated arrays of varying apertures and bandwidth. **Results**: We achieved spatial resolution of 0.6 mm x 0.6 mm at greater than 8.4 mm depth, showing demonstrated improvement using an array with a larger bandwidth compared with state-of-the-art focusing. **Conclusions**: Simulation results suggest that a broadband ultrasonic array has the potential to perform real-time, steerable stimulation at an unprecedented small focal volume thru skull. This opens up applications on the use of low-intensity, frequency-agile, ultrasound for non-invasive treatment of neurological disorders (e.g., insomnia, anxiety, depression, post-traumatic stress disorder, and attention deficit hyperactivity disorder) and the potential for neurofeedback to accelerate learning of cognitive and motor skills to assist with rehabilitation.

**Abstract:** Large-scale recording of cortical neural activity in awake and behaving animals is essential to understand the neural correlates of behavior. Wavefront-engineered multiphoton microscopy, combining spatial light modulator-based adaptive optics, multiplane/volume imaging, and three-photon fluorescence excitation, is a compelling approach to monitor such neural activity with cellular and even synaptic resolution at unprecedented recording depths. However, this approach contains several technical hurdles. First, such an integrated microscopy platform requires strict optical conjugation of scanners and wavefront correction devices to the back focal plane of the microscope objective. Second, all the microscope optics need to allow a

wide excitation wavelength range, i.e., from 900 nm to over 1300 nm. Last, the mechanical configuration of such a microscope has to be compatible with an experimental setting for visual behavior studies. We will report on our recent advances in developing a microscope platform for functional imaging of the visual cortex in head-fixed animals with eye tracking and behavior monitoring.

**Title:** Medium-retaining Petri dish inserts to grow and image miniaturized cultured cells

**Authors: *L. KIEDROWSKI**[1,2], A. FEINERMAN[3]
[1]Dept. of Biol. Sci., Univ. of Illinois At Chicago, Chicago, IL; [2]Spot Cells LLC, Chicago, IL; [3]Dept. of Electrical & Computer Engin., Univ. of Illinois at Chicago, Chicago, IL

**Abstract:** We demonstrate that when culture medium is even briefly (one second) removed from cells (neurons, astrocytes, and HEK-293 cells) the cellular $Ca^{2+}$ homeostasis becomes acutely destabilized. This data also implies that the cells grown on plain coverslips experience similar $Ca^{2+}$ homeostasis destabilization when these coverslips are removed from culture media and installed on microscope stages. We show that a custom sample holder can avoid this destabilization by keeping cells continuously immersed during observations. The background for this work is as follows. In experiments involving superfusion, differential interference contrast and intracellular fluorescence imaging, the cells of interest are typically plated on glass coverslips submerged in culture media in Petri dishes. Prior to these experiments, coverslips must be transferred from a Petri dish to a dedicated superfusion-optimized coverslip holder installed on a microscope stage. The problem is that the cells are exposed to air during the transfer. This exposure and the subsequent mechanical stress associated with re-submerging the cells in medium can affect cellular $Ca^{2+}$ homeostasis. To avoid this potential problem, a special Petri dish insert has been designed and constructed. This insert features a medium-retaining well with a glass bottom. The shape of this well is optimized for superfusion. When the insert is removed from a Petri dish, the culture medium is retained in the well. This property allows the cells to stay submerged at all times during the experiment. In this project, these inserts were used to test the impact of a transient medium removal from the well (an equivalent of a transient coverslip removal from the medium) on intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) in miniaturized

cultures of primary murine cortical neurons and astrocytes and HEK-293 cells. The cultures were plated in the inserts and $[Ca^{2+}]_i$ was monitored using fura-2. The medium was removed from the well for only one second. In all cells, this maneuver induced a micromolar $[Ca^{2+}]_i$ spike. While in neurons this spike was caused by a $Ca^{2+}$ influx, in astrocytes and HEK-293 cells, it was caused by a $Ca^{2+}$ release from intracellular stores. After the spike, a subpopulation of neurons, astrocytes, and HEK-293 failed to restore low $[Ca^{2+}]_i$ promptly. Notably, in 24% of the astrocytes, the spike triggered $[Ca^{2+}]_i$ oscillations. Since the cells growing in the medium-retaining inserts remain constantly submerged, one can use these inserts to avoid disturbing basal $[Ca^{2+}]_i$ levels in the imaged cells.

**Abstract:** Neuroengineering more efficient neural interfaces is crucial to develop better clinical rehabilitation solutions and for neural network exploration. Most of current intra-cortical implants are stiff and generate mechanical strain that results in complex cellular responses and instabilities in neural signal recording. Designing soft intra-cortical neural implant with a high density microelectrode array has therefore become essential to faithfully record several neural units overtime and to facilitate for instance, brain computer interface performances and the study of memory and plasticity. We developed a soft SU-8 polymer neural implant with 64 nanostructured gold 20µm electrodes and vary the design of the 2mm deep intra-cortical part of the implant. Leads were either 50µm, 20µm or 11µm wide with a straight or a wavy shape. We then evaluated the impact of different designs on electrical properties of the implant. In vivo biocompatibility tests in rodents were performed and astrocytes, microglia and cell density were analysed around the different implant lead types.

**Title:** Effects of drugs of abuse on channelrhodopsin 2 kinetics

**Authors: *D. A. GIOIA**[1], W. N. WAYMAN[2], M. XU[5], C. RIEGEL[3], C. M. REICHEL[4], J. J. WOODWARD[4]
[1]Inst. of Psychiatry, [2]Neurosci., [4]Neurosciences, [3]Med. Univ. of South Carolina, Charleston, SC; [5]Med. Univ. South Carolina, Charleston, SC

**Abstract:** Channelrhodopsins are light activated ion channels and have been extensively used in neuroscience research over the past decade to probe the function of genetically defined neuronal populations and distinct neural circuits with high temporal and spatial precision. The widely used Channelrhodopsin 2 variant (ChR2) is an excitatory opsin that undergoes conformational changes in response to blue light, allowing non-selective passage of protons and cations across the plasma membrane. In the addiction neuroscience field, opsins such as ChR2 provide a means to disambiguate the overlapping circuitry involved in mediating the reinforcing and aversive effects of drugs of abuse as well as determine the plasticity that occurs in these circuits during the development of dependence. Although ChR2 has been widely used in animal models of drug and alcohol self-administration, it is not known whether drugs of abuse have acute actions on ChR2 function that may confound its use. Considering that many drugs of abuse directly alter the function of other ion channels, it is important to determine whether ChR2-mediated currents are also directly modulated by these drugs. In this study, we performed whole-cell electrophysiological recordings in HEK293 cells expressing the commonly used ChR2(H134R) variant and examined the effects of various drugs of abuse on light-induced currents. Cells were voltage-clamped at -60 mV and subjected to a series of brief (5 msec; 1 Hz) blue light pulses (470 nm) before, during and after exposure to each drug. The amplitude and rise time of light-activated currents in ChR2(H134R) expressing HEK cells were insensitive to effects of ethanol at physiologically relevant concentrations but were minimally affected by ethanol at concentrations of 100 and 300 mM. Similarly, we found no differences in the amplitude or rise time of ChR2-mediated currents in the presence of 10 or 30 µM nicotine, 30 µM cocaine or 3

mM toluene. There was also no effect of these drugs on the desensitization of ChR2 currents that occurs during repetitive stimulations. Together, the results from this study suggests that biologically relevant concentrations of commonly studied drugs of abuse do not significantly affect the function of ChR2 providing further validation for its use in substance abuse studies. We further examined the effects of various other chemicals commonly used in research and found that 10mM gadolinium chloride as well as 5µM tetrodotoxin significantly inhibited ChR2 mediated currents while 10mM magnesium chloride did not. These results indicate that appropriate control experiments should be used when designing experiments with optogenetic tools.

**Abstract:** Vagus nerve stimulation (VNS) is used for a variety of applications including epilepsy, major depressive disorder, and recovery from neurological injury. Optimizing vagus nerve activation on an individual basis could have significant impact on clinical outcomes given the variety of VNS applications and patient variability. Here we investigate two possible strategies for optimizing the delivery of VNS: use of biomarkers to determine optimal stimulation parameters and changes in nerve cuff geometries. SpO2 and heart rate served as our biomarkers of thick A and thinner B fiber recruitment, respectively. Changes in SpO2 and heart rate were measured in anesthetized animals in both acute and chronic conditions. The magnitude of change in spO2 and/or heart rate was determined as a function of the stimulation parameters (current, frequency, pulse width, and train duration). In addition, multiple cuff geometries were tested to determine how the degree of nerve encompassed within a circumferential electrode affected the fiber recruitment function. Each cuff geometry was tested in an acute, anesthetized preparation on the rat sciatic nerve and the force of gastrocnemius muscle contraction was measured to determine the amount of fiber recruitment. Consistent with our understanding of A

and B fiber thresholds, preliminary results showed drops in SpO2 starting at low currents (~200µA) and drops in heart rate starting at higher currents (~1600µA) in the acute condition. There was an increase in both thresholds observed in the chronic condition. Additionally, results indicated that the steepness of the recruitment function was dependent on the amount of nerve encompassed within the electrode. Covering a greater portion of the nerve resulted in steeper recruitment. This information will be applied in upcoming experiments in which the recruitment function and fiber type activation will be tailored to the experimental conditions with the goal of improving behavioral outcomes dependent on VNS plasticity.

**Title:** Electrochemical neuromodulation using cuff electrodes modified with ion-selective membranes

**Authors: *M. T. FLAVIN**[1,2], J. HAN[1], D. K. FREEMAN[2]
[1]MIT, Cambridge, MA; [2]Draper Lab., Cambridge, MA

**Abstract:** Developing precise and effective means of modulating the nervous system is a major challenge in neural prosthetics. Our approach is to perform localized chemical modulation by polarizing electrodes modified with ion-selective membranes (ISM), creating ion-concentration polarization (ICP). With this physical process, the interstitial concentrations of selected ions can be manipulated in a spatially and temporally precise manner. Here, we report the design and testing of a prototype peripheral nerve cuff electrode with ISM-modified contacts for the purposes of ICP-based neuromodulation. We fabricated a silicone/carbon multi-contact cuff electrode with $Ca^{2+}$ or $K^{+}$ -selective ISM formulations drop-cast onto one of the contacts (depicted in Figure 1). Characteristic behavior was simulated using a Nernst-Planck-Poisson (NPP) model in COMSOL Multiphysics, producing results shown in Figure 2. In order to identify defects and evaluate long-term stability, electrode impedances of coated and uncoated contacts were determined using electrochemical impedance spectroscopy (EIS) (see Figure 3). The ISM cuff electrodes were ultimately used to test the impact of electrochemical

neuromodulation in an *ex vivo* frog sciatic nerve model. In the preliminary results shown in Figure 4, we see that cathodic current applied at the $Ca^{2+}$-ISM contact resulted in lowering of excitation thresholds, consistent with neurons being subjected to depletion of extracellular $Ca^{2+}$. The original excitation threshold was restored following a brief recovery period. Similar experiments with modulation of other ions (e.g. $K^{+}$) will be investigated in the future. As a fully realized technology, an ISM cuff electrode could potentially be used to lower the stimulus energy required to elicit muscle activation (via $Ca^{2+}$ manipulation), or block aberrantly firing nerves that characterize neuropathic pain disorders (via $K^{+}$ manipulation). Furthermore, ISM-based stimulation could eventually be applied beyond the peripheral nervous system to address neurological and psychiatric disorders in the brain.

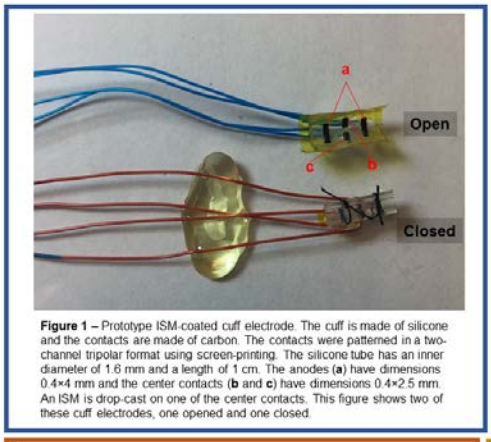

**Figure 1 –** Prototype ISM-coated cuff electrode. The cuff is made of silicone and the contacts are made of carbon. The contacts were patterned in a two-channel tripolar format using screen-printing. The silicone tube has an inner diameter of 1.6 mm and a length of 1 cm. The anodes (**a**) have dimensions 0.4×4 mm and the center contacts (**b** and **c**) have dimensions 0.4×2.5 mm. An ISM is drop-cast on one of the center contacts. This figure shows two of these cuff electrodes, one opened and one closed.

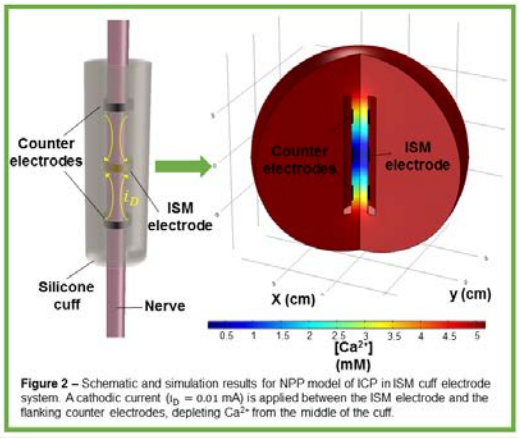

**Figure 2 –** Schematic and simulation results for NPP model of ICP in ISM cuff electrode system. A cathodic current ($I_D$ = 0.01 mA) is applied between the ISM electrode and the flanking counter electrodes, depleting $Ca^{2+}$ from the middle of the cuff.

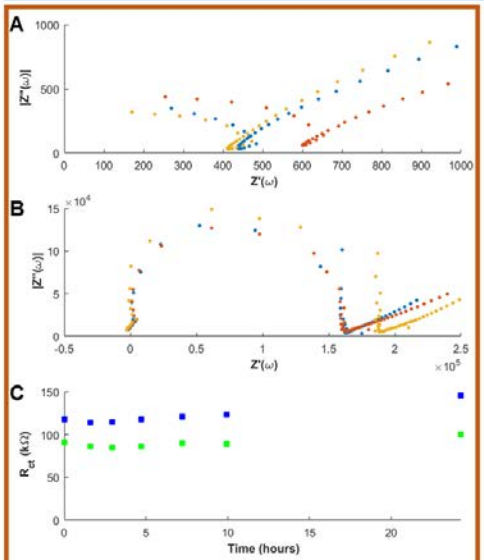

**Figure 3 –** EIS performed on several carbon/ISM cuff electrodes in PBS with Ag/AgCl reference and large-area carbon paper counter (10 mV peak-to-peak, 100 kHz -1 Hz). **A** Nyquist plot showing results with one of the anodes as primary electrode for three separate devices. The charge-transfer resistance estimated from the diameter of the semi-circle is $R_{CT} \approx 400-600\ \Omega$. **B** Nyquist plot showing results with carbon/ISM electrode as primary for three separate devices. The charge-transfer resistance estimated from the diameter of the semi-circle is $R_{CT} \approx 160-190\ k\Omega$. **C** Charge-transfer resistance measured over the course of 24 hours for two different carbon/ISM electrodes, determined from the diameter of the semi-circle on the EIS Nyquist plot.

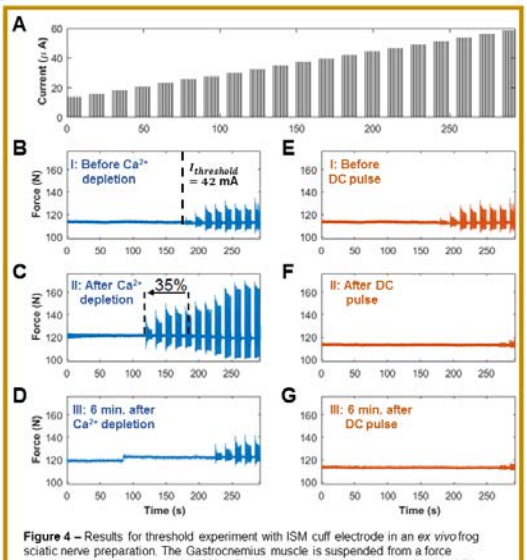

**Figure 4 –** Results for threshold experiment with ISM cuff electrode in an *ex vivo* frog sciatic nerve preparation. The Gastrocnemius muscle is suspended from a force transducer while the nerve, with ISM cuff electrode attached, is immersed in amphibian Ringer's solution. The threshold searching procedure is to apply a ramped train of pulses, recording the smallest amplitude to produce a muscle contraction. During Phase I, the threshold is determined without any $Ca^{2+}$. During Phase II, the threshold is determined immediately after either $Ca^{2+}$ depletion from ISM or DC pulse from uncoated cathode. During Phase III, the threshold is determined after 6 min. of equilibration. **A** Waveform for ramped pulse train. **B-D** Output of force transducer for each respective phase using the ISM electrode. The pulse train ranged from 13.5 µA to 58.5 µA, and the ISM depletion current had a magnitude of 20 µA. **E-G** Output of force transducer for each respective phase using an uncoated cathode (control). The pulse train ranged from 15 µA to 65 µA, and the DC pulse had a magnitude of 20 µA.

**Title:** Targeting of DREADD expressing vectors into cytoarchitecturally different monkey brain regions at high penetrance

**Authors: *W. LERCHNER**, M. A. G. ELDRIDGE, D. MILLER, J. M. FREDERICKS, D. ROSE, V. DER MINASSIAN, V. D. COSTA, B. B. AVERBECK, B. J. RICHMOND

**Abstract:** To make use of chemogenetic tools, such as DREADDs (Designer Receptors Exclusively Activated by Designer Drugs), for behavioral studies in old-world monkeys, it is necessary to express receptor-encoding genes via injections of a viral vector. Here we show that we can use mechanically guided injections of lentivirus (LV), and in some cases adeno-associated virus (AAV), to express a DREADD gene with high neuronal penetrance, in cytoarchitecturally different regions. We analyze expression in three structures: the amygdala – a large, multi-nucleus structure; the tail of the caudate nucleus (ToC) – a small region deep in the brain adjacent to the lateral ventricles; and cortex – a thin laminar structure.
$Mn^{2+}$ can be used for post-surgery verification of injection sites and successful infusion by creating an MRI hypersignal lasting hours to days after surgery. Here we show that the infectious titer of LV containing 10mM of $MnCl_2$ is stable *in vitro* for at least 6 hours. To test *in vivo*, 5µl lentivirus mixed with concentrations of $MnCl_2$ from 0.1, 1.0, and 10mM was injected into monkey cortex, all resulting in a detectable MRI hypersignal. Histological visualization of DREADD expression showed that coverage and penetrance were not affected by addition of $MnCl_2$. In the same monkey, injection of 5µl AAV2 into cortex yielded a four-fold larger expression volume, but the percentage of expressing neurons in the covered area was markedly lower than with LV. We then compared injections of both LV and AAV2 containing 1mM MnCl2 into the ToC. The $Mn^{2+}$ MRI hypersignal was centered at the estimated position of the needle tip on the histological sections. Both LV and AAV resulted in penetrance of up to 100% in the ToC.
In the amygdala, we compared a single 80µl injection of lentivirus with four individual 20µl injections, spaced 2mm apart. The 80 µl injection yielded an average of 75% penetrance over a volume of about $50mm^3$ compared to 55% average penetrance and $65mm^3$ coverage for the four 20µl injections. However, in the 80µl injection nearly 6% of the expressing area also showed a complete shut-down of the neuronal marker NeuN, likely due to toxic overexpression of the DREADD gene, something not seen in the 20µl injections. While there were a few gaps in expression in between the four injections spaced 2mm apart, encouragingly, cell counts indicated

that a majority of expression regions had neuronal penetrance above 90%. From these results, we project that covering the one entire amygdala (approx. 300 $mm^3$) at >90%, a 1.5mm grid of 14 - 15 injections of 20μl each will be required.

**Title:** A deep-brain multi-wire electrode array and cartridge-based implantation system for high-resolution recording and stimulation with demonstration as a visual prosthesis

**Authors: *N. J. KILLIAN**, J. S. PEZARIS
Neurosurg., Massachusetts Gen. Hosp., Boston, MA

**Abstract:** We have developed a multi-wire electrode array (brush-style microwire bundle) and accompanying implantation system for high-resolution physiology and therapeutic stimulation of deep brain structures. The implantation system is suitable for acute, semi-chronic, and chronic applications. The device was implanted bilaterally in the lateral geniculate nucleus (LGN) in one monkey (Macaca mulatta), for one year, as part of the first-generation prototype of a thalamic visual prosthesis.

The electrode array comprises a bundle of 64 platinum-iridium microwires (38 micron O.D.) mated with miniature connectors and sheathed in a polyimide tube, with a second, thick polyimide inner guide tube and a third stainless steel outer guide tube. The inner guide tube is manually positioned to the desired depth above the target structure. The outer guide tube is used to penetrate the dura and is reversibly secured using wax or silicone. The array and guide tubes are all securely located in a cartridge enclosed by a peel-away carrier. Cartridges mate with a positioning rod mounted to a standard microdrive and are readily interchangeable during a procedure. The positioning rod and carrier provide an access port for all array sites and can be adapted to common hydraulic microdrive positioning systems.

To demonstrate the system, wire tips of the bundle were cut to match the geometry of the LGN and then sonicoplated with platinum black in order to reduce the impedance for stimulation

(median 18 kOhm at 1 kHz, 2 weeks post-implant). We first verified the target location using a single-electrode cartridge, and then changed to a bundle-electrode cartridge for implantation. Intraoperative single- and multi-unit recordings were made from the bundle electrode array while the animal was awake and performing a receptive field mapping task. Using the receptive field locations, bundle positioning was fine-tuned with the microdrive before sealing the device in place within titanium recording cylinders. Distinct artificial visual percepts, known as phosphenes, were evoked by stimulating individual wires and mapped with a saccade-based task. To examine the animal's perception through patterned stimulation, phosphenes were simultaneously activated to represent either the letter C or W, artificially presented at a size corresponding to a visual acuity of logMAR 2.2. The animal successfully discriminated the artificially presented letters on 60% of trials ($p < 0.05$, binomial test), consistent with our prior studies using a virtual reality simulation. Second-generation higher channel count implants are in preparation.

**Abstract: Background:** Deep brain stimulation (DBS) technologies have gained increasing interest in the treatment of not only neurological but also psychiatric disease due to growing evidence of aberrant functioning within brain circuits and connectivity in a number of psychopathologies. DBS can target these specific dysfunctioning brain areas, and with its increased use, there is a need for improved devices. Electrophysiological tools are widely used and tested in rodent models, and here we aimed to validate a novel wireless neurostimulator device, the eParticle (EP), using rewarding medial forebrain (MFB) stimulation in a conditioned

place preference (CPP) paradigm. **Methods:** Adult male Sprague Dawley rats received an implantation of a Plastics One electrode into the MFB on one side of the brain and the wireless e-particle on the other side, counterbalancing for hemisphere. Each animal was implanted with both the commercial electrode and wireless EP to enable within-subject comparisons of effective stimulation. After recovery, all animals were tested for conditioned place preference in an open field with a designated quadrant as the stimulation quadrant. Place preference was measured by the percentage of time spent in the stimulation quadrant during 15-minute sessions in an open field. E-particle stimulations were administered via transmitter coils at (monophasic, 50 Hz, 0.1ms pulse width, 0.25s pulse duration). Wired stimulation parameters (biphasic, 350 uA, 160Hz, 0.1ms pulse width, 0.5s pulse duration) were determined by confirmation of rewarding behavior in a bar press self-stimulation task. **Results:** Animals that received EP stimulation of the MFB increased the amount of time spent in the stimulation quadrant, significantly during stimulation ($p \leq 0.05$) and trending towards significance during the post-stimulation test session ($p \leq 0.05$) when the animals were not receiving any stimulation. These EP effects were not as robust as with wired electrodes. Nevertheless, wireless EP stimulation was capable of achieving the rewarding effects of MFB stimulation, suggesting that it may still be a useful and effective tool for brain stimulation. **Conclusions:** These initial results appear to be promising despite the limitations of the EP stimulation parameters compared to wired stimulation. Future studies should assess the efficacy of EP neurostimulation in other behavioral tasks with known neurocircuitry.

**Abstract:** Compounds are screened in variety of animal models during preclinical evaluation; however they often suffer with the limitation of translatability to human. Researchers across globe are in constant search of animal models which will help them in addressing this problem. Electroencephalography (EEG) is one of the preclinical models which show characteristics with great similarities across species. Therefore, drug-induced changes in EEG characteristics in animals may be used to predict central activity of drugs in humans. If the relation of EEG and behavior is established / proved in animals, this approach will be more meaningful and beneficial to evaluate compounds acting on sleep, cognition, locomotor activity. In the current investigation animals were implanted with a telemetric device having two bio-potential electrodes capable of measuring EEG from two brain regions simultaneously. After surgical recovery, animals were subjected for exploration of open field and neuronal oscillations from same animal were simultaneously monitored. Similarly, animals were subjected for the simultaneous object recognition task in parallel to the EEG monitoring. In open field, treatment with psychostimulants produced increase in locomotor activity with simultaneous decrease in theta, alpha and beta power densities. Similarly, during novel object exploration, acetylcholineesterase inhibitors like donepezil increased the power in theta frequency during exploration of novel object. The current model demonstrated the simultaneous monitoring of animal behavior and the changes in neuronal oscillations during different behaviors. Simultaneous monitoring of these parameters in the early stages of discovery program will increase the chances of translatability during development of drugs.

**Abstract:** Whole-cell recordings *in vivo* are a key technique for neuroscience; yet, technical difficulties have precluded their more widespread use. First, the mechanical mismatch between the neuron and stiff patch pipette often leads to recording instabilities in the presence of motion. Second, patch pipettes require the continuous application of pressure while navigating through the brain to avoid clogging and exhibit increased access resistance with depth. Both of these challenges lead to suboptimal recordings and low experimental throughput. There is, therefore, a need for small, flexible, and minimally invasive intracellular electrodes that can enable high throughput, high-signal-to-noise-ratio (SNR) recordings *in vivo*. To address this challenge, we recently introduced quartz nanopipettes (inner diameters ~15nm) as direct electrical interfaces to dendritic spines *in vitro* [1], and rendered them flexible for targeted recordings *in vivo* [2]. Although, we achieved repeatable high-SNR recordings in both anaesthetized and awake animals, the seal resistance between the nanopipette and neuron was variable (~500-800MΩ), and recordings were not completely immune to movement. Here, we introduce "biomimetic nanopipettes" - lipid-coated electrodes that form spontaneous giga-seals with neuronal membranes. We first measured the nanopipette seal resistance *in vitro* by obtaining the input resistance of the neuron before and after lipid-coated nanopipette entry and found seal resistances ≥1.2GΩ. This was accomplished with simultaneous whole-cell patch and nanopipette recordings from the same cell. We corroborated this interaction through detailed molecular dynamic (MD) simulations, and found that the neuronal membrane and lipid-coated nanopipette form a new separate bilayer during entry - the basis for giga-seal formation. This interaction is found to be dependent on lipid grafting density and uniformity. We demonstrate that biomimetic nanopipettes routinely permit stable (~1hr), high-throughput (10 cells/nanopipette), and high-SNR intracellular recordings from awake head-fixed mice running on a wheel.

**Title:** Triple-microdrive assembly for simultaneous juxtacellular neural recording and labeling in freely moving rats

**Authors: *R. G. AVERKIN**, G. TAMAS
Univ. of Szeged, Szeged, Hungary

**Abstract:** We present a microdrive assembly for three pipettes to be used in simultaneous juxtacellular recording and labeling of cortical neurons in freely moving rats. The assembly combines three modified Korshunov type (Korshunov, 1995) microdrives and is capable of independent manipulation of individual glass pipettes filled with 0.5M NaCl solution with 1.5-2.0% Neurobiotin. Each microdrive is tilted at 7 degrees relative to the central axis of the overall assembly axis and has a 12 mm advancing range with 350 μm per revolution. The assembly can be secured to a holding platform to target closely spaced neurons in supragranular layers of the same cortical area (>0.36 $mm^2$). During surgery, a chamber (ID=4.5mm; height =2mm) is attached by acrylic cement to the skull above the agar-coated surgery hole (ID=2.3mm) with the dura left intact. The microdrive assembly preloaded with the three pipettes is placed on to the holding platform and fixed by a single screw on the awake animal, thus the installation procedure does not require pre-anesthesia. The whole construction including the acrylic cement weighs 4.9 g. In initial experiments, we successfully used the assembly for simultaneous juxtacellular recordings and anatomical labeling of three neurons including interneurons and pyramidal cells in freely moving rats during awake state and natural sleep for up to 20 minutes. When searching for a cell on one channel, juxtacellular spikes remained unaffected on the other two channels. Differences were readily identified during the same epochs in the firing of simultaneously recorded pyramidal-pyramidal and pyramidal-interneuron cell pairs and triplets.

**Title:** Major depression index derived from the relationship between hurst exponent and zero crossing rate in voice

**Authors: *S. SHINOHARA**[1], Y. OMIYA[2], M. NAKAMURA[1], M. HIGUCHI[1], N. HAGIWARA[2], T. TAKANO[2], H. TODA[3], T. SAITO[3], M. TANICHI[3], A. YOSHINO[3], S. MITSUYOSHI[1], S. TOKUNO[1]
[1]Dept. of Verbal Analysis of Pathophysiology Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]PST Corporation, Inc., Yokohama, Japan; [3]Natl. Def. Med. Col., Saitama, Japan

**Abstract:** The hypothesis that depression is caused by decreasing monoamines such as serotonin and dopamine in the brain has been proposed. These neurotransmitters are known to affect mood. On the other hand, as you can see from the fact that you can recognize the other's emotion even on the phone, the change in mood appears in the voice. From the above viewpoint, we have studied indicators that can detect depression from speech. In this report, we propose a new depression index based on the relationship between zero crossing rate (ZCR) and hurst exponent (H) of speech signal.ZCR is an index often used in the field of voice activity detection, which represents the rate at which the signal changes from positive to negative and vice versa. On the other hand, H is an indicator often used in the analysis of stock prices and indicates how far away from the initial position with time, and in theory it is H = 0.0 for white noise and H = 0.5 for brown noise. We have found that there is a negative correlation between ZCR and H. The speech signal is divided into small sections, and ZCR and H are calculated in each section. We derived a new major depression index (MDI) from these aggregated data. In this study we collected the voices from both healthy individuals and patients with major depression, reading 17 fixed phrases (N = 43 and N = 25 respectively). The values of MDI were calculated from the voices. The average values of healthy subjects and major depressed patients were -0.251 ± 0.080 and -0.360 ± 0.076, respectively. As a result of the t test, there was a significant difference between them (p = 5.3210 E - 07). To evaluate the performance of MDI in discriminating between patients and healthy individuals, we used area under the curve (AUC) in the receiver operating characteristic plot. The AUC was 0.85.For major depression patients, Hamilton Depression Rating Scale (HAMD) was conducted. The voice data of major depression patients were divided into two with HAMD score less than 14 (mild) or over 14 (severe). The MDI mean values of the mild group and the severe group were -0.313 ± 0.048 and -0.411 ± 0.068,

respectively. As a result of the t test, there was a significant difference between them (p = 0.000343). The AUC was 0.88 for the discrimination performance between mild group and severe group.Thus, it was shown that the proposed index not only distinguished between major depression patients and healthy individuals, but also a good indicator of severity.

**Title:** Robotic automation of *In vivo* two photon targeted whole-cell patch clamp electrophysiology

**Authors: *L. A. ANNECCHINO**, A. R. MORRIS, C. S. COPELAND, O. E. AGABI, P. CHADDERTON, S. R. SCHULTZ
Imperial Col. London, London, United Kingdom

**Abstract:** Whole-cell patch clamp electrophysiological recording (WCR) constitutes the best tool for high-fidelity analysis of post synaptic responses to sensorial stimuli, behavioural states and cognitive processes in healthy and pathological conditions. While in vivo patch clamp recording has recently benefited from automation, it is normally performed “blind”, meaning that throughput for sampling certain genetically and morphologically defined cell types is relatively low.
The inherent cell-type non selectivity of this technique can be overcome by combining WCR with two photon microscopy, and targeting recordings to specifically labelled individual cells or cell classes in vivo. However, combining this with robotic automation is intrinsically difficult, as micropipette penetration induces tissue deformation, moving target cells from their initial location. In particular, the precise vision-guided navigation of patch pipette to an anatomical target requires specialised skills acquired through extensive practice and training by individual operators and remains a challenging task.
In this study we describe a platform for automated two photon targeted patch clamp recording,

which solves this problem by making use of a closed loop visual servo algorithm. Our system keeps the target cell in focus while iteratively adjusting the pipette approach trajectory to compensate for tissue motion. The system automatically controls a micromanipulator, a signal amplifier, a two-photon microscope and a custom-made regulator for controlling pipette pressure. The system acquires images of fluorescently labelled cells, and targets for patch clamp are selected via a point-and-click graphical user interface.
We demonstrate platform validation with patch clamp recordings from a variety of cells in the mouse neocortex and cerebellum. The system was tested in both “blind” and two-photon targeted paradigms. In automatic “blind” WCR mode, when visual targeting was deactivated and therefore no cell or cell-type selectivity implemented, the success rate was 51.4%. In automatic “targeted” mode, success rate for robotic visual guided WCR targeted at fluorescently labelled cells was 19.3%. Such performances are comparable or exceed those obtained by human operators, in terms of yield, recording quality and operational speed in the absence of lengthy user training times. These results prove the feasibility of robotic targeted WCR patch clamp in vivo and establish this system as a powerful tool for automated electrophysiological experiments in the brain.

**Abstract:** There have been attempts to control animals' locomotion via electrical stimulation on brain. For this purpose, it is typical to stimulate dopamine-related reward neural pathways including medial forebrain bundle (MFB). Animals can be trained when MFB stimulation is delivered as a reward immediately after animal correctly follows the external commands such as directional cues. However, one limitation of this strategy is that training is impossible if animals fail to follow the commands because it is only for a "Go" commands. In this study, amygdale nucleus (AMY), the brain center of fear modulation, is additionally targeted for training via punishment. Electrical stimulation is applied on AMY of Sprague-Dawley rats under freely moving condition when the animal goes wrong direction after command signals for directions. All the stimulations including MFB, AMY, directional cues, are performed using a custom-made multichannel microelectrode array (tungsten, 254 μm diameter). As directional cue signals, stimulation of somatosensory barrel cortex is delivered on either of hemisphere. Three animal groups are examined depending on the strategies: 1) Group R (MFB stimulation for reward only), 2) Group F (AMY stimulation for fear only) and 3) Group B (stimulation on both MFB and AMY). The effectiveness for training is quantified by measuring the success rates based on correct directional decision making. As a result, Group B shows the highest success rate and faster training overall, compared to the other groups. This study indicates that the behavioral training using both reward and fear stimulations is more effective for locomotion control than using either of the stimulations.

**Title:** Fear conditioning altered BOLD responses in dexmedetomidine sedated rats

**Authors: *K.-H. CHEN**[1], D.-Y. CHEN[2], K. LIANG[3]
[1]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan; [3]Natl. Taiwan Univ., Taipei, Taiwan

**Abstract:** In search for neural changes altered by learning, recording at specific sites often confined detection of a distributed neural network subserving the engram. While functional MRI may provide a potential *in vivo* measurement of the whole brain activity, head motion has prevented its use in rodent studies. To curtail this problem, we developed a protocol in which rats acquired light-shock association under dexmedetomidine sedation (0.1 mg/kg/hr, s.c.) and subsequently expressed their memory of fear in a fear potentiation of startle (FPS) task. Behavioral results showed that an intense foot shock (1.25 mA) yielded a significant FPS response, while a weak shock (0.63 mA) yielded minimal learning that can be enhanced by pre-training injection of 0.1 mg/kg epinephrine (s.c). We then trained animals with this protocol in a 7T Bruker Biospec scanner to obtain concurrent functional images during learning. To facilitate the detectability for the learning-induced alteration in the BOLD response and functional connectivity, a within-subject paradigm was adopted by arranging the functional scans of CS-only, US-only, and CS/US pairing in sequence and interleaved with a 10-min-resting state scan. The BOLD response during CS-US association showed that the somatosensory and visual pathways had signals significantly enhanced as compared to the sensory stimulation only (corrected $p < .05$). Moreover, the ventroposterior nucleus of thalamus showed increased functional connectivity with the superior colliculus and amygdala ($p < .01$) after sedated rats receiving association training. Our results showed the conditioning paradigm elicits activity change mainly in the sensory processing pathways, and the increased functional connectivity among the sensory thalamic structures and the amygdala might reflect the reverberation of activity during the consolidation phase following initial acquisition.

**Title:** Targeted wireless neuromodulation using magnetoelectric thin films

**Authors: *A. WICKENS**[1], J. ROBINSON[2]
[1]Applied Physics, [2]Electrical and Computer Engin., Rice Univ., Houston, TX

**Abstract:** Chronic neuromodulation for treating neurological disorders and probing neural circuits is growing in popularity; however, testing new stimulation paradigms in animal models like rats and mice often requires lightweight, wireless neuromodulation technologies that can target specific brain areas. Many wireless stimulators designed for humans and NHPs are too large for experiments in mouse models due to the weight of batteries or receiver coils, requiring significant redesign. Here we present a new approach for wireless neuromodulation that uses a material to convert magnetic fields that freely penetrate the brain into an electric field that stimulates nearby neurons. Because these materials act as targeted wireless stimulators, they can be made small enough to be fully implanted in mice. To create these biocompatible "magnetoelectric" materials we fabricated a film of a piezoelectric material polyvinlydene fluoride bonded to a magnetostrictive film of Metglas. We then encapsulated the final films to make them biocompatible. These films can generate voltages above three volts under resonant conditions using alternating magnetic fields with an amplitude of about 1 mT. With these magnetoelectric films we demonstrate that a simple film is able to stimulate cellular activity *in vitro* in excitable HEK cells. Based on this proof of concept work, we fabricated magnetoelectric "micro-films" which weigh less than 5 mg and are compatible with studies in freely moving mice. Our results show that magnetoelectric materials offer great promise for wireless electrical stimulation of specific brain areas. The basic understanding of how this system operates could also be used to develop novel magnetoelectric materials or geometries (such as nanoparticles or nanofibers) to achieve even more targeted and less invasive wireless neural stimulation.

**Title:** Effects of VTA electrical stimulation on whole-brain fMRI activity

**Authors: *S. R. MURRIS**, J. T. ARSENAULT, W. VANDUFFEL
Lab. for Neuro- and Psychophysiology, KU Leuven, Leuven, Belgium

**Abstract:** The Ventral Tegmental Area (VTA) is a small midbrain structure containing dopamine (DA) cells (+/- 60%) that project to a multitude of cortical and subcortical brain regions, with innervation patterns of macaque monkeys being more similar to humans compared to that of rodents [1]. Electrophysiology studies in the VTA indicated that DA neurons broadcast reward prediction error signals suggesting their role in reinforcement learning and motivational behaviour [2]. In support of this, cell type-specific optogenetic stimulation of VTA DA neurons in rodents has established a direct link between reinforcement learning and dopamine neuron signaling [3] [4]. The hypothesized functional roles of VTA dopamine are also supported by recent work in our lab in which electrical microstimulation of the VTA (VTA-EM) can alter choice preference when monkeys are performing a behavioural task [5], findings that are confirmed by a recent DA-specific optogenetic stimulation study [6]. Interestingly, we also showed that VTA-EM combined with fMRI demonstrates an increase in fMRI activity in brain regions commonly associated with reward, which are anatomically connected to the VTA, either directly or indirectly. Stimulation parameters in these experiments were based on cortical stimulation experiments, stimulating at 200 Hz for 200 ms with amplitudes ranging between 100-400 μA. Stimulation frequency, however, has previously been shown to greatly affect signal propagation as measured by the hemodynamic response with fMRI throughout the brain when stimulating thalamic nuclei such as the lateral geniculate nucleus (LGN) in macaques [7] and the ventral thalamus in swines [8]. In addition, endogenous firing patterns of VTA DA cells are highly variable operating at different timescales; which has been proposed to influence behavioural functions and brain wide activity differentially [9]. We investigated frequency-dependent effects of stimulation by applying VTA-EM with concurrent fMRI in two awake macaque monkeys (*Macaca mulatta*) (n=2), with previously implanted chronic electrodes. While the monkeys are performing a passive fixation task in the MR-scanner we stimulated their VTA with biphasic pulses for 200 ms at four different frequencies: 10, 20, 50 and 100 Hz. The order of the frequencies is pseudo-randomized as to minimize anticipation and summation effects of stimulation. We observed substantially different fMRI patterns in cortical and subcortical areas elicited by different frequencies of VTA-EM based on general linear model (GLM) and multivariate pattern analysis (MVPA) methods.

**Title:** Neuromodulation with microelectrodes: Elasticity of water window and implication for tissue damage

**Authors: *P. A. TAKMAKOV**, Y. WANG
CDRH\OSEL, US Food and Drug Admin., Silver Spring, MD

**Abstract:** Neuromodulation devices are undergoing a period of rapid development. The growth of bioelectronic medicine is particularly noticeable with substantial investments from government and private sector being allocated for development of new therapies based on neuromodulation of peripheral nervous system. While a number of innovative approaches based on an acoustic, optical and magnetic interface with neurons have been proposed, electrical neurostimulation with microelectrode arrays remains a key approach to modulation that requires high spatial resolution. One challenge associated with electrical charge injection is a danger of tissue damage that can occur at certain stimulation conditions. This undesirable side effect is particularly important for peripheral nerves, as animal studies point to the lower threshold for tissue damage compare to that in central nervous system. The mechanism of tissue damage is not well understood, but irreversible electrochemical reactions that occur during charge injection and lead to a generation of potentially toxic chemical compounds are thought to be a contributing factor. Water electrolysis is traditionally considered as one of these reactions that defined maximum potential excursions and maximum charge density that can be used safely during neuromodulation. However, quantification of this reaction during rapid current pulses used in neuromodulation has not been performed. In this work, we performed analysis and quantification of irreversible electrochemical reactions that occur during neuromodulation pulses at a rapid time scale (down to 100 us) on platinum electrodes of different diameters (from 10 to 1000 um). We observed that for microelectrodes, water electrolysis occur at much lower cathodic potential (-1.5 V vs Ag/AgCl for 10 um electrode) compare to macroelectrodes (-1.13 V vs Ag/AgCl for 1000 um electrode). This leads to much larger formal charge injection capacity (157 $mC/cm^2$ for 10 um vs 0.16 $mC/cm^2$ for 1000 um). This finding provides a new insight into the mechanism of tissue damage suggesting that electrical neurostimulation at a much large charge injection amplitudes can be performed without production of toxic electrochemical species. Additionally, this work provides a new method to measure charge injection capacity for rapid neuromodulation pulses.

**Abstract:** Open science involves disclosing all methods (open methodology); releasing all raw and processed data (open data); and providing access to all software, as well as, documentation of all hardware utilized in an experiment (open source). Several resources exist within the neuroscience community for sharing this type of information, including OpenNeuroscience, Open Ephys, and OpenOptogenetic. OpenBehavior (http://edspace.american.edu/openbehavior/) was recently developed as a resource to specifically serve the behavioral neuroscience community. OpenBehavior is dedicated to accelerating behavioral neuroscience research through the promotion of collaboration and open-source projects. OpenBehavior aims to foster an international community of sharing by providing a centralized repository of open-source hardware (tools, devices, apparatuses), as well as software for the investigation of animal behavior and cognition. OpenBehavior accelerates behavioral neuroscience research through two principal means: (1) improvement of research methodology, and (2) reduction of research costs. OpenBehavior provides a platform for sharing devices and other resources for behavioral neuroscience research with research groups and educators seeking STEM neuroscience projects. This sort of sharing reduces duplication of effort between labs, as well as refines research methodology by allowing researchers to extend the work of others. Moreover, OpenBehavior dramatically reduces the cost of launching a behavioral research lab or extending existing research methods by providing a platform for sharing alternatives to commercial research equipment.

**Title:** Electrode design and test for spinal cord stimulation

**Authors: L. R. C. CAVALCANTI**[1], H. S. PEREIRA[2], *E. MORYA[3]
[1]Federal Inst. for Education, Sci. and Technol. of Rio Grande do Norte, Ceara-Mirim, Brazil; [2]Edmond and Lily Safra Intl. Inst. of Neurosci., Santos Dumont Inst., Macaiba, Brazil; [3]Edmond and Lily Safra Intl. Inst. of Neurosci., Inst. Santos Dumont, Macaiba, Brazil

**Abstract:** An magnetic anchored electrode design is proposed here to electrically stimulate dorsal column fibers of the spinal cord in rats. One of the application of this electrode is to alleviate motor symptoms in Parkinson's disease under the assumption that that SCS might suppress the aberrant beta-frequency synchronous corticostriatal oscillations, thus restoring neural activity in the primary cortex and dorsolateral striatum to a state observed prior to the onset of spontaneous locomotion. Biocompatible materials were chosen to make a fully functional implantable device. Platinum (Pt) foil (99.9% purity) was used for rectangular electrical contacts measuring
1.0 x 0.8 mm (25 µm thick). Under exhausting repeated cycles of electrical stimulation, Pt foil suffers mechanical deformations on its surface. This can lead to significant electrode, impedance and biocompatibility changes. Thus, these electrodes should undergo electrical stimulation in order to shed light into a systematic therapy using SCS, such as Parkinson, and chronic pain. Electrodes underwent wettability and electrical impedance tests before and after 48 h of electrical stimulation in saline solution 0.9% at a frequency of 100 Hz, and 1.6 mA intensity. Wettablity test was performed to quantifying the hydrophilicity degree as a biocompatibility parameter. Both the silicone paddle and the platinum contacts have shown hydrophobicity before and after stimulation, as desired for implantation in soft tissue such as the spinal cord tissue. Electrical impedance test showed that electrochemical interactions did not cause lack of electrical behaviour consistence.

**Title:** Circuits in the retina: A deep learning framework for biological modeling and experimental design

**Authors: *D. BAGHERIAN**, T. KIM, Y. YUE, M. MEISTER
BBE, Caltech, Pasadena, CA

**Abstract:** Circuit neuroscience aims to describe the computations performed by groups of interconnected neurons in the way one might think of an electronic circuit board. Individual components connected in myriad different patterns can perform arbitrarily complicated transformations of an input signal. In light of the great complexity of the brain and given that its connectivity is at best partially known, a rigorous modeling paradigm is needed to generate a comprehensive list of circuit hypotheses that meet biological constraints and explain electrophysiological data.
We have developed a technique that employs a convolutional neural network (CNN) to fit the relationship between input and output of a neuronal circuit. By rigorously pruning away the synapses in its hidden layers, the network can infer the inner structure of the circuit. Unlike a typical machine learning application, the goal of this deep learning problem is to learn the structure of the neuronal circuit, not simply to predict its output. Success depends heavily on regularization by partial knowledge of the brain structure under study. We apply this technique to ON-OFF direction selective (DS) circuits in the retina, where we have a great deal of anatomical and physiological foreknowledge with which to constrain the CNN model, as well as direct access to the circuit input (visual stimuli) and output (retinal ganglion cell firing).
Given a limited predetermined set of standard stimuli, it is likely that many such CNN models will explain retinal responses equally well. Hand in hand with the development of this modeling paradigm, we aim to improve the efficiency of electrophysiological experiments by optimizing stimulus selection to quickly eliminate ambiguities in the CNN model structure. We investigate an algorithmic sequential experimental design paradigm in which a CNN model is adapted continuously during a retinal recording. At each training iteration, the next stimulus is selected based on uncertainty inherent to the current, partially-trained CNN. This active learning method reduces the experimental time necessary to resolve differences between hypothesized circuit models. The goals of rigorous model selection and adaptive experimental design complement each other in the pursuit of a better workflow for understanding neuronal circuits.

**Title:** Multi-input deep learning models for brain computer interface headset transfer

**Authors: *A. SOLON**[1], S. M. GORDON[2]
[1]DCS Corp., Aberdeen proving ground, MD; [2]DCS Corp., Alexandria, VA

**Abstract:** As brain computer interfaces (BCIs) move toward ‘big data’ approaches, models must learn across different users, experiments, and potentially different electroencephalography (EEG) headsets. While user-to-user transfer learning (TL) is actively researched, TL’s use in cross-experiment and -headset learning remains relatively untouched, as does the use of deep learning (DL) methods for these BCI transfer problems. Building upon EEGNet, a user-independent DL-BCI model, we investigate the cross-headset problem and introduce a multi-input EEGNet variant which can learn across headsets that vary in both electrode number and layout. We validate our approach by improving the performance of a lower performing ‘target’ dataset (collected from one headset) by augmenting the learning process with a higher performing ‘source’ dataset (collected from a different headset). Our target dataset (N=109) was recorded using 64 channels (Physionet Motor Movement/Imagery dataset). When cued, subjects imagined right/left hand movement in 4s increments; we extract trials [1.0s, 3.0s] and [2.0s, 4.0s] post cue onset (45 trials per class, per subject). Our source dataset (N=9) was recorded using 22 channels (BCI Competition IV dataset 2a). We extract trials [0.5s, 2.5s] post cue onset for right/left hand motor imagery trials (144 trials per class, per subject). Each dataset was downsampled to 128Hz and bandpass filtered between 8- 30Hz to remove ocular artifacts. We generate 30 folds of the target dataset (15-40 training, 30 validation, and 15 test subjects). In addition to the available target training data, the multi-input headset transfer model is also trained on all available source data. This headset transfer model learns, per headset, a set of unique spatial filters in its first layer, but shares identical architecture and parameter updates for the remaining, higher level layers. We see a significant improvement (+.02 AUC, p < .05) compared to baseline performance at all target training set sizes, indicating that this novel approach can train a model on, and successfully transfer knowledge between, multiple unique headsets.

**Abstract:** The brain contains multiple neuron cell types which can be classified in different manners based on their morphology, electrophysiological characteristics, and gene expression. Extracellular recordings from large population of neurons in awake animals is widely used, but classification of neurons with this technique is limited to *putatively* excitatory or inhibitory units based the spike shape. Narrow waveforms are considered to be fast spiking inhibitory neurons and broad waveforms excitatory neurons. Thus, a lot of potential important information is not extracted from these large datasets. The aim of this work is to use the rich spatial information from high density Multi-Electrode Array (MEA) (e.g. from Schröder et al. 2015) to make such classification more robust and also be able to classify subtypes of excitatory and inhibitory neurons. To achieve this, we first built, in simulation, a large dataset of action potentials from detailed neural models (Markram et. al 2015) from a multitude of neuron cell types of various morphological and electrophysiological phenotypes (for example different pyramidal cells, basket cells, bitufted cells, double bouquet cells, bipolar cells). Then we extracted spike features from the simulated recordings on a 10x10 MEA model with inter-electrode-distance of 15 μm. Finally we used such features, as spike amplitudes and width, as input for a deep learning algorithm, namely Convolutional Neural Networks (CNN), to classify the different cell types. Compared with the *ground truth* data from the simulated dataset, the results show that this forward modelling/machine learning approach is very robust in recognizing excitatory and inhibitory spikes and to a certain extent, correctly classifies different cell subtypes. As the detail and fidelity of neural models increase, this approach could become a viable and robust alternative for classification of neural cell types from in-vivo extracellular recordings.

**Title:** When to use what algorithm: An empirical exploration of machine learning for prediction with neuroimaging data

**Authors: *L. JOLLANS**, R. WHELAN
Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

**Abstract:** Background: With the increasing availability of large neuroimaging datasets, neuroimaging researchers have adopted machine learning analysis approaches developed for data science. However, there has been no empirical exploration of the strengths and limitations of most analysis tools that are already being used for neuroimaging research.
Method: Here we compared cross-validated linear regression accuracy of standard multiple regression (MR), regularized regression via the Elastic Net (EN), and random forest (RF). Analyses were carried out using simulated neuroimaging data. Sample sizes (N) varied between 75 and 2000, and number of input features (F) varied between 75 and 1000. We also evaluated if the addition of feature selection (FS) and bootstrap aggregation (bagging) improved accuracy.
Results:RF and EN outperformed MR, particularly when F≥N. There were no large differences between EN and RF. EN was less likely to outperform MR with small N, and RF slightly outperformed EN for N≤200. FS improved performance of MR for N=75 and large F, and bagging improved performance of MR when F>N. FS and bagging both improved performance of EN for N≤400, with no consistent additive effect of using both approaches simultaneously. FS reduced performance of RF. Bagging could not be implemented for RF.
Discussion:Machine learning is a substantial improvement over traditional methods such as MR and can produce reliable results even with high-dimensional neuroimaging data. EN and RF are both prefereable to traditional MR, and EN but not RF can be enhanced using additional machine learning techniques. Small datasets benefit more from these techniques, but combining multiple approaches is redundant. Due to the readability of models we recommend EN for use in neuroimaging models.

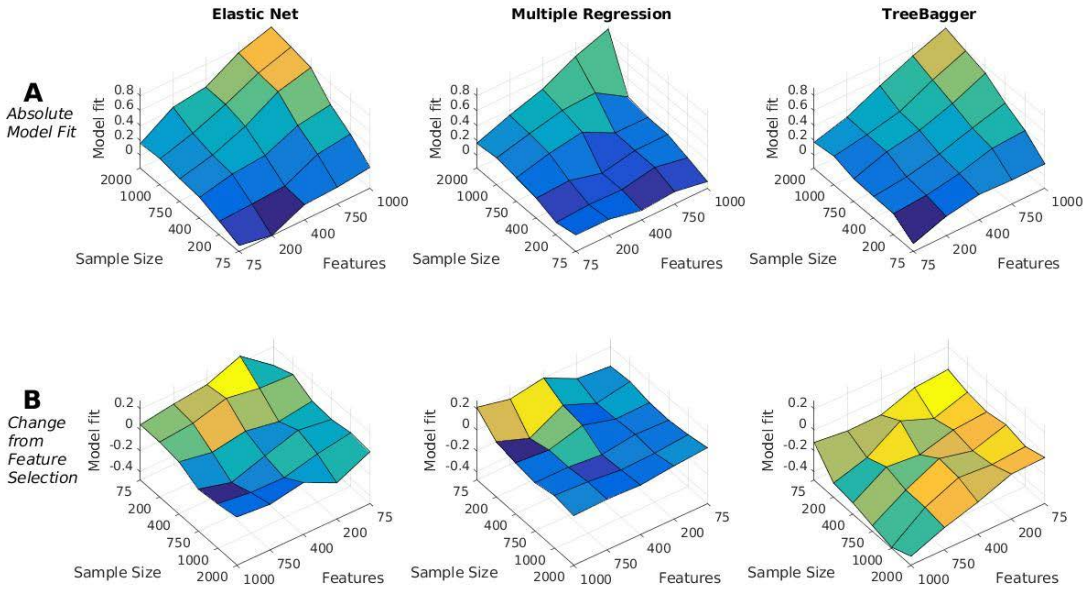

*Figure 1. Model fit across sample sizes and number of input variables for the Elastic Net, standard multiple Regression, and random forest. Model fit is the correlation between predicted and actual values. A: Absolute model fit for EN, MR, and RF. B: Change in model fit from adding Feature selection to each approach.*

For Learning & Memory, MIT and MGH, Cambridge, MA; [8]MIT, McGovern Inst. Brain Res., Cambridge, MA

**Abstract:** In order to use behavioral observations of freely moving animals for neuroscience research, objective measurement and quantification is essential. In the context of vocalization studies involving the common marmoset monkey (Callithrix Jacchus), data processing tends to take the form of analyzing hundreds of hours of audio recordings. Processing this data manually has several drawbacks, such as being slow, labor-intensive, imprecise, and subjective. We present a software framework for automated Animal Call Detection and Classification (ACDC), designed for researchers to be able to easily train and utilize models to turn hours of recordings into structured data that specifies the type and time-stamp of each animal vocalization. There are two main tasks that this software performs: detection, and classification. The detection task involves determining which segments of the audio include relevant animal vocalizations, while

rejecting environmental noise, audio artifacts, human voices etc. The classification task involves taking these extracted audio segments and categorizing them into the types of vocalizations the software has been trained to detect. In order to train ACDC, a “call dictionary” of audio samples of each type of vocalization, as well as samples of noise, is provided. The detection approach then utilizes traditional audio feature extraction techniques in combination with a neural-network-based model to learn from these samples and provide a set of timestamps specifying where vocalizations were detected. The classification approach, in turn, mimics how a human might classify these distinct sounds. Since different types of vocalizations tend to have a unique, easily recognizable shape to their spectrogram, we treat this as an optical character recognition problem. We converted spectrograms into images and trained a convolutional neural network to perform classification on the resulting shapes. We used ACDC to analyze audio from small groups of marmosets, training the models to detect the five or so most common types of vocalizations. Our initial results are promising, reaching > 80% accuracy on the detection task and better than 90% accuracy on the classification task. Our priority for further work is to continue to improve accuracy, while keeping the code clean, modular, and adaptable for use by other researchers, with a view to open sourcing in the future.

**Title:** Learning multi-layer and feedback network structures in mu-ECoG data

**Authors: M. SAHRAEE-ARDAKAN**[1], *A. FLETCHER[1], M. TRUMPIS[2], B. BENT[2], J. VIVENTI[2]
[1]UCLA, Los Angeles, CA; [2]Electrical and Computer Engin., Duke Univ. Dept. of Electrical and Computer Engin., Durham, NC

**Abstract:** Micro-electrocorticography (mu-ECoG) now offers the possibility of recording brain activity over large cortical regions at high spatial and temporal resolutions. However, using these recordings to develop accurate functional models of neural circuits and their responses to stimuli remains challenging. The underlying neural systems are composed of tremendous numbers of

functional units with complex, nonlinear dynamics and interactions. This abstract proposes a novel approach for identification of complex dynamical network models from high-dimensional time series data that is particularly well suited for neural modeling. The key concept is to decompose large-scale systems into networks of low-dimensional linear dynamical subsystems, with memoryless, scalar nonlinear feedback elements, and memoryless, linear interactions. The model, which we call Dynamic Neural Networks (DyNNets), readily applies to a wide range of meso-scale models of neural processes including neural mass models and multi-layer models with or without feedback. We show that the decomposition structure of the proposed DyNNet model greatly reduces the computational challenges in learning large-scale systems. In particular, the posterior density of the hidden states given the unknown parameters of a DyNNet admits a factorable structure that separates the linear dynamics, memoryless nonlinearities, and linear interactions. This factorization enables efficient implementation of MAP state estimation and system identification via the alternating direction method of multipliers (ADMM). The methods are illustrated in learning multi-layer models of the rat primary auditory cortex (A1) using a high-resolution flexible electrode array. The array has 61 electrodes with 400 mu-m spacing. Importantly, these arrays are both flexible and non-penetrating, enabling the arrays to be scaled up to record and stimulate larger areas of the cortex without damage, allowing observations in the changes in the model over durations of months to years.

**Title:** Deep dynamic programming: Learning state-action space on-line to rapidly generate optimal controllers

**Authors: *A. LONSBERRY**, A. LONSBERRY, R. QUINN
Case Western Reserve Univ., Cleveland, OH

**Abstract:** Current model-free learning (machine-learning) systems rely on observable state/action pairs recorded in memory for decision making. In most scenarios, memory of the environment, state, and actions is saved for a fixed number of time-steps. The cost-to-go for the remembered states is only updated if the current state has a reward value associated with it. Systems of this type may not be able to well optimize a controller over a large state-space given

the necessity for large memory and the need to visit much of the state-space. Generally, these approaches are time intensive, especially if the state and action spaces are continuous. To alleviate these issues, we deploy a more biologically inspired system of disjoint deep neural networks that learn and are able to generalize about the environment on-line. The learned knowledge about the environment is then leveraged to more quickly generate a control policy. We present a new method for model-free continuous update control, called Deep Dynamic Programming (DDP), which expands upon the Q-learning structure and dynamic programming. Q-learning only updates the cost-to-go function once a reward state is found and only based on the most recent set of states visited and stored in memory. DDP expands on Q-learning by *also* generating updates to the cost-to-go function for other state-space regions not recently visited by an agent. As an agent explores state-space, it simultaneously learns about itself and the environment. This knowledge of state-action space is encapsulated in a set of neural networks, where each network is responsible for a limited part of the entire state-space. This learned model of state-action space provides the ability to update the cost-to-go function on state spaces that have not been observed or have not been observed recently enough. That is, using the learned model of state-action space, we perform local updates to the cost-to-go using backwards induction. This inclusion of environmental modeling and generalization about the cost-to-go locally provides for rapid generation of control policies.To demonstrate the applicability of this technique, a controller was developed for an underactuated double inverted pendulum moving on a cart. The system was able to learn how to swing both pendulums into the upright position and keep them stabilized against disturbances.

**Title:** Transfer learning model of sensory inputs in the external plexiform layer network of olfactory bulb

**Authors: *A. BORTHAKUR**, T. A. CLELAND
Psychology, Cornell Univ., Ithaca, NY

**Abstract:** Recurrent interactions between mitral and granule cells in the external plexiform layer (EPL) of the mammalian olfactory bulb (OB) transform primary odor representations before relaying them to targets such as piriform cortex. Specifically, EPL lateral inhibition appears to both decorrelate overlapping primary odor representations and transform their underlying coding metric into a dynamically regulated spike timing-sensitive form. We sought to determine experimentally supportable rules for activity-dependent plasticity in the EPL that enable pattern separation among highly-overlapping odor representations, including γ/β-band dynamics and the phase-constrained spiking of mitral cells. We began by assessing the effect of timing-dependent learning rules at EPL recurrent synapses. We show that an asymmetric spike timing-dependent plasticity (STDP) rule in the excitatory (mitral-to-granule) synapses of this network can generate higher order receptive fields(HORF) in granule cells, enabling them to learn patterns of covariance derived from the external environment. In addition, an asymmetric inhibitory STDP rule in the granule-to-mitral cell synapses trains the network to competitively inhibit weakly activated MCs in an odor-specific manner. The weight matrices produced by these learning rules greatly improve the capacity for the multi-class classification of odor stimuli, including their statistically determined generalization gradients, and reduce or eliminate the cross-contamination of plasticity among odorants with overlapping primary receptor activation profiles. Moreover, as this algorithm necessarily consumes granule cells via irreversible differentiation, our simulations indicate that a supply of new, undifferentiated neurons via adult neurogenesis is required for the sustainable operation of odor learning in this network. We therefore offer a theory of the utility of OB adult neurogenesis. Finally, we propose that these irreversibly differentiated GCs serve as informative priors for future odor encounters (transfer learning), facilitating the detection and identification of odors of interest within unpredictable, high-noise environments.

**Title:** A local supervised learning rule protects memories from catastrophic interference during subsequent unsupervised learning

**Authors: *A. J. DECOSTANZO**[1], T. FUKAI[2]
[1]RIKEN, Wakoshi, Japan; [2]Brain Sci. Inst., RIKEN, Wako, Japan

**Abstract:** While human memory is remarkably persistent in the face of new learning, artificial neural networks suffer from 'catastrophic interference', the rapid forgetting of prior memories upon acquisition of new ones. Furthermore, much of human learning occurs without supervision - that is, without a label for every example of some category. Yet it is difficult to achieve such 'unsupervised learning' in artificial networks in a way that clearly improves their performance. These two difficulties suggest that human memory may be encoded with learning rules other than those currently employed in training artificial neural networks. Though these problems may seem distinct, we present a learning rule that reveals a close relationship between successful unsupervised learning (that which improves accuracy on hold-out test examples) and the avoidance of catastrophic interference.

**Abstract:** Whole Brain Architecture (WBA) is considered to be a good candidate for the cognitive architecture of an artificial general intelligence (AGI) computing platform which consists of empirical neural circuit information in the entire brain. It is constructed with the aim of developing a general-purpose biologically plausible AI to exert brain-like multiple cognitive functions and behaviors in a computational system. The goal of our brain-inspired AGI is to develop a software program that can learn and adapt to the environment similar to the way humans do. It will provide innovative solutions in a variety of fields without deploying problem-specific algorithms. We have created a neuroscientific design of the reference architecture called Whole Brain Connectomic Architecture (WBCA) built by utilizing experimental connectomic data acquired from three-dimensional microscopic brain imaging techniques. It includes static information on wiring diagrams of the brain neural circuits with directed graphs to determine neural network flows. We have developed particular functional machine learning modules corresponding to specific brain regions along with the connectomic information, including parts of the cerebral cortex, thalamus, hippocampus and basal ganglia. Those computational modules

we developed are designed at the mesoscopic level neural connectivity, and the individual modules are connected based on the topology of the neural circuits in the brain. We have developed and implemented several functional machine learning modules in collaboration with neuroscientists and developers. Therefore, WBA can help accelerate the development of AGI algorithms on the open platform which has been based on the biological neural circuits.

**Title:** Application of game theory and optimization techniques to intelligent decision making

**Authors:** ***H. C. YUAN**[1], M. CHAO[2]
[1]Independent Lab., San Marino, CA; [2]Independent Lab., Rancho Palos Verdes, CA

**Abstract:** Past studies in neurobiology have used game theory to explore how behavior may require decision making strategies (Alan Sanfrey, “Social Decision-Making: Insights from Game Theory and Neuroscience”, Science Oct 2007). This poster examines how game theory can be applied to a model of human decision making. Game theory is a branch of mathematics that deals with the analysis of games or situations involving parties with conflicting interests and strategies. Game theory can provide an objective, computational tool to intelligently decide and manage these strategies. The principles of game theory has many applications to real-world

problems as diverse as economics, politics, and avionics. Classical game theory features both hidden information and chance elements which contribute to the intelligent decision process. The intelligent selection of strategies in a game usually strives to achieve an objective that is either maximized or minimized, or even a saddle point. The selection of various strategies among opposing players or teams could be considered as a zero-sum game. The level of success of a selected strategy means the equal level of failure of the corresponding strategy in a zero-sum game framework. Together with game theory, linear programming is a method that could be employed to compute the best allocation of strategies to competing activities when expressed as a game aimed to achieving a linear objective function with linear inequality constraints. A linear program is setup with variables, a linear objective function indicating the contribution of each variable to the desired outcome, and a set of linear constraints describing the limits of the variables. The "answer" to a linear program is a set of values for the problem variables that results in the best, largest or smallest, value of the objective function and is consistent with all the constraints. This poster investigates how intelligent decisions can be considered as deciding among strategies to achieve an objective. An application to airborne avionics for radar sensor management and strategy management in surveillance, reconnaissance missions, and combat defense strategies is also given. This poster further examines the use of game theory in an avionics and sensor resource example with a 2-player zero-sum framework for intelligent selection of strategies, and the use of linear programming to compute best allocation of resources and strategies.

**Title:** A dynamic perceptron model

**Authors: *N. GRAYSON**, G. SILVA, V. GEORGE, F. PUPPO
Electrical Engin., UCSD, La Jolla, CA

**Abstract:** Since their conception, Neural Networks have been built of decision making nodes. Hopfield Networks, for example, have used perceptrons which function as simplified models of Neurons. Networks of these perceptrons have a storied history of success in recent years and have, in part, redefined Machine Learning and Artificial Intelligence as fields. We present and construct a dynamic model of a perceptron by extending the existing model to include the additional parameters of signaling delay, refractory period, and dendritic decay.Signaling delay is a simplification of the travel speed and the physical path between neurons. Refractory period is

a time after which a node activates that it can not activate and it ignores input stimulus. When a node is non-refractory and therefore able to receive signals, these signals each contribute to the node's activation energy. Unlike classical perceptrons which sum inputs at each time step, these dynamic perceptrons have a 'memory' of received signals. Signals received further in the past contribute less to activation threshold than recently received signals. This lessened contribution is modeled through a dendritic decay function.The addition of parameters to the classic model of a perceptron naturally leads to an increased number of possible states (refractory, halfway to activation, etc). As such, in (ref), we prove that this dynamic model of a perceptron is able to encode more information. By extending the architectures of Hopfield Networks, Liquid State Machines, and other recurrent networks into the time domain and using our dynamic model of a perceptron, we create trainable dynamic networks.

**Title:** Drowning in Data: Using predictive analytics to advance outcome measures in neurosciences research settings

**Authors: *A. L. ORTIZ-VELEZ**[1,2], A. MARCUZ[3]
[1]Col. of Grad. Studies, Pontifical Catholic Univ. of Puerto Rico (PUC, Jacksonville, NC; [2]Stress Motivated Behavior Inst., Syracuse VA Med. Ctr., Syracuse, NY; [3]Natl. Interpid Spirit of Excellence, Intrepid Spirit Concussion Recovery Ctr., Naval Hosp. Camp Lejeune, Jacksonville, NC

**Abstract:** Preamble
Data, the most used word in research today, but, are we making the best of what we collect? Are we using it effectively to advance the field of neuroscience?
It is the intent of this researcher presentation to stir the mind of neuroscientists on how to expand and advance the neuroscience field by partnership with Data and Computer Science professional(s) to catapult neuroscience to the future of outcome measures. The neuroscientist, choose the data of interest, the computer scientist implement this method of analyzing the collected data samples.
Using regression and predictive analytics models, we can generate predictive outcomes. The method described here does not require expensive and sophisticated proprietary software applications, but it requires partnering of two different but alike disciplines Neuro Medical professional and Computer Science Data Analyst who creates the analytical "engine" for

processing the data.

Method

By using the underlying software interface available on most computers (which is used to generate documents or spreadsheets whether proprietary or Open source) the computer science professional collects the data samples that the Neuroscience professional(s) have recorded. The Computer Science professional creates an analytical engine method which will analyze the intake and outcome data, perform regression analysis, generating statistical modeling. By further associating the statistical analysis with outcome creates a predictive model of outcome.

This method model can be further tuned or re-adjusted after the predictive analysis is performed. The analysis is restarted and quickly the output can be reviewed and evaluated by Neuroscience professionals.

Conclusion

By levering the method and collaborative spirit described in this abstract, neuroscience professionals can greatly advance positive neuroscience clinical outcomes, increase patient wellness and improve data reliability.

**Title:** Robust reservoir computing achieved by self-organized criticality

**Authors: G. ZENG**, X. HUANG, T. JIANG, *S. YU
Brainnetome Ctr., Inst. of Automation, Chinese Acad. of Sci., Beijing, China

**Abstract:** It has been suggested that, through short term synaptic plasticity, neuronal dynamics in the brain are self-organized close to a critical state, which brings various functional advantages in terms of information processing to the system. Inspired by such an idea, here we investigate if and how self-organized criticality (SOC) can improve the performance of a recurrent artificial neural network (RNN) in information processing. To this end, we implemented short term synaptic depression into RNNs in different models of reservoir computing (RC) and tested its effects on sequence memory as well as pattern recognition tasks. We found that a simple form of plasticity greatly expanded the parameters range within which the RC models can perform well. In addition, it makes the system more robust to input noises. These results are achieved through dynamically maintaining the reservoir close to a critical state. Our study suggests that the SOC framework can be instrumental in optimizing the design of RNNs. In addition, these results shed new light on the functional benefits of short term synaptic plasticity for neural networks.

**Title:** Tools for registering 11T ex-vivo MRI of the human medial temporal lobe to a standard atlas coordinate system

**Authors: *D. J. TWARD**[1], T. BROWN[2], B. LEE[1], J. T. RATNANATHER[2], S. MORI[3], J. C. TRONCOSO[4], M. MILLER[1]
[1]Biomed. Engin., [3]Radiology, [2]Johns Hopkins Univ., Baltimore, MD; [4]Neuropathol Lab., Johns Hopkins University, Sch. of Med., Baltimore, MD

**Abstract:** The structures of the medial temporal lobe, such as the amygdala, hippocampus, entorhinal cortex and transentorhinal cortex, constitute the locus of some of the earliest anatomical changes in Alzheimer's disease. Because definitive diagnosis of this disease is made by examining neuropathology at autopsy, establishing reliable clinical neuroimaging biomarkers of the disease is difficult. Our work begins addressing the challenge of uniting clinical imaging and autopsy findings by developing computational tools for registering high field strength MRI of ex-vivo specimens to a standard coordinate system.
We chose the Mai-Paxinos atlas as such a standard, as it is commonly used by pathologists, radiologists, as well as neuroscientists. A surface model of the hippocampus, amygdala, and entorhinal cortex was constructed by first manually segmenting each slice; second rigidly aligning slices to remove small displacements and rotations; and third nonlinearly interpolating between slices by constructing a flow of deforming images to match neighboring slices using large deformation diffeomorphic metric mapping, and sampling the flow at arbitrary locations between them (Fig. 1a-b).
A medial temporal lobe was cut into 3 blocks for magnetic resonance imaging in the small bore of an 11T scanner. The B0 images of each block were rigidly aligned to reconstitute the medial temporal lobe (Fig. 1c), and structures of interest were manually segmented. Surface models were generated and aligned rigidly to the Mai-Paxinos surfaces (Fig. 1d). This transformation was applied to the aligned ex-vivo images (Fig. 1g-h), allowing visualization in standard coordinate system (Fig. 1e-f).
This framework will be used for ex-vivo imaging of up 20 to brains over the next two years, and will be expanded to place Nissl, amyloid, and tau histology of the ex-vivo specimens in the same coordinate system. These tools will be important for demonstrating a direct link between clinical neuroimaging biomarkers and autopsy findings.

**Title:** Application of a novel CLARITY-MRI pipeline to mPFC projections improves connectivity mapping

**Authors:** ***M. GOUBRAN**, C. LEUZE, B. HSUEH, M. ASWENDT, L. YE, Q. TIAN, M. CHENG, A. CROW, G. STEINBERG, J. MCNAB, K. DEISSEROTH, M. ZEINEH
Stanford Univ., Stanford, CA

**Abstract:** **Background**:
Neural networks are altered in many disorders, with implications on the affected region and connected areas. Connectivity atlases based on 2D serial sections are exceedingly valuable resources. However, they do not allow for 3D tractography and terminal zones computation, i.e. distinguishing passing fibers from endpoints (representing synapses). We present an automated resource that allows the assessment of wiring by comparing viral tracing with atlases, and investigation of circuitry based on CLARITY projection terminals.
**Methods:**
We developed a novel pipeline for the connectivity analysis of CLARITY, imaging and mouse atlases. We applied our pipeline to focal stereotactic injections of adeno-associated virus expressing fluorescence protein in the mPFC, to study efferent axonal projections. These

projections were quantified using structure tensors analysis (STA) from the CLARITY images. Terminal maps were automatically generated by computing the number of STA-based streamlines ending in a voxel after tractography, as implemented in *MRtrix3* (**Fig. 1a**). The number of terminating streamlines was then summed per registered atlas label.

**Results and Discussion:**

While connectivity based on tract density (passing fibers) suggested a stronger connection between mPFC and anterior cingulate area (ACA) than ventral tegmental area (VTA), terminal maps revealed a higher number of fibers terminating in the VTA (5.32x) (**Fig. 1c, d**). Similarly, caudoputamen (CP) is shown as a major node based on tracer signal while it is demonstrated to be less prominent based on terminating axons (283k passing vs. 121k terminating) (**Fig. 1d**). To validate our CLARITY streamlines we compared our tract density-based network graph with the graph representing projection density from the prelimbic area (PL) of the Allen connectivity atlas (**Fig. 1d**). A high overlap of 74 % was found between the two experiments. These results are in good accordance with literature of the reward network, which highlights the importance of connectivity based on terminals and its implications on connectome analysis.

Hospital), Charlestown, MA; [5]Dept. of Applied Mathematics and Computer Sci., Tech. Univ. of Denmark, Lyngby, Denmark; [6]MIT, Cambridge, MA

**Abstract:** The human thalamus is subdivided into several nuclei with concrete functions and connectivity. Segmentation of these nuclei can enable neuroimaging studies with higher specificity, compared with analyzing the whole thalamus. Previous work on automatic segmentation of thalamic nuclei relied on clustering diffusion MRI data, supervised classifiers, and non-probabilistic segmentations derived from delineations on histological samples. Here we present a probabilistic atlas of 33 thalamic nuclei and surrounding tissue built from MRI and histology data. Compared to previous work our atlas has the advantages of being probabilistic, modeling surrounding anatomy, and that it can be used in a Bayesian inference framework to segment MRI scans of arbitrary contrast, even if multimodal. Six formalin-fixed human brains were first scanned with a 3T scanner (multi-slab balanced SSFP, 0.25 mm isotropic). Coronal slices (~10 mm thick) were cut, and blocks containing the thalamus were further dissected,

cryoprotected and sectioned at 50-μm thickness, while taking block-face photographs. Every 10th slice was mounted, Nissl stained (thionin), and digitized at 4-μm resolution. An expert neuroanatomist (RI) traced 33 thalamic nuclei on the scanned images. The block-face images were perspective corrected, stacked and rigidly registered to the MRI. MR images were then resampled to the plane corresponding to each histological slice, and nonlinearly aligned the 2D image pairs. The concatenation of the rigid and nonlinear transforms provided a mapping between histology and ex vivo MRI, which was used to warp the manual delineations to MRI space and recover their 3D structure. The gaps between blocks were filled by combining a Gaussian mixture model with a Markov random field. Finally, the atlas was built merging the "filled" segmentations with manual delineations of 36 structures in 39 *in vivo* T1 scans. The atlas was encoded in an adaptive tetrahedral mesh endowed with a deformation model that effectively preserves its topology. A Bayesian segmentation algorithm was also implemented that combines the atlas with a likelihood term and is adaptive to MRI contrast. Using the probabilistic atlas, our segmentation method produces volume estimates of individual thalamic nuclei as well as masks that can be used as seeds for tractography or fMRI analysis. Future work will adapt the likelihood term so that the algorithm can handle diffusion MRI data and evaluate the performance of the segmentation with large datasets. The atlas and companion segmentation algorithms will be made publicly available as part of FreeSurfer.

**Abstract:** Tracing neurons in microscopy data is necessary to create circuit diagrams of the brain. Automatic techniques often fail for large and complex datasets (Peng et al. 2011) and connectomics researchers may spend weeks or months manually tracing neurons using 2D image stacks (Ascoli 2008). Here we present a new virtual reality (VR) system to trace neurons rendered in 3D from microscopy acquired image stacks. We hypothesized that using consumer-grade VR technology to navigate and trace neurons directly in 3D would increase the speed and ease of resolving complex cases and cause less physical and mental strain for the user. To test this hypothesis, we compared tracing accuracy and speed in VR versus the 2D desktop-based tracing tool Neurolucida. We explored different rendering, interaction, and navigation methods in VR, as well as the use of force feedback to improve the quality and speed of neuron tracing. Our VR tool also provides a scalable and flexible paging system built on the IDX file format (Pascucci and Frank 2001) to allow for interactive exploration and tracing of terabyte-sized datasets. The included figure shows a user's view in our tool (background changed to white to improve contrast).
In a set of trials we asked 4 experienced users of Neurolucida software to trace a series of publicly available fluorescently labeled neuron image stacks (DIADEM challenge, Neocortical Layer 1 Axons dataset) in both VR and on a desktop using Neurolucida. For each trial we measured the time it took users to complete the tracing as well as their tracing accuracy compared to the DIADEM reference tracings. We found that overall, there was no statistically significant difference between accuracy scores in VR vs. Neurolucida ($p=0.097$), however VR allowed for faster tracing. Specifically, in cases where subjects produced equivalent quality tracings in both tools, there was a statistically significant speedup in VR, with users being on average 1.7x faster in VR than in Neurolucida ($p=0.005$). We conclude that 3D VR tracing presents a promising alternative to current 2D desktop-based tracing approaches.

**Title:** A computational framework for automated neuron tracing using scalar field topology

**Authors: A. GYULASSY**[1], F. FEDERER[2], A. VENKAT[1], V. PASCUCCI[1], *A. ANGELUCCI[2]
[1]Scientific Computing and Imaging Inst., [2]Ophthalmol, Moran Eye Inst., Univ. of Utah, Salt Lake Cty, UT

**Abstract:** Obtaining a wiring diagram of the brain is crucial to understand brain function and dysfunction at a mechanistic level. As techniques improve, it is becoming increasingly feasible to obtain high-resolution images of macro-scale regions of the brain. However, the great complexity of neural circuits in the mammalian brain makes manual reconstruction time-consuming and impractical, therefore automation is required to sustain data collection and make significant progress in the field. Nevertheless, automatically extracting a wiring diagram from vast amounts of image data continues to be a challenge for researchers. In this work, we introduce a new computational framework for automated and semi-automated extraction of labeled neurons based on scalar-field topology. We have begun applying this framework to extract single neurons in networks sparsely labeled using an AAV9 carrying the gene for green fluorescent protein in tissue blocks of primate visual cortex cleared using the PACT technique (Yang et al. 2014) and imaged on a 2-photon microscope.
The Morse-Smale complex (MSC) is a multi-scale topological structure that extracts the gradient flow behavior of a scalar-valued function. It contains critical points, such as maxima, saddles, and minima, arcs representing ridge- and valley-like structures, as well as spatial decompositions. Recent advances in the ability to compute the MSC for large data has made

application to neuroscience possible. We compute the MSC and use its critical points and arcs as a scaffolding for subsequent computation of wiring diagrams. The arcs of the MSC initially represent every possible ridge-like structure, recasting the problem of computing wiring diagrams to one of selecting which arcs correspond to axons and dendrites. As the graph structure is computationally light-weight, our system allows a user to adjust filtering thresholds interactively to extract labeled neurons and their processes. We plan to use the MSC to guide manual labeling, with the ultimate goal of full automation through machine learning.

**Title:** An online system for continuous image acquisition of long-range circuits in cleared primate cortex

**Authors: *A. VENKAT**[1], F. FEDERER[2], C. CHRISTENSEN[1], A. GYULASSY[1], A. ANGELUCCI[2], V. PASCUCCI[1]
[1]Scientific Computing and Imaging Inst., [2]Moran Eye Inst., Univ. of Utah, Salt Lake City, UT

**Abstract:** The primate brain contains billions of interconnected neurons forming complex circuits. The goal of the connectome is to create a wiring diagram of these circuits across the entire brain. Mapping the non-human primate brain at cellular resolution has become feasible due to the emergence of viral-vector-based high-resolution labeling of neurons, optical tissue clearing, and deep tissue imaging. But these advances introduce new challenges for data management and processing. Three such challenges impede the transformation of these datasets into a comprehensive map of neural connectivity: insufficient storage, lack of quality control, and alignment of hundreds of individual volumes. Raw microscopy data can be very large: 1024x1024 resolution images of the entire mouse brain at 20x-magnification are over 31 TB in size, and those of the macaque primary visual cortex (~6,000 $mm^3$), our target, are over 320 TB. Datasets of this size are infeasible to store and process using existing applications on the average PC workstation. More importantly, acquisitions of this size can take weeks or months to complete, yet most software packages don't provide an opportunity to perform any quality checks during acquisition, leading to errors, and thus wasted time and repetition of work. Finally, stitching and alignment of the images into a single volume is required, due to subtle sample movement and microscope stage imprecisions occurring over long acquisition times; but existing software packages for this task have high memory requirements and cannot directly utilize remotely hosted data. In summary, there exists a need for a unified software framework that works in synchronization with the microscope to seamlessly align and store multiple volumes in a format that allows researchers to assess their data quality and begin analysis during the acquisition process.
At SfN 2015, we presented the ViSUS platform addressing the challenges posed by handling large neuronal microscopy data for scalable analysis and visualization (Christensen et al. 2015). We have integrated the ViSUS technology with our two-photon microscope to facilitate online conversion of the image data to a 3d streaming format, allowing uninterrupted acquisition and immediate remote multi-user access to the data. To address the challenge of stitching terabytes of data, we have developed a robust strategy that uses Normalized Cross Correlation to compute 3d pairwise transformations between adjacent tiles during acquisition. This online processing facilitates efficient resource allocation, allowing users to explore and annotate well-aligned 3d volumes while ongoing acquisitions continue without interruption.

**Title:** Neurocircuitry changes in response to unconditioned fear in mouse models of PTSD

**Authors:** ***A. REVIERE**[1], R. E. JACOBS[2], E. L. BEARER[3,4]
[1]Pathology, Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Zilkha Neurogenetic Inst., USC Keck Sch. of Med., Los Angeles, CA; [3]Dept. of Pathology, UNM Sch. of Med., Albuquerque, NM; [4]Biol., Caltech, Pasadena, CA

**Abstract:** Post-traumatic stress disorder (PTSD) is a serious mental illness affecting up to 8% of the general population, including veterans and victims of domestic abuse. Neurological correlates include changes in the amygdala, hypothalamus, hippocampus, and various areas in the prefrontal cortex. We use manganese-enhanced magnetic resonance imaging of mesolimbic circuitry in living mice with SERT, DAT or NET gene knocked out (KO). We showed that the circuitry from the medial forebrain into the limbic system was altered in KO mice compared to WT, although in different ways. We hypothesize that loss of serotonin regulation will prolong neural activity in response to fear. We used exposure to predator odor, (2,3,5-Trimethyl-3-thiazoline) derived from fox anal gland, as a naturalistic validated approach for eliciting fear and leading to PTSD-like symptomology in rodents. WT littermates and SERT KO mice (12 each) were video recorded in a light-dark box, and pre-scanned in an 11.7 T Bruker magnetic resonance scanner to establish baselines. Each mouse was injected with $Mn^{2+}$ IP and scanned 24hr later to detect uptake of $Mn^{2+}$ in active neurons prior to fear provocation. Immediately following mice were exposed first to saline and then to a predator odor. Behavioral effects (freezing, grooming) were monitored. Neural activity was tracked by capturing MR images at 9d, re-injecting with $Mn^{2+}$ IP and re-scanning 24hr later to test for persistence of $Mn^{2+}$ intensity patterns and detect prolonged neural activity levels after fear in KO mice. Behavior in the light-dark box was monitored at each step. Using statistical parametric mapping (SPM) we compared images within-group between timepoints by paired t-tests (p=0.001 uncorr, 0.05 FDR) which detected strong signal in the paraventricular nucleus, hypothalamus and amygdala in SERT KO mice after 10 days compared to their baseline scans which appeared greater than WT. SPM

between group comparisons of $Mn^{2+}$-induced intensity changes demonstrated that location and intensity of neural activation is altered in the SERT KO compared to WT. An ROI analysis was done to determine the extent of difference in voxel intensity between groups at the 10-day timepoint. Activation of these brain regions was confirmed by c-Fos staining in immunohistochemistry of the same mice. The active brain regions elucidated here in the fear-induced SERT KO animals correlate to known behaviors reflecting PTSD-like symptoms such as avoidance and hyperarousal exhibited by these mice in light-dark box behavioral experiments. This is congruous to evidence implicating these areas in PTSD, both in rodents and in humans.

**Title:** NeuroGFX: A graphical functional explorer for fruit fly brain circuits

**Authors: *Y. ZHOU**, C.-H. YEH, N. H. UKANI, A. A. LAZAR
Electrical Engin., Columbia Univ., New York, NY

**Abstract:** Recently, multiple focused efforts have resulted in a substantial increase in the availability of genetic and connectome data for the fruit fly brain. To help infer the function of various *Drosophila* neural circuits from these data, we have developed NeuroGFX, a tool for scalable and collaborative computational modeling, and integrated it into the architecture of the Fruit Fly Brain Observatory (http://fruitflybrain.org) [1].
The computational infrastructure in NeuroGFX is provided by Neurokernel [2], an open source platform for the emulation of the fly brain, and NeuroArch [3], a database for querying and executing fly brain circuits. The integration of the two enables the algorithmic construction and manipulation of executable circuits on multiple levels of abstraction of the fly brain. The power of this computational infrastructure can be leveraged through a graphical user interface that allows visualizing execution results in the context of biological brain structure. This provides an environment where computational researchers can present configurable, executable neural circuits, and experimental scientists can easily explore circuit structure and function ultimately leading to biological validation.

NeuroGFX enables the exploration of the function of neural circuits at the whole brain, neuropil, and local circuit levels of abstraction. We applied NeuroGFX to the implementation of models of the early visual and the early olfactory systems and the central complex of the fly brain. As an example, we show in Fig.1 an executable cartridge circuit in the lamina neuropil of the wild type fly (top) and a reconfigured circuit that models the silencing of certain neurons (bottom). We demonstrate the usage of NeuroGFX for characterizing the I/O of the three systems and their constituent neuropils by executing a variety of underlying circuits.

**Title:** Fast learning-free 2D segmentation and 3D reconstruction software for sparse neuronal circuit tracing

**Authors: A. SHAHBAZI**[1], M. JOESCH[2], N. B. KASTHURI[3], *W. SCHEIRER[1]
[1]Computer Sci. and Engin., Univ. of Notre Dame, South Bend, IN; [2]IST Austria, Vienna, Austria; [3]Argonne Natl. Laboratory, Univ. of Chicago, Chicago, IL

**Abstract:** Recent innovations in different types of microscopy have turned imaging into a dominant strategy for data collection in neuroscience. For problems like sparse neuronal circuit tracing, the use of microscopy yields 3D stacks of images that can scale to petabytes of data for a single experiment, depending on the modality. But with this abundance of data has come major challenges in automatic data analysis. Machine learning methods, and especially deep learning-based algorithms, designed to automatically segment and reconstruct structures in the tissue are very slow to train over sets of manually annotated images. Moreover, due to constraints in annotator expertise, time and budget, machine learning models are usually trained on small stacks of manually annotated images instead of sufficiently large training datasets that can better represent the variance in the overall data. This has a negative impact on the resulting accuracy of the software.
Therefore we introduce a new fast learning-free method for automatic sparse 2D segmentation and 3D reconstruction of brain micro-structure. Different from prior supervised methods, our algorithm exploits cell-specific context clues and requires no extensive pre-training. The algorithm combines thresholded filters with graph-based matching to achieve its efficiency. Our approach works on different modalities and sample targets, including serial section electron microscopy of APEX2-positive processes and high-energy synchrotron X-ray microtomography of cortical volumes.
Experiments on newly published and novel mouse data sets demonstrate high precision and recall for the proposed algorithm, as well as reconstructions of sufficient quality for further biological work. Compared to existing supervised and unsupervised methods, it is both significantly faster (up to several order of magnitude) and comparable in segmentation and reconstruction performance.This is true even in cases where staining artifacts, grayscale inconsistency, noise and other artifacts negatively impact the prediction capabilities of machine leaning-based approaches.

Use cases for this new method span a number of different tasks. It can be used to create a first-pass reconstruction of a large area of tissue, or to produce comparison data that can be deployed as a sanity check for machine learning-based methods when ground-truth is not available for evaluation. Further, it is possible to rapidly verify image quality of multi-terabyte image stacks using this approach, and to create imperfect, but very large, training sets for deep learning methods without the need for human intervention.

**Title:** Summarization of a brain-wide data set of anterograde tracer injections in mouse using topological skeletonization

**Authors: *S. WANG**[1], X. LI[2], Y. WANG[1], P. P. MITRA[2]
[1]Computer Sci. and Engin., Ohio State Univ., Columbus, OH; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

**Abstract:** Following an initial proposal to map brain-wide connectivity at a mesoscopic scale, multiple data sets are now available or are in the process of being acquired in Mouse and Marmoset. The basic data sets contain 3D volumetric whole-brain images of tracer injections placed on a systematic grid spanning the brain. It has been customary to summarize these data sets in the form of regional connectivity matrices. However, such a representation is highly lossy and does not respect the fundamental tree-like morphology of the projection neurons underlying the inter-areal projections. We use computational topology methods, specifically discrete Morse theory, to skeletonize anterograde tracer injections in the form of tree structures rooted at the injection sites. Each such tree represents a consensus of the set of neurons that have somata

located at the injection site. The collection of these tree structures across the brain provide a richer summary of the tracer injection data set than a connectivity matrix.
The skeletonization of a tracer injection includes two main steps: (i) a detection step which serves to de-noise the raw data and retain only automatically detected axonal fragments or arbors, (ii) extraction of so-called 1-stable manifolds via discrete Morse theory. In previous work, we applied step (ii) to raw volumetric data, but encountered computational bottlenecks due to high computational complexity, preventing scaling to whole brains without significant loss of resolution. In the present work we employ a divide and merge approach to reduce the computational cost, and are able to process entire brain volumes without excessive downsampling. We first subdivide input images into smaller 3D tiles and construct the 1-stable manifold within each tile. We then perform a thickening and merging process by leveraging the same discrete Morse framework used to skeletonize data within the individual tiles. We apply this skeletonization procedure to summarize a brain-wide anterograde injection data set from the Mouse Brain Architecture Project containing 930 injections of AAV1/2 spanning the left hemisphere of the Mouse brain. The divide-and-merge works with simplicial complex inputs and may have applications beyond the neuron reconstruction problem.

**Abstract:** Three-dimensional (3D) visualization of microscopy images of the brain facilitates intuitive understanding of neuronal morphology and circuit connectivity. With the advent of readily available super-resolution techniques such as Expansion Microscopy (ExM, Science 347(6221):543-548), nanoscale imaging of large specimens producing terabyte-sized datasets is becoming commonplace. In order to help scientists investigate such large-scale datasets, we implemented a high resolution visualization system with an 8K rendering resolution (7,680 x 4,320 screen pixels), so that millimeter-scale and nanoscale features can be displayed at the same time. The system runs our custom volume renderer on a standard workstation equipped with commodity graphics processing units (GPU) and solid-state drives (SSD), driving an 85” large

format monitor with an optical multi-touch sensor for immersive and direct interaction with visualized datasets. In order to deal with terabyte-sized datasets and the 8K rendering resolution given the currently available off-the-shelf computing hardware, the renderer implements three levels of data caches, the first two of which reside on the GPUs for efficient utilization of the limited GPU memory while the last level is on the CPU main memory as a cache for the SSDs, since datasets we consider are much larger than the main memory. We split datasets into 128 x 128 x 128-voxel cubes along with multi-resolution representation to increase spatial data locality. Asynchronous prefetching of such formatted data combined with the aforementioned caching allows us to keep the data transfer rate to the GPUs, which would otherwise go up to 100 GB/s, well within the effective hardware link speed (PCI Express 3.0, x16 lanes) of around 10 GB/s. To demonstrate the system, we imaged a slice of a mouse hippocampus measuring 1.5 x 0.8 x 0.1 mm using ExM with a Zeiss Lightsheet Z.1 fluorescence microscope, leading to an effective imaging resolution of 60 nm via 4.5x physical specimen expansion. This yielded a 4-color, 5 TB dataset consisting of roughly 25,000 x 14,000 x 2,000 voxels. The rendering speed for this dataset is up to 7 frames per second depending on the viewpoint, allowing the user to interactively rotate and zoom into the dataset. The user can investigate the brain sample at a 60 nm resolution while maintaining a large portion of the sample (0.5 mm horizontal) on display, thereby keeping a good sense of cellular context and spatial orientation. Even when zoomed out and the entire dataset fits within the screen, the individual screen pixels still correspond to 180 nm at the specimen level, providing macroscopic and microscopic views simultaneously.

**Title:** Identification of driver regions in macaque brain network using controllability analysis

**Authors: *V. TRIPATHI**[1], R. BADHWAR[2], G. BAGLER[1]
[1]Ctr. for Computat. Biol., Indraprastha Inst. of Information Technol., Delhi, India; [2]Dept. of Biosci. and Bioengineering, Indian Inst. of Technol. Jodhpur, Jodhpur, India

**Abstract:** Cognitive state of brain is an emergent property arising out of interactions among brain regions. Neuronal connections serve as conduits of communication forming the underlying architecture giving rise to brain functions. Structural controllability analysis is a promising method for investigating control mechanisms of brain network and for finding 'driver regions' that are central to its control. Neuronal connectivity has been investigated for various animal systems including *C. elegans*, drosophila, zebra fish, cat and macaque. Within the limited data available, these studies have probed the structural organization and circuits in an attempt to infer their functional relevance. By investigating controllability of *C. elegans* neuronal network, the only complete connectome available till date, earlier studies have identified and characterized its driver neurons. *Macaca mulatta* is an extensively studied model organism having neuroanatomy very close to that of human. Tract tracing studies of macaque brain have been compiled in an accessible database called CoCoMac.

We constructed the Macaque Brain Network (MBN) using data from CoCoMac that encodes directional connectivity of brain regions. MBN comprises of 6602 directed connections among 360 brain regions spanning the brain. This network was observed to have small world nature with an exponential connectivity distribution. Using controllability analysis, we identified a total of 39 (24 distinct) 'driver regions' that are critical for achieving full control over the state of the network. Among them the major brain regions are: Thalamus, Prefrontal Cortex, Motor cortex, Caudal SMA, Broca's area, Granular retrolimbic area, Dorsolateral visual cortex, Orbitofrontal cortex, Visual area 3A, Amygdala, Posterior parietal area, Prestriate cortex, and Ventral occipito temporal area. These regions, associated with vision, attention, memory, motor, speech, information relay and sensory integration, emerged as critical for driving the brain network in any desired cognitive state.

**Abstract:** In the field of connectomics, a central goal is to reconstruct neural anatomical structure and synaptic connectivity from 3D volumetric data collected by applying various imaging techniques. With recent advancements in automated serial electron microscopy(EM) and micron-resolution Xray tomography(uCT), our ability to acquire images has increased tremendously in both resolution(10nm for EM, 1um for uCT) and volume(1mm2 for EM, 1cm2 for uCT). However, the amount and variety of data pose great computational challenges to our ability to process, analyze and approach biological questions.
A major part of the pipeline is to segment various features of interest from data of various modalities. Recent works often approach segmentation problem with a supervised deep neural network. We propose an end-to-end multi-purpose segmentation pipeline for neural data analysis based on fully convolutional neural networks. For uCT data, we are interested in segmenting cell bodies, blood vessels, and myelinated axons with the goal of reconstructing a coarse neural anatomical map, while for EM data, with much higher resolution, we focus on cell membranes and mitochondria which lead to full segmentation of neurites. We are also exploring solutions to several major challenges in connectomics: 1. Reliance on laborious manual labelling. We have developed a semi-automated training label preparation scheme that allows fast label proposal generation and minimal human correction. 2. Low transferability between different learning sessions. We observed that networks trained for EM and uCT share some resemblance in early layers. Also our fully convolutional design allows arbitrary input data size and retraining with data from different sources, which reuses trained weights and saves training time. 3. Swiftness in designing new neural network architecture. We used a highly modular design in generating neural networks, which allows easy generation of specialized neural networks for different scenarios and rapid testing. Apart from algorithm design, another push is to deploy and optimize the pipeline on high performance computing facilities.

**Abstract:** Computational models have been an integral part of the analysis of dynamical behavioral signals. These models are widely used in clinical and basic neuroscience research to infer underlying mental or cognitive states that shape behavior and study their correlates brain dynamics. Despite the importance of these models, a significant challenge is their development. Development of these models generally gets complicated and requires an extensive time for debugging and verification. A general modeling software toolbox would help researchers to perform their analysis without extensive code development, and would also provide a medium to assess parallel research outcomes. In this research, we introduce a computational modeling toolbox suitable for analysis of dynamical behavior signals. The toolbox utilizes a state-space modeling framework, which can model and process dynamical behavioral and physiologic signals from many modalities. The modeling output using the toolbox not only includes an estimate of the latent variables of interest, but also provides a set of goodness-of-fit analysis, which might be used in assessment and refinement of the models. Under the state-space modeling assumption, the mental or cognitive state dynamics over time is represented by the state-equation, and the behavioral signals are the observation process. The toolbox estimates both model free parameters and underlying mental or cognitive state. Behavioral signals might be a continuous signal such as reaction time, a discrete signal like decision choice, or a combination of continuous and discrete signals. Models can be fit to behavioral signals with Normal, Gamma, or Bernoulli (binomial) distributions, as well as mixtures of continuous and discrete distributions. The toolbox has utilities to deal with missing or censored data points. We demonstrate the

toolbox application in analysis of two different behavioral tasks. The first task is an associative learning task, where a subject learns multiple associations simultaneously. The objective is to infer a single "learning state" that estimates how well the overall set of associations has been learned, optimally integrating performance over all available stimuli. The second task is an approach-avoidance task designed to analyze schizophrenia patients' sensitivity to loss and reward. The objective is to combine common reinforcement learning models, "actor-critic" and "Q-learning", with the key parameter controlling how much each model drove behavior. We show the step-by-step implementation of these models using the toolbox, and we further discuss goodness-of-fit analysis and modeling result interpretation.

**Abstract:** Recent advances in large-scale neural calcium imaging allow neuroscientists to visualize the concurrent dynamics of hundreds to thousands of individual neurons in live animals, but analysis of these datasets remains a bottleneck. Existing methods for extracting individual cells and their activity traces from calcium imaging datasets have several limitations, including inherent tradeoffs between signal detection fidelity and crosstalk between nearby cells. To date, no algorithm has demonstrated the requisite speed, scalability, accuracy, and versatility to provide a general solution. Here we present CELLMax (Cell Extraction by Log Likelihood Maximization), a high-fidelity cell extraction method that makes no assumptions about the

temporal structure of cells' activity traces. The algorithm is highly parallelizable, and under suitable conditions its runtime scales sub-linearly with dataset size. To demonstrate the statistical optimality of CELLMax, we show that its estimator variance approaches the mathematical lower bound and that the algorithm achieves a maximum likelihood solution. In validation studies with simulated datasets, we found that CELLMax generally yielded superior estimates of cells' fluorescence activity traces as compared to the most commonly used cell sorting algorithms. In studies with real data acquired in the hippocampus of freely behaving mice, neural activity traces extracted by CELLMax allowed superior positional estimates of the mouse's running trajectory. Overall, our results show that CELLMax is a versatile, reliable, and scalable approach for extracting cellular signals from a wide variety of calcium imaging datasets; thus, we expect its usage should help improve the pace and accuracy of experiments relying on large-scale neural calcium imaging.

**Title:** Utilizing state of the art rendering techniques and virtual reality to better visualize neuroscientific data

**Authors: *T. D. ARD**, J. STANIS, D. DUNCAN, A. W. TOGA
USC Stevens Neuroimaging and Informatics Inst., Los Angeles, CA

**Abstract:** Visualization is a critical component in neuroscientific investigation, enabling researchers to intuitively understand and meaningfully navigate complex data. This is becoming even more crucial as methodologies such as magnetic resonance imaging (MRI) and microscopy advance in spatial and temporal scales, resulting in truly massive and unwieldy datasets. While these large datasets hold the key in unlocking the next generation of breakthroughs, they pose unique challenges for comprehension and visualization. We have developed software that bridges state of the art graphical, cinematic, and gaming industry technology with very large neuroimaging datasets, creating several novel tools to better visualize and explore cellular and neuroimaging data, both in and outside of virtual reality (VR). Outside of virtual reality, our novel MRI visualizations include a new approach to visualizing diffusion imaging through particle motion, functional MRI rendering through sparse particle clouds, and advances in

tractography and structural rendering demonstrating all of the fine detail available in high-field MRI. Additionally our novel cellular visualization techniques are able to reconstruct, enhance, and portray large-scale datasets in a navigable manner while maintaining the ability to portray perceivable fine cellular structures. Inside virtual reality, we've leveraged VR's intuitive spatial exploration and 3D display capabilities to offer optimal navigation of neuroscientific data. By employing various real-time rendering techniques we can navigate volumetric MRI data and extracted surfaces from individual subjects as a 'virtual dissection.' Furthermore we can view tractography data, as well as cellular structure and datasets in their natural 3D setting to more accurately and naturally comprehend their 3D structure. Overall, our visualization software begins to modernize neuroscientific data visualization, offering more comprehensive, navigable and detailed exploration of large and complex datasets.

**Title:** Software tools for high-throughput stitching and processing of micron-resolution 3D images of brain samples

**Authors: *G. MAZZAMUTO**[1], L. SILVESTRI[1,2], P. FRASCONI[3], L. SACCONI[1,2], F. S. PAVONE[1,2]
[1]European Lab. For Non-Linear Spectroscopy, Sesto Fiorentino, Italy; [2]Natl. Inst. of Optics (INO-CNR), Sesto Fiorentino, Italy; [3]Dept. of Information Engin. (DINFO), Univ. of Florence, Florence, Italy

**Abstract:** Whole-brain imaging using advanced high-resolution microscopy techniques such as Light-Sheet Fluorescence Microscopy and Two-Photon Fluorescence Microscopy produces big amounts of volumetric data. Microscopic imagery of brain tissues acquired with such techniques include a wealth of valuable information that needs to be processed in an automatic fashion to produce reliable quantitative results. We developed a software pipeline that allows us to perform different levels of processing including: stitching of overlapping 3D tiles, cell counting, cell segmentation, vascular segmentation.
The first and most delicate step in the pipeline is tile stitching. Given the extent of our datasets (several TB of data) and the need for high-throughput processing, we found that existing open source software solutions do not perform and scale well. On the other hand, commercial software products for image stitching already exist, but these are costly and closed source. Our dedicated stitching tool computes optimal alignment of adjacent tiles by evaluating the cross-correlation of overlapping areas at selected stack depths. This ensures a high throughput, since a large dataset need not be processed in its entirety. Furthermore, cross-correlation is computed efficiently by means of FFT. The software is fully written in Python and makes use of state of the art computing libraries. The tool exposes a public Application Programming Interface (API) that can be used to perform queries on the stitched dataset for further processing.
In the second stage of processing, stitched images produced with the software tool described above are fed to cell segmentation, identification and counting algorithms based on machine learning. Here, high throughput is obtained by exploiting the parallel computing capabilities of modern GPUs.

**Title:** Tackling the normalization of 2-D rodent histology sections in a 3-D coordinate space

**Authors: C. COELLO**, T. B. LEERGAARD, *J. G. BJAALIE
Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway

**Abstract:** The increasing deluge of reported experimental neuroscience data calls for efficient approaches to integrating and comparing data. The new generation of 3-D rodent brain reference atlases and accompanying tools provide new opportunities for spatial co-registration (integration) and comparison of different types of brain images, including microscopic images of serial sections through the brain. Spatial registration of serial 2-D section images to a 3-D reference space using affine transformations is useful and relatively practical to implement, whereas non-linear and thus potentially more accurate methods are complex and in most cases require spatially coherent input data. 3-D reconstruction of serial 2-D images is manageable if block face imaging is used, but otherwise quite tedious. We here present a methodological framework to non-linear registration of purely 2-D (not spatially coherent) images to 3-D space. The framework is built to address variability in acquisition parameters (cutting plane, single section or stack, number of slices in a stack, distance between successive slices, etc⋯) between experiments. We initially employ a global manual anchoring of the section material (Figure 1A) within the reference coordinate space (step 0) followed by estimation of a multi-level transformation using intensity- and/or landmark- similarity metrics (step 1). The transformation model was selected as diffeomorphic and calculated between the transformed source (Figure 1B) and the resliced target (Figure 1C and 1D) at the level given by the initial anchoring step (2-D to 2-D). The combination of global anchoring followed by multi-level transformation (Figure 1F) perform similarly or better than anchoring only (Figure 1E) at normalizing individual 2-D slices to a 3-D space at the cost of additional pre-processing steps that we aim to automatize to facilitate the use of this spatial integration framework.

**Title:** A semi-automated lesion mapping approach for rhesus macaques

**Authors: *M. PUJARA**[1,2], E. A. MURRAY[2]
[1]NIH, Bethesda, MD; [2]Natl. Inst. of Mental Health, NIH, Section on the Neurobio. of Learning and Memory, Lab. of Neuropsychology, Bethesda, MD

**Abstract:** Studies of rhesus macaques (*Macaca mulatta*) with intended focal brain lesions provide critical insights on the relationships between brain structure and behavior. Current techniques allow researchers to damage cell bodies selectively, while sparing fibers of passage. A major challenge of the lesion method in rhesus macaques is documenting the degree to which the lesion is both complete and selective for the region of interest. Currently, lesion extent is manually drawn on a series of sections of a reference brain from visual inspection of a postoperative T1 MRI scan (in which damage appears as relative hyposignal), T2 MRI scan (in which damage appears as relative hypersignal), or histology slides. However, this approach is time-consuming and difficult to standardize. Recent advances in automated nonlinear registration algorithms and the advent of a standard template for rhesus macaques (Seidlitz, Sponheim, et al 2017) may improve the speed and standardization of lesion mapping via automated registration of a monkey's lesion to a common anatomical reference space. Here, we employ a semi-automated method to map cortical lesion boundaries (e.g., orbitofrontal cortex, prelimbic cortex, premotor cortex) from multiple subjects to a single standard template. This two-step process involves: 1) manually tracing the lesions in native space on the subject's postoperative MRI scan, and 2) warping the traced lesion mask and postoperative scan to template space using a nonlinear algorithm provided by a validated neuroimaging software package, ANTs (Avants et al, 2010). We further evaluate the extent to which the damage registered in the *in vivo* scans are representative of the actual surgical damage by comparing these digitized masks to traditional Nissl-stained histological material. This approach provides an improved method for lesion mapping that saves time, standardizes results, and provides multiple options for quantifying lesion extent and generating informative 2D and 3D visualizations.

**Authors: *J. HWANG**[1], A. R. MITZ[2], E. A. MURRAY[1,2]
[1]Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD; [2]Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

**Abstract:** MonkeyLogic (ML1) is an open source MATLAB (Mathworks) toolbox for complex behavioral control and data acquisition with sub-millisecond temporal precision (Asaad &

Eskandar, 2008). To date, ML1 has been cited in >50 peer-reviewed publications and is used by >30 research groups worldwide. However, ML1 does not support the 64-bit computing environment and has incompatibility issues with MATLAB's new HG2 graphics engine. In addition, ML1 requires the MATLAB Data Acquisition Toolbox and two identical interface boards to operate at full speed. We now report the development of NIMH MonkeyLogic 2 (ML2), which resolves these key issues and adds new features to broaden the user base.
ML2 fully supports the 64-bit MATLAB environment and the latest versions MATLAB, while keeping nearly full compatibility with ML1 behavioral task files. The cost for implementing ML2 is significantly less than ML1 for two reasons. First, because ML2 requires only one interface board to achieve sub-millisecond timing precision, whereas ML1 required two, moving from ML1 to ML2 will free-up an interface card and thereby reduce the cost of running a new ML2 installation for existing users. Second, the MATLAB Data Acquisition Toolbox is no longer needed. It has been replaced by a new, open-source NIMH Data Acquisition Toolbox (NIMH DAQ), which both reduces the cost and greatly enhances performance. ML2 also uses a new NIMH MonkeyLogic Graphics Library (MGL) that draws both subject and control screens with hardware accelerated application programming interfaces. As a result, ML2 has rapid control screen updates so that the experimenter's control screen can reproduce the graphics seen on the subject's screen.
In sum, ML2 has improved timing precision, supports transparent images, has a greater analog channel count and supports multiple new input devices (e.g., touchscreens, USB joysticks). ML2 also employs a more efficient and flexible data file structure without sacrificing backward compatibility at the MATLAB programming level. Examples and benchmark results will be presented along with a more complete description of the changes.

**Title:** Using spike train distances to evaluate neuronal population coding, Part II

**Authors: *E. A. SATUVUORI**[1,2,3], M. MULANSKY[2], T. KREUZ[2]
[1]Univ. of Florence, Sesto Fiorentino, Italy; [2]Inst. for Complex Systems, CNR, Sesto Fiorentino,

Italy; [3]MOVE Res. Institute, Dept. of Human Movement Sciences,, Vrije Univ. Amsterdam, Amsterdam, Netherlands

**Abstract:** This part II continues from the greedy algorithm introduced in part I [1]. The Victor-Purpura distance and the van Rossum distance extensions for population coding [2, 3] use a parameter to scale between labelled line coding (LLC), where each neuron is treated separately, and summed population coding (SPC), where all spikes are pooled and the identity of the neuron that emitted the spike is not important.
Instead of simply taking a set of spike trains and assuming that the all the recorded neurons are coding neurons, we here identify the best performing subpopulation using the SPIKE-distance. We test two versions of greedy algorithms presented in Part 1 together with a new heuristic simulated annealing algorithm, that provides significantly faster analysis times when compared to brute force solutions but evaluates many more subpopulations and is thus considerably slower than the greedy algorithm.
In order to assess the performances of our algorithms we use small enough test sets so that brute force is feasible and the correct solutions can be used as reference point to search for situations in which each algorithm is not able to reach the globally optimal solution. To test the algorithms, we use Poisson neurons with different levels of noise. For the LLC population, we limit our study to discrimination between different stimuli with minimum number of neurons and identify the SPC population by using our new algorithms.
The measures of spike train synchrony ISI-distance [4], SPIKE-distance [5] and SPIKE Synchronization [6] as well as the new directional measure SPIKE-Order [7] are freely available in the Matlab-based graphical user interface SPIKY [6], the Matlab command line package cSPIKE, and the Python library PySpike [8]. Source codes of SPIKY, cSPIKE, and PySpike are available at [9,10,11].

**Title:** Using spike train distances to evaluate neuronal population coding, part I

**Authors: *T. KREUZ**[1], E. A. SATUVUORI[2], M. MULANSKY[1]
[1]Inst. For Complex Systems, Sesto Fiorentino, Italy; [2]Univ. of Florence, Sesto Fiorentino, Italy

**Abstract:** During the last decade spike train distances **[1-4]** have become an essential means to characterize neural coding in a wide range of neurophysiological contexts. In a typical setup different stimuli are presented repeatedly and a pairwise similarity analysis is carried out to evaluate whether responses to the same stimulus exhibit smaller distances than responses to different stimuli. With the increasing availability of multi-neuron recordings these kinds of analyses can now be performed not just for individual neurons but rather for simultaneously recorded neuronal populations.
The bivariate Victor-Purpura and the van Rossum distance **[1, 2]** have been extended to quantify dissimilarities between multi-unit responses. These population measures **[5, 6]** estimate the discrimination performance of either the population as a whole (summed population) or of individual neurons (labelled line). However, if the two extremes fail, these approaches do not answer the question which subpopulation within the larger population discriminates the presented stimuli best.
The brute-force approach of evaluating every possible neuronal subpopulation is not feasible. Thus, in the first part of this study we follow a complimentary approach and present an iterative algorithm which considerably restricts the number of subpopulations for which the pairwise distance matrices and the stimulus discrimination performance have to be calculated. The second part of this study proposes a simulated annealing approach **[7]**.
The three measures ISI-distance **[3]**, SPIKE-distance **[4]** and SPIKE-Synchronization **[7]** as well as the new directional measure SPIKE-Order **[9]** are implemented in the Matlab-based graphical user interface SPIKY **[8]**, the Matlab command line library cSPIKE, and the Python library PySpike **[10] [11]**.

**Title:** A novel approach to biomarker discovery through conceptual integration of multimodal datasets

**Authors: H. UNG**, M. C. HOLLENBECK, A. CHRISTINI, *J. B. WAGENAAR
Blackfynn Inc., Philadelphia, PA

**Abstract:** Biomarker discovery in large-scale multimodal datasets requires a thorough understanding of the underlying data, its structure, and their relationships. Data preparation to explore these relationships for analysis is a significant barrier to testing hypotheses and validating existing findings. Recent advancements in multimodal analyses have shown promising results, yet mapping between data modalities is often a difficult task. The ability to easily explore multimodal relationships significantly improves a researcher's ability to generate hypothesis and construct models for discovering novel biomarkers.
Here, we describe a use case for the integration and analysis of a large-scale public multimodal dataset. The Parkinson's Progression Markers Initiative (PPMI) dataset consists of over 600 subjects with imaging, genomics, and behavioral data. Concepts were abstracted from these data using a graph representation, which links individual subjects to modality-specific features. The conceptual mapping and integration of these data were conducted using the Blackfynn scientific data management platform, which enables intelligent data exploration with integrated variable ranking and efficient machine learning analysis. Using the platform, we performed supervised machine learning analysis on the multimodal dataset to classify early Parkinson's versus healthy controls with greater than chance accuracy. From the constructed models, we identified key

features that drove our predictions, which included previously published CSF biomarkers in addition to novel biomarkers that may warrant further investigation.
This use case provides an example of how conceptual multimodal data integration significantly improves the ability of the researcher to discover biomarkers from multi-modal datasets, and how novel platform technologies can facilitating data exploration and scientific analysis.

**Title:** A digital 3D atlas set of the marmoset brain based on multimodal MRI

**Authors: *C. LIU**[1], F. Q. YE[2], C. C.-C. YEN[3], J. D. NEWMAN[4], A. C. SILVA[5]
[1]NINDS/NIH, Bethesda, MD; [2]Natl. Inst. of Hlth., Bethesda, MD; [3]NINDS/LFMI/CMS, Natl. Institues of Hlth., Bethesda, MD; [4]NICHD /NIH, Kensington, MD; [5]NINDS, NIH, Bethesda, MD

**Abstract:** The common marmoset has become a valuable primate model in neuroscience research. Neuroimaging techniques, especially magnetic resonance imaging (MRI), are essential tools to unveil the anatomical and functional organization of the brain. To facilitate identification of regions of interest (ROI) in the MRI images, it is desirable to register the MRI images to an atlas of the brain. However, all of the currently available atlases of the marmoset brain are based on two-dimensional histological data, which are difficult to be applied to 3D MRI and connectome studies. Here, we constructed a 3D digital atlas set of the marmoset brain that is based on high-resolution ex-vivo MRI images. The atlas was constructed from MRI acquired with different contrasts, including magnetization transfer ratio (MTR, a T1-like contrast), T2-

weighted images, and multi-shell diffusion MRI. Based on the manifold contrasts provided by multimodal images, we manually delineated 54 cortical areas and 16 subcortical regions per brain hemisphere (version 1; MRI-based). The 54 cortical areas were merged into 13 larger cortical regions according to their spatial locations and hierarchical organizations (version 2; location-based). Meanwhile, we also mapped the detailed connectivity profiles of each cortical area based on MR diffusion tractography, and refined the original 54 cortical areas into 106 subregions (version 3; connectivity-based), using a connectivity-based parcellation method that was optimized for the marmoset brain. These three atlas versions are designed for neuroimaging studies of different purposes. Finally, we evaluated the reliability of the atlas across different individuals and demonstrated its application in current studies using diffusion tractography, resting state functional connectivity and connectome analyses. Featured by multimodal contrasts and multilevel parcellations, the atlas set provides a readily usable template space with anatomical labels that can facilitate various current and future neuroimaging studies of marmosets.

Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway

**Abstract:** Reference atlases of the brain are important tools for assigning location to data captured in neuroscience experiments. Spatial alignment of histological section images to reference atlases is challenging to perform for several reasons. Manual approaches are time consuming when applied to large series (e.g., brain-wide) of images and, moreover, histological sections are often cut at angles deviating from the principal anatomical planes presented in conventional reference atlases. Novel 3D reference atlases and accompanying tools provide new opportunities for rapid and accurate spatial registration and integration of data in common reference atlas space. We here present QuickNII, a new tools for use with the Waxholm Space atlas for the rat brain and the Allen brain atlas for the mouse brain, and a workflow allowing users to 1) interactively generate customized atlas images (slices of the 3D reference atlas) corresponding to the plane of sectioning of any experimental image series, 2) superimpose atlas images onto experimental images using affine transformations to match key anatomical landmarks, 3) propagate the transformations across a series of images, 4) assign spatial reference atlas coordinates to the experimental images, and 5) allow viewing and analysis of the experimental data integrated in the reference atlas. We exemplify the workflow and use of our methods with a range of experimental data from neuroanatomical and neurophysiological investigations. The method has been extensively tested on a large number of different image series in several laboratories, and has been shown to be practical and efficient in use. The tool is available from the Neuroimaging Informatics Tools and Resources Clearinghouse (www.nitrc.org), and through HBP services.

**Title:** Formats, tools and services for efficient data management, reproducibility and collaboration in neuroscience

**Authors: A. KOUTSOU**[1], C. GARBERS[1], M. SONNTAG[1], *C. J. KELLNER[1], A. STOEWER[1], J. GREWE[2], T. WACHTLER[1]
[1]Ludwig-Maximilians-Universität München, Planegg, Germany; [2]Eberhard Karls Univ., Tübingen, Germany

**Abstract:** Management of scientific data, including consistent organization and storage of data, is a challenging task. Data needs to be annotated with metadata to provide information about the underlying experiment to ensure reproducibility. Accessing and managing data from multiple workplaces while keeping it in sync, backed up, and easily accessible from within or outside the lab, is even more demanding. To minimize the time and effort scientists have to spend on these tasks, we here present formats and tools designed for comprehensive and reproducible management of scientific data. To easily store, select, retrieve and share data using an open format we provide the NIX[1] format, which offers convenient organization of data and metadata, supporting various data types including electrophysiology and imaging, and enables to effectively link data and corresponding analysis results as well as the associated metadata. NIX builds on the odML[2] metadata format and is supported by the Neo[3] Python package for electrophysiology, enabling Neo users to store their data in a common open format. Keeping data organized in the lab is made easy via the GIN[4] services. GIN keeps track of changes to the contents and organization of the files and provides secure remote access, making it convenient to work from multiple workplaces while keeping all data available and in sync. Data can be managed from web and file browsers or through a command line interface, enabling even integration into data acquisition and analysis procedures. The system works with any kind of directory structure and file types, using established technologies to keep previous versions accessible when datasets are updated. The service furthermore makes it straightforward to share data within a lab or with off-site collaborators and to work on it together. Any data hosted with the service can easily be made persistently available with digital identifiers for publication.

Combining GIN and NIX allows streamlining data workflows and eases the sharing of well-annotated datasets within the lab, among collaborators between labs, or with the public.

**Title:** Towards real-time, online spike sorting for large-scale extracellular recordings

**Authors: B. LEFEBVRE**, G. SPAMPINATO, E. ESPOSITO, H. KHABOU, M. STIMBERG, D. DALKARA, J. DUEBEL, *O. MARRE, P. YGER
Inst. de la Vision, Paris, France

**Abstract:** Understanding how assemblies of neurons encode information requires recording of large populations of cells in the brain. In recent years, multi-electrode arrays and large silicon probes have been developed to record simultaneously from thousands of electrodes packed with a high density. These new devices challenge the classical way to perform spike sorting. We recently developed a fast and accurate spike sorting algorithm (available as an open source software, called SpyKING CIRCUS), validated both with *in vivo* and *in vitro* ground truth experiments. The software, performing a smart clustering of the spike waveforms followed by a greedy template-matching reconstruction of the signal, is able to scale to up to 4225 channels in parallel, solving the problem of temporally overlapping spikes. It thus appears as a general solution to sort spikes from large-scale extracellular recordings.
Here we aim at implementing this algorithm in an “online” mode, sorting spikes in real time while the data are acquired, to allow closed-loop experiments for large-scale extracellular recordings. Template corresponding to the different cells were extracted and tracked over time to take into account progressive drifts in the extracellular waveform associated with each cell. We built a robust architecture for distributed asynchronous computations. Our software is parallelized to use optimally the computing resources: all the different processing steps of the algorithms can be distributed across different nodes. Our software is therefore a promising

solution for future closed-loop experiments involving recordings with hundreds of electrodes. We are currently testing the performance of the algorithm on various ground truth datasets.

**Abstract:** Recording of extracellular action potentials generated by spiking neurons (units) is one of the cornerstones of understanding brain microcircuit function in vivo and in vitro. Inferences about network activity can be made by identifying coincident activity and other temporal relationships among different units. However, distinguishing the number of units present within recordings from a single electrode remains a fundamental technical issue. The first step in identifying distinct units begins by clustering unlabeled spike trains with any of unsupervised learning algorithms such as c-means, single linkage, or Gaussian mixture decomposition, that all require one of two approaches: specification of a fixed value of c, the number of clusters to seek; or generation of candidate partitions for several possible values of c, followed by selection of a best candidate based on various post-clustering validation criteria. In this work, we explore the use of a pre-clustering method *improved Visual assessment of Clustering Tendency* (iVAT) to estimate the number of clusters to seek prior to employing a clustering method to assign memberships. We show the need for such a strategy by using "ground truth" data from both synthetic data and simultaneous intracellular and extracellular recordings to provide labeled clusters of spike waveforms. Different combinations of randomly occurring trains of labeled waveforms of 2 or 3 units (neurons) are presented to demonstrate the inconsistency between different feature extraction techniques (e.g. Principle component analysis (PCA), and T-student stochastic neighbour embedding (t-SNE)). Projection of the data to a lower dimensional space enables visual inspection to identify potential clusters, and our examples show

that this often leads to an incorrect interpretation of the number of clusters. iVAT is based on an algorithm that enables the visualization of possible cluster structure in the data without dimensionality reduction by imaging a measure of similarity in the high dimensional space. Following application of iVAT we then compute clustering validation indices such as Dunn's index to illustrate the relationship and compatibility of the pre- and post-cluster assessments. Finally, we show that iVAT is appropriate for assessing clusters of sets of neuronal spike waveform data since: 1) iVAT enables the visualization of possible cluster structure in the data without dimensionality reduction. 2) iVAT is not computationally intensive (O(n2)) which would allow for online implementation. 3) iVAT can be used with any distance measure; and 4) this method is conceptually independent from any specific spike sorting algorithm.

**Title:** Efficient deformable alignment of large EM image volumes: A matrix solver approach

**Authors: *K. KHAIRY**, G. DENISOV, S. SAALFELD
Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

**Abstract:** Large electron microscopy image datasets are typically composed of thousands to millions of partially overlapping two-dimensional images (tiles), which must be registered into a coherent volume prior to detection of anatomical features. A common registration strategy is to find point-matches between neighboring and overlapping images pairs, followed by an estimation of optimal image deformation using a so-called solver program. Existing EM solvers are inadequate for large data volumes. In this work, an efficient and accurate matrix-based solver method is presented. A linear system is constructed that combines minimization of point-pair distances with explicit constraints in a regularization term. In absence of reliable priors for regularization, we show how to construct a rigid-model approximation to use as prior. The linear system is then solved by any of a number of available strategies. So scalability and accuracy are delegated to efficient numerical codes, leveraging hundreds of thousands of man-hours that went into developing linear system solutions. Our method has been applied to multi-terabyte electron microscopy datasets of the adult fruit fly brain

**Abstract:** Wide-field optical mapping (WFOM) methods can resolve neurodynamics on fast time-scales over the entire surface of a rodent brain. Various fluorophores can be employed to target membrane-voltage, calcium dynamics, or neurotransmitters, with each indicator having unique signal-to-noise and time-resolution characteristics. All WFOM methods, however, are confounded by hemodynamic artifacts, which include the BOLD (Blood-Oxygen Level Dependent) signal, pulse, and breathing artifacts. These artifacts arise due to fluctuations in hemoglobin abundance and differences between the wavelength-dependant absorbence of oxygenated and de-oxygenated hemoglobin. The relative strengths of these factors depend strongly on the imaging wavelengths, as well as the dominant tissue type represented in each pixel, i.e. neuropil, arterial, venous, or capillary. We have developed a set of pre-processing algorithms based on three-dimensional total-variation denoising (TVD) and local-regression methods, which can remove optical noise and pulse/breathing artifacts, and estimate the BOLD signal. We apply our methods to a variety of data sets, and compare BOLD estimates with results from ratiometric approaches (W. Akemann et. al., J. Neurophysiol 108, 2012; M. Carandini et. al. J. Neuroscience 53, 2015; Y. Ma et. al., Phil. Trans. R. Soc. B 371, 2015). Preprocessing can have a significant effect on the results obtained by commonly used dimension-reduction algorithms, such as Principal Components Analysis (PCA) and Non-negative Matrix Factorization (NMF).

**Title:** To infinity and beyond Bitcoin: Blockchain technology for beginners

**Authors: L. V. LONG**, J. H. REUSING, *S. T. MANION
Network Centric Sci., Baltimore, MD

**Abstract:** Blockchain technology is a new system of de-centralized databases that allows for sharing of data with increased security, authenticity, validation, and speed. Essentially, the individual computers running a blockchain comprise the database and are updated simultaneously every time a data point changes. Incongruence in the data (between computers) forces a pause in the blockchain until the point of divergence is identified and remedied. Originally developed for use underlying digital currencies, it is now being adapted for use in many industries, including banking establishments, military contractors, and in facilitating product sales. There is a strong role for it in research and the scientific community in general. Topics ranging from combatting fraudulent data to improved patient care will be explored further in the poster.

**Title:** Kilosort and Suite2p: robust and scalable frameworks for neural activity extraction in large-scale recordings

**Authors: *M. PACHITARIU**, C. STRINGER, N. STEINMETZ, S. N. KADIR, M. DIPOPPA, F. ROSSI, S. SCHRÖDER, M. CARANDINI, K. D. HARRIS
Univ. Col. London, London, United Kingdom

**Abstract:** Recent advances have greatly expanded our ability to monitor large neural populations, either by direct, dense electrical recordings or optical recordings of intracellular calcium levels. While the electrode arrays, calcium sensors and microscopes have matured over several generations of development, computational methods to process the resulting data remain inefficient. To overcome this difficulty, we developed Suite2p and Kilosort, two fast, scalable and accurate pipelines that can run on inexpensive workstation computers. To achieve this rapid processing, both pipelines take advantage of dimensionality reduction techniques, and GPU-based computing. Kilosort and Suite2p are freely available on GitHub, and are actively supported by an expanding user community.

Kilosort is a spike sorting framework that models the recorded voltage as a sum of template waveforms, allowing overlapping spikes to be identified and resolved (Pachitariu et al. bioRxiv 2016). A novel post-clustering merging step based on the continuity of the templates substantially reduces the requirement for subsequent manual curation operations. We compare Kilosort to an established algorithm on data obtained from 384-channel electrode arrays, and show superior performance, at much reduced processing times (~ real time). Kilosort is an important step towards fully automated spike sorting of multichannel electrode recordings.

Suite2p is a complete pipeline for processing 2-photon calcium imaging, that registers raw movies, detects active cells, extracts their calcium traces and infers their spike times (Pachitariu et al. bioRxiv 2016b). Suite2p runs in approximately one hour for typical two-hour long recordings, on standard workstations, and recovers ~2 times more cells than previous standard methods. The low computational load of our method allows routine detection of ~10,000 cells simultaneously from the visual cortex of awake mice with standard two-photon resonant-scanning microscopes. Recordings at this scale promise to reveal the fine structure of activity in large populations of neurons.

**Abstract:** The Neurogram Deconvolution Kit (NDK) is a software suite for warehousing, compression, visualization, and analysis of local field potential recordings taken from peripheral nerves, with specific attention to Vagus nerve neurograms. NDK is built on Python and is portable to Windows, Linux, and MacOS X environments. The use of Python affords us a large degree of portability and interoperability with other languages and systems. As a partial result, NDK is able to draw on Python libraries like scikit and Theano for GPU-enabled signal processing and machine learning, and libraries like neo for interoperability with various file formats and storage schemes. NDK contains a Matlab-accessible API for performing data analysis within Matlab. The NDK is designed to accomodate a variety of signal types in both the peripheral and central nervous systems. Continuous Vagus nerve local field potential (LFP) recordings are organized into a NoSQL database system (Apache Cassandra) for efficient access to high-volume time series data. Features extracted from LFPs are organized into SQL databases (e.g. sqlite or MySQL), for representing discrete-time features and their relationships (e.g., spike clusters and behavioral events). Vagus nerve neurograms are further processed by clustering spike events to decompose the neurogram into constituent components. In many cases, multiple channel configurations provide information about the direction and speed of action potential propagation. All of these issues motivate the development within NDK of relational data models that support these needs, and the consequent use of database technology.

**Abstract:** Modern neuroscientific experiments require coordinating disparate pieces of hardware, each which distinct interfaces and control software, for the collection of different signals of interest (e.g. electrophysiological, optical, behavioral) and generation of stimuli in multiple modalities (e.g. electrical, optical, auditory, tactile). One approach to achieving this is to write custom experimental control routines, but this is time-consuming, requires programming skills, and is relatively inflexible if the experimental configuration needs to be changed. WaveSurfer (wavesurfer.janelia.org) – which incorporates features of an earlier software package, Ephus (Suter et al., 2010) – represents an alternative approach. WaveSurfer coordinates electrophysiological recording & stimulation, acquisition & generation of arbitrary 1D analog signals, and triggering of external devices. WaveSurfer has a simple yet flexible user interface, which allows experiments to be reconfigured on the fly. Custom Matlab code can be invoked at different points to allow for online analysis or more sophisticated experiments, including closed-loop experiments. WaveSurfer is compatible with National Instruments X series data acquisition boards and any patch-clamp amplifier, with particular integration for Axon and Heka amplifiers. WaveSurfer can be integrated with ScanImage (Vidrio) for laser scanning microscopy and photostimulation, including two-photon imaging. Here, we demonstrate how WaveSurfer's capabilities allow it to be used in a variety of experimental configurations.
WaveSurfer can be used for slice electrophysiology to deliver arbitrary voltage or current stimuli, as well as multi-wavelength optical stimulation using LEDs or lasers. We have also used WaveSurfer for in-vivo transcranial calcium imaging combined with Micro-Manager (Edelstein et al., 2014) and Retiga 2000DC cameras (QImaging), for synchronizing optical recordings with piezoelectric tactile stimulation, and for monitoring breathing to deliver respiration-locked

optogenetic stimulation.
In conclusion, WaveSurfer is a simple yet powerful, flexible, and extensible experimental control and data acquisition program. Originally designed for slice-based electrophysiology, we are currently using it in our labs for a wide variety of neuroscientific experiments.

**Title:** Spike sorting via source localization

**Authors:** ***P. GREENE**[1], J.-M. FELLOUS[2], K. LIN[3]
[1]Program in Applied Mathematics, [2]Dept. of Psychology; Program in Applied Mathematics, [3]Dept. of Mathematics, Univ. of Arizona, Tucson, AZ

**Abstract:** Extracellular, multi-unit recordings allow the spiking activity of multiple cells in the vicinity of a probe to be recorded in awake, behaving animals. To make use of this data, it is often necessary to perform spike detection and sorting, i.e., determine when a cell spikes and which cell was responsible for a given spike. A common method is to detect spikes by thresholding, then perform spike-sorting via, e.g., clustering or template-matching [1]. Though such methods can be made relatively fast, they have a number of known short-comings, including: (i) cells with similarly-shaped spikes can be difficult to distinguish, (ii) it can be difficult to detect and sort overlapping spikes, (iii) there is a bias for cells with larger spikes, (iv) estimating the number of cells in the recording often relies on human judgement, and (v) it is difficult to systematically quantify the uncertainty in spike assignments [2].
We propose a Bayesian framework for spike detection and sorting designed to address these issues. Building on earlier work of Mechler, Victor, and collaborators [3, 4], our method combines a dipole-based model of spiking units and a biophysical model of the source-probe transfer function, allowing explicitly for multiple spiking units at fixed but unknown locations.

We show that a version of the expectation maximization algorithm can effectively perform both spike detection and sorting. Simultaneously, our method yields rough estimates of the location of each spiking unit relative to the probe, which can be used to give a more complete picture of local spiking activity and information processing.

**Abstract:** Hand function is critical for independence, and neurological injury often impairs dexterity. To measure hand function in people or forelimb function in animals, sensors are employed to quantify manipulation. These sensors make assessment easier and more quantitative and allow automation of these tasks. While automated tasks improve objectivity and throughput, they also produce large amounts of data that can be burdensome to analyze. We created MATLAB software called Dexterity that simplifies data analysis of both automated and non-automated forelimb tasks. Through a graphical user interface, files are loaded and data are

identified and analyzed. These data can be annotated or graphed directly. Analysis is saved, and the graph and corresponding data can be exported. For additional analysis, Dexterity provides access to custom MATLAB scripts created by other users. To determine the utility of Dexterity, we performed a study to evaluate the effects of task difficulty on the degree of impairment after corticospinal injury; the task analyzed was an automated forelimb supination task for rodents (Vulintus, Inc.). Dexterity analyzed two months of data quickly and allowed new users to annotate the experiment, visualize results, and save and export data. We also analyzed data from a non-automated task, the Vermicelli Manipulation task, and another automated task, the isometric pull task (Vulintus, Inc.) before and after motor cortex lesion. Dexterity made the tools required to analyze, visualize and annotate data easy to use by investigators without data science experience.

**Title:** Automated identification of dendritic spines for live imaging

**Authors: *M. S. SMIRNOV**, R. YASUDA
Max Planck Florida Inst., Jupiter, FL

**Abstract:** Synaptic plasticity, the cellular basis for learning and memory, is mediated by a complex biochemical network of signaling proteins. These proteins are compartmentalized in dendritic spines, the tiny, bulbous, post-synaptic structures found on neuronal dendrites. The ability to screen a high number of molecular targets for their effect on dendritic spine structural plasticity will require a high-throughput imaging system capable of stimulating and monitoring hundreds of dendritic spines in various conditions. In order to screen many spines over long periods of time, reliance on human input has to be minimal. For this purpose, we present a program capable of automatically identifying dendritic spines in live, fluorescent tissue. Our software relies on a machine learning approach in order to minimize any need for parameter tuning from the user. Custom thresholding and binarization functions serve to “clean” fluorescent images, and a neural network is trained using features based on the relative shape of the spine perimeter and its corresponding dendritic backbone. Our algorithm is rapid, flexible, and has over 90% accuracy in spine detection. Furthermore, our software is built to easily interface with Scanimage, an open-source, MATLAB - based imaging suite. Therefore, we have designed a system capable of automatically identifying, imaging, and stimulating dendritic spines in live tissue.

**Title:** Inter-patient seizure classification using 1-D convolutional neural networks

**Authors: *G. CHAU**
Pontificia Univ. Catolica Del Peru, Lima, Peru

**Abstract:** Epilepsy is the fourth most common neurological disorder affecting around 50 million people worldwide (Megiddo *et al.*, 2016). The idea of automatic detection of epileptic seizures has long been researched as it can help relieve the burden of visual analysis performed manually

and can work in tandem with adaptive stimulation devices.
An extensive variety of studies in the literature has focused on patient-specific methods that are trained only with data from one specific patients (c.f. Gadhoumi *et al.* 2015 and Schoeb *et al.* 2010). However, these systems are not able to generalize well to other patients. An inter-patient seizure detection system, i.e. one that does not have to be trained individually for each new patient, is still an open topic. Some studies like Wilson *et al.* (2004), Fergus *et al.* (2014), and Thodoroff *et al.* (2016) have tried to tackle this problem, with this last one obtaining a sensitivity of 85% and a false positive rate (FPR) of 0.8/hours using a classical 2D convolutional neural network (CNN) on images projected from EEG time series data of the CHB-MIT database (Goldberger *et al.*, 2000).Here, we show that 1-D CNNs (in contrast with 2-D CNNs used by previous studies) applied directly on EEG time series may be more suitable for this classification tasks as we obtained improvements with respect to previous studies. We designed a 1-D CNN consisting of three convolutional layers and five dense layers. The convolutional filters were applied along the time dimension considering the different EEG channels as separate time series. The 1-D CNN system was tested on a subset of the CHB-MIT database consisting on EEG recordings from 23 pediatric patients. For each patient, all seizure records and an equal number of randomly selected non-seizure records were taken to form the dataset. Each recording was segmented into non-overlapping 2 second samples and labeled as positive (seizure) or negative (non-seizure) according to the provided groundtruth. A dropout value of 0.2 was added between layers to reduce risks of overfitting and class frequency loss weights were added in order to accommodate for the unbalanced number of positive and negative training samples. The 1-D CCN was trained with the stochastic gradient descent algorithm (initial learning rate: 0.01, momentum: 0.9, decay: 1E-6) over 150 epochs.
Using a leave-one-patient-out test scheme, we obtained an average sensitivity of 90%, which improves by around 5% the current state-of-the-art, while maintaining a comparable FPR of 0.8/hour.
