stimuli designed to selectively activate the M and P pathways, in relation to different levels of trait anxiety. In keeping with previous findings, M- and P-selective stimuli evoked distinct early VEPs, implicating segregated neural pathways. We observed a positive-going P1 component (around 128 ms) for M-selective stimuli [i.e. low-spatial-frequency (LSF), low-contrast achromatic Gabor patches in Studies 1 & 2; LSF, low-contrast achromatic oval gratings in Study 3; and LSF, achromatic neutral scenes in Study 4] and two negative-going components, C1 (around 90 ms) and N1 component (around 120 ms), for P-selective stimuli [i.e. high-spatial-frequency (HSF), red-green isoluminant Gabor patches in Studies 1 & 2; HSF, low-contrast achromatic gratings in Study 3; and HSF, achromatic scenes in Study 4]. Importantly, individual levels of trait anxiety were positively correlated with the magnitudes of P-specific VEPs (C2 or C1) across all four studies (r's: .27~.40, p's: .016~.05), whereas the relations between trait anxiety and the magnitudes of M-specific VEPs were less clear [negative in Study 1 (r's: -0.42~-.39, p's: .004~.011), but not significant in the other studies (p's > .16)]. Furthermore, in Study 1, we assessed these VEPs among the same subjects at three time points (initial assessment, 30 minutes later, and 2 weeks later). Not only were the VEPs highly reliable over time, the correlation with trait anxiety was significant at all three assessments. Together, these results unveil a trait-like property of visual pathway sensitivity that varies with the level of trait anxiety. Specifically, trait anxiety is associated with hypersensitivity of the P visual pathway. A possible implication of this finding is that trait-anxious individuals are particularly tuned to visual input engaging the P pathway, which could underpin their tendency to perceive local (vs. global) features and explain their known bias to see the trees but not the forest.

Title: Effects of cortical feedback and behavioral state on naturalistic movie responses in mouse dLGN

Authors: *M. A. SPACEK[1], G. BORN[1,2], L. BUSSE[1,3]
[1]Div. of Neurobiology, Dept. Biol. II, LMU Munich, Planegg-Martinsried, Germany; [2]Grad. Sch. of Systemic Neurosciences, Munich, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Munich, Germany

Abstract: Relay cells in the dorsal lateral geniculate nucleus (dLGN) of the thalamus receive feedback from primary visual cortex (V1) layer 6 corticothalamic (CT) neurons, via both direct excitation and disynaptic inhibition. How does CT feedback modulate responses in dLGN? Past studies using simple grating visual stimuli have shown diverse effects [1-3], but CT feedback might be particularly relevant during processing of complex visual stimuli, and its effects might depend on behavioral state [4].

We examined how CT feedback and behavioral state shape responses to naturalistic movie clips. Channelrhodopsin-2 (ChR2) was conditionally expressed in V1 of PV-Cre mice by local viral injection (AAV9). Activity in V1 was suppressed by optogenetic activation of parvalbumin (PV) positive interneurons, thereby suppressing CT feedback. Mice were head-fixed, but free to sit or run on a floating ball, while single unit responses in dLGN were recorded with high-density silicon probes. Grayscale naturalistic movies of mostly foliage (5 s long, 60 fps) with motion simulating saccades/head movements (up to 275 deg/s), were presented full screen on an LCD (108 x 68 deg) for 100s of trials per experiment.

dLGN responses to movies were generally sparse and reliable, with spikes often concentrated into short periods of time within each trial, separated by periods of relative silence. Responses were characterized by their mean firing rates, sparseness [5], reliability [6], and burst ratio [7]. Regardless of behavior, feedback increased mean firing rates ($p < 10^{-6}$), and decreased sparseness ($p < 10^{-8}$) and burst ratio ($p < 10^{-5}$), compared to when feedback was suppressed. Similarly, regardless of feedback, running increased mean firing rates ($p < 10^{-9}$), and decreased sparseness ($p < 10^{-9}$), reliability ($p < 10^{-6}$) and burst ratio ($p = 0.008$), relative to periods of sitting. The effects of feedback and behavioral state on dLGN were generally independent for all 4 response measures.

With feedback and during running, responses were more tonic, while without feedback and during sitting, responses were more burst-like. The presence or absence of either feedback or running may switch dLGN between burst and tonic mode firing. Because feedback and running have independent effects, this could be via separate mechanisms. Given the tradeoffs between tonic and burst mode firing [8], feedback and running may make dLGN encode stimulus information more linearly, while their absence might make dLGN more sensitive to salient events.

Title: Role of early visual experience in shaping binocularity in the thalamocortical pathway

Authors: *C. HUH[1], K. ABDELAAL[1], K. J. SALINAS[1], D. GU[2], J. ZEITOUN[1], D. X. FIGUEROA VELEZ[1], J. P. PEACH[4], C. FOWLKES[3], S. P. GANDHI[1]
[1]Neurobio. and Behavior, [2]Statistics, [3]Computer Sci., Univ. of California Irvine, Irvine, CA; [4]Whiting Sch. of Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Recent research indicates that binocular integration occurs at multiple stages of the central visual pathway, including in the dorsolateral geniculate nucleus (dLGN) of the thalamus. How binocular information is relayed and transformed at each stage of visual processing remains incompletely understood. Moreover, the role of early visual experience in the development of dLGN binocularity is unclear. To address these issues, we performed in vivo two-photon calcium imaging of dLGN axons innervating superficial layers of V1. A calcium sensor, GCaMP6s, was specifically targeted to thalamic neurons using VGLUT2-Cre mice and Cre-dependent viral GCaMP6s expression. We measured the responses of dLGN boutons in superficial layers of binocular V1 to drifting gratings in awake, head-fixed adult mice. Bouton responses were compared between normal mice and mice that were monocularly deprived (MD) during the critical period for visual development (postnatal days 19-33); in MD mice, dLGN bouton responses were recorded from V1 contralateral to the deprived eye. We found that in normal mice, 10% of visually responsive dLGN boutons exhibited significant responses to both eyes (i.e., binocular). Interestingly, binocular bouton responses were much stronger than monocular bouton responses. In comparison, ~30% of V1 L2/3 neurons were binocular and their responses were only slightly stronger than those of monocular neurons. Overall, dLGN boutons were tuned to higher spatial frequencies (SF) than V1 neurons; binocular and monocular boutons displayed a median peak SF of 0.12 cpd compared with 0.06 cpd in V1 neurons. Binocular boutons were relatively well-matched in terms of SF preference; 45% of binocular boutons showed matched peak SF between contralateral- and ipsilateral-eye responses. We found that MD had multiple long-lasting deleterious effects on dLGN boutons. Overall, 30% fewer visually responsive dLGN boutons were recorded per field of view in MD mice compared with control mice. Binocular boutons were particularly affected; only 3% of all visually responsive boutons were binocular in MD mice, a 67% reduction compared with control mice. In the remaining binocular boutons, MD led to a significant mismatch in preferred SF between the eyes (only 13% matched in peak SF) without a significant reduction in response amplitude. These findings indicate that binocular dLGN axons supply the visual cortex with high-fidelity visual inputs that are particularly vulnerable to monocular deprivation during the critical period. Binocular input from the dLGN may play an important role in the critical period for the development of binocular vision.

Title: Modulation of binocular rivalry with monocular visual tetanization and non-invasive stimulation of the visual cortex

Authors: *D. ABULEIL, D. L. MCCULLOCH, B. THOMPSON
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Purpose: Binocular rivalry (BR) alternation rates have been associated with primary visual cortex GABA concentration, whereby faster alternation rates are correlated with lower GABA levels. In addition, the relative input strength from each eye affects BR dynamics. We assessed the effect of three neuro-modulation techniques on BR. The first two techniques, anodal transcranial direct current stimulation (a-tDCS) and intermittent thetaburst transcranial magnetic stimulation (iTBS) reduce and increase GABA concentration in the motor cortex respectively. If similar effects occur over the visual cortex, the two techniques should have opposing effects on BR alternation rates. Rapid visual tetanization induces stimulus-specific LTP within the visual cortex. Therefore, monocular tetanization (MT) should increase perceptual dominance of the tetanized eye during BR. **Methods and Materials:** Alternation rates were recorded using dichoptic red/green orthogonal gratings (0.5cpd) before and after MT (N=20 active, 20 controls), tDCS (N=15 active, 7 controls) or iTBS (N=9 active, 9 controls). The gratings were presented for a minimum of 3 min and participants indicated red, green or piecemeal percepts using a button press. MT involved passive monocular viewing of the red or green grating flickering at 9Hz for 2 min followed by 2 min of eye closure. The control condition was identical except that both the red and green gratings were viewed binocularly. a-tDCS involved 15 min of 2mA (active) or sham (controls) stimulation (anode Oz, cathode Cz). iTBS involved 600 pulses delivered over V1 in 50Hz bursts for 40 sec at 100% of active motor threshold. The control condition used the same protocol with a sham coil. **Results:** a-tDCS and iTBS had no effect on BR dynamics. MT did not affect alternation rates but did significantly increase the duration of piecemeal percepts ($t_{19} = 2.9957$, $p < 0.01$). **Discussion and Conclusion:** a-tDCS and iTBS did not modulate BR alternation rates as predicted. This may indicate that motor cortex GABA concentration changes induced by these techniques do not occur for the visual cortex. Alternatively, GABA modulations induced by non-invasive brain stimulation may not exert an

effect on perception. Rather than increasing the dominance of the tetanized eye, MT reduced BR leading to increased piecemeal percept durations.

Title: Monocular V1 neurons are sensitive to both eyes

Authors: *K. DOUGHERTY[1], M. A. COX[2], J. A. WESTERBERG[2], A. V. MAIER[1]
[1]Dept. of Psychology, [2]Vanderbilt Univ., Nashville, TN

Abstract: Our brains combine the separate outputs of the two eyes, which leads to a singular view of the visual field. Where this combination occurs in the primate primary visual pathway remains an open question. Receiving the main projections from the retina, neurons in the lateral geniculate nucleus of the thalamus (LGN) are excited by stimulation of one eye and not the other, and for this reason are called monocular neurons. Next, in the primary visual cortex (V1), many neurons are excited by stimulation of either eye, and for this reason are called binocular. Because most V1 neurons are binocular, some form of binocular combination is thought to have occurred once these neurons fire. However, where within the V1 laminar microcircuit this binocular combination first occurs is unclear. We asked where binocular combination first occurs in the V1 laminar microcircuit by testing the degree to which macaque V1 neurons in all layers are sensitive to stimulation of one or both eyes. We found that more than 94% of V1 neurons were binocular, driven by stimulation of either eye. Congruent with previous work, monocular neurons were primarily located in the main geniculate input layer of V1. Surprisingly, we found that while these monocular neurons were excited by one eye only, they also showed systematic firing rate differences between stimulation of their driving eye alone compared to stimulation of both eyes. This finding suggests that V1 monocular neurons encode what is shown to both eyes. We conclude that, while V1 geniculate inputs are primarily separated by eye, the outputs of their V1 target neurons are sensitive to what both eyes view, suggesting binocular combination in the primate visual system occurs either before or at the initial cortical processing stage.

Title: Optokinetic eye movements in mouse to stereoscopic motion

Authors: *V. CHOI[1], N. J. PRIEBE[2]
[1]Dept. of Neuroscience, Ctr. for Perceptual Systems, Ctr. for Learning a, Univ. of Texas at Austin, Austin, TX; [2]Univ. Texas, Austin, Austin, TX

Abstract: Vertebrates make eye movement to stabilize moving objects. One such eye movement is the optokinetic reflex (OKR) which is an involuntary conjugate eye movement. The OKR also evokes vergence eye movements in primates when an object moves in depth (Busettini et al.,1996; Kodaka et al.,2007; Inoue et al.,1998; Yang et al.,2003; Sheliga et al.,2016). These vergence eye movements reflects the binocular integration of visual signals. To demonstrate that mice, a mammal with laterally placed eyes, also perform binocular integration, and gain access to the the underlying neuronal mechanisms for OKR, we examined vergence eye movements in awake mice viewing stereoscopic stimuli. Random dots were presented that contained both interocular velocity difference (IOVD) and change in disparity (CD) signals using polarizing lenses. The dots were presented such that they moved smoothly in a sinusoidal motion towards and away from the animals. We found vergence eye movement associated with random dot stereogram stimuli similar to what has been reported in primates. The two eyes converged when the dots moved in the toward direction and diverged when the dots moved in the away direction. We also found that IOVD signal is crucial for the optokinetic reflex (OKR) as eliminating the IOVD signal diminished the eye movement associated with the stimuli. In contrast, eliminating the disparity signals had little impact on the vergence eye movements. Finally we assayed the role of cortical processing in this behavior by silencing visual cortex while presenting the toward and away motion. We found that cortical silencing also had little impact on vergence eye movements. These results indicate that IOVD signals provide the dominant input to vergence OKR in mice and that the visual cortex plays little role in these eye movements. The binocular computation required for these vergence eye movements likely occurs in subcortical structures.

Title: Ocular dominance and homeostatic opponent cortical processing

Authors: *D. Y. TS'O, R. MILLER
Dept of Neurosurg., SUNY - Upstate Med. Univ., Syracuse, NY

Abstract: The classical view of binocular interactions in primate V1 is one of competition between the two eyes, at least during the development of the ocular dominance (OD) columns, if not also in adult life. Yet there is also evidence for ongoing interocular cooperativity and homeostatically-regulated balance. A re-examination of OD data from optical imaging studies suggests an interocular process that seeks to maintain a set level of left/right eye opponency (an L-R signal) atop other ongoing cortical activity.
Optical imaging of OD columns (ODCs) is performed by acquiring sets of V1 images during left eye (L), right eye (R), both eye (binocular) and no eye (blank) stimulation. Invariably and surprisingly, the OD (L-R) image yields a far "cleaner" spatial (functional organization) map of the ODCs than is observed in the "single condition" maps (e.g. L-blank). Extracting a line profile across the ODCs in an L-R map confirms a smooth, nearly sinusoidal OD signal. This OD signal exhibits near-zero DC offset, indicating normally well-matched inputs from the two eyes. In contrast to the OD (L-R) signal, the line profiles derived from the L or R single-condition maps appear more disjoint and irregular with the ODC signal often buried. The calculation of L-R is equivalent to removing the "cocktail blank", i.e. removing common mode cortical activity signal. The common mode activity includes a binocular response component that might explain the robust L-R maps by “washing out” the ODC signal in single-condition maps. A comparison of the response to binocular vs monocular stimulation revealed a 1.5X to 2X increase in cortical activity under binocular stimulation that may correspond to the classical advantage afforded by binocular summation. This analysis however, allows for the isolation of the binocular-only cortical activity and shows that it cannot explain the surprisingly robust L-R signal.
Similarly, short-term monocular deprivation (STMD) experiments in which a 1-2 hour monocular deprivation yielded a disruption of interocular balance and monocular gains lasting an hour. Yet immediately following STMD, the OD (L-R) signal "bounced back" to near normal amplitude and form even though each eye's activity had not yet returned to baseline. The implication is that homeostatic V1 circuits regulating interocular gain strive for a robust OD (L-R) spatial signal despite local and monocular perturbations, perhaps a by-product of maintaining proper interocular balance.

Title: Interocular normalization in monkey primary visual cortex

Authors: *A. REYNAUD[1], S. ROUX[2], S. CHEMLA[2], F. CHAVANE[2], R. HESS[1]
[1]McGill Univ., Montreal, QC, Canada; [2]CNRS, Marseille, France

Abstract: The slight difference in the signals coming from the two eyes is used by our brain to compute a tridimensional representation of the visual world. The monocular inputs reach the cortex in layer 4 in segregated ocular dominance domains. Then they are first combined by binocular neurons in layer 2/3. Studying how the information coming from the two eyes is integrated in ocular dominance map's referential at the mesoscopic scale is however still unknown. For this purpose, we used voltage sensitive dye imaging (VSDI) in anesthetized and awake behaving monkeys to analyze how these signals are integrated and summed at the population level in V1.
In order to identify the signals originating from the two eyes, we used a steady-state frequency-tagging paradigm. Visual stimuli of different contrasts were presented at 6Hz and 10Hz to the left and right eye respectively, separately or simultaneously with a passive 3D monitor. The frequency analysis of the evoked response was used to identify the contribution of each eye. We observed that the population activity in V1, elicited by the stimulation of one eye, is suppressed by a dichoptic stimulation compared to monocular stimulation. This signal integration was accurately accounted for by an interocular normalization model of population activity.
These approach and model confirm an implication of V1 population in the combination of the two eyes signals. Whether this normalization originates locally, or from feedback, feedforward or long range connectivity remains to be investigated.

Title: Novel evidence of high resolution and high field diffusion mri reveal a primate lgn-lgn connection

Authors: J. R. KORENBERG[1], L. DAI[2], D. PRITCHETT[3], A. VAN HOEK[4]
[1]Brain Institute, Pediatrics, [2]Dept. of Pediatrics, Univ. of Utah, Salt Lake Cty, UT; [3]Korenberg Research/Neurology, [4]Neurol., Univ. of Utah, Salt Lake City, UT

Abstract: Establishing a primate brain connectivity and linking it function and human diseases remain an elusive goal. Diffusion MRI, which quantifies the magnitude and anisotropy of water diffusion in brain tissues, offers unparalleled opportunity to link the macroconnectome to histological-based microconnectome at synaptic resolution, providing opportunity to confirm the known connection and propose novel connection. In this report, we show evidence using high resolution diffusion spectrum imaging (DSI) in primate brain to support the existence of a novel brain connection between the left and right lateral geniculate nucleus (LGN). We obtained high resolution diffusion MRI data on *ex vivo* brain from Macaca fascicularis: MRI 7T, resolution 0.5 mm isotropic, 515 diffusion volumes up to b-value (aka diffusion sensitivity) of 40,000 s/mm^2 with scan time ~100 hrs. Tractography results show direct connection between the left and right LGN. This finding is supported by previous functional and neuroanatomic data. First, Gitlin and Lowental (1969), reviewing 150y of literature including and post Gudden, there is no evidence from either Gudden or others, for the existence of a commissure connecting the two medial geniculate (MGN) in humans or even rabbits. Rather, the "medial root of the optic tracts" likely is what has been seen connecting the optic chiasma-related to optic tract bulges that go to the ventral medial aspect of the LGN. Second, although a number of very well done papers referred to above, identify other tracts in the region, no reports find or confirm the predicted Commissure of Gudden. It is interesting that Dougherty's review (2018) set out the possible modulatory circuitry responsible for binocular modulation, in the LGN, something they refer to as "an apparent paradox", and note that this may be explained not only by their proposals but also "through mechanisms yet to be uncovered". We propose that simplest explanation for their data may be found in the multiple paths of evidence for the LGN-LGN connection supported by our new finding. In conclusion, by combining the previous data in literature and our new tractography results, we hypothesize that there is direct LGN-LGN connection, and this finding will provide a flush of new interest and funding for the field to identify the mechanisms, the

molecules responsible, the embryo/fetogenesis and pruning, and the consequences for disease malfunction and correction.

Cognitive, Bron Cedex, France; [4]Univ. of Zurich, Zurich, Switzerland; [5]UMR 5229 - Inst. des Sci. Cognitives Marc Jeannerod, CNRS & Univ. Lyon 1, Bron Cedex, France

Abstract: The dopamine (DA) and serotonin (5-HT) systems are the two major neurotransmitters targeted in several neuropsychiatric disorders affecting motivation, value-based decisions and the context-adapted behaviors (approach or avoidance). The broad spectrum of processes on which DA can be involved is coming from its actions on Basal Ganglia (BG) that are partitioned into different functional territories. The 5-HT system that projects on a larger number of cerebral structures, especially limbic territories, also projects on BG. Their therapeutic actions in motivation and anxiety-relative behaviors could thus passed by the same BG territories also modulated by DA. To test this hypothesis, we compared the effects of DA and 5-HT treatment on 4 monkeys trained to perform an approach/avoidance task in which they had to adapt a behavior (approach or avoidance) in an appetitive (reward) or aversive (air puff) contexts. During this task, the CS provides essential information to select the context-adapted behaviors. To modulate the DA and 5-HT systems, we used drugs that act as a reuptake inhibitor; fluoxetine (FLX) at 4 mg/kg for the 5-HT system and methylphenidate (MPH) at 0.1 and 0.6 mg/kg for DA modulation. These drugs were tested on task performance and positron emission tomography (PET) imaging, using [^{11}C]DASB for the 5-HT transporter (SERT) and [^{11}C]PE2I for the DA transporter (DAT). First, we observed that both drugs induced, for all monkeys, an increase of completion rate (number of daily completed trials) reflecting an increase of

motivation. This benefit effect of both drugs was associated to a strong reduction of two behavioral markers of anxiety expressed in aversive context, non-initiated choices and escape behaviors in risky condition. This behavioral results shown that both drugs, DA and 5-HT, have benefit effects on motivation and anxiety. Secondly, the PET imaging investigation shown that the therapeutic dose of FLX led to a decrease of DASB binding in limbic cortical regions and also in ventral striatum, the putamen and the anterior caudate nucleus where the MPH led to a decrease of PE2I binding. These results allow us to highlight the importance of serotonin and dopamine modulation inside the BG, especially the striatum to modulate motivational disorders and anxiety-relative disorders.

Title: A rodent two-hit model of task-specific dystonia

Authors: *K. KERNODLE[1], W. T. DAUER[2], D. K. LEVENTHAL[3,2]
[1]Neurosci. Grad. Program, [2]Neurol., Univ. of Michigan, Ann Arbor, MI; [3]Neurol., VA Ann Arbor Hlth. Syst., Ann Arbor, MI

Abstract: Task-specific dystonia typically develops after extensive training on specific tasks. Such tasks are typically highly dexterous, such as writing or playing a musical instrument. A prominent hypothesis posits that excessive repetitive training stresses normal plasticity processes, causing abnormal sensorimotor associations. We have developed a “two-hit” model for the pathogenesis of task-specific dystonia, by challenging mice carrying a human dystonia mutation with an environmental trigger. The mice lack torsinA in forebrain neurons and have no abnormal movements at baseline. These mice develop task-specific abnormal movements after repeated training on the dexterous single pellet skilled reaching task. In contrast, they do not develop any abnormal movements following repeated training on the non-dexterous rotarod task. These results support a two-hit model of dystonia pathogenesis and establish a model that will enable unique studies of dystonia pathogenesis and pathophysiology.

Abstract: Dystonia is a movement disorder characterized by sustained muscle contractions, twisting, repetitive movements, and abnormal postures of the affected body part. Increasing evidence has suggested involvement of neural circuit connecting the sensorimotor cortex (SMC), the basal ganglia, and the ventrolateral thalamus. The globus pallidus internus (GPi) of the basal ganglia plays a critical role in this circuit. Decreases and increases in discharge of the GABAergic neurons of GPi could facilitate and suppress, respectively, the activity of recipient thalamocortical circuits and, eventually, the muscle activity. We propose that among with firing rate changes there are significant changes in spiketrain patterns in dystonia patients. We used microelectrode recording (MER) of GPi and GPe cells to analyze the differences of pallidal patterns in patients with cervical (CD) and generalized (GD) dystonia. The data was obtained during microelectrode-guided stereotaxic DBS surgeries. We used asymmetry index (AI) to separate tonic (AI>0,7) and burst (AI<0,7) cells. We measured 25 objective spike train parameters for each cell types. We estimated oscillations scores (OS) for each frequency band: theta, alpha, beta and gamma.We found robust differences in tonic and burst cells distributions in both GPi and GPe segments between CD and GD patients. CD patients had more tonic cells, while GD had more burst cells. There were no significant changes in indices of tonic or burst GPi cell discharge, with an exception of differential entropy, which was higher in GD patients and theta oscillations, which was higher in CD patients. At the same time, we didn't find any changes in GPe cells. Our finding showed the differences in burst and tonic cells distribution with no changes of unit activity patterns. We showed that GD patients are more bursty. Our results can be explained by the imbalance of direct pathway.

Title: Temporal variability in the firing of external globus pallidus neurons in monkeys

Authors: *A. GALVAN, X. HU, A. DEVERGNAS, T. WICHMANN
Yerkes Natl. Primate Res. Ctr. and Dept. of Neurology, Sch. of M, Emory Univ., Atlanta, GA

Abstract: Based on extracellular recordings obtained *in vivo* in monkeys, most neurons in the external segment of the globus pallidus (GPe) show high frequency firing interspersed by pauses while a smaller proportion of neurons show low frequency firing with bursts. Traditionally, these two patterns of firing have been considered to arise from distinct subpopulations of GPe neurons, but it is possible that the heterogeneity of firing patterns originate, instead, from temporal variations in the firing behavior of individual neurons. In rodents, GPe neurons show significant variation in firing rates across several minutes of recording (Diester et al, 2013). To examine the temporal stability of GPe neuronal firing in monkeys, we obtained long duration (10-60 min) recordings of well-isolated GPe neurons. Two monkeys (one male, one female, young adults) were prepared with chronic recording chambers aimed at the GPe. Extracellular recordings were conducted using tungsten electrodes and standard recording procedures, while the monkeys were sitting on a primate chair. The data was collected to a computer disk and spikes sorted. Timings of spikes were converted to inter-spike intervals (ISIs) for further analysis. The data were binned in one-minute bins, and for each bin we obtained several firing parameters (firing rate, ISI-coefficient of variability (ISI-CV), bursting parameters). We then calculated the maximal change observed (highest value minus lowest value) for each parameter during the recorded time. In most of the recorded 58 GPe neurons, substantial changes in firing parameters were seen across the recorded time. The firing rate changed (from minimal to maximal values obtained throughout recording), in average, 445% (SD 430%); while ISI-CV changed 291% (SD 289%), and the time the neurons spent in bursts changed in average 307% (SD 312%). We are currently in the process of studying the relationship of these long-term shifts in firing patterns to subtle changes in the state of wakefulness of the animals (based on analyses of electrocorticogram signals). Our results suggest that the firing of individual GPe neurons shows very high temporal variability. This

could explain, at least in part, the heterogeneous firing patterns that have been ascribed to GPe neurons in *in vivo* monkey recordings.

Title: The contribution of the globus pallidus and the entopeduncular nucleus to the preparation and execution of voluntary gait modifications in the cat

Authors: *Y. MULLIE, I. ARTO, J. A. LEONARD, T. DREW
Dept. de Neurosciences, Univ. de Montreal, Montreal, QC, Canada

Abstract: The locomotor deficits observed in Parkinson's disease suggest that the basal ganglia (BG) exert a strong effect on the control of locomotion. However, despite this, we have little information on the properties of neurones in different parts of the BG circuit during this essential behaviour. In this study we examined the discharge patterns of neurons in the globus pallidus (GP) and the entopenduncular nucleus (EN) (equivalent to the external and the internal segment of the primates' pallidum, i.e. GPe and GPi respectively) of 4 cats during unobstructed locomotion and during visually guided locomotion as cats stepped over obstacles attached to a moving belt. Most neurons recorded in both nuclei (N=250) showed relatively high discharge at rest (10-72 Hz) and showed either no, or relatively weak, modulation of their discharge pattern during unobstructed locomotion. When the cats stepped over an obstacle, 125/250 showed modification of their activity related to the step over the obstacle by the forelimb contralateral to the recording site. In most cells, in both nuclei, the change in activity during the step over the obstacle, as compared to that during unrestricted locomotion was relatively weak, although some cells in both nuclei did show robust changes in activity. In both nuclei, most cells discharged either just before or during the gait modification of the contralateral forelimb (coFL) (step-related cells: EN 63/75, 85% and GP, 33/50, 66%). The other modified cells (EN, 12/75, 16% and GP, 17/50, 34%) showed weak sustained activity prior to the gait modification and were classified as step-advanced cells. A substantial proportion of the step-related cells in the EN showed either a single period of increased (12/63, 19%) or decreased (13/63, 21%) activity during the step over the obstacle by the coFL. Other cells in the EN showed either increased activity related to the coFL regardless of whether the contralateral or ipsilateral forelimb was the first to step over the obstacle (9/63, 14%), or reciprocal changes in activity (8/63, 13%). Cells

showing increased activity related to the coFL regardless of lead limb were more prevalent in the GP 11/33, 33%). The results suggest that the EN exerts a more focused effect on limb activity than the GP, compatible with a view that the EN(Gpi) is more involved in specifying the required movement while the GP (GPe) may be more involved in producing anticipatory changes prior to the movement and in modulating activity in both forelimbs. Nonetheless, there was also substantial overlap in the discharge patterns observed in each nucleus.

Title: Neuronal correlates of beat-based timing in the primate striatum

Authors: *M. KAMEDA[1], S. OHMAE[2], M. TANAKA[1]
[1]Med., Hokkaido Univ., Sapporo-Shi, Japan; [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Both the basal ganglia and cerebellum are implicated in "beat-based timing" for isochronous repetitive events. To clarify how neurons in these areas represent event timing, we trained monkeys to perform the missing oddball task, in which temporal prediction of periodic visual stimuli was needed. We previously found that neurons in the cerebellar dentate nucleus (DN) showed temporally specific firing modulation during the task (Ohmae et al., 2013). In this study, we examined neuronal activity in the caudate nucleus and compared them with those recorded previously from the DN. So far, we have recorded from 84 neurons exhibiting a gradual increase of response to each stimulus as the repetition progressed, like neurons in the cerebellum. However, unlike neurons in the DN, many striatal neurons (87%) also exhibited a transient activity around the time of saccades. Furthermore, approximately 24% (12/50) of striatal neurons exhibited greater firing modulation for shorter inter-stimulus intervals, while the majority of neurons in the striatum and all neurons in the DN showed a preference for the longest interval. To clarify the functional difference, we assessed how precisely the time courses of neuronal activity predicted the next stimulus timing. Assuming that stimulus timing was predicted when the population activity surpassed a certain threshold, we searched for the optimal threshold that minimized the prediction error of the next stimulus timing (Δt) in trials with three inter-stimulus intervals (300, 400, 600 ms). We found that stimulus timing was better predicted by neuronal signals in the DN than the striatum ($\Delta t = 65 \pm 22$ ms vs. 28 ± 17 ms, bootstrap mean ± 95% CI). We also attempted to dissociate sensory from motor-related signals by locating repetitive visual stimuli and saccade target independently in either or both visual hemifields. Although most

neurons in both structures showed a significant interaction, we found that many neurons in the striatum exhibited greater firing modulation for saccade direction, while those in the cerebellar DN exhibited greater modulation for stimulus location. These results suggest that neurons in the striatum might be involved in the prediction of motor timing while those in the cerebellum in the prediction of sensory timing.

Title: Spectral-spatial separation of motor conflict and stopping in the basal ganglia-cortical circuits

Authors: *J. CHOI[1], M. MALEKMOHAMMADI[1], S. NIKETEGHAD[2], A. R. ARON[3], U. RUTISHAUSER[4], N. POURATIAN[1]

Abstract: Introduction: Action regulation and suppression are key parts of everyday behavior. This includes suppressing competing actions when initiating a specific action, suppressing all responses when presented with conflicting information, and suppressing a response when the environment rapidly changes indicating a pre-planned response must be stopped. Our overall hypothesis is that action suppression during conflict and stopping involve dissociable fronto-basal ganglia (BG) circuits. **Methods:** We took advantage of deep brain stimulation surgery for Parkinson disease, to obtain cortical and BG recordings across two action suppression tasks (Eriksen flanker task and stop signal task). We recorded local field potentials from multi-site frontal cortical regions including motor cortex, pre-supplement motor area (pre-SMA), and right inferior frontal gyrus (rIFG) and BG including subthalamic nucleus (STN) and globus pallidus (GP). **Results**: Specifically, across tasks and across the motor fronto-BG circuits, we found beta (13-35 Hz) desynchronization and low-frequency oscillations (LFOs, <8 Hz) synchronization, which were locked to the movement cue. By contrast, at the time of the stop signal there were beta activations within the rIFG, STN, and GP. Importantly, successfully stopping seemed to link to a stop signal occurring prior to reaching the peak of beta desynchronization related to the initial movement cue. The other task, which required conflict processing, showed a different spectral patterns of LFOs, in BG and involved pre-SMA and SMA rather than rIFG.

Furthermore, there was coherence between BG and pre-SMA in this low-frequency range. **Conclusions**: Our work shows spectrally and spatially task-specific patterns of neural activation based on invasive neurophysiological recordings. These findings bear on the basic science of action regulation, and on the role of parallel long-range brain networks for action.

Abstract: Cortico-basal ganglia processing can be heavily affected in Parkinson's disease (PD), where neuronal communication that enables motor control gradually breaks down. LFP recordings from the human subthalamic nucleus (STN) suggest that 60-80 Hz gamma phase coupling between the STN and motor cortex may be important for movement initiation. To test if STN-spike-to-cortical-gamma phase coupling relates to selective activation of a contra- or ipsilateral effector and to motor performance, we analysed STN spike and cortical ECoG activity recorded in PD patients undergoing deep brain stimulation surgery. Patients performed a visually cued hand grip task with either the left or right hand. When gamma coupling was high already at the time of the GO cue, about 300ms before movement onset, reaction times were faster, consistent with a role in motor preparation. This relationship was only present for contralateral grip trials, where STN spikes were modulated in a specific pattern relative to the cortical gamma cycle. STN spikes phase-led cortical gamma fluctuations and thus may help to shape cortical gamma synchrony by temporally structuring inhibitory basal ganglia output. We also found that

the average cortical gamma phase coinciding with STN spikes was offset by half a cycle during ipsilateral compared to contralateral gripping. This may be a mechanism that contributes to selective contralateral limb control while other effectors remain still. The same cells were also coupled to cortical beta oscillations after movement completion, which provides evidence that neurons may be dynamically entrained to more than one rhythm as a task unfolds. Movement-related gamma coupling was present irrespective of whether cells increased or decreased their firing rates with movement or remained stable in their firing. Thus, the temporal pattern of STN spikes with respect to cortical phase provides important information in interpreting basal ganglia function beyond average changes in firing rate. To understand the mechanisms that underlie basic basal ganglia input-to-output transformations, it will be key to perform multi-site recordings and analyse spike patterns relative to LFP oscillations in strictly controlled movement tasks.

Title: Electrophysiological correlate of Upper and Lower limb in the human basal ganglia

Authors: *G. TINKHAUSER[1], S. SHAH[1], K. PETERMAN[2], P. FISCHER[1], T. NYGYUEN[3], I. DEBOVE[2], A. NOWACKI[3], F. TORRECILLOS[1], S. KHAWALDEH[1], A. POGOSYAN[1], H. TAN[1], M. SCHUEPBACH[2], C. POLLO[3], P. BROWN[1]

Abstract: Background: Upper and lower limb somatotopy in the human sensorimotor system is well described in the cerebral cortex. However, cortical inputs to the basal ganglia are highly convergent. Is body part organisation lost or retained in this convergence?
Objective: Here we address the above question by recording directly for the subthalamic nucleus (STN) in patients with Parkinson's disease (PD) undergoing functional neurosurgery. Recordings

were made with the new generation of segmented “directional” DBS electrodes.
Method: Local field potentials were recorded from 8-contact directional DBS electrodes in 12 PD patients during repetitive contralateral and ipsilateral upper and lower limb movements. Movement-related spectral changes were estimated and compared between limbs. The spatial distributions of band-limited spectral changes were also estimated, aided by projection of the coordinates of the directional contacts in MNI space to give weighted probability density functions within the STN.
Results: Upper and lower limbs showed a striking difference in their movement-related beta desynchronization with greater involvement of the high beta band (21-35Hz) during lower limb movement, regardless of whether this was contralateral or ipsilateral to the nucleus and also independent of the strength of upper and lower limb movement. The spatial distribution of upper and lower limb movement related activities was similar in the beta (13-35Hz) frequency range.
Discussion: STN activities related to upper and lower limb movements are differentially expressed within the beta band. Given the relative lack of spatial discrimination between patterns of beta modulation related to upper and lower limb movements, the frequency difference may serve to help tag different activities in the frequency rather than spatial domain. Whether greater spatial differentiation between limb activities might be seen with higher resolution electrodes, at higher frequencies or in healthy subjects remains to be seen.
Conclusion: We provide evidence for the organisation of limb representations in the frequency domain within the STN. This information could be used to fine-tune the delivery of deep brain stimulation and to increase the potential information available from the STN for the control of neuroprostheses.

Title: Magnetothermal deep brain stimulation in freely moving mice

Authors: *S. HESCHAM[1], P.-H. CHIANG[2], J. MOON[2], M. CHRISTIANSEN[2,3], Y. TEMEL[1], P. ANIKEEVA[2]
[1]Maastricht Univ., Maastricht, Netherlands; [2]MIT, Cambridge, MA; [3]ETH Zürich, Zürich, Switzerland

Abstract: Deep brain stimulation (DBS) has long been used to alleviate symptoms in patients suffering from psychiatric and neurological disorders. Here, we demonstrate that a wireless magnetothermal approach to DBS can provide tetherless neuromodulation sufficient to evoke motor behavior in freely moving mice. Magnetothermal DBS exploits hysteretic heating of magnetic nanoparticles in the presence of an alternating magnetic field. Therefore, we heat-sensitized neurons in the subthalamic nucleus (STN) and premotor cortex (M2) by expressing the cation channel TRPV1. While magnetothermal stimulation in the M2 did not result in any difference in motor behavior, stimulation of the STN caused rotations around the body-axis. The duration of the behavior extended for 30 sec even after the alternating magnetic field was turned off. Immunohistochemical analysis revealed increased neural activity in the primary motor cortex for STN stimulated mice. This approach may provide attractive means to activate deep-brain circuits without the need for surgical implants and connectors.

Hosp., London, United Kingdom

Abstract: The movement-related modulation of beta band oscillations in the cortico-basal ganglia motor network is well established and suggests a role of these oscillations in voluntary

movement. However, most of the studies linking beta power to motor performances are based on data averaged across trials that ignore the fast dynamics of oscillatory activity and the trial-by-trial variability of motor responses. Recently it has become apparent that beta activity comes in transient bursts, which are prolonged in untreated patients with Parkinson's disease. Here, we test the hypothesis that the timing and amplitude of the bursts present in treated patients may help explain more physiological variations in motor behaviour at the single trial level. Local field potentials (LFP) were recorded from the subthalamic nucleus (STN) in twelve parkinsonian patients while they performed a visually cued joystick task. Patients were on medication, so that motor performance was optimised as far as possible. Beta bursts were defined as periods surpassing a threshold of the 75th percentile of the mean beta power. We found that beta bursts occurring in a time-limited window around the Go cue, well before movement onset, reduced the peak velocity of the subsequent movement and that this effect was further amplified by the amplitude of the beta burst. Additionally, prolonged reaction times were observed when bursts occurred immediately after the GO signal. Importantly, we confirmed that these behavioural effects were specifically related to the beta bursts and not secondary to beta power fluctuations, were limited to the STN contralateral to the active limb and confined to the beta frequency band. Together, these results suggest that the timing of beta bursts might serve to dynamically adapt moment-to-moment motor performance.

Title: Optogenetic stimulation of thalamocortical projections alters cortical phase-amplitude coupling

Authors: *M. CAIOLA[1], A. GALVAN[2], T. WICHMANN[3]
[1]Yerkes Natl. Primate Res. Ctr., [2]Yerkes Natl. Primate Res. Ctr. and Dept. of Neurology, Sch. of M, Emory Univ., Atlanta, GA; [3]Dept Neurol, Emory Univ. Sch. Med., Atlanta, GA

Abstract: Studies of phase-amplitude coupling (PAC) have become popular to examine the coherence between the slow and fast oscillations of a recorded signal due to its offline computation capability and its ease to compute over a wide range of frequencies. Recently, the coupling of the amplitude of gamma band oscillations to the phase of alpha- or beta-range oscillations has been shown to increase in electrocorticogram (ECoG) signals recorded in parkinsonian patients and primates (compared to recordings in normal individuals or those with other diseases), leading many to believe that it may be suitable as a possible biomarker for the disease and its associated motor symptoms. The reasons for the cortical PAC changes are not clear, but it is likely that cortical PAC patterns are heavily dependent on thalamic efferents to the cerebral cortex. We studied this issue directly with a series of optogenetic experiments in Rhesus macaques.

In two animals, we virally transfected neurons in the basal ganglia receiving territory of the ventral motor thalamus to express the excitatory opsins C1V1 and Chronos. We then recorded ECoG signals from the primary motor cortex and the supplementary motor area during somatic (thalamic) or terminal (cortical) stimulation. We compared PAC during stimulation with single pulses or with trains of pulses of light stimulation with PAC results based on pre- or post-stimulation ECOG recordings, using the Kullback–Leibler divergence method of quantifying PAC. We found that optogenetic stimulation caused significant PAC in gamma amplitude during periods of light pulses. The effect of terminal stimulation was stronger than that of somatic stimulation of the thalamocortical projecting neurons. These results suggest that activation of thalamic inputs to the frontal cortex may result in a temporary entrainment of gamma oscillatory activity to oscillations at lower frequencies. Conceivably, such entrainment effects triggered by thalamic activation could, in part, explain the finding of globally altered PAC patterns in the parkinsonian state.

Title: Corticothalamic functional connectivity in healthy and parkinsonian (MPTP-treated) nonhuman primates: An optogenetic study

Authors: *D. ALBAUGH[1], Y. SMITH[3], A. GALVAN[2], T. WICHMANN[4]
[1]Yerkes Natl. Primate Res. Ctr., [2]Yerkes Natl. Primate Res. Ctr. and Dept. of Neurology, Sch. of M, Emory Univ., Atlanta, GA; [3]Yerkes Res. Ctr., Udall Ctr. Excel. For Parkinson's Dis. and Dept. of Neurol., Atlanta, GA; [4]Dept Neurol, Emory Univ. Sch. Med., Atlanta, GA

Abstract: While it can be expected that cortical inputs strongly impact the activity of thalamocortical projection neurons in the basal ganglia receiving territory of the motor thalamus (BGMT), the processing of cortical inputs within the primate BGMT is likely to be complex, as these inputs target both principal cells and inhibitory interneurons in the thalamus. In traditional models of the pathophysiology of Parkinson's Disease (PD) abnormal activity patterns within the basal ganglia alter the processing of the (otherwise normal) cortical inputs to the BGMT. Our anatomical data suggests, however, that the cortical projections to the BGMT may themselves be morphologically abnormal in the parkinsonian state. Compared to healthy controls, parkinsonian (MPTP-treated) nonhuman primates (NHPs) show a reduction in cortical inputs to BGMT. The purpose of this study is to directly compare the functional influence of activation of the motor corticothalamic pathway in NHPs on the electrophysiological activity of single BGMT neurons in the healthy and parkinsonian states (induced by exposure of the animals to MPTP). The study is conducted in Rhesus macaques because the anatomy of corticothalamic interactions and intrinsic BGMT anatomy in these animals is very similar to that found in humans, specifically including the presence of extensive numbers of BGMT interneurons (which are not present in rodents). To selectively stimulate corticothalamic terminals in the BGMT, we use an optogenetic approach, virally transducing deep-layer motor cortical neurons with excitatory opsins, and optically stimulating their terminals in the BGMT. In previous studies, we found that corticothalamic pathway stimulation elicits diverse responses among BGMT neurons, including inhibitions in nearly half of all responding neurons in normal animals. Here, we report preliminary results from two subjects in an ongoing study in which the animals are first studied in the normal state, and then be rendered parkinsonian using chronic, low-dose MPTP exposure. If, as expected, corticothalamic inputs contribute less to the shaping of BGMT output to the cortex, the influence of other BGMT afferents, including those from the basal ganglia, may proportionally gain in strength, contributing to the abnormal bursting and oscillatory patterns in BGMT neurons that we and others have previously demonstrated.

Title: The chemogenetic suppression of the primate subthalamic nucleus impairs voluntary movements by disturbing the firing pattern in the internal segment of the globus pallidus

Authors: *T. HASEGAWA[1], S. CHIKEN[1,3], K. KOBAYASHI[2,3], A. NAMBU[1,2,3]

Abstract: The "rate model" of the basal ganglia (BG) functions proposes that the neuronal firing rate changes in the BG impair voluntary movements as seen in hemiballism, which is caused by lesions in the subthalamic nucleus (STN). The STN receives inputs from the cerebral cortex and the external segment of the globus pallidus and sends strong excitatory outputs to the internal segment of the globus pallidus (GPi), the output nucleus of the BG; STN lesions induce hemiballism presumably due to activity decrease in the GPi. To explore the neural mechanisms of this movement disorder, the Designer Receptors Exclusively Activated by Designer Drugs (DREADD) system was utilized to reversibly inhibit the STN activity.
We injected an adeno-associated viral vector expressing the inhibitory DREADD receptor, hM4Di, to the motor area in the STN of a male Japanese monkey (*Macaca fuscata*). The intravenous administration of 1.0 mg/kg BW of clozapine N-oxide (CNO) was performed 3-22 weeks after vector injection during a behavioral task and/or electrophysiological recordings. The STN multi-unit activity decreased by 50-55% in a few recording sites (2 out of 11) starting 15 min after the administration. This partial STN suppression induced abnormal involuntary movements on the contralateral upper limb. In addition, in a reaching task, hand movements became unstable, while the movement initiation timings were not affected.
The motor area of the GPi was electrophysiologically identified and single unit activity was recorded before and after the CNO administration (n = 19). The GPi neurons exhibited the excitation, inhibition, or mixed activity change during the reaching task. With the STN suppression, the baseline firing rates were not affected and the trial-averaged neuronal activity during movements was relatively unchanged in the GPi; however, the Fano factors and coefficient of variation, measures of the dispersion of spike trains, increased, ($P < 0.005$ and $P < 10^{-4}$, respectively) and the pauses, breaks in spike trains, became longer ($P < 0.001$). In summary, the suppression of the STN induces high variability in the spike trains in the GPi, which would cause aberrant movements and impair voluntary movements. Our results imply that the STN may dynamically modulate GPi activity to control on-going movements, contrary to the movement control through firing rates as proposed in the "rate model."

Title: The impact of glutamatergic and GABAergic inputs to the subthalamic nucleus activity in monkey

Authors: *Z. POLYAKOVA[1,2], N. HATANAKA[1,2], S. CHIKEN[1,3], H. KITA[4], A. NAMBU[1,2]
[1]Div. Syst. Neurophysiol, Natl. Inst. Physiol Sci., Okazaki, Japan; [2]Dept Physiol Sci., SOKENDAI, Okazaki, Japan; [3]Dept Physiol Sci., Sokendai, Okazaki, Japan; [4]Dept Anat and Neurobiol, Univ. Tennessee Hlth. Sci. Cent, Memphis, TN

Abstract: The symptoms of basal ganglia (BG) disorders are linked to abnormal activity of the subthalamic nucleus (STN). Modulating STN activity by deep brain stimulation or surgical lesion is an effective treatment of movement disorders. The STN receives glutamatergic inputs directly from the cortex and GABAergic inputs from the external segment of the globus pallidus (GPe), which compose the cortico-STN *hyperdiret* and cortico-striato-GPe-STN *indirect* pathways, respectively. Then, the STN drives the internal segment of the globus pallidus, the output nucleus of the BG. Thus, it is important to clarify how STN neuronal activity is controlled by these inputs. In the present study, we performed STN neuronal recording in awake monkeys (*Macaca fuscata*). Electrical stimulation of the motor cortices induced bi-phasic response in STN neurons: early excitation (*e-ex*) and following late excitation (*l-ex*). To examine the origin of each response component, we performed local micro-injections of blockers in the vicinity of recorded STN neurons and blocker injections into the striatum or the GPe. Spontaneous neuronal activity and cortically induced neuronal responses were compared before and after drug application. The amplitude and duration of cortically evoked *e-ex* in the STN were decreased after local application of 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP, NMDA receptor antagonist). Local injection of 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f]quinoxaline-2,3-dione (NBQX, AMPA-kainate receptor antagonist) decreased the amplitude of *l-ex*. Local application of mixture of NBQX and CPP into the STN decreased the amplitude and duration of *e-ex*, amplitude of *l-ex* and spontaneous firing rates. STN spontaneous firing rates increased in case of local gabazine ($GABA_A$ receptor antagonist) injection. The amplitude and duration of cortically evoked *l-ex* were decreased after muscimol ($GABA_A$ receptor agonist) injection into the striatum. Application of gabazine or muscimol into the GPe decreased the amplitude and duration of cortically evoked *l-ex*. Muscimol injection into the GPe increased STN spontaneous firing rates. Gabazine injection into the GPe decreased STN spontaneous firing rates and

increased burst index and coefficient of variation. These findings suggest that the bi-phasic response in the STN is mediated by the *hyperdirect* and *indirect* pathways, which causes *e-ex* and *l-ex*, respectively. The *hyperdirect* pathway is mainly mediated by NMDA receptors.

Title: Influence of dbs lead model and brain shift on electrode position and bending of proximal lead: A high-resolution postoperative ct study

Authors: *J. NIEDERER[1], R. PATRIAT[1], R. R. SHAMIR[2], D. P. DARROW[3], M. C. PARK[3], L. E. SCHROCK[4], N. HAREL[1]
[1]Radiology, Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Surgical Information Sciences, Inc., Minneapolis, MN; [3]Dept. of Neurosurg., [4]Dept. of Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: Deep brain stimulation (DBS) is a neurosurgical treatment requiring the implantation of electrodes in deep target regions of the brain. Precise placement of the DBS electrode has been shown to be crucial for DBS success and optimal patient outcomes. Intracranial air (ICA) can accumulate between the cranium and the brain during surgery, causing movement of brain tissue relative to its natural anatomical position. The purpose of this study was to investigate ICA volumes following surgery and DBS lead model as potential factors affecting electrode tip migration and proximal lead bowing. ICA can be measured immediately following surgery and typically resolves within four weeks post-surgery. High-resolution postoperative CT scans (≤1.0 mm resolution in all directions) at 24 hours (24-hr) and 4-week-follow-up (4-wks) were acquired after 32 DBS surgical cases, in which six cases were bilateral surgeries. A total of 38 DBS leads (n=38) were available for analysis of ICA volume and electrode position. DBS leads included Boston Scientific Vercise, Abbott/St. Jude Medical Infinity (Abbott/SJM) and Medtronic 3389. ICA volume was measured within 24-hr postoperative and correlated with electrode tip displacement and radiographic measurements of proximal lead bowing at 4-wks postoperative

CT. A one-way ANCOVA test was used to model proximal lead bowing (mean±SD: 2.2±1.2 mm) as a function of DBS lead model, ICA volume (8760±984 mm^3), and the interaction between DBS lead model and ICA volume. DBS lead model ($F=8.7$, $df=2$, $p<0.001$) and ICA volume ($F=29.2$, $df=1$, $p<10^{-5}$) were found to be significant predictors of proximal lead bowing. A Tukey-Kramer post hoc test revealed that proximal lead bowing for the Medtronic 3389 DBS lead (2.9±1.2 mm) was significantly different from the Boston Scientific Vercise (2.0±1.1 mm, $p=0.008$) and Abbott/SJM Infinity DBS leads (1.7±0.6 mm, $p=0.001$) although the Vercise and Infinity DBS leads did not differ from one another. No significant relationship was observed between DBS lead model or ICA volume and electrode tip migration (1.1±0.5 mm). Though differences in proximal DBS lead bowing were observed between DBS lead models, electrode tip migration was not affected by ICA volume or bending of the DBS lead. This may indicate a potential stretching of the electrode around the location of maximum proximal lead bowing. The significant difference observed between the Medtronic 3389 electrode and Abbott/SJM Infinity and Boston Scientific Vercise electrodes may reflect hardware engineering subtleties in the construction of segmented (Abbott/SJM) and eight contact (Boston Scientific) electrodes compared to the Medtronic 3389 four contact electrode.

Title: Deep brain stimulation at the interface of ventroanterior and ventrolateral nuclei of the thalamus as a novel effective neuromodulatory approach for Parkinson’s disease

Authors: *H. R. TUCKER[1], E. MAHONEY[1], A. CHETRI[1], G. KIM[1], A. AUDIL[1], B. MOOLICK[1], E. MOLHO[2], J. G. PILITSIS[1], D. SHIN[1]
[1]Neurosci. & Exptl. Therapeut., [2]Neurol., Albany Med. Col., Albany, NY

Abstract: The gold standard treatment for Parkinson's disease is the levodopa. However, long-term use can cause disabling abnormal movements called dyskinesias. An alternative treatment option is deep brain stimulation (DBS). The two FDA-approved DBS targets for PD are the subthalamic nucleus (STN) and globus pallidus pars interna (GPi). Both approaches improve quality of life and motor scores by ~50-70% in well-selected patients, but can also elicit adverse effects on cognition and other non-motor symptoms. Therefore, identifying a novel DBS target having greater and more expansive therapeutic efficacy for patients not optimally responsive to current targets with fewer side-effects has clear clinical merit.
A plausible DBS target is the ventroanterior (VA) and ventrolateral (VL) nuclei of the thalamus (VA+VL). Despite being critically positioned in the basal ganglia-thalamic-cortical motor loop, the VA+VL thalamus has been largely ignored as a DBS candidate in the clinical and preclinical research domains. We aim to be the first to investigate this notion.
After optimization, we noted that 10 Hz, 100 µsec pulse width and 100 µA cathodic bipolar stimulation improved forelimb akinesia in hemiparkinsonian rats.
Specifically, they touched with their left impaired forepaw 6.5% prior to DBS, but 51.4% with VA+VL DBS. Electrical stimulation of the space between the VA and VL caused higher spiking frequency in VL neurons, transition from evoked burst APs to many single spikes and presence of large depolarizing potentials. In conclusion, VA+VL can serve as an effective DBS target for treatment of PD akinesia by altering thalamic neuronal spike frequency and pattern.

Title: Effects of dopaminergic medication on choice bias in Parkinson's disease

Authors: *A. J. VAN NULAND[1], R. C. HELMICH[2,1], I. TONI[1], R. COOLS[1], H. E. M. DEN OUDEN[1]

[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [2]Dept. of Neurol., Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Bradykinesia, rigidity and resting tremor are core symptoms of Parkinson's Disease (PD), and are relieved by dopaminergic medication. However, many patients also show cognitive and motivational dysfunction. We see that PD patients have an increased ability to learn from aversive outcomes, that is reversed by dopaminergic medication, leading to preferential learning from rewards (Cools 2006). More recent ideas have posited a role of dopamine in the interaction between these processes in the form of motivational biases in motor activation (Frank 2004). Here we test this in PD patients, where we hypothesized that dopaminergic medication may alter this interaction.

Our second question concerns the large heterogeneity in PD. Specifically, we see that patients without tremor show more cognitive decline (Jankovic 2011), higher substantia nigra (SN) degradation (post mortem studies, Jellinger 1992), and reduced DAT binding in the striatum (Helmich 2011) compared with tremor-dominant patients; suggesting differences in their cognitive and motivational dysfunction. Accordingly, we hypothesized the effects of dopaminergic medication on reward and punishment learning to differ between tremor-dominant and non-tremor patients.

We included 60 patients with idiopathic PD without severe cognitive dysfunction; 40 tremor-dominant, 20 non-tremor patients and 20 controls. Patients were measured in pseudorandomized order, both OFF and ON dopaminergic medication (200/50 mg of levodopa-benserazide-dispers). In both sessions, participants performed a reinforcement learning task to disentangle the separate but interacting axes of motor response requirement (Go/NoGo) and motivational valence (reward/punishment). We investigated the effect of dopamine (OFF vs. ON) on choice and response speed.

Due to test-retest bias, we restricted analysis to session one. Contrary to our expectations, we found no overall effect of medication on motor or motivational processing, nor their interaction. However, there was a significant effect of PD group on the interaction between medication and valence: Non-tremor patients behaved as expected, performing better for reward trials ON medication, while tremor-dominant patients showed declined punishment learning OFF medication. This was independent of the motor response domain. This finding suggests that effects of dopaminergic medication on reward sensitivity are modulated by the Parkinson phenotype (tremor-dominant or non-tremor), which may be related to differences in cognitive decline between these groups, and potentially, differences in SN degradation, underlining the diversity of disease expression in PD.

Title: Aberrant striatal activity in parkinsonism and levodopa-induced dyskinesia

Authors: *M. RYAN[1], C. BAIR-MARSHALL[2], A. B. NELSON[2]
[1]UC San Francisco, San Francisco, CA; [2]Neurol., UCSF, San Francisco, CA

Abstract: In Parkinson's Disease (PD), the loss of dopaminergic input profoundly alters the activity of the striatum, the input nucleus of the basal ganglia. The mainstay treatment for PD, levodopa, relieves many of the motor symptoms of the disease, but long-term treatment is often complicated by the development of involuntary movements, known as levodopa-induced dyskinesia (LID). While the mechanisms underlying PD and LID are currently unknown, aberrant firing of striatal neurons is response to chronic dopamine loss and dopamine replacement therapy is a prevailing hypothesis. Using single-unit recordings of optically identified direct and indirect pathway neurons in a mouse model of PD and LID, we sought to dissect the responses of striatal neurons to chronic and acute changes in dopamine. Using this approach, we found that dopamine loss was associated with a profound loss of direct pathway firing, while levodopa robustly modulated both direct and indirect pathway neuron firing beyond rates typically observed in healthy controls. Both direct and indirect pathway neurons also exhibited impaired correlations to movement following dopamine loss, which was not restored by levodopa. Finally, we identified a distinct subpopulation of direct pathway neurons which showed aberrant excitation in response to levodopa, with firing rates tightly correlated to dyskinesia.

Title: Massively sparse coding of dynamics in basal ganglia

Authors: *T. D. SANGER
Biomed. Engin., USC, Los Angeles, CA

Abstract: Deep-brain stimulation surgery provides an opportunity for single-unit recording in the basal ganglia and thalamus of humans. Firing rates in the internal globus pallidus (GPi) of adults with Parkinson's disease and in non-human primates are typically 40hz or greater. In GPi and thalamus of children with dystonia due to cerebral palsy (CP), we find firing rates are typically 5-10hz, and there is a large subpopulation of slow-firing cells with rates less than 1hz. Simultaneous firing (within 0.5msec) is counted for all pairs of neurons and compared to the predicted rate for independent firing. The chi-squared statistic for autocorrelation between different cells is highly significant. The pattern indicates that coincident spikes occur much more frequently within the same region, and are seen most often in GPi, Voa/Vop, and STN. Significant coincidence at 0 delay suggests that simultaneous spikes are due to common inputs to each region. These findings are consistent with a digital hash code, in which sensory-motor events are encoded in time-locked patterns of firing. There are approximately 350,000 neurons in each human GPi [Hardman et. al. 2002], sufficient to allocate 50 two-neuron pairs for every second, and 17 three-neuron triplets for every millisecond of an 80-year life. This supports an algorithm in which all experience is stored, and learning (through dopamin- ergic systems) identifies which experiences are rewarded and selected for future repetition. Generalization is predicted to occur only after sufficient repetitive practice of similar senso- rimotor tasks, so that variability is experienced and learned. The structure is consistent with common observations of motor learning, including highly context-specific generalization, "one- shot" learning, minimal interference between dissimilar tasks, and absence of forgetting. I provide simulations of a spike-based persistent memory algorithm for robot control that reflects the human recordings and possesses these properties.

Title: Identifying gait dysfunction in Parkinson's disease using local field potentials

Authors: C.-H. YEH[1], P. FISCHER[1], C.-C. CHEN[2], *H. TAN[1], P. BROWN[1]
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Chang Gung Mem. Hosp., Taoyuan, Taiwan

Abstract: Parkinson's disease (PD) is characterized by several motor signs. Standard deep brain stimulation (DBS) of the subthalamic nucleus (STN) treats rigidity, bradykinesia and tremor, but can fail to improve freezing of gait (FOG). This has prompted trials of alternative stimulation patterns and brain sites. An ideal approach might be to automatically switch between stimulation regimes according to need. We set out to identify periods of increased risk of FOG from local field potentials (LFP) recorded directly from the DBS electrode so as to keep invasive or peripheral instrumentation to a minimum in any chronic realization of adaptive DBS. Recordings took place off dopaminergic therapy, in the interval between electrode implantation in STN and connection to a subcutaneously placed stimulating device a few days later. LFPs were recorded bilaterally (15 patients, 30 STNs), together with the signal from a triaxial accelerometer (ACC) fixed over the upper thoracic level spinous processes to record trunk acceleration. Two conditions, simple walking and dual task gait (walking and simultaneous performance of either a calculation, color Stroop or spatial memory task) were tested. Total power and the FOG index (iFOG) derived from the ACC were used to identify standing, walking and periods of increased risk of FOG. As expected, iFOG was higher during dual task gait. LFP β power was significantly higher during walking when iFOG was low, and higher still during standing. In addition, alpha power was elevated during dual task gait, and β power variability and the fractal α value over θ to α frequencies were highest during walking with a high iFOG (all $p<0.05$ in ANOVAs and post-hoc testing). The α/β power ratio, β power variability and fractal values were positively correlated, whereas β power was negatively correlated with iFOG across the different tasks (mean $r=0.34\pm0.04$, 0.22 ± 0.04, 0.22 ± 0.06 and -0.30 ± 0.06, respectively). The data suggest that it might be possible to decode iFOG and therefore risk of FOG from STN LFP recordings. Other than avoiding peripheral instrumentation, the LFP potentially offers the opportunity for early prediction. To explore this and to confirm the feasibility of closed-loop DBS for gait dysfunction, a Wiener cascade model was used to decode iFOG based on STN LFP using the

above features. Weight distribution across the features indicated that the α/β power ratio contributed most to decoding vulnerable gait periods. Critically, this contribution began 0.4s and peaked 0.1s before iFOG changes, potentially allowing anticipatory stimulation regime switching.

Title: Motor synchronization to rhythmic auditory stimulation (RAS) attenuates dopamine responses in the ventral striatum in young healthy adults

Authors: *Y. KOSHIMORI[1,3], A. STRAFELLA[2,3,4,5], M. VALLI[2,5], V. SHARMA[1], S.-S. CHO[3], S. HOULE[3], M. THAUT[1,3]
[1]Music and Hlth. Res. Collaboratory, [2]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [3]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [4]Toronto Western Hosp., Toronto, ON, Canada; [5]Krembil Res. Inst., Toronto, ON, Canada

Abstract: Objective and rationale: External auditory stimuli such as metronome clicks and rhythmic beats in music facilitate motor behaviors in healthy adults and clinical populations such as people with Parkinson's disease (PD).[1,2] Auditory-motor entrainment modulates activities in the basal ganglia (BG).[3,4] However, the exact underlying neurochemical mechanisms of dopamine (DA) are entirely unknown. The current study is sought to investigate the role of DA in BG during rhythmic entrainment in young healthy adults. **Methods**: Eleven (M:5) right-handed young healthy adults aged between 18 and 35 were included in this study. Each participant underwent two [^{11}C]-(+)-PHNO-PET scans. During one PET scan, a participant performed a finger tapping task synchronized to RAS with different tempi (RAS condition). During the other scan, he/she performed the same finger tapping task without RAS (No-RAS condition). The PET images were processed using the in-house software platform and binding potential relative to the non-displaceable compartment (BP_{ND}) values were used as outcome measures for DA responses and derived using the simplified reference tissue method using PMOD. DA responses were compared between conditions in the BG structures including the ventral striatum, putamen, caudate and globus pallidus bilaterally. **Results**: RAS reduced the

absolute tapping period error (p = 0.077) and significantly reduced tapping variability (p = 0.034). Nine of the 11 participants showed reduced DA responses during the RAS condition in the left ventral striatum (VS) compared to the No-RAS condition (p = 0.035). In addition, the DA responses in the left VS showed a significantly positive correlation with the DA responses in the left globus pallidus during the No-RAS condition (p = 0.026), which was not observed during the RAS condition. Additionally, using the [^{11}C]-(+)-PHNO data with partial volume correction, eight of the 11 participants showed greater DA responses during the RAS condition in the right VS compared to the No-RAS condition. **Conclusions and future directions**: Our data have corroborated that RAS facilitates motor behavior and demonstrated that RAS attenuates DA responses in the left VS in young healthy adults, suggesting that finger tapping without RAS may require more motivational/attentional effort to perform the task. The future studies will investigate whether RAS has the similar effect on DA responses in healthy older adults and people with PD who have altered DA systems. 1.Thaut et al (1996). Mov. Disord; 2. Abstract: Neurosurgical interventions that use active patient feedback, such as the implantation of a deep brain stimulating electrode, create an opportunity to conduct human behavioral experiments during the acquisition of invasive neurophysiology. Here, we present a modular, inexpensive system for auditory decision-making tasks, including stimulus presentation and collection of motor responses. We characterize behavioral responses with latency to respond and accuracy of response. In addition, we analyze the temporal pattern of substantia nigra pars reticulata (SNr) spiking relative to specific task events. We validate a decision-making task designed for use in the intraoperative setting. We have created an auditory-stimulus guided, two-

alternative forced choice (2AFC) task using the PsychToolBox suite developed in Matlab. Task responses are collected using an Arduino based single-hand held controller that has been customized with a 3D printed attachment. Neural activity is recorded from microelectrodes via a NeuroOmega system (Alpha Omega, Alpharetta GA). Task and neural data are aligned according to TTL signals sent from DATAPixx (VPixx Technologies, Montreal, Quebec), triggered by Matlab. We demonstrate the utility of a simple-to-implement sensory-motor task amenable to an intraoperative setting that can be combined with invasive neurophysiology. Data collected and analyzed to date demonstrates that single-unit activity reflects task variables associated with our 2AFC. For very low cost and minimal effort, most clinical neural recording system can be adapted for concurrent intraoperative behavioral testing using our framework. Barriers to conducting intraoperative electrophysiological studies in awake behaving human subjects remain high, but our work should significantly decrease the effort needed to implement a system with rich recording capabilities.

Title: Control of dynamic force tasks: Low-frequency oscillations in force and modulation of muscle activity

Authors: *S. PARK, C. KIM, B. YACOUBI KEYHANI, E. A. CHRISTOU
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Force variability during steady force tasks is strongly related to low-frequency oscillations (<0.25 Hz) in force. However, it is unknown whether low-frequency oscillations also contribute to the variability of dynamic force tasks. To address this, twelve healthy young participants (21.08 ± 2.99 years, 6 females) performed a sinusoidal force task at 15% MVC at two different frequencies (0.5 and 1 Hz) with isometric abduction of the index finger. We recorded the force from the index finger and surface EMG from the first dorsal interosseous muscle and quantified the following outcomes: 1) trajectory variability and accuracy; 2) power spectrum of force and EMG bursting below 2 Hz; 3) power spectrum of the interference EMG from 4-60 Hz. The trajectory variability and error significantly increased from 0.5 to 1 Hz task ($P < 0.01$). Increased force oscillations <0.25 Hz contributed to greater trajectory variability and

error for both the 0.5 and 1 Hz sinusoidal task ($R^2 > 0.33$; $P < 0.05$). The <0.25 Hz oscillations in force were positively associated with greater power in the <0.25 Hz for EMG bursting ($R^2 > 0.52$; $P < 0.01$). The modulation of the interference EMG from 35-60 Hz was a good predictor of the <0.25 Hz force oscillations for both the 0.5 Hz task and 1 Hz task ($R^2 > 0.66$; $P < 0.01$). These results provide novel evidence that, similar to steady contractions, low-frequency oscillations of the motor neuron pool appear to be a significant mechanism that controls force during dynamic tasks.

Title: Influence of transcranial static magnetic field stimulation over primary motor cortex on pinching force control

Authors: *K. NAKAGAWA[1,2,3], K. NAKAZAWA[1]
[1]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Toronto Rehabil. Inst., Toronto, ON, Canada

Abstract: Transcranial static magnetic field stimulation (tSMS) has recently been demonstrated to modulate cortical excitability (Oliviero et al. 2011; Kirimoto et al. 2014; Nojima et al. 2015) and sensory function (Gonzaletz-Rosa et al. 2015; Carrasco-Lopez et al. 2017) for human, but the effect of tSMS on motor behavior is still unknown. This study was performed to investigate whether tSMS on primary motor cortex (M1) can alter voluntary force control. Fourteen able-bodied subjects performed ballistic pinching contractions with predetermined submaximal force level without visual feedback. Tasks were performed in bilateral hands alternatively, before, 5 mini, 10 min after start of the intervention, immediately and 5 min after the end of intervention. A compact magnet for tSMS and a stainless steel cylinder for sham stimulation were positioned on either right or left M1 for 15 minutes. Results demonstrated that there was no difference between hands in mean force output level. However, we found significant differences in absolute error to the target force level between tSMS and sham conditioned hands during and after intervention, while there was no differences between right and left hands. Compared to the pre-intervention session, the absolute error increased in tSMS-conditioned hand, but not in sham-conditioned hand. These results suggested that perceptive or planning function in M1 rather than

final descending output function would be impaired in tSMS. In conclusion, tSMS on M1 can impair the accuracy of submaximal pinching force control.

Title: Motor cortical excitability was modulated after strong voluntary contraction

Authors: *W. DAI[1], K. KATO[2], J. ZHANG[3], K. KANOSUE[2]
[1]Grad. Sch. of Sport Sci., Waseda Univ., Tokorozawa, Saitama, Japan; [2]Fuculty of Sport Sciences, Waseda Univ., Saitama, Japan; [3]Sch. of kinesiology, Shanghai Univ. of Sport, Shanghai, China

Abstract: Motor learning facilitates motor cortical excitability through long-term potentiation (LTP). However, a single session involving a simple muscle contraction can also enhance motor cortical excitability. It is not yet clear whether the mechanisms that underlie the two phenomena are the same. This research examines whether changes in cortical excitability after a single session of simple muscle contraction are related to excitability changes that are produced by paired associative stimulation (PAS), which is known to elicit LTP. Eleven healthy subjects performed three types of rapid voluntary thumb contraction 90 times at 0.2Hz. In the "comfortable" task (T-C), the subjects were only required to flex their thumb as quickly as possible. In the "strong" task (T-S), the subjects were required to flex their thumb at 65%-85% of maximum voluntary contraction as measured by electromyography (EMG). In the "comfortable but control" task (T-CC), subjects were required to control the EMG level of thumb contraction at the same level as in the T-C task. The target EMG levels were viewed by the subjects on a computer screen. In the separate PAS experiment, repetitive pairing of median nerve stimulation and transcranial magnetic stimulation (TMS) over the contralateral motor cortex with a 25ms latency was applied 90 times at 0.2Hz to induce LTP (PAS25). Motor cortical excitability was measured with motor-evoked potentials (MEP) using TMS. We utilized a 1 mV MEP intensity baseline for each subject and stimulated with the same intensity at 0, 5, 10, 15, 20, 25, 30, 45, and 60 min after executing one of the three tasks or the PAS25. The average EMG level for T-C was significantly lower than that of T-S but was not different from T-CC. MEP amplitudes increased over time for both
PAS25 and T-S with a very similar time course. Among the three contraction tasks, only the peak value of T-S had a significant positive relationship with both the under-curve area (AUC) and the peak value of PAS25. Thus, it might be that the MEP modulation similar to that observed

in PAS25 occurred only in the T-S, in which strong contraction should be controlled. Thus, for MEP modulation, the crucial factor in the correspondence between PAS and a single session of simple muscle contraction involves the subject's voluntary control over a strong muscle contraction.

Title: Rapid learning and unlearning of sensory delays in self-touch

Authors: *K. KILTENI, C. HOUBORG, H. EHRSSON
Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Prevalent theories of motor control posit that our brain uses internal models to predict the sensory consequences of our voluntary movements. Due to these predictions, the perception of the sensory feedback of our movements is attenuated compared to unpredictable stimuli of external origin and same intensity. It has previously been shown that these predictions are time-locked to our movements and even small delays between the movement onset and the sensory feedback can significantly reduce the attenuation of the latter. Here we test whether the brain can learn to predict a new temporal relationship between movement and somatosensory feedback.
A total of ninety volunteers participated in three experiments. All experiments included the same force discrimination task, in which the participants were asked to press a sensor with their right index finger that delivered a tap (2 N) on their left index finger. The tap was applied either immediately (0 ms) or with a 100 ms delay. Thereafter, a second tap (between 1 and 3 N) was applied on the left index finger and participants had to indicate which tap felt stronger using a foot pedal. Prior to the force discrimination task, participants were repeatedly exposed to either a 0 ms or a 100 ms delay between the press of the right index finger and a tap on the left index finger in a training session consisting of 50 (Experiment 1), 200 (Experiment 2) or 500 exposure trials (Experiment 3).
In Experiment 1 (50 exposure trials), we found a reduction in the participants' attenuation of immediate touch **(**N=30, $t(29)=2.86$, $p=0.008$**)** but no attenuation of the delayed touch (N=30, $t(29)=-1.23$, $p=0.231$). When including 200 exposure trials (Experiment 2), the new set of participants showed again a reduced attenuation of immediate touch (N=30, $t(29)=4.73$, $p<0.001$) but also exhibited an increased attenuation of the delayed touch (N=30, $t(29)=-2.65$, $p=0.013$).

With 500 exposure trials (Experiment 3) we found the same pattern with the new set of participants: decreased attenuation of immediate touch (N=30, t(29)=3.03, p=0.005), and increased attenuation of delayed touch (N=30, t(29)=-3.5156, p=0.002). We further observed that the reduction in the attenuation of immediate touch was correlated with the increase in the attenuation of delayed touch **(***r*=0.473, *t*(28)=2.84, *p*=0.008**)**. Taken together, the data from all three experiments consistently show that participants can rapidly learn and unlearn sensory feedback delays in their movements. These findings suggest that the brain can update the internal forward models by recalibrating the temporal relationship between our movements and their sensory consequences.

Title: Action observation suppresses I-waves in a muscle specific manner

Authors: *A. CRETU[1], N. WENDEROTH[2]
[1]Health, Sci. and Technol., Neural Control of Movement Lab., Zürich, Switzerland; [2]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland

Abstract: Studies using single-pulse transcranial magnetic stimulation (spTMS) demonstrated that corticospinal excitability changes during action observation are similar to those obtained during action execution (i.e., motor resonance). However, the amplitude of motor evoked potentials (MEPs) elicited by spTMS reflects a combination of excitatory and inhibitory inputs which converge onto descending pyramidal tract neurons. It is unclear which of these components contribute to the muscle-specific modulation of M1 during action observation. One theory proposes that the late excitatory inputs to M1 come from premotor cortex which is one main node of the action observation network.
Here, we explored the modulation of early and late excitatory indirect inputs to M1 (I-waves) during action observation by employing a short intracortical facilitation (SICF) TMS protocol whereby suprathreshold TMS is followed by a subthreshold pulse which is separated by 1.3, 2.5 or 4.1 ms i.e., targeting the first (I1), second (I2) or third (I3) I-wave.
We measured changes in MEP amplitude in the index (FDI) and little finger (ADM) while participants observed snapshots from videos depicting the grasping of a jar using either a whole-hand (WHG) or precision grasp (PG). We used a succession of the three snapshots (reach, grasp, lift) which gave the impression of a continuous movement. TMS pulses were administered 200ms after grasp presentation since previous electrophysiological and TMS research showed

that motor resonance can be observed around 200ms after action onset.
We first tested whether motor resonance was present during the observation of grasp snapshots by assessing the muscle specificity elicited by spTMS during the observation of WHG and PG actions. We found a higher MEP amplitude in the ADM muscle when observing whole-hand versus precision grasping and the reversed result pattern for the FDI (revealed by significant muscle specificity p=.001).
Next we calculated the amplitude of the I-waves as the ratio between the average amplitude of MEP evoked by paired-pulse TMS and the average amplitude of the single-pulse MEPs, separately for each muscle, grasp type and paired-pulse protocol. Here, we found a grasp type x muscle specificity interaction which reached significance for the I2-wave (p=.023). Interestingly, the modulation pattern is reversed compared to the one obtained with single pulse, i.e. the I2-wave amplitude is higher during precision than whole-hand grip in the ADM muscle. We hypothesize that this apparent suppression of facilitation might be required for the inhibition of overt movements in the observer.

Title: Modulation of capacity for motor learning by transcranial alternating current stimulation

Authors: *H. SUGATA[1], K. YAGI[2], S. YAZAWA[3], Y. NAGASE[4], K. TSURUTA[3], T. IKEDA[5], K. MATSUSHITA[6], K. KAWAKAMI[1]

Abstract: Transcranial alternating current stimulation (tACS) is a non-invasive brain stimulation technique that can facilitate motor learning. Although many tACS studies have focused on immediate motor performance or retention of motor learning by stimulation at 10, 20, and 70 Hz, few studies have examined the effect of tACS on the modulation of the capacity for motor learning. Considering that tACS affects motor performance, it may increase the capacity for motor learning. To resolve this issue, we investigated the capacity for motor learning before and after tACS. In addition, to clarify the brain activity during motor learning, we examined

oscillatory neural activity with magnetoencephalography (MEG) before and after tACS. Fifty-five healthy volunteers participated in this study. By means of a between-subject design, participants were randomly assigned to four stimulation groups (10 Hz, 20 Hz, 70 Hz, or sham). The subjects performed a visually cued button press motor learning task before and after tACS. MEG measurements were performed using a 306-channel whole-head MEG system during the motor learning task in a magnetically shielded room. After the initial motor learning task, tACS was delivered with a battery-driven constant current stimulator through a pair of saline-soaked sponge electrodes. The target and reference electrodes were placed over the C3 and right orbita, respectively. Stimulation was applied for 10 min at 1 mA. Impedance values were maintained below 10 kΩ. The results showed that there was a significant increase in the capacity for motor learning after 70 Hz tACS compared with that after sham stimulation ($p < 0.05$). In addition, MEG analysis showed a significant increase in beta band power after 70-Hz tACS ($p < 0.05$), but not in the other stimulation groups. Recent studies have reported that 70-Hz tACS over M1 facilitates force generation and movement velocity. In the present study, the capacity for motor learning significantly increased in the 70-Hz tACS group compared with that in the sham group. Furthermore, beta band cross frequency modulation was observed in the 70-Hz tACS group. Our results suggested that 70-Hz tACS increases the capacity for motor learning by cross-modulating beta oscillatory activity.

Title: Digit force magnitude and inter-digit force coordination effects on performance of a complex isometric pinch force tracking task

Authors: J. VINES[1], M. SCHLEICHER[1], R. ADLIS[2], D. LEE[3], C. HILTON[1], R. T. EAKIN[1], *L. D. ABRAHAM[1]
[1]Kinesiology and Hlth. Educ., Univ. of Texas at Austin, Austin, TX; [2]Neurosci., [3]Biol., The Univ. of Texas at Austin, Austin, TX

Abstract: This study investigated how different required force levels and digit coordination patterns affect performance on a complex isometric pinch force tracking task. Forty-eight healthy volunteers (24 females, 24 males) ages 18-30 years (mean = 20.8 +/- 2.7) manipulated a cursor

with their right thumb and index finger pinch forces to track a target traveling counterclockwise around a square diamond path. Accuracy and error variability were compared across four different force-level diamond paths. Each path required continuous simultaneous but independent changes in the patterns of force application and release by the thumb and index finger. Participants were pseudo-randomly assigned to a practice order so that two were assigned to each of the 24 possible orders of tracking on the four diamond paths. Instructions were to keep the cursor on the moving target, or as close as possible, while it steadily moved counter-clockwise twice around the diamond. Pre- and post-test pinch force maximal voluntary contraction (MVC) measures were used to scale the actual force levels tested to each participant's strength and to assess fatigue. Each participant completed 15 practice trials and 5 test trials per diamond path for a total of 80 trials. Two dependent variables, root mean squared error (RMSE) and coefficient of variation of the error (CVE), were calculated to assess accuracy and variability, respectively, for the individual digits and for combined-digit scores. Four-way repeated measures ANOVA was used to determine how accuracy and variability varied among the 4 diamond paths, the two circuits in each trial, and the four sides of each diamond. No significant differences in RMSE and CVE were found between the diamond locations, suggesting that MVC-scaled force level was not a significant factor for this task. Interestingly, the second circuit had higher RMSE and CVE than the first circuit, which may have been related to fatigue. Performance on the four sides of each diamond differed in some conditions, evidenced by a main effect of sides in CVE and significant interactions between sides and other factors for both RMSE and CVE. For accuracy, the combined-digit RMSE was significantly greater than the horizontal and vertical components generated by the two digits. For variability, all of the components were significantly different from each other. The results of this study suggest that, unlike previous results with a simple isometric pinch force tracking task, tracking performance accuracy and variability are not simply affected by MVC-scaled task force level but are differentially affected when the required coordination pattern of the two digit forces varies during the task.

Title: Kinematic fluctuation contributes to unintentional error in writing movements

Authors: *C. YAMADA[1], Y. ITAGUCHI[2], K. FUKUZAWA[3]
[1]Waseda Univesity, Tokyo, Japan; [2]Dept. of Syst. Design and Engin., Keio Univ., Kanagawa, Japan; [3]Waseda Univ., Shinjuku-ku, Japan

Abstract: A slip of the pen is one of the most typical action slips in our daily life. Action slip is unintentional error in action or sequence of behavior that cannot be attributed to failure of memory. It has been said that action slip occurs when people perform many simple skilled action automatically, and they do not explicitly monitor the feedback from each action. In terms of action slips in writing, previous studies reported that an experimental approach called Rapid Repeated Writing (RRW) can induce slips of the pen. RRW requires participants to write one character repeatedly as fast as possible for a few minutes. During RRW, some people mistakenly write different characters from what they intend to write.
Previous models assumed that improper activation and triggering of a schema (a motor memory unit) contribute to slips of the pen. Though several studies had suggested that improper activation caused by repetitive movement of RRW results in slips of the pen, it remains unclear what is a critical factor for improper triggering of a schema of an unintended character. We hypothesized that kinematic fluctuation in writing movements causes temporal discrepancy in the timing of the predicted and actual feedbacks and leads to improper triggering of an unintentional schema. The present study investigated how kinematic aspects of writing movements change just before slips of the pen occur.
In the experiment, 30 participants performed two-minutes RRW of one Hiragana character for five trials. We recorded their writing movements to calculate writing time per character, interval time between characters, and trajectory and velocity of the movements. These indices were compared between three periods: the initial period and the last period of a trial, and a period just before a slip occurred.
As a result, slips of the pen was observed in 14 participants. The one-way ANOVAs showed that both writing time and time interval in the pre-slip and the last periods were significantly longer than that in the initial period, and the variance of time interval in the pre-slip and the last periods were also significantly larger than that in the initial period. In contrast, the variance of writing time was significantly larger in the pre-slip period than in the initial and the last periods. In addition, kinematic fluctuations in trajectories of writing movements were observed in the pre-slip period. The larger variance of writing time and useless kinematic fluctuations in the pre-slip period suggest that temporal discrepancy in the timing of the predicted and actual feedbacks leads to improper triggering of schemas and induces slips of the pen.

Title: Ipsilateral corticospinal excitability and contralateral corticomuscular drive are related phenomena

Authors: *C. M. LAINE[1], N.-H. KO[1], F. J. VALERO-CUEVAS[1,2], B. E. FISHER[1]
[1]Div. of Biokinesiology and Physical Therapy, [2]Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstract: Cortical drive to contralateral muscles contains a beta-band (~20 Hz) oscillation during constant-force isometric tasks, such as a precision pinch, but subsides in more complex tasks. Several lines of evidence suggest that transitioning away from isometric force production engages dispersed networks, many of which project to bilateral motor cortices. Separately, others have shown that complex unimanual tasks also increase ipsilateral corticospinal excitability. Here we test the hypothesis that these two phenomena are related. We recorded beta-band drive to the right abductor pollicis brevis (APB) and first dorsal interosseous (FDI) muscles of 10 participants as they pinched either 1) a wide spring or 2) slender spring, at matched forces (< 3N). The slender spring is prone to buckling, and thus requires more dynamic, but minute, changes in the direction of pinch force. Compression of this spring has been shown to reduce beta-band synchronization between the EMG signals recorded from the FDI and APB muscles (a measure of shared corticomuscular drive). In contrast, compressing a wide spring is known to maximize beta-band intermuscular synchronization. During spring compression of each spring, single-pulse transcranial magnetic stimulation (TMS) of the ipsilateral (right) motor cortex was used to measure ipsilateral corticospinal excitability by producing motor evoked potentials (MEPs) in the unengaged (left) FDI. Our results show that slender spring compression was associated with decreased right hand FDI-APB synchronization ($p = 0.004$, signed rank test) and increased left hand MEP amplitudes ($p = 0.014$, signed rank test), as compared with compression of the wide spring. Across participants, the average change in MEP amplitudes between the two tasks was negatively correlated with the average change in FDI-APB synchronization (Spearman's $rho = -0.82$, $p = 0.007$). This strong association suggests that the oscillatory content of cortical drive to contralateral muscles is modulated by the same processes that inhibit the excitability of the ipsilateral cortex during unimanual tasks. While further work is needed to understand the connection between motor cortex oscillations and excitability, our data do emphasize that the oscillatory drive to muscles is indicative of extensive (and bilateral) upstream network activity.

Title: An fNIRS study of sensorimotor cortical hemodynamics in hand motor tasks coupled with pneumotactile stimulation at different traverse velocities

Authors: *M. HOZAN[1,2,3], J. GREENWOOD[1,2,3], M. K. SULLIVAN[1,3], S. M. BARLOW[1,2,3]
[1]Ctr. for Brain, Biol. and Behavior, [2]Biol. Systems Engin. Dept., [3]Dept. of Special Educ. and Communication Disorders, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: BACKGROUND: The cerebral hemodynamic response (HR) is accessible by functional near-infrared spectroscopy (fNIRS) while participants perform repetitive motor activity and simultaneously receive patterned somatosensory stimulation. OBJECTIVE: Assess the spatiotemporal pattern of the cerebral HR in response to controlled sensorimotor pacing during precision grip in one hand performed at two distinct velocities (25 & 45 cm/sec) simultaneous with saltatory pneumotactile stimulation of the glabrous hand. The effects of specific motor and sensory velocities on the evoked HR, and the correlation between them will be assessed. 1) Activation of both pre- and post-central hand/digit representation is predicted in hemisphere contralateral to the active hand. 2) Evoked HR responses (HbO) expected to show dependence on task and stimulation velocity. METHODS: Prospective study involving 20 neurotypical adults (19-35 yrs). Saltatory pneumotactile stimulation (60 ms pulses, 8-chan array) traversed the glabrous hand (D1-D5) at 25 and 45 cm/s, while subjects performed precision grip at a matching velocity. A random-balanced block design was used for stimulus presentation (20s stim ON; 20s stim OFF; 10 reps/velocity) during fNIRS data acquisition (NIRx Scout, montage of 16 dual-tip LED emitters (760 nm, 850 nm) and 20 detectors (7.8125 Hz sampling rate) placed bilaterally over motor and somatosensory cortices. Anatomic MRI (3T; MPRAGE; 0.5x0.5x1.0 mm; TE=4.92 ms; TR=20 ms) was acquired for fNIRS co-registration using a Polhemus head digitizer. RESULTS: 1) A primary HR peak in HbO at 4.5 s on the contralateral hand pre- and post-central gyri, with a significantly larger evoked HbO signal for the 45cm/s compared to the 25cm/s condition. 2) A secondary HR peak at 13 s, including expansion of evoked HbO signal Broca's area, face M1, and supramarginal gyrus. CONCLUSION: Non-invasive fNIRS methodology reveals sensorimotor topography associated with grip dynamics and saltatory pneumocutaneous stimulation at controlled velocities. Title: Reconsolidation task performed with untrained limb enhances motor skill acquisition

Authors: *T. GYODA, K. ISHIDA, T. WATANABE, I. NOJIMA
Nagoya Univ., Nagoya, Japan

Abstract: Motor skills are acquired through training and rely on consolidation (stabilization of the motor memory obtained during training). Reconsolidation, in which previously consolidated memories become temporarily unstable, can further enhance the skill acquisition by re-stabilization. Also, motor skill acquisition is greater with variable than constant practice (Wymbs et al., Curr Biol, 2016). Moreover, intermanual transfer is a well-accepted phenomenon of motor learning and has important implications for rehabilitation. Here, we investigated whether a reconsolidation task performed by the hand opposite to the one originally used for practice would enhance performance gain and whether the performance gain would depend on the type of reconsolidation task (variable or constant practice). Subjects performed a sequential visual isometric pinch force task (SVIPT), which required them to move a horizontal screen cursor

between a start position and different target gates as accurate and fast as possible by producing pinch force with their right (R) or left (L) hand. In this task the skill was acquired by shifting the speed-accuracy-tradeoff function. In addition to the original SVIPT (task A), we create the modified version of the SVIPT (task B), in which the original sequence was intermixed (variable practice). The subjects were assigned into one of three groups (RA-LA-RA, RA-LB-RA, or RA-RA). In session 1, all subjects performed RA task (task A with R hand) for 4 blocks. In session 2 (6 hours after session 1), the subjects in the RA-LA-RA and RA-LB-RA groups practiced either LA or LB task 4 blocks, depending on the group assignment, after a brief reactivation RA (1 block). In session 3 (24 hours after session 1), all subjects were tested with the RA task. Based on the average movement time and error rate, we evaluated the motor skill acquisition by quantifying changes in the speed-accuracy tradeoff function (Reis et al., PNAS, 2009). We found that the motor skill acquisition in session 3 in the RA task was higher for the RA-LA-RA and RA-LB-RA groups than the RA-RA group. However, there was no significant difference between RA-LA-RA and RA-LB-RA groups. These findings suggest that a reconsolidation task performed by the unpracticed hand can enhance the acquisition of fine motor skills regardless of the reconsolidation task type (variable or constant).

Title: Multimodal reference frame during rhythmic arm movements in different body orientations with respect to gravity

Authors: *L. OPSOMER[1,2], F. CREVECOEUR[1,2], J. MCINTYRE[3,4,5], J.-L. THONNARD[1,2], P. LEFÈVRE[1,2]

Abstract: Dexterous manipulation of objects requires predicting the inertial consequences of one's movements, but also taking into account the action of gravity on our body and the objects we interact with. One consequence is that we expect movement kinematics and dynamics to be parameterized in an allocentric (gravity-based) reference frame. The present work addressed this

aspect of motor control by studying object manipulation during rhythmic arm movements in different body orientations with respect to gravity.
Eight subjects participated in the experiment. They were instructed to perform arm oscillations with an object held in precision grip. The oscillations were performed with stretched arm in the vertical direction with respect to the body. The subjects were seated and attached to a chair that could take three positions: UPRIGHT (head up), SUPINE (face up) or UPSIDE-DOWN (feet up). They performed four blocks of 25 oscillations per position. The position and acceleration of the manipulated object as well as the forces applied by the fingers on the object were measured. Analysis of the movement kinematics revealed a strong influence of the change in position consistent with an allocentric reference frame. Indeed, the Positive Acceleration Duration of the movement (PAD, acceleration being positive when directed towards the head) was significantly influenced by the position of the chair: while significantly lower than 50% of a full cycle duration in UPRIGHT position, this asymmetry was neither observed in SUPINE nor in UPSIDE-DOWN position. However, because the asymmetry did not completely reverse in UPSIDE-DOWN position (PAD was not significantly higher than 50%), we cannot conclude that the kinematics obeyed to a strictly allocentric coding. It could be that more repetitions are necessary for a complete adaptation to this unfamiliar condition to occur. Analysis of the dynamics showed that the subjects were able to anticipate the variations in load force and to modulate their grip force adequately in the three chair positions. This was revealed by the time lag measured between the load force rate and the grip force rate, which was similar in the three positions and close to zero, and by the correlation between the two forces, which was similar or larger in UPSIDE-DOWN position in comparison with the UPRIGHT position. These results show that the CNS rapidly accounts for changes in the direction of the gravitational force during movement planning and control. However, more training might be needed for gravity to be integrated optimally in UPSIDE-DOWN position.

Title: Enhancement of intermuscular coherences in human upper limb during natural manipulation task

Authors: *H. OHTSUKA[1,2], S. SUZUKI[3], S. IRIE[1], R. ARIYASU[1], T. KOMIYAMA[4], T. NAKAJIMA[1]
[1]Dept Integrative Physiol, Kyorin Unversity Sch. of Med., Tokyo, Japan; [2]Dept Rehab, Heisei Ougi Hosp, Tokyo, Japan; [3]Sch. Rehab, Hlth. Sci. Univ. of Hokkaido, Hokkaido, Japan; [4]Facul Edu, Chiba Univ., Chiba City, Japan

Abstract: During the dexterous manipulation, the central nervous system regulates the neural activities of various upper limb muscles as a presumed functional unit for the motor execution. In general, natural manipulation task in the air consists of two kinematic components; a grasping component with activation of hand muscles and a lifting component with that proximal muscles. However, little is known about the coordinated and synchronized activities of these multi-joint muscles under this task.
Intermuscular electromyogram (EMG) coherence could be used to evaluate the frequency domain of the synchronous cortical drive onto motoneuron (MN) pool between different muscles.
Therefore, we examined whether the coherences during manipulation tasks was modulated depending on the muscle combinations and different motor tasks.
Healthy volunteers participated in the experiment, who all gave written informed consent. EMGs were recorded from the right biceps brachii (BB), triceps brachii (TB), flexor digitorum sperficialis (FDS), and extensor digitorum communis (EDC) muscles. Subjects were required to maintain grasping and lifting task of cubical box (4 cm on a side, 70 g weight) with thumb, index and middle fingers (G&L task) for 30 s. Coherence spectrum were calculated from six EMG pairs (BB-TB, BB-FDS, BB-EDC, TB-EDC, TB-FDS, or FDC-EDC pair) for 4 trials (4 trials x 30 s).
As a result, peak coherence values (range of values: 15-35 Hz) in BB-TB, BB-FDS, and TB-EDC pairs during G&L task were significantly larger than that the isolated co-contraction task with the target muscle pairs. As for the coherences of BB-EDC and TB-FDS pairs, however, there were no significant differences between both tasks. These effects were also obtained from recording of intramuscular EMG using needle electrodes. Interestingly, the enhancement of coherent values was not observed when mimicking the shape of fingers and elbow angle in the air (no object) under the similar situation of EMG activities with G&L task.
Taken in sum, these results suggest that the central nervous system during execution of manipulation task regulates oscillatory synchronous drive onto MN pool depending on the combination of muscles, and the combined effect of manipulation-related afferent feedback (e.g., tactile afferents of finger tips and object load) and central commands promotes the synchrony of these pairs.

Title: MEG correlates of fine motor control

Authors: *P. FERRARI[1], C. HAN[2], L. D. ABRAHAM[4], M. H. MCMANIS[5], D. M. SCHNYER[6], J. S. SULZER[3]
[2]Biomed., [3]Mechanical Engin., [1]Univ. of Texas At Austin, Austin, TX; [4]Kinesiology and Hlth. Educ., [5]Univ. of Texas at Austin, Austin, TX; [6]Univ. of Texas, Austin, Austin, TX

Abstract: Fine motor control is essential for activities of daily living, but is often the first casualty of neurological injury. Restoration of fine motor control depends on our ability to characterize it. Recent research in functional magnetic resonance imaging suggests models of fine motor control from connectivity in the sensorimotor (SM) network to distributed patterns of activation in the motor cortex. However, these models lack temporal specificity. Thus, we aimed to identify the modulation of sensory-motor networks involved in fine motor control using magnetoencephalography (MEG). Viewing fine motor control as a dynamic operation combining sensory, motor and attentional networks within a predictive based system, we hypothesize that these networks will reflect task demands and be predictive of behavioral performance. This study used a custom-designed MR/MEG compatible force sensor capable of measuring differential forefinger and thumb forces which were mapped to the position of a two-dimensional cursor. Our precision grip task required subjects to control forefinger and thumb forces (~20N) at increasing and decreasing magnitudes as they tracked a constant velocity visual target along a 45 degree edge with a 6 sec duty cycle. In an 'Uncoupled' condition, forefinger and thumb forces push the cursor horizontally and vertically, respectively, requiring fine-motor control. A 'Coupled' condition was also tested where the forces were averaged and cursor position fixed along the edge, required only force magnitude control. 10 subjects (5 females, mean age 26.0 years) performed 120 trials of each condition at force ranges dependent on their maximum voluntary contraction. In a preliminary approach, we analyzed the movement-evoked fields anticipating larger activation in the ipsilateral hemisphere for the uncoupled over the coupled task. MEG was time-locked to initial movement parameters and filtered from 0.5 - 40Hz. After artifact cleaning, cortical source estimation was performed using a minimum norm solution utilizing a BEM head model, within the MNE python toolbox. Individual anatomy and brain activity were normalized using freesurfer and the group-averaged responses represented as statistical parametric maps. The initial results reveal that within the first 50ms after movement

onset a more distributed activation pattern for the uncoupled vs the coupled task evolves, with fine-motor control involving an extensive contralateral network involving motor, sensory and visual cortices, as well as ipsilateral involvement. These findings may reflect widespread coupling between sensory and motor systems underlying the performance of fine-motor control.

Title: Mismatch between expected and observed movements: Uncertainty alters motor resonance

Authors: *G. RENS, M. DAVARE
Dept. of Movement Sci., KU Leuven, Heverlee, Belgium

Abstract: Accurate estimation of an object's weight is an important prerequisite for predictive force scaling in the context of skilled object lifting. It has been demonstrated that humans are not only capable of extracting information about object weight from visual object properties and sensorimotor memories, but also by observing hand-object interactions performed by other individuals. In the present study, we investigated (1) how lifting actions are implemented into the observer's motor repertoire and (2) used to plan a skilful lift. Subjects first observed an actor grasping an object and then performed the same action on the same object. In order to probe motor resonance mechanisms, we applied single pulse transcranial magnetic stimulation (TMS) over the primary motor cortex (M1) and measured corticospinal excitability (CSE) while subjects observed the actor's movements. Subjects were divided into two groups. The first group *(n=18)* observed lifts of two objects with congruent properties (i.e. large-heavy and small-light objects). In the second group *(n=13)*, we added two objects with incongruent properties (i.e. large-light and small-heavy objects). In the first group of subjects observing lifts of objects with congruent properties, we found that CSE was significantly higher when subjects observed lifts of the large-heavy compared to the small-light objects (*p=0.04)*. However, in the second group of subjects observing both congruent and incongruent objects, modulation of CSE was not driven by the perceived object weight but rather by a surprise factor. That is, irrespective of weight, CSE was significantly lower when subjects observed lifts of congruent compared to incongruent objects *(p<0.01)*. Interestingly, at the behavioural level, the second group of subjects was still able to accurately extract information about weight for each of the four objects and correctly scale their

own fingertip forces. These results reveal that motor resonance can be driven by perceived movement kinematics and that introducing uncertainty between predicted and observed kinematics alters motor resonance. We therefore argue that the influence of mirror neurons on M1 is not robust, but can be biased by cortical areas processing the expectation uncertainty.

Title: Decoding muscle activation patterns from kinematics using a detailed musculoskeletal model with active muscle stiffness

Authors: *A. SOBINOV[1], M. BOOTS[1], V. GRITSENKO[1], M. MANSOURI[3], C. BERINGER[4], M. BONINGER[4], L. E. FISHER[5], J. L. COLLINGER[4], R. A. GAUNT[5], S. YAKOVENKO[2]

Abstract: An intuitive myoelectric prosthesis controller would responsively follow a user's motor intent. In transradial amputees, the motor signals from residual muscles can be accessed using implantable electromyography (EMG) electrodes. Our approach to create an intuitive controller is to extract signals from spared muscles and compute intended prosthesis movement from the movement of a dynamic musculoskeletal model of an intact limb. The main obstacles responsible for discrepancies between intended and simulated movements in this biomimetic approach are the complex EMG to muscle recruitment relationship and muscle identification errors.
To compensate for these problems, we developed a transformation between the full complement of task-dependent computed muscle activations (CMA) and EMGs recorded from extrinsic hand muscles in healthy subjects and a transradial amputee. The CMAs were obtained from recorded and simulated hand kinematics (e.g., hand grasp, wrist flexion, and thumb movement in multiple wrist postures) using an inverse of the musculoskeletal system with Hill-type muscle models. The generation of CMAs is an underdetermined problem requiring joint stiffness and metabolic cost constraints to transform 18 degrees of freedom to 34 muscle activations. Task-dependent

active joint stiffness was introduced to impose the coactivation of antagonistic muscles, which is commonly present in hand movements. Using published measurements of wrist joint stiffness in similar movements (0.1 Nm), we decreased stiffness for the distal joints (CMC, MCP, PIP, DIP) in proportion to segment inertia. The solution to the inverse problem was tested by replay of CMAs for each movement in real-time forward dynamic simulations. CMAs reproduced the desired kinematics with less than 5° error for each joint. To test that the resulting CMAs can be used in a prosthesis, we did a regression with the CMAs against a dataset of surface and intramuscular EMGs from subjects performing hand movements.
Our preliminary results suggest that CMAs are closely related to recorded EMGs (normalized residuals <10%). The correlation between CMA and EMG patterns was stronger in the presence of the variable stiffness constraint than without it or with constant stiffness. The regression coefficients could identify mislabeled muscles (e.g. finger instead of wrist flexors) from synergies with distinct functions in the selected movement set. The method of computing muscle activity using joint stiffness constraints matches experimental data. The CMAs can be used for automatic calibration and lead to intuitive control of a biomimetic prosthesis.

Title: Characterizing motor cortex interhemispheric inhibition and relationships with manual dexterity in older adults

Authors: *M. R. BORICH[1], S. L. WOLF[2]
[1]Emory Univ., Atlanta, GA; [2]Emory Univ. Sch. Med., Atlanta, GA

Abstract: Unimanual and bimanual movements are mediated by interhemispheric inhibition (IHI) and facilitation between primary motor cortices (M1). IHI is hypothesized to be abnormal after stroke, and may contribute to persistent motor impairments. IHI can be characterized non-invasively using transcranial magnetic stimulation (TMS)3. Younger, healthy populations (age 20-40) demonstrate maximal IHI under specific TMS conditions. Despite evidence of changes in brain structure and function with aging, IHI has not been comprehensively characterized in older adults. The purpose of this study was to characterize IHI and evaluate relationships with hand

dexterity in older adults without history of neurologic conditions. Fifteen neurologically intact right handed individuals (age: 53-81, mean ± SD: 68.7 ± 6.6y, 6 female) completed a single TMS evaluation of IHI. Standard TMS hotspot and resting motor threshold (RMT) procedures were performed with the first dorsal interosseous (FDI) as the target muscle. To elicit IHI, a single suprathreshold (120% RMT) conditioning stimulus (CS) was applied over the contralateral motor cortex (M1) prior to a single suprathreshold (120% RMT) test stimulus (TS) at different interstimulus intervals (1, 5, 8, 9, 10, 11, 12, 15, 25, 50ms). Responses were normalized to unconditioned TS responses (IHI ratio: Conditioned/Unconditioned). Timed performance on the Nine Hole Peg Test (NHPT) was used to evaluate manual dexterity bilaterally. The TMS protocol was repeated with 10 individuals on a separate day to evaluate inter-session variability. Results demonstrated that in older individuals, significant IHI was present for ISIs 8-12ms and the ISI eliciting maximum IHI varied between individuals and between sessions. It was also observed that greater maximal IHI was associated with better NHPT performance bilaterally. These findings demonstrate that IHI is present in similar magnitudes and at similar ISIs compared to previous reports in young adults. However, there is substantial inter-individual and inter-session variability that makes between-individual comparisons and longitudinal assessments challenging. Results show that greater IHI is associated with better hand dexterity which may inform future studies aimed at evaluating neural markers of and developing treatments for motor dysfunction in clinical populations.

Title: Effects of TMS over the anterior intraparietal area on force and perceptual estimates in the size-weight illusion

Authors: V. VAN POLANEN[1], G. BUCKINGHAM[3], *M. DAVARE[4,2]
[1]Fac. of Kinesiology and Rehabil. Sci., KU Leuven, Heverlee, Belgium; [2]Dept. of Movement Sci., KU Leuven, Leuven, Belgium; [3]Univ. of Exeter, Exeter, United Kingdom; [4]Inst. of Neurol., London, United Kingdom

Abstract: When lifting an object, its physical properties (e.g. size) are used to appropriately scale fingertip forces, usually ensuring a smooth and efficient lift. If this motor plan is incorrect, forces are rapidly adjusted and the scaling is updated for next lifts with similar objects. However,

while force parameters are precisely fine-tuned, perception of object weight can still be biased. For instance, in the size-weight illusion, a smaller object is consistently reported as feeling heavier than a large object of equal mass. The neural mechanisms underlying the control of either motor or perceptual parameters remain unclear. We hypothesised that the anterior intraparietal area (AIP), known for encoding visual object properties and for planning fingertip forces during lifting, could play a role in the size-weight illusion. To address this issue, we applied continuous theta burst stimulation (cTBS) over AIP in three different subject groups before they lifted size-weight illusion inducing objects. Individuals received cTBS (80% of active motor threshold) on either AIP, the primary motor cortex (M1) or took part in a control condition in which cTBS was applied over AIP with a weak, inefficient, intensity (40% of active motor threshold). After stimulation, subjects were asked to lift small light, small heavy, large light, or large heavy objects in a randomized order, and to verbally report the object's weight. These four objects allowed us to compare force scaling and weight perception between different object sizes and weights. We found no effects of cTBS on the perception of object weight. In all conditions, subjects reported a size-weight illusion and were able to distinguish between light and heavy objects. However, we found that force scaling was affected by cTBS. The loading phase duration was not scaled to size following cTBS over either AIP or M1 (size × cTBS interaction), where these effects seemed larger in the AIP cTBS group. In the very first trials, where the object weight was still unknown, grip force scaling to object size was reduced following cTBS over AIP (size × cTBS interaction). These results suggest that AIP is involved in force scaling to object size, without playing a role in object perceptual properties. This specific effect on motor parameters is in line with previous research reporting independent effects on force scaling and weight perception in size-weight illusion objects.

Title: Motor unit coherence indicates changes in corticospinal influence during different hand motor tasks

Authors: C. KIM[1], M. A. PEREZ[2], *L. M. MCPHERSON[1]
[1]Florida Intl. Univ., Miami, FL; [2]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: There is increasing evidence that both corticospinal and reticulospinal motor pathways contribute to the control of hand muscles in humans and that the relative extent of this

contribution may differ during tasks that require precise vs. gross control. For example, recent findings using transcranial magnetic stimulation over the hand representation of the primary motor cortex showed that corticospinal excitability and intracortical inhibition decreased to a larger extent during power grip (gross motor control) than during index finger abduction and precision grip (fine motor control; Tazoe and Perez, 2017). Here, we aim to characterize the neural drive across these hand motor tasks using motor unit coherence analysis.We asked uninjured subjects (n = 6) to perform index finger abduction, precision grip, and power grip while maintaining 10% of maximal voluntary contraction with the right first dorsal interosseous (FDI) muscle. High-density surface electromyography (EMG) was obtained from a 64-channel grid placed on the FDI, and real-time visual feedback of rectified, smoothed EMG from a central channel of the grid was provided during each trial. High-density EMG was decomposed into motor unit spike trains using an established algorithm (Negro et al., 2016). Composite spike trains containing the discharge of multiple simultaneously firing motor units were used to calculate motor unit coherence, which was compared among the three tasks by summing the coherence within four different frequency bins: common drive (1 - 2 Hz), alpha (5 - 12 Hz), beta (15 - 30 Hz), and gamma (30 - 60 Hz).We found that motor unit coherence in the beta and gamma bands decreased by ~50% during power grip compared with index abduction and precision grip. Because coherence in these higher frequency bands is thought to reflect motor cortical/corticospinal influences, our preliminary findings suggest a decreased contribution from these structures during gross compared with fine hand motor tasks, consistent with previous results (Tazoe and Perez, 2017).

Title: High-dimensional control of volitional hand movements

Authors: Y. YAN, D. D. MOORE, J. M. GOODMAN, *B. P. DELHAYE, S. J. BENSMAIA
Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: The hand - an extraordinarily sophisticated and versatile organ - is our primary means for interacting with objects. Despite its staggering complexity, hand control is precise and effortless. A compelling hypothesis for how the brain manages to achieve this level of dexterity is that it restricts its control of the hand to a smaller, more manageable subspace than the full

range of movements of which the hand is capable. This subspace can be broken down into sets of coordinated movement primitives termed synergies. However, the vast majority of studies on putative synergies have examined the kinematics within a single task paradigm, which may lead to underestimation of the dimensionality of hand movements. Moreover, the total number of synergies is generally inferred from the explained variance in the kinematics, which may discard some meaningful (volitionally controlled) components of these movements. To address these potential limitations, we measure - using a camera-based motion tracking system - hand kinematics as human participants perform several manual tasks, namely grasping, typing, fingertip-to-fingertip touching, and American Sign Language finger spelling. We then analyze the measured kinematics with principal component analysis (PCA), as has been previously done, and explore the generalizability of high-variance principal components across tasks. We also implement machine learning techniques to assess the degree to which the dimensionality of hand kinematics can be reduced without losing any precision in hand shaping prior to contact. First, we find that hand synergies inferred using the standard approach fail to generalize across paradigms. Second, lower-variance principal components are important for correctly conforming the hand to task demands, suggesting that they are under volitional control rather than reflecting experimental or motor noise. We conclude that volitional hand movements occupy a higher-dimensional space than previously suggested.

Title: The perception of the angle of a finger joint is independent of load

Authors: *B. PRENDERGAST, J. M. GOODMAN, M. BOYARINOVA, J. E. WINBERRY, S. J. BENSMAIA
Dept. of Organismal Biol. & Anat., Univ. of Chicago, Chicago, IL

Abstract: Hand proprioception plays a key role in our ability to dexterously interact with objects. Little is known, however, about how precisely and accurately we sense hand kinematics and kinetics. We attempt to fill this gap with a series of psychophysical experiments to determine the acuity of human hand proprioception and to assess the extent to which kinematic and kinetic components of proprioception might interact with one another. First, we assessed how resistive

force impacts subjects' ability to perceive index finger position. Second, we investigated whether changes in joint angle might modulate the perception of loads applied to the finger. We found that varying the load acting on the finger did not affect subjects' perceived joint angle when the posture was produced actively. In contrast, load did affect the perceived finger angle when it was imposed by the experimenter. Furthermore, changes in joint angle did not affect subjects' perception of loads applied to the finger; we verified that the stability of load perception across postures was not mediated by cutaneous signals. We conclude that the perception of hand posture is robust across torques imposed on the fingers despite (presumed) changes in the peripheral sensory input and that the perception of load is independent of joint angle.

Title: Modeling functional dependencies in high-dimensional spike-field activity

Authors: *R. BIGHAMIAN[1], Y. WONG[3], B. PESARAN[4], M. M. SHANECHI[2]
[2]Electrical Engin., [1]USC, Los Angeles, CA; [3]Physiology, and Electrical and Computer Systems Engin., Monash Univ., Clayton, Australia; [4]New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Behavior is simultaneously encoded across multiple spatiotemporal scales of brain activity, from neuronal spikes to local field potentials (LFP). Estimating the functional dependencies between spikes and fields during behavior can help build more accurate neural encoding models and decoders. However, learning these dependencies in high-dimensional recordings is challenging because of the large number of spike-field pairs, which makes standard learning techniques prone to overfitting. Thus functional spike-field dependencies are often explored only between one or few electrode pairs rather than simultaneously across a large network. Here we present a sparse model-based approach for estimation of functional dependence in high-dimensional spike-field networks during behavior, and incorporate these dependence terms in neural encoding models. We model the spiking activity of each neuron as a

point process whose firing rate is modulated not only by behavior, but also by the field features across the entire recorded network. We then develop a learning technique that enforces sparsity in the number of spike-field network dependencies to train parsimonious encoding models. We assess the learned encoding model within cross-validation by computing the accuracy of spike prediction in the network. We validate the method using both numerical simulations and experimental data recorded from non-human primates. We find that by enforcing sparsity, our method detects the spike-field dependencies more accurately. Furthermore, compared to the model with no dependencies, our method significantly improves the spike prediction accuracy. Finally, by enforcing sparsity, the number of detected dependencies become significantly smaller without incurring any loss in prediction performance. This sparse model-based estimation technique could help learn more accurate encoding models and decoders, and investigate brain connectivity patterns across spatiotemporal scales.

Title: Learning dynamic neural encoding models with behaviorally-relevant latent states

Authors: *O. G. SANI, M. M. SHANECHI
Electrical Engin., USC, Los Angeles, CA

Abstract: Learning a neural encoding model that describes the representation of a desired behavioral state (e.g., movement kinematics) in neural signals is critical in decoding of behavior in brain-machine interfaces (BMIs) and in studying its underlying neural mechanisms. Recent evidence suggests the existence of latent dynamics in the brain that underlie behavior. Linear state-space models (LSSM) provide a general formulation for linear neural encoding models with latent dynamics and have been successfully employed in BMI decoders. An important problem to address is the method by which behaviorally-relevant dynamics can be learned using an LSSM with a latent state. One approach is to use an unsupervised learning method such as expectation-maximization to learn an LSSM, followed by a separate supervised learning step to relate the latent states of the LSSM to behavior. However, due to the unsupervised nature of the LSSM learning step, this approach may not be efficient in terms of the dimension of the latent state (i.e., model complexity) required for describing and decoding the behavior. Here, we introduce a novel learning algorithm that can combine the flexibility of dynamic neural encoding models with latent states with the benefits of supervised learning of a desired behavior. Our algorithm aims to uncover a low dimensional latent state that is most behaviorally-relevant. For a specified

dimension, our algorithm learns an LSSM with a latent state of the specified dimension that is more accurate in describing the behavior compared with other possible states of the same dimension that are learned using unsupervised methods. This new learning algorithm can help uncover low-dimensional neural representations of a desired behavior. The learned low-dimensional encoding models also lead to efficient decoders of behavior for BMIs.

Title: Learning causal graphs in spike-field multiscale network encoding models

Authors: *C. WANG, M. M. SHANECHI
Electrical Engin., USC, Los Angeles, CA

Abstract: Simultaneous recordings of spikes and fields could enable analyses of causal functional connectivity patterns in the brain at multiple spatiotemporal scales and lead to accurate encoding models and decoders for brain-machine interfaces (BMIs). However, analyses of functional connectivity also necessitate deriving novel algorithms to assess causality between binary-valued spikes and continuous-valued fields, which have fundamentally different statistical characteristics and time-scales. Thus, standard measures of causality cannot be directly applied in multiscale spike-field networks.We design a novel algorithm to assess causality for multiscale spike-field activities by computing directed information, which is an information theoretic measure of causality. Directed information is difficult to estimate for general probabilistic models. Thus we develop an algorithm to estimate the directed information using two parametric models. First, we build point process generalized linear models (GLM) for each neuron's spike train to estimate its firing rate using the history of both spikes and fields and compute the directed information to a spike node from any node in the network. Second, we build linear Gaussian models for fields using the history of the estimated firing rates and the history of fields, and then compute the directed information to each field node from any node in the network. We use maximum likelihood to fit the model parameters. We then construct statistical tests to

evaluate the significance of the estimated directed information to assess causality in the network. Using simulated data from networks of various sizes, we show that our algorithm can asymptotically identify the true causality. This method could help uncover causal connectivity patterns in the brain at multiple spatiotemporal scales, and also enable accurate encoding models and decoders for BMIs.

Title: Identifying multiscale hidden dynamics to decode movement

Authors: *H. ABBASPOURAZAD[1], Y. WONG[2], B. PESARAN[3], M. M. SHANECHI[1]
[1]Electrical Engin., USC, Los Angeles, CA; [2]Physiology, Electrical and Computer Systems Engin., Monash Univ., VIC, Australia; [3]New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Dynamical modeling of neural activity can help investigate the encoding of behavior and has been an emerging direction in neuroscience. Indeed, recent work has suggested the existence of hidden neural dynamics during motor behavior. This evidence motivates developing dynamical encoding models with hidden states that represent behavior. Such models may also benefit future brain-machine interface (BMI) decoding systems. To date, dynamical encoding models have vastly characterized a single scale of activity, e.g., spikes. However, behavior is encoded across multiple spatiotemporal scales of activity, from spikes of individual neurons to larger network activity measured using local field potentials (LFPs) and electrocorticogram (ECoG). Learning a dynamical model from hybrid spike-field activity is challenging because of fundamental differences in statistical characteristics and time-scales of these signals. Spikes are binary-valued with a millisecond time-scale while fields are continuous-valued with slower time-scales. Here we present a method to learn a multiscale dynamical state-space model that identifies a hidden neural state to characterize spike-field activity simultaneously. We developed an unsupervised multiscale Expectation-Maximization (EM) algorithm that can learn the multiscale model parameters in the presence of hidden states. We validated the algorithm using

motor cortical spike-LFP data recorded from a non-human primate (NHP) performing a reach task. We used the EM to learn the multiscale state-space model and then derived the corresponding multiscale decoder to estimate the hidden states from spike-field activity. Finally, we explored whether a projection of these hidden multiscale states could decode the 7 joint angular trajectories of the arm. We found that the multiscale EM identified hidden states that could decode movement. Moreover, adding LFPs to spikes and vice versa improved decoding performance, suggesting that the hidden state was conveying non-redundant information about both spike and field dynamics. This multiscale learning algorithm can be used to study the encoding of behavior across spatiotemporal scales and has important implications for future motor BMIs.

Title: Approaching a 24/7 at-home Braingate BCI system through design thinking, user-centered design and agile development

Authors: *J. R. BREA[1,2], B. E. SHANAHAN[1,2], J. SAAB[1,3,2], T. HOSMAN[1,2], J. D. SIMERAL[3,1,4,2], L. R. HOCHBERG[3,1,4,5,2]
[1]Sch. of Engin., [2]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [3]VA Med. Ctr., VA RR&D Ctr. for Neurorestoration and Neurotechnology, Providence, RI; [4]Neurol., Massachusetts Gen. Hosp., Boston, MA; [5]Neurol., Harvard Med. Sch., Boston, MA

Abstract: The BrainGate intracortical BCI has been used by clinical trial participants with tetraplegia to perform daily activities including rapid typing and email, controlling devices (TV, lights) and using a robotic limb to eat or drink. Having recently demonstrated in-home 24-hour intracortical wireless recording, we are working to transform this research platform into a BCI for operating off-the-shelf devices that would be usable 24/7 by a participant and caregiver with little to no technical support. Long-term, we envision a BrainGate platform that would provide user benefit and facilitate intracortical research with remote management. To meet the right user and caregiver needs, we have taken a user-centered design (UCD) approach. UCD is a process for developing products from an end-user perspective used in industries from consumer electronics to healthcare to ensure a quality user experience. Kubler et al. (2014) first introduced the BCI field to UCD methods with usability testing EEG BCIs. Here we introduce two additional methods for transforming a predominantly Matlab-based research platform into a modern user-friendly system. First, we use a framework within UCD called Design Thinking originally developed at Stanford d.School and refined by design consulting firm, IDEO. This process involves iterative, overlapping activities: empathizing with the end user, defining the problem, ideating on solutions, prototyping, testing. By leveraging our unique experience in participants' homes 2-3 days / week and engaging key stakeholders (participant-facing team members, caregivers) and members of the broader ALS community, we create scenarios using realistic personas to guide us toward the most important end-user needs and solution design. As key system features are identified and prioritized, we use a software development methodology called "Agile" to structure our efforts into collaborative team "sprints" by which 3-5 individuals rapidly prototype and test potential solutions with stakeholders in an iterative, incremental fashion. For example, sprints to date have refined the user interface to reflect distinctions between caregiver and technician needs; enabled a single-action participant self-calibration tool; and implemented a paradigm shift to websocket methods for data flow. Leveraging Design Thinking and Agile frameworks, we continue progress toward an innovative and intuitive intracortical BCI that supports both in-home research and continuous in-home use by individuals with tetraplegia and their caregivers.

Title: Closed-loop BCI simulation through replay of recorded neural signals

Authors: *J. N. KELEMEN[1], D. MILSTEIN[2,3], L. R. HOCHBERG[6,4,1,7,3], D. M. BRANDMAN[5,3], J. D. SIMERAL[6,4,1,3]

Ctr., Providence, RI; [7]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Intracortical brain-computer interfaces (iBCIs) provide individuals with tetraplegia a means to communicate and otherwise interact with their environment. Some iBCIs achieve this by decoding neuronal firing patterns and local field potentials to infer the user's intention to move a computer cursor and click. Because the quality of iBCI control is contingent upon the decoding algorithm and its chosen parameter values, decoder testing and parameter optimization are essential components of iBCI development. However, the number of possible combinations of parameter values can be large compared to the available testing time with iBCI study participants. Fortunately, optimal values for decoder parameters can be estimated through closed-loop simulation given sufficiently accurate simulated neural activity that can be decoded into cursor kinematics and click. Here we introduce a simulator that uses real human intracortical data recorded from implanted microelectrode arrays rather than synthetic neural activity. The data consists of spike threshold rates and local field potential power (20 ms bins) originally computed from 30kS/s signals from each electrode while participants used an iBCI to command directional cursor movements and make on-screen item selections by clicking or dwelling on the item. In order to render simulated neural activity corresponding to an instantaneous “intended” cursor movement in a particular direction, the simulator determines current direction to target and then draws samples (96 electrodes, 20 ms bins, 120 ms snippet) from instances of neural data when the participant had been commanding cursor movements in a similar direction. To render neural activity for a click, the simulator samples from snippets of data recorded when the participant was commanding a click. Using 6 distinct data sets from 3 participants, we show that cursor trajectories produced by decoding these re-sampled neural signals are comparable, according to angular error distributions, to those from real closed-loop iBCI use by trial participants. We demonstrate how, unlike in real-time testing with participants, decoders can be efficiently tested in simulation under a large number of parameter values, providing powerful initial evaluation of novel decoder parameter choices and performance. These results suggest that

this new method of simulating iBCI control by sampling from real neural data can be an efficient and effective way to investigate, test optimize, and compare decoders.

Title: Comparison of decoding accuracy: Retrospectively trained recurrent neural network and Kalman vs the same-day Kalman decoder

Authors: *T. HOSMAN[1,2], M. VILELA[1,2], J. SAAB[1,2], C. D. HEELAN[1,4], D. BRANDMAN[3,2], J. D. SIMERAL[5,1,6,2], L. R. HOCHBERG[6,2,7,1,5]

Ctr., Providence, RI; [6]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA; [7]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Intracortical brain computer interfaces (iBCIs) can enable individuals with paralysis to control a computer cursor via intended movement. Linear decoders that map motor activity to 2D cursor velocity have provided rapid on-screen typing for individuals using the BrainGate iBCI. However, linear decoders commonly degrade in performance over time, reflecting their sensitivity to nonstationarities in the neural signals. Recurrent neural networks (RNNs) can model complex nonlinear time series and are promising candidates for inferring cursor kinematics from neural signals. Sussilo et al. (2016) showed in two non-human primates that an RNN trained on days or months of previously recorded data provided equivalent or better online

control than Kalman filter trained on same-day neural data. Further, the RNN was more robust to neuron drop-out, suggesting a putative stability advantage. Although offline RNN training can be computationally demanding, Sussilo et al., demonstrated the feasibility of online RNN iBCI in NHPs, and more recent work (Heelan et al., EMBC 2018) demonstrated that an RNN with 10K inputs could run at sub millisecond update speeds. Here, we evaluated how well an RNN could decode human motor cortical signals in 2D target acquisition cursor tasks.
Data were analyzed from two participants in the BrainGate pilot clinical trial diagnosed with ALS (T7, T9). Both had two 96 channel Blackrock microelectrode arrays implanted in the hand region of dominant motor cortex. In offline analyses, an RNN and a Kalman filter were trained on 10 days of historical data (r-RNN and r-Kalman, r indicating "retrospective"). We compared the decoded kinematics from each decoder on a test data set, drawn from the subsequent research session. We also evaluated their kinematic outputs relative to the Kalman filter originally used online by the participant during that test session (termed "same-day Kalman" as it was calibrated from only within-day neural data). Decoders were evaluated using the angle error between the decoded cursor direction and the direct cursor-to-target path for every 20 ms decode step across each day tested (Mann-Whitney U test, $p<0.05$).
Across 36 (69) test days for T7 (T9), the r-RNN decoded significantly better than the r-Kalman on 84% (86%) of the days and significantly better than the same-day Kalman 53% (63%) of the test days. Overall, the retrospective RNN yielded less angle error than the r-Kalman decoder when trained on the same historical data and had similar or better performance than the same-day Kalman. These results motivate further investigation of RNNs for decoding in iBCI applications for people with paralysis.

Title: Processing thousands of full-broadband neural channels in real-time on a mobile platform

Authors: *C. D. HEELAN[1,3], B. E. SHANAHAN[1], L. R. HOCHBERG[4,1,5,6,2], A. V. NURMIKKO[1,2], J. D. SIMERAL[4,1,5,2]
[1]Sch. of Engin., [2]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [3]Connexon Systems, Providence, RI; [4]VA RR&D Ctr. for Neurorestoration and Neurotechnology, Dept. of VA Med. Ctr., Providence, RI; [5]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA; [6]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: We present a novel FPGA circuit ("BGPipeline") capable of processing thousands of full-broadband neural channels in real-time on the mobile NeuroCoder neural processing platform. Current intracortical brain-computer interfaces (iBCIs) for human use can process and decode several hundred channels of microelectrode voltages sampled at 30kS/s. However, these desktop computer-based systems are immobile and cannot scale to the needs of high channel-count next-generation systems. We recently demonstrated wireless recording of 192 channels of wireless broadband simulated neural signals using the mobile battery-powered NeuroCoder signal processing platform (Heelan et al., 2017). Here, we extend this work with the BGPipeline FPGA circuit that implements the entire BrainGate neural preprocessing and feature extraction chain for iBCI decoding applications (Jarosiewicz et al., 2015).
We used Xilinx Vivado High-Level Synthesis (VHLS) to design the BGPipeline FPGA circuit. In that circuit, a common-average reference (CAR) circuit denoises the data by calculating the mean across a subselection of channels and subtracting this mean from each channel. A linear phase systolic FIR filter (0.3 Hz to 5.0 kHz) then bandpass filters the signals. Neural features are subsequently extracted as thresholded action potential counts ("spike rates") and frequency-band powers ("spike powers") that are summed over non-overlapping 20 ms time bins.
Two tests were used to validate the functionality of the BGPipeline circuit. First, we generated neural feature outputs using a Python reference implementation of BGPipeline given a known input test vector (sum of sinusoids). We then passed the same input test vector into a BGPipeline VHLS simulation that successfully verified the VHLS outputs against the Python outputs. Second, we examined whether BGPipeline could extract features from raw 30 kS/s multichannel data recorded from a Blackrock Digital Neural Signal Simulator (NSS). We passed signals captured from the NSS into the BGPipeline VHLS simulation and obtained outputs that exhibited the expected patterns of spiking activity and spike power.
On the current NeuroCoder hardware, BGPipeline successfully scales to 6,528 full-broadband neural channels. FPGA synthesis and implementation (placement and routing) estimate a Zynq power utilization of 2.16 watts giving this fully-mobile implementation a performance metric of ~3,022 processed channels per watt. This translation of multichannel iBCI signal processing into FPGA logic running on the mobile NeuroCoder platform in real-time is a critical step toward practical next-generation iBCIs.

Title: Implantable wireless brain computer interface

Authors: *J. NAKAHARA[1], V. RANGANATHAN[2], J. SMITH[2], C. T. MORITZ[3]
[1]Computer Sci. & Engin., The Univ. Of Washington, Seattle, WA; [2]The Univ. of Washington, Seattle, WA; [3]Rehabil. Med., Univ. of Washington, Seattle, WA

Abstract: Nearly 17,000 people are left paralyzed from Spinal Cord Injury (SCI) every year, according to the NSCISC. Along with epilepsy, these neural disorders lead to a very limited and constrained lifespan for the patients. The aim of this work is to develop a Brain-Computer Interface that leverages point-of-care neural recording and subsequent neural stimulation to treat or rehabilitate these patients for better living conditions. The current generation of devices has state-of-the art solutions for neural signal acquisition and stimulation. However, combining the two to use the recorded signal for triggering accurate, autonomous stimulation has proved to be extremely challenging. This is primarily due to the phenomenon of neural plasticity, where the evolving neural connections lead to change in signals and signal path, and the inability of existing devices to autonomously detect this change and adapt to it. Another major concern that surfaced with long term use of implanted devices is the requirement of power and communication cables that exit the skin surface from the implant and pose a risk of infection. In the best cases, implants that use batteries also have limited lifetime and have to be surgically removed to replace them. Apart from lifetime, large volume, and cost overhead of adding batteries makes them a challenge when used with implants. To address these two issues, our contribution lies in implementing a device that will enable closed-loop stimulation while incorporating wireless communication and power transfer to increase the implant's operational lifetime. Using FPGA based reconfigurable computation platform enables implementation of energy-aware reconfigurable processing for spike/LFP data. Specifically, 1) the device harvests energy from a 13.56MHz source and stores it in a supercapacitor to meet the power budget of recording, communication, computation, and stimulation. 2) It is capable of low-power wireless communication - radio frequency (RF) backscatter at 915MHz, to establish high data-rate communication between the implant and external world.
These key features eliminate any data and power cables and make the device fully implantable.

Title: A 'Divide-and-Conquer' strategy to avoid overfitting when decoding brain state from field potentials for closed-loop control applications

Authors: *D. M. TAYLOR[1,2,3], T. JOHNSON[1,2,3], V. GOPALAKRISH[1], E. TUNC[1], S. MORALLE[1], S. RUSS[1]
[1]Neurosciences, Cleveland Clin., Cleveland, OH; [2]Cleveland VAMC, Cleveland, OH; [3]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Brain state information from field potential data is often used in closed-loop neuromodulation and neuroprosthetic applications, and used for basic science studies. However, overfitting can become a problem when using power features from field potentials, because each recorded signal can be expanded into hundreds of individual power features. The number of power features can increase even further by extracting power from different linear combinations of the raw signals or when using features based on interactions between frequency bands. All of these permutations result in a nearly infinite number of features available from just a handful of electrodes. Such a large number of features can lead to "overfitting" when building decoding functions to predict brain state from a limited amount of data. Typically, this problem is addressed by either discarding some of the power features or averaging groups of individual features together, such as averaging the output of an FFT function into alpha, beta, & gamma bands, or averaging a phase-amplitude coupling metric over an arbitrarily-determined pair of frequency ranges. While effective, these feature reduction methods are likely discarding useful

information and/or including unnecessary noise. Therefore, we have explored what we call a 'divide & conquer' strategy for extracting more task-specific information from high-dimensional field potential power features without overfitting. The most successful divide & conquer option used a two-step process where common spatial pattern analysis was performed first to compress the useful information into a smaller number of raw signal before calculating power. In the second step, various statistical methods optimally weighted and combined different groups of the full FFT power feature set to further compress information into a smaller number of more-useful features for decoding. We applied these methods to EEG, stereo-EEG, ECoG, and LFP data collected from humans and animals to predict intended movements or predict Parkinsonian symptom state. Although optimal methods for subdividing the data varied by data type and application, significant improvement in brain state prediction could be achieved using these methods. For example, cross-validated limb movement prediction accuracy from EEGs could be improved by 25% using common spatial pattern analysis to reduce the number of signal followed by either A) building one feature per FFT frequency bin weighted across all channels or B) building one feature per channel weighted across all FFT frequency bins and then doing further feature elimination before final decoding.

Title: EEG-based brain-computer interface using deep neural network for point by point decoding: A pilot study

Authors: *Y. FUJIWARA[1], S. HONDA[2], J. USHIBA[3,4]
[1]Grad. Sch. of Sci. and Tech., Keio Univ., Yokohama, Japan; [2]SDM Res. Institute, Keio Univ., Kanagawa, Japan; [3]Dept. of Biosci. and Informatics, Fac. of Sci. and Technology, Keio Univ., Kanagawa, Japan; [4]Keio Inst. of Pure and Applied Sci. (KiPAS), Kanagawa, Japan

Abstract: Recently, decoding technology of Brain-Computer Interface (BCI) has been rapidly evolving. It is possible to decode Electromyogram (EMG) from Local Field Potential (LFP) (Agamemnon Krasoulis, et al.,2014) and heard speech from Electrocorticogram (ECoG) (Brian N. Pasley, et al.,2012). On the other hand, BCI decoding from Electroencephalogram (EEG) can classify the states whether participant is resting or moving right hand or left hand or legs, although the decoding time resolution remains low compared with LFP and ECoG. Generally, since, on EEG-based BCI, a waveform segmented into time windows converts into a frequency

domain features using fast Fourier transform (FFT) or the like, the refresh rate (decoding time resolution) of classification can not be raised unless time windows are overlapped. Moreover, unless we can solve the theoretical time delay problem due to the window function like the Hanning window, we can not classify on real-time no matter how much the performance of the computer improves. Even if the features are calculated in the frequency domain divided with the time window, it is difficult to distinguish by the features in the high frequency region, and there is a circumstance that it is necessary to use the feature in the low frequency region. Due to these circumstances, it is difficult to decode a dynamically changing state (EMG or speech) even when trying to update the refresh rate by overlap. Therefore, in this research, we made it possible to predict in the same refresh rate as the sampling frequency, and to solve the time lag problem by the window function. In this development, by sequentially inputting point by point data to the deep neural network including Long short-term memory (LSTM) as it is, the time resolution was improved by successively classifying the states at that time, and the time lag problem due to the window function was solved. This is a framework of END to END learning aiming for deep learning in recent years. We report to verify the result of learning by using GPU and movement classification data of at least 100 healthy participants, in order to prevent from overfitting the model of deep neural network for training data as much as possible.

Title: Decode predictive cortical activity for dynamic brain-machine interface

Authors: *H. CUI, C. LI, Y. ZHANG, T. WANG, X. XU, Q. WANG
Lab. of Neural Mechanism of Motor Control, Inst. of Neuroscience, CAS, Shanghai City, China

Abstract: Despite considerable advances in brain-machine interfaces (BMIs) over the past 20 years, it is still difficult to decode neural signals for predictive control of artificial actuators in response to dynamic stimuli. In contrast to naturalistic limb movements largely based on forward planning, most brain-controlled prosthetic systems largely rely on visual feedback without prior trajectory formation. In the present study, we recorded neuronal activity from the posterior parietal cortex and the motor cortex in rhesus monkeys performing center-out reaching arm

movement to intercept a target appearing at random locations and circularly moving with random speeds around the center of the touch-sensitive screen. Instead of a pre-defined zone, the monkeys might choose to intercept the moving target anytime within 1 s after its appearance. Our recent behavioral results demonstrated that manual interception could fully compensate for sensorimotor delays based on the forward prediction of the future target location at interception (Li et al. J Neurophysiol 2018). Although directional tunings of individual neurons appear to be heterogeneous and dynamic, a finite impulse response (FIR) Wiener filter based on regression analysis of neuronal population activity was built to decode pre-movement activity (750ms to 250ms prior to movement onset, ~40 neurons) and provide accurate (SD = 12º in movement direction) control signals for guiding BMI systems in dynamic environments.

Title: Decoding and modeling parietal cortex activity to probe representational drift

Authors: *A. LOBACK, D. RAMAN, T. O'LEARY
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Understanding how local brain circuits are able to compute robustly despite ongoing spine dynamics and other processes is a fundamental challenge in neuroscience. At the population coding level, recent work from multiple groups has shown that neural population activity representing learned environments continually drifts, so that specific environmental variables are represented by different neuronal ensembles over days or weeks [1,2]. Here we take a data-driven and modeling approach to probe the nature of this representational drift in the parietal cortex. We analyze two-photon calcium imaging data of ensembles of hundreds of neurons in the posterior parietal cortex (PPC) recorded from mice performing a PPC-dependent cue-action association task in a virtual reality environment. We first show that two different linear dynamic models - a linear time-invariant model decoder with a latent state variable and a Kalman filter decoder - can be used to reliably decode multiple kinematic and behavioral variables from PPC ensemble activity. Concurrently, we explore an observer framework model of the PPC, a concept from control engineering, in which the PPC computes an internal prediction of the kinematic and environmental state. This modeling framework allows us to

explore questions about stochastic optimization algorithms that are consistent with the previously-observed activity drift in the PPC, and consequences within a larger network of coupled neural systems that are involving in learning.

Abstract: Treatments of neurological disorders utilizing active implantable devices which interact with the activity of the brain are demonstrating increasingly promising advances. Next to the continuous improvement of established therapies for movement disorders, Epilepsy and chronic pain, new therapies for depression, paralysis and many more are under investigation. The current technology available for the development of these treatments is derived from the first active implants, the cardiac pacemakers, developed in mid to late 20th century: battery powered devices with few channels and limited intelligence. The Brain Interchange technology, developed in a joint effort by the University of Freiburg and CorTec, is a new system, enabling battery-free, intelligent closed-loop applications with up to 32 channels in its first version. The implantable part, including a novel hermetic encapsulation, custom electronics and firmware, were presented last year. The electrode technology will be presented in a companion poster. Here we present the progress in the development of the external parts and the software of the system and discuss potential applications.

The first version of the external parts of the system manages power and communication with the implant, as well as the software for controlling the system. Physically, these parts consist of a head piece, a relay- and a controller unit. The main functions, accessible via a graphical user interface, are: managing recording and stimulation, measuring impedance and reading out humidity, temperature, supply voltage and unique ID of the implant. A filter pipeline for signal processing and feature extraction, suitable for computationally demanding closed-loop algorithms, and the control of external devices with minimal latency has also been implemented. For future collaboration partners programmable interfaces for C++, Matlab and Python are available. The development has been done under ISO-13485 and according to EN 62304. Potential applications range from closed-loop stimulation for the treatment of Parkinson's disease or Epilepsy to the control of assistive technology in chronic paralysis or for rehabilitation purposes. Further applications could lie in closed-loop treatments in the peripheral nervous system.

Title: Neuromorphic computing algorithms and hardware for low-power neural decoding and brain-machine interfaces

Authors: *D. G. CLARK[1], J. A. LIVEZEY[1], E. F. CHANG[2], K. E. BOUCHARD[1]
[1]Biosci., Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Neurosurg., UCSF, San Francisco, CA

Abstract: Decoding neural population activity is a ubiquitous task in systems neuroscience. A common application is brain-machine interfaces (BMIs), which restore lost function by mapping neural recordings to control signals in real-time. However, challenges remain in deploying such systems. For example, decoding algorithms are often computationally demanding and thus dissipate significant energy operating continuously. We address this problem by mapping the Kalman filter (KF) onto a low-power neuromorphic architecture: IBM's TrueNorth. The

resulting decoder consumes only ~10-100 mW of power running in real-time and reproduces the KF with high accuracy. In contrast to previous research, our decoder is run on actual neuromorphic hardware. We have also derived a full analytical model describing the error between the spiking KF and an equivalent non-spiking KF which we validate numerically. We demonstrate the utility of our decoder offline by decoding human vocal pitch from ECoG.
While several groups have raised the possibility of neuromorphic decoders, none have directly addressed the inherent tradeoffs imposed by a neuromorphic chip. Our work required us to encounter and address many fundamental limitations related to performing computations on spike trains in a streaming fashion. For example, in a neuromorphic architecture featuring spiking neurons, such as TrueNorth, data are typically encoded using a rate code (i.e. value = # spikes / time). This encoding scheme induces a tradeoff between numerical precision and latency. For real-time decoding, this tradeoff must be mitigated: the decoded signal must have reasonable numerical precision, ~10 bits, and the latency must be low, ~10-100 ms. We simultaneously achieve these requirements by introducing a method that reduces the latency of the system by increasing the number of neurons, while exactly preserving the computation performed. The ability to smoothly trade-off between latency and on-chip neuronal footprint widens the scope of applicability of spiking neuromorphic architectures.
Overall, our findings demonstrate that neuromorphic technology presents a promising and practical path forward for low-power, portable neural decoding.

Title: A scalable closed-loop network of wireless implants with up to 128 channels of recording and stimulation

Authors: *C. A. SEGURA, J. G. HELLMAN, A. CZARNECKI, A. J. MIRANDA, M. C. MURESAN, E. H. GREENWALD, C. K. BJUNE, J. R. LACHAPELLE, J. R. BURNS, IV, B. D. NUGENT, D. J. GUYON, W. T. UY, C. J. WARDMAN, G. D. GRANT, T. S. SRIRAM, A. G. STODDARD, A. M. ZORN, J. J. WHEELER
Draper, Cambridge, MA

Abstract: Advanced close-loop neuromodulation systems aim to provide precision coordinated therapies across multiple distributed targets. Potential applications include neuropsychiatric illness, memory loss, sensorimotor restoration, pain management, bladder control, and more.

While communication between multiple neural targets is advantageous for coordinated therapies, networked lead wires and connectors add considerable bulk to the overall implanted volume. Here, we present our wirelessly networked Gemstone implant system that eliminates the need for lead wires and connectors and achieves a total implanted volume less than 1.5 cm^3. Each Gemstone implant is wirelessly powered by, and communicates with, a single external antenna module for coordinated closed-loop control of 32 channels each. As few as one, and as many as four Gemstones can be implanted for up to 128 electrodes for recording and stimulation. Each Gemstone can be re-configured on-the-fly for a variety of mixed recording and stimulation settings, including differential and single-ended recording, variable bandwidths and sampling rates, and arbitrary stimulus waveforms. Custom Draper ASICs provide low-noise recording (under 1µV RMS), precision stimulation (µA/µs resolution up to +/-9V compliance), and wireless data networking (20 Mb/s). Gemstone implants are packaged within a dime-sized biocompatible hermetic enclosure and can be mated with a variety of different electrode arrays for many uses.

Title: A backscatter communication technique for distributed microimplantable wireless neural interfaces and implementation with neural dust

Authors: *D. K. PIECH[1,2], J. M. CARMENA[3,4,2], M. M. MAHARBIZ[3,2]
[1]Univ. of California Berkeley, Berkeley, CA; [2]UCB - UCSF Grad. Program Bioengineering, [3]EECS, [4]Helen Wills Neurosci., UC Berkeley, Berkeley, CA

Abstract: Microimplantable wireless neural interfaces are an emerging class of neural interfaces which consist of fully self-contained sensing or stimulating devices placed directly at electrophysiological recording or stimulation sites. A goal of these systems is to leverage extreme miniaturization, low power, and efficient communication to situate wireless interface devices in the tissue of interest, including intracerebral sites. Such microimplantable neural interfaces may reduce micromotion and gliosis, enable distributed recording and stimulation throughout the brain without cable management constraints, and present options for low-risk implantation, thus leading to improved safety, longevity, and channel count.
The neural dust platform utilizes ultrasound for power and backscatter communication via an acoustic wireless link between an external interrogator and implanted devices ('dust motes'). The acoustic link safely penetrates through tissue and scales to smaller implantable devices sizes as compared to a radio frequency (RF) wireless link. Some capabilities of RF systems, such as continuous wave and narrow band communication, though, are less viable with an acoustic link. This provides both challenges and opportunities toward designing a backscatter wireless link paradigm optimized for ultrasound.
We present a new pulse-backscatter communication technique designed to enable robust and flexible communication with a freely floating cloud of microimplantable neural sensors. Much of the processing burden of the link is transferred from the mote to the external interrogation system, keeping the motes as simple - and therefore small and low power - as possible.
We demonstrate (1) improved SNR as compared to baseline pulse-backscatter methods, (2) robustness to misalignment and drift motion of the acoustic link, (3) communication through an attenuating and scattering skull phantom, and (4) simultaneous communication with multiple motes.
These results show that a robust wireless link can be established while maintaining the small size and simplicity of the implanted devices. This paves the way toward the long-term goal of a distributed cloud of microimplantable neural sensors.

Title: Technological challenges for large channel count, high bandwidth human brain-interface systems

Authors: *C. CLEMENT, T. L. LAABS, J. P. DONOGHUE
Wyss Ctr. for Bio and Neuro Engin., Geneve, Switzerland

Abstract: Interfacing a pulse generator, a recorder, or any implanted electronics, with the nervous system is very challenging, due to the fragile nature of the tissues, the immense complexity of the brain, the capture of tiny signals on hundreds of electrodes, and the large flow of information to be transferred in and out the body. In the cases where we want to have electrodes interfacing directly with the brain (subcutaneously, epi- or subdural, penetrating the cortex or deep brain stimulation), it is appropriate to locate the implanted electronics 'above the neck'. With the exception of cochlear implants, current neurological stimulators, like Deep Brain Stimulation for Parkinson Disease, are still too big. The pulse generator is then implanted in the pectoral area, with cables tunneled along the neck and under the scalp. Miniaturization and new encapsulation technologies make it possible to move the electronics in the head. The human head is a very special environment which imposes specific design constraints on implants. We describe the criteria that should be taken into account to optimize the design of 'above the neck' active implants, in the perspective of efficacy of the therapy and that also takes the needs of patients and doctors into consideration. The poster covers a broad spectrum of the new challenges induced by moving the implant technology above the neck, especially in terms of energy, size, material, fixation, aesthetics, reliability, connectivity, surgical insertion and wireless communication. Devices that interface with the brain usually include many channels for either reading signals or stimulating specific brain areas. Having more than 100 channels or electrodes creates new challenges especially in terms of connections. Compared to active implants placed in the chest and abdomen, 'above the neck' devices must adhere to different design rules. Several key building blocks, like hermetic feedthroughs or batteries, must be re-invented to meet the specificities of multi-channel wireless long term implanted brain interfaces. We focus on understanding the 'environment', including the physical specificities of the human head. A careful analysis of advantages and drawbacks of existing active implants used for many therapies and diagnostics in various places in the body will show us the direction to take for neuro-stimulators of the future. The Wyss Center for Bio and Neuroengineering, based in Geneva, Switzerland, is a non-profit translational organization that accelerates the development of neurotechnologies for human benefit.

Abstract: Medically-induced coma, a profound brain inactivation state induced by administering anesthetics, is a critical therapy needed to be maintained for long periods of days in the intensive care unit. Personalized automatic control of the therapy could thus significantly improve the safety and efficacy of anesthesia care but has not yet been demonstrated. In current clinical practice, medically-induced coma is maintained manually by monitoring the electroencephalogram (EEG) burst suppression pattern. To enable personalized automatic control, both inter- and intra-subject variabilities in the EEG response to anesthetics need to be tracked in real time while simultaneously delivering the therapy, which is not possible in current control systems. Here, using an adaptive stochastic control framework, we develop a personalized closed-loop anesthetic delivery system for medically-induced coma that tracks both inter- and intra-subject variabilities in real time during closed-loop anesthetic delivery. We tested the personalized closed-loop system in a rodent model by administrating propofol to control the EEG burst suppression. The closed-loop system achieved precise control in each subject without a separate offline model fitting experiment, thus tracking inter-subject variability without therapy interruption. In addition, the closed-loop system tracked intra-subject variability, thus providing a tool to uncover how the EEG response to propofol changed during the course of control. Moreover, by tracking these intra-subject variabilities, the closed-loop system significantly reduced control bias and error. This personalized closed-loop anesthetic delivery system has significant implications for clinical feasibility of automated and personalized care in medically-induced coma and provides a new tool to investigate the dynamics of brain response to anesthetics.

Title: A low-invasive microcoil integrated neural probe for deep brain magnetic stimulation

Authors: *J. KIM[1], H. PARK[1,2], Y. HUH[3], J. CHO[3]
[1]KIST Korea Inst. of Sci. & Tech., Seoul, Korea, Republic of; [2]Sch. of Mechanical Engin., Yonsei Univ., Seoul, Korea, Republic of; [3]Catholic Kwandong Univ., Incheon, Korea, Republic of

Abstract: Although the conventional transcranial magnetic stimulation (TMS) method has the advantage of non-invasive stimulation, it is still unable to perform deep brain stimulation, simultaneous neural signal monitoring, stimulation of a specific region less than square centimeter, and repeatable stimulation of the same region due to the movements of the external system and the patient.
In this study, we propose a neural probe with microcoils and tetrode type electrodes capable of acquiring neural signals while simultaneously providing deep brain magnetic stimulation. It has more focused and efficient stimulation performance than the conventional TMS system. Unlike the conventional probes with monolayer microcoils that have been studied in the past, we propose a single neural probe integrated with three-layered microcoil for magnetic stimulation and tetrode-type electrodes capable of real-time neural signal acquisition.
In order to verify the applicability, the Finite Element Analysis (FEA) was used to confirm the electromagnetic field distribution and intensity according to the depth of the magnetic field generated by the three-layered microcoil model. Microcoil design parameters were set based on the result, and the proposed device was fabricated with micro-fabrication technologies.
To apply various types of magnetic stimulation patterns such as iTBS and cTBS using the microcoil integrated in the neural probe, an external stimulation system was developed that consists of a function generator, a power supply, an amplifier, and a control software based on Labview program. The developed software consists of a stimulation control panel and a stimulation cycle control panel. The stimulation control panel was designed to set the type, frequency, current size, and duty cycle of the stimulation signal waveform individually. The stimulation cycle control panel was made to adjust the signal waveform to stimulate at regular intervals.
The proposed monolithic neural probe for magnetic stimulation overcame the size and configuration limitations of the conventional microcoil based magnetic stimulation systems or neural probes. This specific and selective magnetic stimulation would be beneficial to study the mechanism of brain stimulation in various regions of the brain, such as the, the Brain-Computer Interface (BCI) that require precise activation of specific regions in the brain, and could further be applied to clinical uses in the future.

Title: The possibility of low TMS field for neuronal stimulation

Authors: *H. BAGHERZADEH[1], Q. MENG[1], X. DU[2], L. HONG[2], F.-S. CHOA[1]
[1]Computer Sci. and Electrical Engin. Dept., Univ. of Maryland, Baltimore County, Baltimore, MD; [2]university of Maryland school of Medicine,MPRC, Baltimore, MD

Abstract: In recent years, a variety of non-invasive techniques of neuronal stimulation such as transcranial magnetic stimulation (TMS), transcranial direct current stimulation (tDCs) and transcranial alternating current stimulation (tACs) have been developed. The development of these techniques has opened new horizons for the treatment of neuropsychiatric diseases like depression, Obsessive Compulsive Disorder (OCD), Alzheimer, Schizophrenia, etc. The neuronal stimulation in TMS requires electric fields near 400 V/m to reach activation threshold while in tACs and tDCs, the strength of the applied field hardly passes 1 V/m. In the current study, the reasons behind this phenomenon are investigated among which duration of applied magnetic field is of importance. The effects of short period application of TMS is compared with that of longer period applications of tACs and tDCs, in terms of charging up the membranes of targeted neurons and reaching threshold. The possibility of having lower TMS field but running at longer duration has the potential to greatly reduce TMS system size, cost, and portability. For this purpose, the mechanisms of these neuronal stimulation techniques were thoroughly studied. The induced electric field upon the nerve is governed using a cable model containing Hodgkin-Huxley model elements considering both Lorentz and Coulomb gauges.

Title: Frequency specific effects of direct intracranial electrical stimulation in the human brain

Authors: *S. BICKEL[1], J. L. HERRERO[2,3], E. M. YEAGLE[3,2], M. R. MERCIER[4], S. KHUVIS[2,3], P. LAKATOS[5], A. D. MEHTA[2,3]

Abstract: Direct intracranial electrical EBS stimulation (iEBS) is a fast developing technology, which already has clinical applications in epilepsy, select movement, and neuropsychiatric disorders. Traditionally used paradigms with open-loop, high frequency, high amplitude stimulation do not take ongoing network dynamics into account and likely disrupt them. However, such, often rhythmic dynamics have been implicated in processes from motor preparation and execution to cognitive processes such as attention. Developing novel iEBS paradigms to systematically modulate rhythmic neuronal activity patterns or neuronal oscillations may provide a promising approach to not only causally test their mechanistic significance but ideally also provide novel iEBS based therapeutic approaches.
Since little is known about the degree to which ongoing oscillations can be modulated by iEBS in humans, in the current study, we applied rhythmic electrical stimulation protocols covering several frequency bands to selected cortical regions (pre-central, superior temporal, parietal). Our goal was to test if we could achieve stimulation frequency specific effects in the stimulated and connected brain areas in epilepsy patients being evaluated with intracranial electrodes for seizure onset localization. We repeatedly applied brief bursts (<2secs) of low amplitude (0.5 - 3mA) electrical pulses (<0.4msec) through electrodes implanted in the frontal, temporal, and parietal regions. We stimulated in a closed-loop approach at different frequencies centered around the prominent spectral peaks of the activity in the targeted brain areas, as well as open-loop at a wider range of frequencies. We found that this rhythmic, low amplitude stimulation can indeed entrain neuronal oscillations. Notably, the effects outlasted the electrical stimulation in a frequency specific manner. These findings may help to develop iEBS paradigms paired with

sensory stimulation in behavioral experiments to elucidate the mechanistic roles of neuronal oscillations.

Title: Real-time convolutional compressed sensing enables online spike recovery from high-density electrode recordings with inherent overlap resolution

Authors: *S. WEINGÄRTNER, X. CHEN, T. MOORE
Stanford Univ. and Howard Hughes Med. Inst., Stanford, CA

Abstract: Extracellular electrophysiological recordings from single neurons have been instrumental for much of our present understanding of functioning neural circuits, particularly in behaving animals. Recent advances have facilitated the fabrication of electrodes with 100s of channels, potentially revolutionizing electrophysiology by enabling population scale recordings (Jun et al. 2017). However, while this advancement was driven by hardware development, multi-electrode recordings pose new challenges for the post processing and analysis of data with spike sorting, especially in terms of resolution of overlapping spikes and computational efficacy (Lefebvre et al. 2016). In this work, we apply concepts of sparse signal processing to study online spike detection, a problem that is highly relevant for closed loop neuroscience and brain-machine interfaces (Fetz 2007). We use a generative model describing the extracellular recording as a linear sum of waveform templates convolved with spike times and pose a sparsity assumption on the spiking activity (Ekanadham et al. 2014). This characterization inherently enables the resolution of spatio-temporal overlap. We employ the results of Demko, Moss and Smith on banded matrices (Demko et al. 1984), to demonstrate that accurate signal recovery can be performed in an online setting by processing finite buffers, despite continuously updated measurements. To achieve practical buffer sizes we improve upon the classic results, by characterizing the error propagation in the linear system using Neumann series expansion, allowing for partial decoupling of the subproblems. We propose an adaptation of the CoSAMP method (Needell et al. 2008) to enable online processing. Iterative processing is restrict to a buffer whose size is continuously updated based on the results of the Neumann series. Noisy, ground-truth simulations using waveform templates from recordings in the macaque visual

cortex reveal negligible performance difference between the proposed algorithm with online and batch (i.e. all data available at once, prohibitive for online use) processing (noisefree: $p = 0.32$, noisy: $p = 0.14$). Good resolvability of overlapping spikes is achieved in application to real data from trodal recordings, with increased performance when waveforms are present on multiple channels. In conclusion we demonstrate that greedy sparse signal recovery with limited buffer size enables efficient and accurate online spike detection. In combination with offline waveform extraction from an initial training phase, this provides a means for using single-neuron spiking activity in closed loop experiments.

Title: Role of nucleus reticularis gigantocellularis in control of posture

Authors: P. V. ZELENIN, M. D. G. VEMULA, V. F. LYALKA, *T. DELIAGINA
Karolinska Inst., Stockholm, Sweden

Abstract: Terrestrial quadrupeds actively stabilize dorsal side up orientation of the body in space due to activity of the closed-loop postural control system. It consists of three relatively independent subsystems, stabilizing orientation of the head, anterior and posterior parts of the trunk, respectively. Supraspinal influences play a crucial role in operation of these sub-systems. The aim of the present study was to reveal the role of supraspinal signals originating from nucleus reticularis gigantocellularis in operation of sub-systems stabilizing the body orientation in space. For this purpose, effects of DREADD-based chemogenetic activation and inactivation of all neurons, as well as only CaMKIIα glutamatergic neurons in nucleus reticularis gigantocellularis on different aspects of postural control, were studied. Wild type mice were trained to stand still on a platform, which was subjected to left-right lateral tilts with the amplitude ±20º. Tilts of the platform caused postural corrections moving the dorso-ventral axis of the head and trunk toward the vertical. Then the mice were subjected to a virus injection into nucleus reticularis gigantocellularis unilaterally. To target all neurons, AAV5-hSyn-hM3D(Gq)-mCherry or AAV5-hSyn-hM4D(Gi)-mCherry was injected, while to target CaMKIIα glutamatergic neurons only, AAV5-CaMKIIα-hM3D(Gq)-mCherry or AAV5-CaMKIIα-hM4D(Gi)-mCherry was injected. In two weeks after the injection, the animals with markers on

hindlimb joints and spine were video recorded from the front and back (when standing on a horizontal platform, as well as during its lateral tilts) before and during chemogenetic activation/inactivation of infected reticular neurons (in 1 hour after CNO injection). We found that unilateral activation of all reticular neurons in nucleus reticularis gigantocellularis, as well as only CaMKIIα glutamatergic reticular neurons, evoked ipsilateral, while their inactivation - contralateral roll tilt of the head and trunk in animals standing on the horizontal platform. The asymmetrical (tilted) orientation was actively stabilized on the tilted platform. We found that the efficacy of postural corrections was similar before and after CNO injection. Thus, left-right asymmetry in activity of neurons located in nucleus reticularis gigantocellularis caused a shift of the equilibrium point of the postural control sub-systems stabilizing the head and trunk orientation in the transverse plane, but did not affect the efficacy of the postural corrections. Most likely this shift is caused by left-right asymmetry in activity of reticulospinal neurons.

Title: Cutaneous reflexes from the hand are influenced by the reliability of a light touch reference during standing

Authors: A. J. MCMAHON[1], H. HACKETT[1], J. KRUTZ[1], *J. E. MISIASZEK[1,2,3]
[1]Univ. of Alberta, Edmonton, AB, Canada; [2]Occup. Therapy, Fac. of Rehabil. Med., Edmonton, AB, Canada; [3]Neurosci. and Mental Hlth. Inst., Edmonton, AB, Canada

Abstract: Light touch of a stable reference reduces sway during standing. Moreover, unexpected displacement of a light touch reference leads to short-latency reactions in ankle muscles consistent with a balance reaction. However, these responses were only observed following the first displacement, replaced by responses in arm muscles on subsequent trials. Thus, balance-related touch feedback can be quickly repurposed in a context-dependent manner, such as when the touch reference becomes unstable. We anticipate that sensorimotor pathways arising from finger cutaneous afferents would reflect these changes in behavior. In this study, we tested inter- and intralimb cutaneous reflexes arising from median or radial nerve stimulation while participants touched a stable reference and after the touch reference became unreliable. We hypothesized that 1) interlimb reflexes derived from median nerve stimulation would be

facilitated when touch was stable, but reduced when touch was unreliable, 2) intralimb median nerve reflexes would be facilitated when touch was unreliable and participants tracked the touch reference with arm movements, and 3) radial nerve evoked reflexes would be unaffected, given that the radial nerve innervation territory is not involved in the light touch task. Cutaneous reflexes were recorded from arm and leg muscles with median (n = 12) or radial (n = 11) nerve stimulation during each of three conditions: standing on foam with eyes closed a) without touch, b) while lightly touching (< 1N) a stable reference, and c) touching a reference that has been unexpectedly and repeatedly displaced. Median nerve evoked interlimb reflexes recorded in soleus (SOL) were significantly ($p<0.05$) larger when touching the stable reference (mean ± sd %MVC; 4.78 ± 1.31) than when not touching a reference (1.00 ± 1.05) or when touching an unstable reference (1.07 ± 1.16). Median nerve reflexes in other leg muscles were not different. Median nerve evoked intralimb reflexes in anterior deltoid (AD) were significantly ($p<0.05$) larger when touching an unstable reference (4.50 ± 1.31), compared to touching a stable reference (1.34 ± 1.01) or not touching (1.50 ± 1.00). Median nerve reflexes in other arm muscles were not different. In contrast to the median nerve evoked reflexes, radial nerve evoked interlimb reflexes in SOL were significantly ($p<0.05$) larger when not touching (4.29 ± 4.34), compared with touching a stable (1.50 ± 2.78) or unstable reference (2.30 ± 4.01). Radial nerve reflexes in other muscles were not different. These findings indicate that light touch influences the excitability of sensorimotor pathways depending upon the relevance of the contact to balance control.

Title: The nociceptive withdrawal response in intact, unanesthetized rats preserves postural stability over accuracy

Authors: *C. L. CLELAND, Y. KIM, K. M. SAMMONS, G. VERDI, C. A. CHRZAN, K. SEAMON
Biol., James Madison Univ., Harrisonburg, VA

Abstract: The nociceptive withdrawal response (NWR) is a protective movement in response to noxious stimuli in which multi-joint rotation rapidly removes the affected limb or appendage. However, recent work from our laboratory has shown that the direction of withdrawal either does

not depend (Cleland et al., unpublished observations) or depends weakly (Cleland & Bauer 2002, Cleland et al. 2017) on stimulus location, raising the question as to what factors determine withdrawal direction. Given that a strong, rapid NWR may destabilize posture, the goal of our experiments was to explore the role of posture on the NWRs of the foot and tail in response to noxious heat stimuli. The NWR was evoked by noxious heat created from laser (980nm) stimulation applied to the plantar surface of the paw and along the lateral aspect of the tail in intact, unanesthetized Sprague-Dawley rats (n=131). The resulting movement was recorded with conventional (60 fps) and high speed (650 fps) video. The initial posture was varied by either positioning the tail at different angles or curvature, positioning the foot at various rostral/caudal locations, or depending on the spontaneous positioning of the rat foot. Heat stimulation uniformly evoked brisk withdrawal responses in various directions. For both the foot and the tail, the response direction varied with initial placement of the appendage. For the foot, there was an inverse dependence on initial position. For example, if the foot were placed relatively rostral the movement was relatively caudal. For the tail, the direction of rotation around the base of tail reversed direction for large angles or curvature of the tail, directing the tail back toward a straight posture. In both model systems, the NWR served to minimize deviations from "normal" (tail straight, hind foot aligned with the opposing hind foot), thus potentially improving postural stability and allowing the greatest possible number of secondary movements. Combined with classic descriptions of the crossed extension reflex and more recent accounts of postural aspects of the NWR (Blivis et al. 2017), our results suggest that the quantitative characteristics of the NWR may have evolved in response to the need for postural stability rather withdrawal movement accuracy.

Title: Synaptic coupling of median nerve cutaneous afferents with ankle muscle motor pools

Authors: *A. TOTH[1], K. K. FENRICH[2], K. E. JONES[3], J. E. MISIASZEK[2,1]
[1]Dept. of Occup. Therapy, [2]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [3]Fac Kinesiology, Sport, and Recreation, Univ. Alberta, Edmonton, AB, Canada

Abstract: Lightly touching a stable reference point can greatly improve balance. Unexpected displacement of a light touch reference at the finger can lead to rapid activation of ankle muscles in standing participants. Percutaneous electrical stimulation of the median nerve generates short latency reflexes in the muscles of the legs, suggesting that cutaneous afferents from the hand are functionally coupled with the ankle muscles and might be involved in generating these interlimb responses. In the present study, we wished to delineate the specific tactile afferents from the hand that might mediate these interlimb responses. Specifically, we hypothesized that activity of individual cutaneous afferents of the median nerve will modulate the electromyographic (EMG) activity of ankle muscles. To do so, microneurography of the median nerve at the level of the wrist was used to record from single afferents from 10 participants. Discharge from discretely resolved afferents was used for generating spike-triggered average surface EMG traces of the bilateral tibialis anterior (TA) and soleus (SOL) muscles. Single units were characterized as slow or fast adapting type I and II afferents (SAI, SAII, FAI, FAII) and their receptive fields were mapped. SA units were activated by applying a constant pressure, and FA units via gentle tapping, within their receptive fields. Participants were seated comfortably in a reclined chair and asked to maintain a 50% maximal voluntary contraction (MVC) of plantarflexion or dorsiflexion during tactile unit activation. At all other times, participants were asked to remain completely relaxed and minimize movements. Responses in the spike-triggered average EMG traces were identified when the trace exceeded a 99% confidence band, calculated from the background EMG activity, for a minimum of ≥ 2.5 ms. The background EMG activity was calculated from 50 ms prior, and 40 ms post, spike onset. Over 14 experiments, 17 single units were recorded, including: 4 FAI (24%), 1 FAII (6%), 6 SAI (35%), 4 SAII (24%), with 2 ectopic units (12%). Three latency epochs were used, early (40-80 ms), middle (80-120 ms), and late (>120 ms). In TA there were 13 early, 7 middle, and 16 late responses that met significance criteria, and in the SOL there were 5 early, 8 middle, and 13 late. These data demonstrate that activity from single mechanoreceptors of the hand are coupled to motoneuron pools of ankle muscles. The short-latency of some of these connections suggests that sensory input from the hand is capable of quickly adapting motor activity in the legs, which would be functionally important for stabilizing balance.

Title: Revealing abnormal lower-limb reflex couplings in post-stroke gait using H-reflex stimulation

Authors: *J. S. SULZER[1], T. AKBAS[1], K. MANELLA[2], R. K. LEE[3]
[1]Mechanical Engin., Univ. of Texas at Austin, Austin, TX; [2]Col. of Rehabilitative Sci., Univ. of St. Augustine for Hlth. Sci., Austin, TX; [3]St. David's Med. Ctr., Austin, TX

Abstract: It is widely believed that hip circumduction during gait is a compensatory strategy for reduced swing-phase knee flexion angle in people with post-stroke Stiff-Knee gait (SKG). However, our previous work refutes this hypothesis. In one study, we showed that alleviating the supposed cause of circumduction using robotic knee flexion assistance did not improve circumduction, but instead exaggerated it. These observations suggest an abnormal neuromuscular coupling between quadriceps and abductors in those with post-stroke SKG. In a follow-up study, we used musculoskeletal modeling and simulation to explore which muscles may have been involved in this abnormal coupling. We found that rectus femoris (RF) and gluteus medius (GMed) to be the most likely candidates. Yet this model requires experimental validation, and mechanical knee flexion assistance during gait can produce confounding effects including palpitation, coupled torques on other joints, and increased weight on the limb of the robotic orthosis. As such, in this study we employ electrically-induced reflexes in the RF using H-reflex stimulation of the femoral nerve in people with post-stroke SKG and age-matched healthy controls. We have developed a framework to consistently elicit quadriceps H-reflexes during walking and standing postures with and without increased voluntary RF contraction for healthy controls by providing RF EMG measures as feedback in real-time. Following RF H-reflex recruitment curves, we stimulated the RF at the peak H-reflex amplitude during a standing posture. We also stimulated RF during treadmill walking at toe-off walking at 0.5 m/s. We measured RF, GMed, tensor fascie latae, medial hamstrings, adductor longus, and vastus medius EMG during stimulation as well as 3D kinematic data during gait. Our preliminary analyses indicate increased RF H-reflex response and increased corresponding abductor EMG response following electrical stimulation in participants with post-stroke SKG compared to healthy controls. We are continuing to acquire additional data and perform additional analysis to derive more robust conclusions. Whereas our earlier evidence points out that hip circumduction in post-stroke SKG is not due to compensatory motions, this study helps define whether abnormal reflex mechanisms during gait could be the driving force behind this phenomenon.

Title: Electrophysiological window into the neuromodulation of the functional dynamics of spinal sensorimotor networks

Authors: *G. TACCOLA[1], S. CULACLII[2], P. GAD[3], H. ZHONG[4], N. KOKIKIAN[3], R. M. ICHIYAMA[6], W. LIU[2], V. EDGERTON[5]

Abstract: Continuous, tonic electrical stimulation of the spinal cord at motor sub-threshold levels can neuromodulate spinal sensorimotor networks to physiological states, which enable human subjects clinically diagnosed with complete paralysis to generate voluntarily controlled movement. A series of sub-threshold electrical pulses delivered directly to the spinal cord through epidural electrodes can also evoke intrinsically variable reflex responses. This effect impacts the spinal cord in such a way that each effective amplitude during the successive stereotyped input train is unpredictably affected, including occasionally failing to generate a response. Weak pulses were applied directly through a sophisticated epidural micro-scaled electrode array, which is chronically implanted in the lumbosacral spinal cord and continuous EMG recordings were collected from awake intact rats at rest. The pulses elicited a rhythmically modulated motor output measured from bilateral hind-limb muscles. A similar pattern of rhythmic modulation is evoked even after an incomplete spinal cord injury that impairs both the descending drive from the cortex and locomotion. Under full anesthesia, in both intact and injured spinal cords, spontaneous rhythmic modulation decreased, resembling a stochastic profile that likely reflects a random basal modulation provided by propriospinal circuits. These results suggest that this stochastic signal might be an intrinsic feature of the neuromotor system, which can be exploited by an asynchronous stimulation pattern (Dynamic Stimulation), which induces motor output resonance. In addition, the novel epidural interface used in the present study demonstrates the ability to electrophysiologically monitor the dynamics of multiple motor pool-specific spinal networks in vivo and trace changes in spinal motor pool connectomes post-injury, with and without anesthetics. The existence of a spontaneous pattern of modulation of the motor output has important practical implications for spinal cord neuromodulation at low intensity and should be considered into the design of more effective neurorehabilitation protocols for persons living with a spinal cord injury.

Title: Inhibitory pathway specifically modulated in the contralateral leg during walking

Authors: *O. D. LAFLAMME, T. AKAY
Dalhousie Univ., Halifax, NS, Canada

Abstract: Sensory afferents play an important role in coordinating the movement of multiple joints within and between legs during locomotion, as removal of sensory feedback severely impairs locomotion. It has been established in cats that sensory information from one leg influences the motor neuron (MN) activity of the contralateral leg (crossed reflex) through spinal commissural interneurons (CINs). Experiments in humans have shown that similar pathways exist since sensory stimulation can evoke motor responses in the contralateral leg. However, the neural circuits transmitting sensory afferents to the contralateral side of the spinal cord remains poorly understood. Experiments with mice revealed that left-right motor coordination is controlled by at least two genetically distinct classes of CINs (V0 and V3). Despite the insights regarding V0 and V3 involvement in locomotor activity, the role of these CINs in crossed reflexes remains unknown. Recently, crossed reflex pathways have been shown in mice *in vitro (Jiang et al, 1999, Brain Res, 816:493) and in vivo (Nakanishi and Whelan, 2012, J Neurophysiol, 107:500)* by applying a moderately strong toe pinch suggesting that crossed reflex pathways are also present in mice. Our goal is to characterize crossed reflex pathways in fully awake mice *in vivo* and investigate the involvement of different CINs implicated in walking in the transmission of sensory information to the contralateral side. Here, we describe crossed reflex motor output after the contralateral stimulation of cutaneous and proprioceptive afferents (tibial nerve stimulation), or only cutaneous afferents (sural nerve stimulation). The electromyogram (EMG) activity of different flexor and extensor muscles in the contralateral leg will be recorded simultaneously while adults mice are resting or walking *in vivo*. In summary, our data shows 1) that crossed reflex responses can be evoked in freely behaving mice in both flexor and extensor muscles following proprioceptive and cutaneous afferent stimulation; 2) that sensory information is transmitted to contralateral motor neurons through an inhibitory and

excitatory pathway, where the inhibitory influence is most likely mediated by cutaneous afferents; and 3) that crossed reflexes in mice are subject to modulation depending to the activity of the muscle prior to stimulation during walking. These experiments will serve as ground work in the mouse model to identify specific CIN pathways involved in crossed reflexes and the role of these crossed reflex pathways during motor behaviour. In the future we aim to assess the involvement of V3 and V0 CINs in crossed reflex.

Title: Stochastic resonance effects in mechanically-evoked cutaneous reflex responses

Authors: *T. SHARMA[1], R. M. PETERS[2], L. R. BENT[1]
[1]Human Hlth. and Nutritional Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Fac. of Kinesiology, Univ. of Calgary, Calgary, AB, Canada

Abstract: During stance, cutaneous mechanoreceptors sense pressure distribution across the foot sole and generate reflexes to modulate lower-limb muscle activity to successfully maintain upright balance. Decreased cutaneous reflex generation has been proposed to contribute to increased fall risk in populations such as the elderly. Therefore enhancing the generation of these reflexes may be a method of improving standing balance in these populations. A possible mechanism of enhancing cutaneous reflexes is through stochastic resonance (SR), which is a phenomenon where the detection of a signal is enhanced by the addition of subthreshold noise. SR-mediated enhancements have been shown in many neurophysiological systems such as tactile stimulus detection but have yet to be explored in cutaneous reflexes. Therefore, this study was conducted to explore the possibility of enhancing mechanically-evoked cutaneous reflex responses by introducing an electrical noise component to the system. Vibrotactile (input used to evoke a reflex) and electrotactile (noise component) stimuli (both Gaussian in nature, bandwidth: 0 - 50 Hz) were applied to the plantar skin at the heel of 11 young, healthy subjects (mean age = 20.9 years, SD = 1.14). The vibration intensity was 10 times perceptual threshold (PT) while electrotactile noise intensity varied between 0 and 100% of PT. Electromyography recordings were taken from the soleus (SOL), tibialis anterior (TA) and both medial (MG) and lateral gastrocnemius (LG). Cutaneous reflexes were quantified by measuring the peak to peak amplitude (PTP) of the cumulant density plot at each noise intensity for each subject. When

averaged across all subjects, no statistically significant differences were found in PTP across noise intensities in any muscles (SOL: p=0.091 MG: p=0.45, LG: p=0.42, TA: p=0.24). Separation of subjects based on their response to noise-mediated enhancements of SOL reflex (responders: n=6, non-responders: n=5), resulted in significant differences in SOL mean PTP of non-responders (p=0.028), while approaching significance in responders (p=0.059). No significant differences were observed in other muscles for both groups. Therefore, we conclude that trends of noise-enhancements of cutaneous reflexes may be observed in a subset of the population. In the rest of the population, noise seems to decrease cutaneous reflex generation. This information may help inform the design and application of biomedical aids to improve balance in clinical populations.

Title: Whole body vibration: Effects on soleus and flexor carpi radialis h-reflexes in healthy subjects

Authors: *M. M. SABBAHI[1], F. OVAK BITTAR[2]
[1]Texas Electrophysiology and Physical Therapy, Houston, TX; [2]Texas Physical Therapy and Rehab, Houston, TX

Abstract: Whole body vibration (WBV) has more frequently been utilized with athletic training. It was claimed that WBV increases the strength of healthy subjects. The WBV's physiologic effect on reflex functions has not been thoroughly evaluated. Tendon vibration is known to be a strong stimulus to Ia afferents causing tonic vibration reflexes. This presentation discusses the effect of WBV on Soleus and flexor carpi radialis (FCR) H-reflexes in healthy subjects. Subjects were tested for the Soleus and FCR H-reflexes using the method of Sabbahi & Khalil (1990). Surface electrodes were applied on the Soleus and FCR muscles while electrically stimulating the tibial and the median nerve (1 ms. pulses at 0.2 Hz at H-max). Recording parameters were 500 µv. /div., 10 Hz-1000 Hz bandwidth. Subjects were tested in standing (Soleus) and sitting (FCR) to evaluate the WBV effect on H-amplitude. WBV;11.6 vibration trainer of Freemotion inc. was used to elicit the vibration at 30- 50 Hz. at low or high amplitude for a period of 90 sec. H-reflexes were tested before and after different combinations of vibration frequencies and amplitude (low or high). Soleus H-reflex was tested during neutral stand, tiptoe, heel stand or during knee squat. FCR H-reflex was tested in sitting with hand rested on the vibration plate, or in wrist extension position. Five H-reflex traces were averaged for each trial with 3 min rest in

between trials. The peak-to-peak amplitude and reflex and muscle latencies were measured. Results showed H-amplitude inhibition for both the Soleus and FCR muscle (50-70% for Soleus & 30-40 % FCR)amplitude was substantially facilitated, during rest, post vibration for the Soleus and FCR muscles (10-20% for Soleus and 10-15% for the FCR). Tiptoe standing resulted in facilitation in the Soleus H-reflex. Heel standing and knee flexion resulted in complete H-reflex inhibition. Both maneuvers showed the minimal effect of vibration. Three minutes of continuous vibration of different frequencies and amplitudes resulted in Soleus H-reflex inhibition post-vibration. No measurable changes were recorded in the H or M-latencies. These results indicate a strong inhibitory effect on the motoneurone excitability of the lower and upper limbs, possibly due to a barrage of afferent pathways signal. The post-vibration facilitation indicates an increased excitability of the motoneurons pool that might be longer lasting. Such effect may result in the observed increase in the muscle strength recorded by studies in athletes and might be useful in rehabilitation of patients with neuromuscular disorders.

Title: Influence of inter-stimulus intervals on transcranial magnetic stimulation-conditioning of soleus H-reflexes

Authors: *J. XU, A. LOPEZ, M. HOQUE, M. BORICH, T. KESAR
Dept. of Rehabil. Med., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Objective: Paring sub-threshold transcranial magnetic stimulation (TMS) with peripheral nerve stimulation (PNS) at specific inter-stimulus intervals (ISIs) can result in modulation of the Hoffman's reflex (H-reflex). Short latency facilitation (SLF) of the H-reflex is elicited by activation of a direct, fast-conducting descending corticospinal projections to the spinal lower motor neuron (LMN) when TMS is applied 1-5 ms after PNS. Long-latency facilitation (LLF) measures the excitability of indirect, polysynaptic, slower-conducting descending corticofugal pathways when TMS is applied 10 ms before PNS. However, the influence of ISI on the magnitude of TMS-facilitation of H-reflexes has not been systematically investigated. The purpose of this study was to investigate how varying the interval between the cortical and peripheral stimuli affects short- and long-latency TMS-conditioned H-

reflexes.Method: Ten able-bodied, young adult individuals participated this study. Sub-threshold TMS (90% active motor threshold, or AMT) was delivered at different stimulus intervals relative to electrical stimulation of tibial nerve. The ISI between the PNS and sub-threshold TMS was varied from -6 to +12ms. Negative ISIs indicate that the PNS was delivered prior to TMS, while positive ISIs indicate that PNS occurred after the TMS. We plotted the relationship between ISI and the amplitudes of conditioned H-reflexes at each ISI normalized by unconditioned H-reflexes.Results and Discussion: The mean ISI at which the earliest-onset of short-latency facilitation was observed for the group was -3.50 ± 0.85ms. The timing at this ISI was considered to represent the fastest TMS descending activity coinciding with the afferent volleys from PNS at the spinal motoneurons. ISI -1ms for SLF and ISI 10.5ms for LLF were determined to be 'standard' ISIs that may elicit maximal or near-maximal facilitation for the group. LLF showed greater variability in the optimal ISI eliciting peak facilitation compared to SLF, which may relate to the more complex and poly-synaptic physiological pathways involved in LLF.Conclusion: Measurement of SLF at a single, standardized ISI may suffice. For measurement of LLF, determining an individual's optimal ISI may provide a more accurate measure. Our findings suggest that evaluating short- and long-latency facilitation of H-reflexes at a range of ISIs may provide a unique opportunity to index the excitability of descending corticofugal projections onto spinal motor neurons.

Title: Evidence for separate descending control of clasp-knife inhibition and force feedback in the feline spinal cord

Authors: *E. KAJTAZ[1], M. A. LYLE[2], K. A. CHEFFER[3,4,7,5], L. R. MONTGOMERY[4,3,7], D. R. HOWLAND[4,3,6,7,5], T. NICHOLS[1]

Abstract: Spinal cord injury (SCI) can amplify and redistribute intermuscular inhibitory force feedback (iFFB) from Golgi tendon organs and release clasp-knife inhibition (CKI), a powerful inhibition arising from group III and IV muscle receptors. The CKI can be evoked experimentally by transecting the dorsal spinal cord, and the reorganization of iFFB can be evoked by lateral hemisection. Since dorsal and lateral hemisections share disruption of the dorsolateral spinal cord, it is not clear whether CKI and iFFB are regulated by the same supraspinal system. Prior data from our group implicates the vestibulospinal tract, a ventral pathway, in iFFB regulation. To investigate whether inhibitory feedback from these receptor groups are regulated by separate pathways, we sought to determine whether dorsal hemisection alters the organization of iFFB. In the absence of SCI, iFFB between muscles is often bi-directional or evenly balanced and CKI is rarely observed, while following lateral hemisection iFFB is strongly biased toward one member of each muscle pair. Observation of bi-directional iFFB between muscle pairs and presence of CKI following dorsal hemisection would support the hypothesis that iFFB is regulated separately from CKI by descending signals in ventral pathways. We utilized the decerebrate cat and measured the strength and distribution of inhibitory feedback between extensor muscles spanning one or more joints of the feline hind limb. The muscles included members of the quadriceps and triceps surae groups, a long toe flexor, and plantaris. The animals had received either chronic dorsal or lateral hemisections prior to the terminal experiments. Following the decerebration and removal of anesthesia, muscles in pairs, denoted as recipient and donor, were stretched in different combinations and intermuscular inhibition assessed as a decrease in the stretch reflex of the recipient muscle. Intermuscular reflexes due to iFFB were indicated by short-latency, force dependent inhibition, while CKI was indicated by profound and long-lasting inhibition often including autogenic inhibition. The results indicate that iFFB between members of several muscle pairs remained bidirectional following dorsal hemisection, supporting the hypothesis that CKI and iFFB are regulated by distinct descending systems, further distinguishing these two spinal networks. This finding has important clinical implications as presence of either CKI or redistributed iFFB points to the damage to distinct spinal cord columns and can be used as an early diagnostic tool to evaluate the extent and location of the injury. Title: Impact of spinal cord injury on adaptations in stance during down-slope walking

Authors: *L. R. MONTGOMERY[1,2,4], K. A. CHEFFER[1,2,3,4], E. KAJTAZ[5], M. A. LYLE[6], T. NICHOLS[5], D. R. HOWLAND[1,2,3,4]

Ctr., Louisville, KY; [5]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [6]Div. of Physical Therapy, Emory Univ., Atlanta, GA

Abstract: Features of the step cycle stance phase are finely controlled to ensure stable, efficient weight support during locomotion. Early stance (E2) encompasses the critical period of weight acceptance (yield). During level walking, transition to the second subphase of stance (E3) begins with extension across the hip, knee, ankle. Currently, we are interested in how features of E2 and E3 change with declining walking surfaces, walking speed and following spinal cord injury (SCI). Further, we are interested in understanding how changes in underlying length and force feedback (FFB) systems may contribute to the instability and decreased efficiency of weight support following neurological injury. Given that effective community ambulation involves negotiating different environments at various cadences, understanding these issues may improve rehabilitation outcomes. In the current study, the adult cat, low thoracic, lateral hemisection model is used. Cats are conditioned to step with their hind limbs on a treadmill at various decline angles (0^o to -26^o) at two speeds (0.5 and 0.8 m/s). Angular kinematics are generated and analyzed using a Vicon motion capture system. Our findings indicate that, in the intact cat, with increasing decline slope E2 duration increases, at times lasting throughout stance. The increase in duration of E2 is primarily due to changes at the knee. Further, on the steeper decline(s), a period emerges in which the knee and ankle angular positions remain constant before extension of one or both joints. Amplification of these adaptations is seen at the slower gait speed. Following hemisection, normal adaptations to slope angle during E2 and E3 are disrupted. These disruptions are greater at slower speeds. Impairments in the adaptations to increasing slope are present bilaterally despite the asymmetry of the lesion model. Some features of these impairments in the ipsi- and contra-lesional hind limbs, however are not symmetrical suggesting different combinations of deficit, recovery and compensation across the two hind limbs. How these features change across time, their correlation(s) with underlying changes in length and FFB, and the effect of decline training on recovery are being investigated. This work will help refine our understanding of the E2, E3 subphases during decline walking and the effect of SCI on key features of stance. Title: Cutaneous reflex modulation in arm muscles during self-triggered and prolonged stimulation

Authors: *Y. SUN, G. PEARCEY, E. ZEHR
Sch. of Exercise Science, Physical and Hlth. Educ., Univ. of Victoria, Victoria, BC, Canada

Abstract: Sensory feedback plays important roles in regulating movement. Some research suggests that cutaneous reflex amplitudes are reduced when the stimulation is self-triggered instead of externally triggered. Corticospinal and spinal excitabilities are altered with different stimulation durations and frequencies. However, the importance of stimulation mode (self or externally triggered) and duration (brief or sustained) is unclear. This study investigated how different combinations of trigger modes and stimulation parameters could affect the modulation of cutaneous pathways to arm muscles. Cutaneous reflexes in the wrist muscle extensor carpi radialis were evoked in neurologically intact young adults with brief (15ms, 300Hz) or sustained (300ms, 50Hz) stimulation trains. Stimulation was applied to the superficial radial nerve at the wrist and triggered by 1) computer; 2) muscle contraction; 3) participant button press. During each condition, wrist extensor muscles were contracted at 10, 25, 35, and 50% of maximal voluntary contraction. Larger cutaneous reflex amplitudes were found with increasing background muscle activities at early and middle latency. Reduced reflex amplitudes were found in the EMG-trigger condition with brief stimulation, but was not seen in the sustained stimulation condition.These results suggest reflex amplitudes following brief stimulation are altered when sensory feedback is enhanced at the onset of muscle contractions. Modulation of cutaneous reflex pathway excitability is specific to the timing when sensory cue was applied. This method can be applied to study sensory regulation of movement performance or facilitate training outcomes.

Title: The arms and legs work better when used together: Amplification of rhythmic activity-dependent suppression of soleus Hoffmann reflexes

Authors: *G. E. PEARCEY[1], E. ZEHR[2]
[1]Rehabil. Neurosci. Lab., Univ. of Victoria, Victoria, BC, Canada; [2]Rehab Neurosci. Lab., Victoria, BC, Canada

Abstract: Arm cycling causes suppression of soleus (SOL) Hoffmann (H-) reflex amplitudes that outlasts the activity period. Arm cycling presumably activates propriospinal networks that modulate group Ia presynaptic inhibition. These interlimb pathways are thought to relate to the control of quadrupedal locomotion, allowing for smooth and coordinated movement of the arms and legs. We examined whether the number of active limb pairs affects the amount and duration of activity-dependent plasticity of the SOL H-reflex. On separate days, twelve participants completed 4 randomly ordered 30 minute experimental sessions: 1) quiet sitting (CTRL); 2) arm cycling (ARM); 3) leg cycling (LEG); and, 4) arm and leg cycling (A&L) on an instrumented ergometer. H-reflex and M-wave amplitudes in the SOL were evoked via electrical stimulation of the tibial nerve at the popliteal fossa. M and H-reflex recruitment curves were recorded while the participants sat quietly prior to, 10 and 20 minutes into, immediately after, and at 2.5, 5, 7.5, 10, 15, 20, 25, and 30 minutes after the experimental session. Normalized maximal H-reflexes were unchanged in CTRL but were suppressed by ~30, 45 and 50% for the ARM, LEG and A&L conditions, respectively. Suppression of maximal H-reflexes outlasted activity duration for ARM ($\leq$2.5 mins), LEG ($\leq$5 mins), and A&L ($\geq$30 mins) conditions. The non-linear duration of suppression of reflexes in the A&L condition was greater than the algebraic summation of effects in ARM and LEG. This non-linear summation suggests that using the arms and legs simultaneously—as in normal locomotor synergies—causes amplification of networks responsible for the suppression of soleus H-reflexes. This enhanced activity of spinal networks may have important implications for the implementation of locomotor training for targeted rehabilitation.

Title: Neurophysiological and performance changes during long-term Yuishinkai martial arts training: A pilot study

Authors: *A. HARRISON, P. ZEHR, H. MUSTAFA, Y. SUN, G. PEARCEY
Univ. of Victoria, Victoria, BC, Canada

Abstract: Corresponding Author: AMH
Senior Author & Principal Investigator: EPZ
Dynamic postural regulation is a key variable for quality of life and function as we age. Widely available interventions to maintain or enhance integrated function across the lifespan and in the neurologically impaired are needed. Previous research has shown exercise programs to have beneficial effects, yet evidence is lacking in the mind-body exercise interventions. The goal of this research was to advance current findings in a cost-effective therapeutic manner. We investigated the effects of a 5-week mind-body martial arts exercise intervention on postural control, spinal cord excitability and strength. A convenience sample of apparently healthy young adults participated 3 x 1 h per week martial arts sessions lead by an experienced, certified Yuishinkai karate instructor. Using a multiple-baseline control in in pre- and post-assessments, dynamic balance, postural sway, spinal cord excitability (via Hoffmann reflex modulation) and strength were measured. Results showed changes in grip strength, dynamic balance performance and spinal cord excitability suggesting increased postural integration.
It can be anticipated that implementation of a similar karate mind-body exercise program will have a beneficial effect on the overall physical functioning in neurologically compromised individuals.

Title: Transspinal stimulation during treadmill walking alters soleus H-reflex excitability in healthy humans

Authors: *L. M. MURRAY[1], J. LI[2], M. A. ISLAM[3], T. S. PULVERENTI[1], M. KNIKOU[4]
[1]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY; [2]Staten Island Tech. High Sch., Staten Island, NY; [3]Physical Therapy, [4]The Grad. Ctr., City Univ. of New York, Staten Island, NY

Abstract: Non-invasive transspinal stimulation over the thoracolumbar region produces significant modulation of cortical and spinal neural circuits. However, the effects of transspinal stimulation on the phase-dependent modulation of the soleus H-reflex during human walking remain largely unexplored. In this study, we investigated the phase-dependent modulation pattern of the soleus H-reflex following transspinal conditioning stimulation, as well as the phase-dependent modulation pattern of the transspinal evoked potentials (TEPs) during treadmill walking. The soleus H-reflex was conditioned by transspinal stimulation delivered at an individualized negative conditioning-test (C-T) interval that produced reflex facilitation, and at the corresponding positive C-T interval that produced reflex inhibition at rest. During walking, the soleus H-reflex was elicited following posterior tibial nerve stimulation with a 1-ms single pulse at an intensity that the M-waves ranged from 2 to 8 % of the maximal M-wave (Mmax) elicited 60-80 ms after the test reflex stimulus. This protocol was utilized for both unconditioned and conditioned H-reflexes. Soleus TEPs were evoked following cathodal pulsed transspinal stimulation over the thoracolumbar enlargement based on established experimental protocols utilized extensively in our laboratory. Soleus H-reflexes and TEPs were recorded randomly across the step cycle, which was divided equally into 16 bins with bin 1 corresponding to heel contact, and bins 9 and 16 corresponding approximately to stance-to-swing and swing-to-stance transition, respectively. Conditioned and unconditioned H-reflexes and associated M-waves were normalized to the Mmax evoked at each associated bin. TEPs during walking were normalized to the homonymous TEP recorded during standing. The soleus H-reflex was depressed from bins 2

to 9 following positive transspinal conditioning, and facilitated at bin 1 whilst reaching control reflex values at the remaining phases of the step cycle following negative transspinal conditioning. Changes in H-reflex amplitudes occurred with constant M-waves for all conditions. Lastly, the TEPs of distal and proximal limb muscles were modulated in a phase-dependent pattern and linearly with the homologous EMG. We conclude that transspinal stimulation may be utilized as a means to decrease spinal reflex hyper-excitability during walking, as is the case for neurological disorders, and thus promote a physiological gait pattern.

Title: Transspinal stimulation affects muscle activation patterns during treadmill walking in healthy humans

Authors: *M. A. ISLAM[1], J. LI[3], T. S. PULVERENTI[4], L. M. MURRAY[4], M. KNIKOU[2]
[1]Physical Therapy, [2]The Grad. Ctr., City Univ. of New York, Staten Island, NY; [3]Staten Island Tech. High Sch., Staten Island, NY; [4]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY

Abstract: Non-invasive transspinal stimulation over the thoracolumbar region produces bilateral transspinal evoked potentials (TEPs) from proximal and distal limb muscles during treadmill walking, which are modulated in a phase-dependent manner. However, the effects of transspinal stimulation on the muscle activation pattern during human walking remain largely unexplored. In this study, we recorded the EMG activity from leg muscles when transspinal stimulation was delivered as a single 1 ms pulse and/or as a pulse train at 30 Hz delivered randomly across the step cycle based on a signal from the foot switches. Each step cycle was divided equally into 16 bins with bin 1 corresponding to heel contact, and bins 9 and 16 corresponding approximately at stance-to-swing and swing-to-stance transition, respectively. We found that the EMG activation patterns from the steps before transspinal stimulation were similar to the homologous EMG

activation patterns recorded after transspinal stimulation. However, the EMGs from the steps during transspinal stimulation indicated different activation patterns. The EMG activation patterns of the ankle extensors shifted from stance to swing phase when stimulation was delivered at bins 5-15, while for ankle flexors these patterns shifted from swing to stance phase when stimulation was delivered at bins 4-16. Importantly, despite this shift, the principle component analysis revealed that bins 1-7 contributed mainly to the ankle extensors EMG activity, and bins 8-11 and 15-2 contributed largely to the ankle flexors EMG activity. We conclude that transspinal stimulation produces complex effects on EMG activation patterns in both ankle extensors and flexors.

Title: Spinal neural interactions during transspinal and afferent stimulation in humans

Authors: *M. KNIKOU[1], L. M. MURRAY[3], T. S. PULVERENTI[3], M. ISLAM[2]
[1]The Grad. Ctr., [2]Physical Therapy, City Univ. of New York, Staten Island, NY; [3]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY

Abstract: Non-invasive transspinal stimulation may constitute a novel method of neuromodulation and neuroplasticity. However, neural interactions between transspinal evoked potentials (TEPs) and spinal monosynaptic reflexes remain poorly understood. In this study, we established the modulation profile of soleus H-reflexes and TEPs in healthy human subjects, when both stimuli evoked equal in amplitude responses relative to the soleus maximal M-wave. Soleus H-reflexes were evoked by posterior tibial nerve stimulation based on established experimental protocols utilized extensively in our laboratory. Soleus TEPs were evoked by placing two re-usable self-adhesive electrodes (anode), connected to act as one electrode, bilaterally on the iliac crests or parallel from the umbilical line depending on each subject's comfort. A re-usable pre-gelled electrode (cathode) was placed on the thoracolumbar region at T10-L1 under constant pressure throughout the experiment whilst the subject was lying supine. Soleus H-reflexes and soleus TEPs were recorded at conditioning-test (C-T) intervals ranging

from negative to positive 100 ms. A negative C-T interval refers to the interval that transspinal stimulation was delivered after tibial nerve stimulation. The soleus H-reflexes were facilitated at the negative C-T intervals ranging from 16 to 9 ms, and coincided with concomitant depression of soleus TEPs. In contrast, at the negative C-T intervals of 4 and 1 ms, and at the positive C-T intervals of 0 to 100 ms the soleus H-reflex was depressed while soleus TEPs amplitude remained unchanged. Based on these findings, it is apparent that neural interaction of TEPs and monosynaptic Ia excitation of soleus motoneurons are complex in nature, and that changes in excitability depend largely on the timing between the two stimuli. The soleus H-reflex facilitation at negative C-T intervals may be the result of increased depolarization of soleus motoneurons by transspinal stimulation. The soleus H-reflex depression at long C-T intervals suggests the involvement of complex spinal interneuronal circuits following transspinal stimulation. Further research is needed to delineate the specific nature (synaptic vs. non-synaptic and presynaptic vs. postsynaptic) of transspinal stimulation induced reflex actions. Better understanding of the neuronal pathways of action will enable the development of targeted neuromodulation protocols via transspinal stimulation.

Title: Novel zebrafish models to understand respiratory depression and analgesia by opioids and to identify safe opioid pain therapies

Authors: S. ZAIG[1], C. DA SILVEIRA SCARPELLINI[1], X.-Y. WEN[1,3], *G. MONTANDON[2,1]
[2]Dept. of Medicine, Univ. of Toronto, [1]St. Michael's Hosp., Toronto, ON, Canada; [3]Med. & Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: Opioid drugs are the mainstay of pain management, but their use is limited by their severe side-effects that can be lethal with overdose. Indeed, opioid drugs induce respiratory depression, that can lead to severe hypoxemia and respiratory arrest when opioids are abused. The current antidote naloxone (Narcan) is a life-saving therapy, but its use is limited because it can only be given after the overdose occurs, so it is not a preventive treatment. The main challenge in opioid drug discovery is therefore to develop new opioid therapies with potent analgesia but reduced respiratory depression, so opioids can be safely prescribed. **Objectives:** To accelerate drug discovery, we established phenotype-based approaches using *in vivo* zebrafish

models of respiratory depression and analgesia. Zebrafish is an amenable model to study respiratory depression because its respiratory circuits are similar to mammalian circuits. Also, zebrafish μ-opioid receptors have 70% homology of amino acids with their mammalian counterparts. Our aim was to developed a high-throughput screening platform that combines drug screening and behavioural profiling so new preventive therapies can be identified. **Methods:** To determine respiratory depression, we assessed buccal movements, as an index of respiratory activity, in zebrafish larvae (day post-fertilization 14), and its response to the μ-opioid receptor analgesic fentanyl. We used a video-recording system to assess zebrafishes in multi-well microplate. To assess opioid analgesia, we induced mild pain in zebrafish larvae by submerging it in a solution of acetic acid, or acetic acid/fentanyl, and measuring its subsequent locomotor or swimming response. **Results:** Fentanyl (1 μM) significantly decreased the rate of buccal movements by 84% (baseline 41.7 breath/min, fentanyl 6.71 breath/min, n=3, *P=0.011*), a depression reversed by naloxone (10 μM, 44.3 breath/min). Our preliminary data show that acetic acid (0.01%) strongly increased locomotion, and this response was significantly reduced by fentanyl (1 μM), an analgesic effect blocked by naloxone (10 μM). **Discussion:** Our novel and unique zebrafish models mimicked well the effects of opioid drugs on respiratory activity and nociception observed in mammals. This proof-of-principle study suggests that zebrafish can be used to develop phenotype-based high-throughput drug and gene screening. Using these assays, we will knock-down key-genes involved in opioid inhibition using morpholino oligonucleotides, and test chemical screens to identify preventive therapies to reduce opioid-induced respiratory depression without altering their analgesic properties.

Abstract: Botulinum neurotoxins (BoNTs) are recognized as one of the most deadly toxins to human. Their long-lasting nerve effects combined with a high toxicity profile make them a potentially lethal chemical warfare agent. BoNTs have two domains: a neuron-specific receptor-binding domain called the heavy chain (HC), which is responsible for presynaptic compartment translocation, and a metalloprotease, or light chain (LC), domain that cleaves one or more soluble NSF attachment protein receptor (SNARE) proteins. BoNTs act within nerve terminals to prevent acetylcholine release, resulting in neuromuscular paralysis. Current treatment for BoNT poisoning relies on neutralization of circulatory toxins via passive immunization with antitoxins. However, this approach is ineffective once the toxin has been internalized into peripheral neurons. Patients that do not respond to antitoxin require intensive care, consisting of ventilator support and parenteral nutrition. As a way to combat the toxicity of BoNT/A, we have developed a recombinant derivative of botulinum neurotoxin serotype C (BoNT/C ad) as a molecular vehicle to deliver therapeutic moieties to the neuronal cytosol. BoNT/C ad has been modified to eliminate catalytic activity against neuronal SNARE proteins, putatively rendering it atoxic. By fusing a function-blocking, single-chain antibody to BoNT/C ad, Dr. Ichtchenko (NYU) produced a new molecular entity (called Cyto-111) that delivers a therapeutic moiety directly to the intra-neuronal site of toxic activity. In murine efficacy studies, a single dose of Cyto-111 prevented death in mice intoxicated with 2x LD_{50} BoNT/A at times when antitoxin was completely ineffective. However, in mouse safety studies, we found that Cyto-111 had an inherent toxicity with an estimated median lethality of 2.2 mg/kg. Mice administered this dose developed symptoms similar to botulism, which resolved within 48 h in survivors. Patch clamp recordings from cultured neurons intoxicated with Cyto-111 demonstrated significant decreases in evoked release, suggesting a novel non-proteolytic toxic mechanism. To investigate the mechanism(s) involved in Cyto-111 toxicity, we created a tet-regulated viral construct expressing Cyto-111 and are testing the effects of conditional overexpression on neuronal function in cultured primary neurons. We anticipate these data will identify the novel mechanism of non-proteolytic toxicity of Cyto-111 through whole-cell patch clamp electrophysiology data.

Title: The regulator of G-protein signaling 4 modulates opioid-induced respiratory depression

Authors: *J. DANAF[1,2], H. LIU[2], R. HORNER[2,3], G. MONTANDON[1,2], C. DA SILVEIRA SCARPALLINI[1], W. WANG[1]

Abstract: **Rationale** Opioid drugs are widely used clinically as analgesics, but present the severe side effect of respiratory depression that can be lethal with overdose. Over 90 Americans die of opioid overdose every day due to respiratory depression. It is therefore critical to better understand the mechanisms regulating opioid-induced respiratory depression to identify new preventive treatments for it. Respiratory depression is due to opioids binding to μ-opioid receptors (MORs) in brainstem respiratory circuits. The preBötzinger Complex (preBötC), a site in the medulla critical for respiratory rhythm, is an important component of respiratory rate depression by opioid drugs (*Montandon et al., 2011, J. Neuroscience*). Binding of opioid drugs to MORs activate intracellular G-proteins and open G-protein-activated inwardly-rectifying potassium (GIRK) channels (*Montandon et al., 2016, Anesthesiology*). Regulators of G-protein signaling (RGS) inhibit GIRK channel activation, but their role in MOR inhibition, especially in the context of respiratory depression, is unknown. Here we aim to identify the molecular mechanisms regulating MOR inhibition of respiratory circuits and the role of RGS4 protein, a common RGS protein found in neurons. **Methods** To determine whether RGS4 is present in the preBötC and whether it is co-expressed with MORs, we used *in situ* hybridization for RGS4 and OPRM1 genes, the genes coding for RGS4 and MORs (RNAscope). To identify the functional role of RGS4, we microperfused RGS4 inhibitors and MOR agonists in the preBötC while recording respiratory muscle activity in anesthetized male Wistar rats. We used the RGS4 inhibitor CCG 50014 (20 μM) in combination with the MOR agonist DAMGO (5 μM) or DAMGO alone. **Results** RGS4 was co-expressed with OPRM1 in the preBötC as well as the nucleus tractus solitarius. RGS4 was also expressed in the facial nucleus, and OPRM1 in the nucleus ambiguus. Microperfusion of DAMGO (5 μM) into the preBötC of anesthetized rats elicited a 24.8±1.2% decrease in respiratory rate (*n=3, P=0.04*). Microperfusion of CCG 50014 (20 μM) and DAMGO (5 μM) potentiated DAMGO inhibition and decreased respiratory rate by 43.5±6.8% (*n=9, P=0.06*), a decrease significantly more pronounced than DAMGO alone (*P=0.04*). **Conclusion** RNA transcripts showed that RGS4 is co-expressed with Oprm1 in the preBötC and other key respiratory circuits, suggesting a role for RGS4 in MOR inhibition. Indeed, inhibition of RGS4 accentuates respiratory inhibition by MOR ligands. Our data suggest that RGS4 plays a functional role in opioid-induced respiratory depression and could potentially constitute a new target to prevent respiratory depression by opioids.

Title: Sympathetic overactivity after chronic intermittent hypoxia has different mechanisms in male and female rats

Authors: *W. H. BARNETT[1], G. M. P. R. SOUZA[2], B. H. MACHADO[2], Y. I. MOLKOV[1]

Abstract: Untreated sleep apnea may lead to hypertension, which is an indicator of early death. Enhanced respiratory modulation in sympathetic nerve activity (SNA) is thought to mediate hypertension in sleep apnea patients. The mechanisms by which this enhancement occurs are not well understood. Rats subjected to chronic intermittent hypoxia (CIH) are an animal model of obstructive sleep apnea. During CIH conditioning periodic excursions in blood-gas balance repetitively activate peripheral chemoreceptors. Long term exposure evokes plasticity in brainstem neuronal circuitry which appears as changes in respiratory and sympathetic motoneuron output. In male rats, a hallmark of CIH conditioning is the appearance of active expiration during restful breathing. It is thought that late-expiratory activity in the SNA contributes to elevated blood pressure in these animals. Female rats subjected to CIH develop hypertension, but they do not experience a change in the threshold for active expiration. Instead, there is a notable facilitation of early-inspiratory activity in the sympathetic motor output. By what mechanism do female rats respond to CIH conditioning? Previously, we investigated the formation of abdominal activity and SNA in male CIH rats in the context of central chemoreflex activation. In our computational model, we showed that sensitization of the central chemoreceptors to CO_2 was sufficient to lower the threshold for respiration in hypocapnia and lower the threshold for emergence of active expiration to occur during normocapnia. Here, we use our computational model to recapitulate experimental observations of female rats exposed to CIH. From this data, we assimilate (1) the facilitation of early-inspiratory SNA and (2) evidence that inspiratory neurons recorded in the ventral respiratory group decrease firing rate. Via model simulations we generate the hypothesis that there is decrementing inspiratory inhibition on pre-sympathetic rostral ventrolateral medulla (RVLM) neurons in naive animals that is necessary for

SNA pattern formation. Taking into consideration that the caudal VLM (CVLM) is the main source of inhibition to RVLM, we implemented an inhibitory population in CVLM that is modulated by inspiration in the model. In simulation of CIH conditioned female rats, the suppression of this population disinhibits pre-sympathetic neurons in the RVLM which facilitates SNA during early inspiration. These results suggest that male and female rates develop different plastic changes in the medullary respiratory-sympathetic network that both result in enhancement of sympathetic motoneuron output following CIH conditioning.

Title: cAMP-dependent modulation of I_h underlies the $P2Y_1$receptor-mediated excitation of the preBötzinger complex inspiratory network *in vitro*

Authors: *Y. ZHANG[1], T. A. JAIB[1], A. V. GOURINE[4], S. KASPAROV[5], T. ALVARES[1], F. D. GREGORY[1,2,3]
[1]Dept. of Physiol., [2]Women & Children's Hlth. Res. Inst., [3]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [4]Dept. of Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom; [5]Sch. of Physiol. & Pharmacol., Univ. Bristol, Bristol, United Kingdom

Abstract: The ventilatory response to hypoxia comprises an initial, peripheral chemoreceptor-mediated increase in ventilation followed by a centrally-mediated secondary depression that can be life-threatening in premature infants with apnea. Recent evidence suggests that the secondary depression is not just the result of central inhibitory mechanisms but an interaction between inhibitory and excitatory mechanisms. Specifically, ATP appears to be released from astrocytes in the preBötzinger Complex (preBötC, critical site for inspiratory rhythm generation) during hypoxia where it attenuates the secondary depression via a $P2Y_1$ receptor (R)-dependent excitation of inspiratory neurons. Here we apply nerve and whole-cell recording methods to

rhythmic medullary slices (700 µM) from neonatal rat to test the hypothesis that the $P2Y_1R$-mediated excitation of the preBötC network is mediated via cAMP-dependent modulation of the hyperpolarization-activated inward current, I_h, in inspiratory neurons. Local application of MRS2365 ($P2Y_1R$ agonist, 100 µM) evoked, in a subpopulation of inspiratory neurons (~33%), inward currents that reversed between -50 and -60 mV, consistent with activation of I_h. MRS2365 also potentiated the sag current, characteristic of I_h, that was progressively activated with hyperpolarizing voltage pulses from -50 to -110 mV (10 mV increments; 32 ± 6% potentiation measured at -100 mV, n=8). Comparison of I_h activation curves, produced via analysis of tail currents evoked by a series of 10 mV hyperpolarizing steps from -50 mV to -140 mV, in control and MRS2365, revealed a 9.8 mV, MRS2365-induced depolarizing shift in $V_{1/2}$ (V_m at which I_h activated to 50% of maximum, n=6). The MRS2365 inward current and its potentiation of I_h were blocked by local pre-application of ZD 7288 (open channel blocker of I_h, 100 µM). At the network level, pre-application of ZD 7288 at 100 µM (n=6) and 25 µM (n=10) reduced the MRS2365-induced increase in inspiratory-related frequency by 94 ± 3% and 70 ± 12%, respectively. $P2Y_1Rs$ typically operate through activation of the G_q second messenger pathway, whereas I_h is modulated via G_s activation of cAMP. We therefore examined the involvement of cAMP in the $P2Y_1R$ modulation of preBötC neurons and rhythm. 15-min intracellular dialysis of SQ 22536 (adenylyl cyclase inhibitor, 100 µM) via the whole-cell pipette significantly attenuated the MRS2365 currents by 60 ± 4% (n = 9). Similarly, SQ 22536 (100 µM) attenuated the MRS2365-induced frequency increase by 67 ± 8% (n = 8). These data suggest that the $P2Y_1R$-mediated excitation of the preBötC network is produced via a cAMP-dependent modulation of I_h in a subpopulation of inspiratory neurons.

Abstract: Botulinum neurotoxins (BoNTs) are acknowledged as a serious military and civilian mass casualty threat with the potential to rapidly overwhelm medical resources due to their remarkably high potency and easy of production from natural sources. From the seven BoNT serotypes recognized by the CDC (/A - /G), BoNT/A is the most prevalent in human botulism. BoNT/A blocks acetylcholine release by cleaving SNAP-25 in neurons, stalling neuromuscular communication, which results in flaccid muscle paralysis, respiratory failure, and death in the absence of intensive intervention (ventilatory support and intravenous feeding). Presently, there is no treatment to inactive the protease activity of BoNT/A within the neuron to reverse clinical symptoms of muscle paralysis. The only FDA-approved treatment is infusion of antibody-based antitoxins to neutralize BoNT that is circulating in the blood stream by passive immunization. Here, we described a first-in-class treatment based on the targeted intra-cellular delivery of single-domain antibodies (SDA) to the presynaptic compartment of neurons. This technology was used to engineer an antidote treatment (Cyto-111), intended to block the toxin's activity at the site of intoxication (pre-synaptic compartment of neurons) and prevent death when administered after the onset of symptoms. When injected into mice, Cyto-111 traveled to the pre-synaptic compartment of the neuromuscular junction of the diaphragm. In murine efficacy studies, treatment with Cyto-111 prevented death at stages of disease that are completely refractory to antitoxin treatment (standard care treatment). In guinea pig efficacy studies, treatment with Cyto-111 had a 55% statistically significant increase in survival compared to vehicle-treated animals. Currently, we are evaluating the safety and efficacy of Cyto-111 in Rhesus macaques. Collectively, these data show that Cyto-111 successfully reverses clinical symptoms of botulism and prevent mortality following exposure to lethal doses of BoNT/A. Cyto-111 represents a first-in-class, novel therapeutic approach that allows the delivery of single domain antibodies to the presynaptic compartment of neurons.

Title: Effects of bilateral suprachiasmatic nucleus lesion on circadian rhythms of baseline breathing and hypercapnic ventilatory responses in mice

Authors: *B. S. PURNELL[1], G. F. BUCHANAN[2,1]
[1]Interdisciplinary Grad. Program in Neurosci., [2]Neurol., Univ. of Iowa, Iowa City, IA

Abstract: It is widely agreed that breathing is subject to circadian regulation. Circadian differences in respiratory physiology and responsiveness to hypercapnia are relevant to diseases such as obstructive sleep apnea (OSA) and sudden unexpected death in epilepsy (SUDEP). SUDEP is the leading cause of death in refractory epilepsy and tends to occur at night. The nocturnal occurrence of SUDEP has been attributed to seizures originating from sleep being potentially more dangerous, but circadian variations in seizure occurrence or breathing could play a role. Notably, an endogenous free-running respiratory rhythm has not previously been demonstrated. Also, it is assumed that circadian rhythms in breathing are dependent on the master circadian oscillator in the hypothalamic suprachiasmatic nucleus (SCN), but this has not been shown experimentally. To determine whether breathing is subject to endogenous circadian regulation, the breathing of adult, male, C57BL/6 mice (n = 17) at baseline and in response to 7% CO2 was monitored using whole body plethysmography at 6 different times-of-day (zeitgeber time 2, 6, 10, 14, 18, and 22) while being housed under normal light-dark conditions and at 6 different circadian phases (circadian time 2, 6, 10, 14, 18, and 22) in constant darkness. Mice were housed with running wheels, and the daily running wheel activity was used to assess light entrainment and free-running circadian period. EEG and EMG was recorded concomitant to respiratory monitoring so that sleep state could be determined. Epochs of breathing which occurred during sleep were excluded from this analysis. To determine whether circadian regulation of breathing requires the SCN, this structure was electrolytically (1 mA, 15 s) lesioned bilaterally (n = 11) or a sham surgery was performed (n = 6). After surgical recovery, breathing

was measured at different time points in constant darkness. At baseline, minute ventilation was significantly higher during the active phase in both entrained and free-running conditions. This difference was primarily driven by an increase in respiratory rate, with no change in tidal volume. Furthermore, the respiratory response to CO2 was more robust during the active phase in both conditions. Circadian variations in ventilation and in respiratory responses to CO2 were abolished by SCN lesion. Lesion size and placement were histologically verified post hoc. These results suggest that breathing is under endogenous circadian control via the SCN. Insights into the mechanism of circadian regulation of breathing may lead to targeted interventions which could reduce the morbidity and mortality associated with diseases such as OSA and SUDEP.

Title: In-vivo implementation of a neuromorphic controller for ventilatory pacing

Authors: *R. SIU[1], J. J. ABBAS[2], B. K. HILLEN[1], R. JUNG[1]
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Ventilation is driven by a complex biofeedback loop that drives pulmonary gas exchange to maintain homeostasis. Trauma or disease in any of the components in this loop can disrupt it and cause ventilatory impairment. Cervical spinal cord injury, for example, may lead to ventilatory paresis or paralysis. Mechanical ventilators have been used as the standard for treatment, but they have risks such as damage to lung tissue and muscle atrophy. Ventilatory pacing systems address these issues by electrically stimulating the diaphragm muscle to cause a contraction of the muscle and thus evoke a breath. Commercially-available pacing systems are all open-loop systems that require lengthy or subjective calibration procedures in a clinical or surgical setting. Any changes to the system during its use requires calibration, which can be inconvenient and costly.
A neuromorphic closed-loop adaptive controller for ventilatory pacing has been developed that can account for biomechanical, physiological, or metabolic change to provide the necessary ventilation. This neuromorphic controller is composed of a pattern generator (PG) that applies a mathematical model of the respiratory central pattern generator to generate a ventilatory pattern based on end-tidal CO_2 input and an adaptive single-layer neural network as the pattern shaper

(PS) that uses measured breath volume to determine the stimulation parameters required to evoke a volumetric profile that matches the pattern generated by the PG.
The PG/PS controller was tested in-vivo in an intact Sprague-Dawley rat. Urethane was used as the anesthetic agent. Bilateral stimulating electrodes were implanted in the diaphragm muscle proximal to the innervation point. A pneumotachometer and a capnograph were used to collect flow and $etCO_2$ values, respectively; flow was integrated to obtain breath volume. After pacing had initiated and adapted to match an initial ventilatory pattern determined by the PG, in order to assess the controller's capabilities, a change in metabolism was mimicked by manually altering the $etCO_2$ input to the controller. A decrease in input to the PG from the initial value of 49 mmHg $etCO_2$ to 48 mmHg $etCO_2$ resulted in a reduction of the weight-matched desired ventilatory profile by 0.15 ml tidal volume and respiratory rate by 11 breaths/min, which the pacing matched after a period of desynchronization lasting 7 cycles. These results show the capability of the controller to modulate both breath volume and respiratory rate in-vivo on a breath-to-breath basis in response to changes in measured $etCO_2$.

Title: Effects of serotonin depletion on respiratory and cardiac responses to the 5-HT agonist 8-OH-DPAT and on brain tryptophan hydroxylase immunoreactivity

Authors: J. L. BUTLER[1], N. MICHALAK[2], *B. A. HEIDENREICH[2]
[2]Psychology, [1]Illinois State Univ., Normal, IL

Abstract: Activation of 5-HT1A receptors by systemically administered 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) increases respiratory rate and decreases heart rate. These responses appear to be central in origin, as local application of 8-OH-DPAT to the ventral medulla also produces these effects. However, it is unknown if the 5-HT1A receptors that influence respiratory and cardiac activities are presynaptic autoreceptors or are post-synaptic receptors. This experiment investigated this issue by examining the effects of (±)8-OH-DPAT (0.5-256μg/kg iv) on respiration and heart rates in urethane anesthetized male Sprague-Dawley rats after serotonin depletion with the synthesis inhibitor para-chlorophenylalanine (PCPA; 400 mg/kg sc for 3 days). We then examined tryptophan hydroxylase immunoreactivity in the pons.

Basal respiration rate after treatment with PCPA was 70.5 ± 2.4 breaths/min (n=30), which is significantly slower ($p<.02$) than the breathing rate of 86.8 ± 2.9 breaths/min seen in controls (n=36). 8-OH-DPAT increased breathing rate in 17/27 PCPA-treated rats and 15/22 controls, with no significant difference in either the maximal effect (112-119% of baseline) or the ED50 (20-36μg/kg). Thus, serotonin depletion reduced basal respiration rate without altering the increase in breathing produced by systemic 8-OH-DPAT. Basal heart rate in PCPA-treated rats (5.3 ± 0.1 beats/sec, n=32) did not differ from that in controls (5.0 ± 0.1 beats/sec, n=37). 8-OH-DPAT decreased heart rate in 27/29 PCPA-treated rats and 24/28 controls. The maximal reduction produced by 8-OH-DPAT was significantly greater ($p<.05$) in PCPA-treated rats (76.1 ± 1.6% of baseline), compared to controls (81.6 ± 2.0% of baseline). While serotonin depletion did not alter basal heart rate, the decrease in heart rate produced by 8-OH-DPAT was potentiated, suggesting 5-HT1A receptor supersensitivity. Interestingly, immunostaining for tryptophan hydroxylase in the dorsal raphe nucleus was comparable between control and PCPA-treated rats. While PCPA inactivates tryptophan hydroxylase, thus reducing serotonin levels, the enzyme is still present and immunoreactive within serotonergic neurons. Together, these data indicate that while basal breathing rate may be regulated by tonic serotonergic neuronal activity, postsynaptic 5-HT1A receptors likely mediate the effects of 8-OH-DPAT on respiration and heart rates.

Title: Leptin regulates breathing by potentiating a background conductance in LepRb-expressing galaninergic neurons in the Nucleus of the Solitary Tract (NTS)

Authors: *J. DO[1], L. FLOREANI[2], G. SEKERKOVA[1], D. R. MCCRIMMON[1], M. MARTINA[1]
[1]Physiology, Feinberg Med. Sch., Northwestern Univ., Chicago, IL; [2]Neurobio., SISSA, Trieste, Italy

Abstract: A remarkable characteristic of the respiratory system is the matching between ventilation and metabolism which is so precise that there is almost no change in arterial blood gases in the presence of different metabolic rates, suggesting that chemoreceptor activation cannot explain the ventilatory response. We speculate the existence of a neural circuit that receives chemosensory information but also receives information related to metabolism. The

caudal nucleus of the solitary tract (NTS) receives dense innervation from sensory afferents of the vagal and glossopharyngeal nerve and there is a noticeable group of cells in the NTS that express the functional long-form leptin receptor (LepRb). Leptin is known to stimulate breathing, and as leptin also increases energy expenditure, the concomitant change in respiration is essential to maintain arterial blood gas homeostasis. Our study has three main goals: 1- to characterize the neurochemical and electrophysiological properties of LepRb-expressing cells in the NTS; 2- to uncover the identity of the ion channel(s) mediating the action of leptin in these different cellular populations; and 3- to identify the properties of fast and slow synaptic transmission of LepRb-expressing NTS neurons that control breathing. To pursue these goals, we combine genetic tagging of leptin receptor expressing neurons, electrophysiological recordings, single cell RT-PCR and in situ hybridization to test the expression of a list of channels and neuropeptides. We found that LepRb-expressing NTS neurons consist of at least two populations based on distinct firing patterns. Type1 cells have burst-like firing patterns whereas type2 cells show delayed spike onset. Leptin depolarizes type1 cells by activating a current mediated by NALCN channels and a major percentage of type1 cells co-express galanin. Together our data suggest that LepRb-expressing NTS neurons form different subpopulations and that the depolarizing action of leptin on galaninergic LepRb cells is at least in part mediated by NALCN channels. To investigate whether galaninergic LepRb-NTS neurons control breathing, we are conducting virus injections into the caudal NTS to map afferents in the ventral respiratory columns.

Title: Automated analysis of breathing using BreathMetrics: A respiratory signal processing toolbox

Authors: *T. J. NOTO
Ward Building 13-270, Northwestern Univ., Chicago, IL

Abstract: Our ability to investigate questions about the neuroscience of respiration and olfaction can only be as good as our ability to link biological events to features of respiratory waveforms.

Human respiratory flow recordings are difficult to analyze because there are inherently noisy, non-stationary, non-sinusoidal, and imbued with a multitude of meaningful features that vary across individuals. With no tool for automatically extracting the full set of features hidden in raw respiratory recordings, researchers must build time-intensive, custom analysis protocols that often require hand-labeling each respiratory event in a recording. This methodology limits comparison across studies as well as the range and precision of possible insights that can be gained about the brain's respiratory and olfactory processing. Here we present BreathMetrics: an open-source respiratory signal processing toolbox that automatically calculates the full set of features embedded in airflow recordings (including sniff onsets), calculates statistical summaries of these features, and visualizes them. Here we show that BreathMetrics passes a rigorous validation process by evaluating BreathMetrics' feature estimation accuracy using several techniques on recordings from human subjects, mice, and simulations. BreathMetrics' feature estimates were more accurate and revealed stronger odor-evoked theta power in electrophysiological recordings of human olfactory cortex compared to other techniques, these features resemble those that were hand-labeled, and feature estimations had 95% confidence intervals on the order of single milliseconds. Using this tool, we were able to glean new insights about how respiratory waveforms change when individuals perform an emotional task in basal and induced anxious states. In this way, we show that our algorithm accurately and thoroughly analyzes respiratory waveforms, allowing researchers to address novel questions about how respiration relates to body, brain, and behavior.

Abstract: It is well known that progesterone acts both centrally and peripherally as a respiratory stimulant, as women who are in the luteal phase of their menstrual cycle or during pregnancy experience periods of hyperventilation, and post-menopausal women display an increased

frequency of sleep disordered breathing compared to pre-menopausal women.
Congenital central hypoventilation syndrome (CCHS) is a disorder caused by a genetic mutation of the transcription factor paired-like homeobox 2b (PHOX2B), which is essential for neural development of several classes of neurons in the brainstem. CCHS is associated with the inability to maintain proper ventilation and blood gas levels during sleep. There is no effective cure for the disease and the only option for treatment is mechanical ventilation or diaphragm pacing. Respiratory stimulants have proven ineffective, with the exception of a recent report that indicated a 2-3 fold increase in the ventilatory response to hypercapnia in female CCHS patients with the onset of desogestrel, a potent progestin into their daily regimen.
In this study we hypothesized that etonogestrel (ETO; the active metabolite of desogestrel) stimulates progesterone receptor expressing neurons to increase ventilation. Adult female rats were instrumented with implants to chronically deliver ETO (or sham rats) over a four-week period. An additional group of rats was also treated with 17β estradiol (E2) to increase progesterone receptor expression in presence of ETO or sham rats. Rats were then tested weekly in whole-body plethysmographs to determine changes in respiratory parameters (frequency, tidal volume, and minute ventilation) during baseline conditions (normoxia) and respiratory challenges (hypercapnia and hypoxia). At the end of the experiment, response to hypoxia and hypercapnia was also tested under isofluorane anesthesia.
Our results indicate that ETO does not affect the hypercapnic or hypoxic ventilatory response in freely behaving healthy female rats. However, ETO or E2 induce potentiation in the second phase of the hypoxic ventilatory response under isofluorane anesthesia.

Title: Mitochondrial density and morphology in phrenic motor neurons is size-dependent

Authors: *S. RANA[1], M. J. FOGARTY[2], C. B. MANTILLA[3], G. C. SIECK[2]
[1]Neurobio. of Dis., [2]Physiol. & Biomed. Engin., [3]Anesthesiol., Mayo Clin., Rochester, MN

Abstract: Neuromotor control of diaphragm motor units is dependent on the orderly recruitment of phrenic motor neurons (PhMNs) in a size-dependent manner. Type S and FR motor units comprise smaller, more easily recruited PhMNs that innervate fatigue resistant, lower force-

producing type I and type IIa muscle fibers. Type FInt and FF motor units, comprise larger, rarely recruited PhMNs innervating the more fatigable, higher force-producing type IIx and/or IIb muscle fibers. The activity and energy demand upon PhMNs of type S and FR motor units is greater than that of PhMNs from type FInt and FF units, due to the high duty cycle (~35%) of ventilation. Accordingly, activity of type FInt and FF motor units is largely the domain of higher force behaviors, performed over much shorter durations, including expulsive/straining maneuvers such as coughing, sneezing, defecation and parturition. The energy demand in both PhMNs and diaphragm muscle fibers is met by mitochondria. To preserve homeostasis, mitochondrial functions are regulated by dynamic, continuous cycles of fusion and fragmentation. We hypothesized that mitochondrial density and mitochondrial fusion will be greater in smaller PhMNs, due to their more frequent activation during ventilation. In six adult (6-month old) Fischer 344 rats, PhMNs were retrogradely labeled by intrapleural injection of Alexa488-conjugated CTB. Three days later, cervical transdural infusion of MitoTracker Red was performed every 10 min for 1.5 h under anesthesia. Spinal cord tissue was collected following transcardial perfusion with 4% paraformaldehyde, sectioned longitudinally at 70 µm, and mounted onto slides. Two-channel sequential confocal z-stack (0.50 µm step size) mosaics of PhMNs and mitochondria were acquired using a 60x oil immersion objective and analyzed using Nikon Elements software. The surface areas of PhMNs were measured and divided into tertiles. The lower tertile of PhMNs (comprising type S and FR motor units) had greater mitochondrial volume densities, greater mitochondrial aspect ratios and form factors and greater mean individual mitochondrial volumes than upper tertile PhMNs (comprising type FInt and FF motor units). We further characterized the differences in mRNA expression of mitochondrial dynamics associated proteins (Mfn2 and Drp1) in large vs. small PhMNs using fluorescent in-situ hybridization techniques. Our results suggest that PhMNs of type S and FR motor units have increased mitochondrial density, supporting their high energy demand to sustain ventilation. Their increased mitochondrial fusion may underlie their resilience to PhMN loss in aging and disease.

Title: Glutamatergic synaptic input to phrenic motor neurons depends on motor neuron size

Authors: *G. C. SIECK[1], S. RANA[2], W.-Z. ZHAN[3], C. B. MANTILLA[4]
[1]Physiol. & Biomed. Engin., [2]Neurobio. of Dis., [4]Anesthesiol., [3]Mayo Clin., Rochester, MN

Abstract: Excitatory glutamatergic (Glu) synaptic input responsible for inspiratory drive to phrenic motor neurons (PhMNs) emanates primarily from the ipsilateral ventrolateral medulla. This excitatory input is disrupted by unilateral C2 hemisection (C2SH), resulting in cessation of inspiratory-related diaphragm muscle (DIAm) activity. In previous studies we found that while inspiratory-related DIAm EMG activity disappears immediately after C2SH, DIAm activity during higher force behaviors persists. These higher levels of DIAm force are necessary to generate greater intra-abdominal pressures during expulsive airway clearance and straining behaviors. In a model of PhMN (DIAm motor unit) recruitment, we hypothesized that smaller PhMNs innervating more fatigue resistant DIAm motor units are recruited to accomplish ventilatory behaviors, whereas larger PhMNs innervating more fatigable motor units are recruited to accomplish more forceful expulsive/straining behaviors. These two general classes of DIAm motor behaviors are likely to have different synaptic drive to PhMNs. Accordingly, we hypothesize that C2SH primarily disrupts Glu synaptic inputs to smaller PhMNs, whereas Glu synaptic inputs to larger PhMNs are preserved after C2SH. To address this hypothesis, we examined changes in Glu presynaptic input onto retrogradely labeled PhMNs using immunohistochemistry for VGLUT1 and VGLUT2. We found that following C2SH (by 7 days), there was substantial reduction in Glu synaptic input to smaller PhMNs. In contrast, Glu synaptic input to larger PhMNs was relatively unaffected. These results are consistent with a more pronounced impact of C2SH on smaller PhMNs (fatigue resistant DIAm motor units), which are responsible for lower force, ventilatory behaviors of the DIAm. In contrast, the preservation of Glu synaptic input at larger PhMNs (more fatigable DIAm motor units) after C2SH is consistent with the preservation of higher force behaviors after C2SH. These results indicate that the source of Glu synaptic input to PhMNs varies depending on motor neuron size and reflects different functional control -perhaps separate central pattern generator and premotor circuits. For smaller PhMNs, the central pattern generator for respiration is located in the pre-Botzinger complex and premotor neurons in the ventrolateral medulla, sending predominantly ipsilateral projections via the dorsolateral funiculus. C2SH disrupts this Glu input. For larger PhMNs, the central pattern generator for expulsive/straining behaviors and the premotor neurons mediating these behaviors appear to reside below the C2 level, since C2SH does not eliminate Glu input.

Title: Cervical spinal hemisection induced changes in phrenic motor neuron TrkB mRNA expression depend on motor neuron size

Authors: *C. B. MANTILLA[1], S. RANA[2], W.-Z. ZHAN[2], G. C. SIECK[2]
[1]Anesthesiol., [2]Physiol. & BME, Mayo Clin., Rochester, MN

Abstract: Among patients with spinal cord injury (SCI), more than 50% involve the cervical spinal cord, with many cases resulting in diaphragm muscle (DIAm) paralysis and impaired ventilation. Importantly, most SCIs are incomplete with sparing of descending excitatory inputs to phrenic motor neurons (PhMNs). Unilateral C2 hemisection (C2SH) is an animal model of incomplete SCI widely used to examine neuroplasticity in the neuromotor control of breathing following injury. In recent studies, we found that the amplitude of ventilatory-related DIAm activity (generally accomplished by recruitment of smaller PhMNs) is reduced after C2SH. Gradual recovery of rhythmic ventilatory-related DIAm activity ipsilateral to injury is evident over time, and is enhanced by BDNF signaling through its high-affinity TrkB receptor in PhMNs, reflecting neuroplasticity. In contrast, DIAm EMG activity during higher force, non-ventilatory behaviors (generally accomplished by recruitment of larger PhMNs) is only minimally impaired. The mechanisms underlying the observed spontaneous recovery remain poorly understood, particularly in light of potential cell specific effects (e.g., across PhMNs of differing size). Thus, we hypothesized that there are size dependent differences in TrkB expression at PhMNs that underlie neuroplasticity after C2SH. To address this hypothesis, TrkB.FL mRNA expression in retrogradely-labeled PhMNs was measured using RNAscope in situ hybridization (ACDBio) up to 21 days post-C2SH in adult male rats. We found that immediately following C2SH (by 3 days), there was absence of ipsilateral DIAm EMG activity during eupnea. TrkB.FL mRNA expression, primarily in smaller PhMNs, was reduced by 3 days post-C2SH. In contrast, TrkB.FL mRNA expression in larger PhMNs was relatively unaffected. By 21 days post-C2SH, 50% of rats displayed recovery of ipsilateral DIAm EMG activity during eupnea and there was a marked increase in TrkB.FL mRNA expression, predominantly in smaller PhMNs. Ipsilateral DIAm EMG activity during sigh (~40% of maximal DIAm activity) was not impacted at any time post-C2SH. These results support an important role for TrkB signaling at PhMNs in the spontaneous recovery of ipsilateral DIAm EMG activity after C2SH and suggest fundamental differences between small and large PhMNs in the mechanisms underlying neuroplasticity and recovery.

Title: Diaphragm neuromuscular transmission failure in aged rats

Authors: *M. J. FOGARTY[1], G. C. SIECK[2], C. B. MANTILLA[3]
[1]Dept. of Physiol. & Biomed. Engin., [2]Physiol. & Biomed. Engin., [3]Anesthesiol., Mayo Clin., Rochester, MN

Abstract: In the aging Fischer 344 (F344) rat, phrenic motor neuron loss and diaphragm muscle weakness and atrophy (sarcopenia) are present by 24-months. Type FInt and FF motor units are particularly vulnerable, with larger MNs more susceptible to age-associated loss and type IIx and/or IIb muscle fibers in old rats having marked reductions in cross-sectional area. Neuromuscular junctions of type FInt and FF motor units are fragmented in old F344 rats. The likelihood of neuromuscular transmission failure is frequency-dependent with type FInt and FF motor units more likely to display neuromuscular transmission failure. Thus, we hypothesized that neuromuscular transmission failure would be evident in older diaphragm muscle preparations, particularly at the higher stimulation frequencies. We stimulated diaphragm muscle-phrenic nerve preparations of adult Fisher 344 male and female rats using supramaximal trains of 330 ms duration (33% duty cycle) at 10, 40 and 75 Hz via the nerve or directly at the muscle. Direct nerve-evoked train stimulations occurred every second for 2 min while indirect muscle stimulations were superimposed every 15 s. Effective neuromuscular transmission and neuromuscular transmission failure was compared between 6-and 24-months of age. Muscle strips were weighed and absolute measures of muscle specific force (normalized to cross-sectional area) and relative force measures were assessed. Effective neuromuscular transmission (initial nerve-evoked contractions compared to initial muscle stimulations) at 40 and 75 Hz was reduced by ~35% in old rats. Continuous stimulation for 2 mins led to neuromuscular transmission failure at 10, 40 and 75 Hz. However, only during 40 and 75 Hz stimulations were we able to detect a further likelihood of failures (increased by 20%) in old compared to young F344 rats. There were no observable age-associated differences at 10 Hz stimulations in F344 rats. The negligible difference in 10 Hz stimulations is consistent with the relative resilience of type S and FR motor units whereas failure at the higher frequencies likely reflects susceptibility of type FInt and FF motor units. These data suggest are consistent with motor unit type-specific neuromuscular impairments contributing to sarcopenia in old rats.

Title: Optineurin inhibits C2C12 myogenesis but is not associated with TWEAK-related muscle atrophy

Authors: *Y. NAGANO[1], M. ARAKI[1], K. ISHIKAWA[1], T. SHISHIDO[1], T. KURASHIGE[3], T. TAKAHASHI[1], H. KAWAKAMI[2], M. MATSUMOTO[4], H. MARUYAMA[1]
[2]Epidemiology, [1]Hiroshima Univ., Hiroshima, Japan; [3]Neurol., NHO Kure Med. Ctr., Kure, Japan; [4]Sakai City Med. Ctr., Sakai, Japan

Abstract: Mutations in optineurin (*OPTN*) have been identified in a small proportion (<1%) of sporadic and familial amyotrophic lateral sclerosis (ALS) cases. Previous reports have shown that OPTN functions as an autophagy receptor and a negative regulator of nuclear factor kappa B (NF-κB), however the exact role of OPTN in the pathogenesis of ALS remains unclear. To further examine the role of OPTN, we examined whether OPTN is involved in muscle homeostasis *in vitro*. To investigate the molecular role of OPTN in muscle atrophy, we used cultured C2C12 myotubes treated with tumor necrosis factor-like inducer of apoptosis (TWEAK) as an *in vitro* model of muscle atrophy. TWEAK treatment induced muscle atrophy and increased the mRNA levels of muscle ring-finger 1 (MuRF1), which plays an important role in the muscle atrophy process. However, the expression levels of OPTN protein and mRNA did not change significantly. C2C12 myoblasts were transfected with siRNA to knock down the expression of OPTN, differentiated, and then treated with TWEAK. OPTN knockdown had no effect on the process of muscle atrophy in this model. On the other hand, we found that myogenic differentiation was affected by OPTN. Immunoblotting analysis showed that OPTN protein levels gradually decreased during C2C12 differentiation. Furthermore, OPTN knockdown promoted C2C12 differentiation, accompanied by stable expression of myogenic factor 5 (Myf5). These findings suggested that although OPTN was not involved in TWEAK-induced muscle atrophy, OPTN could be a negative regulator of myogenic differentiation.

Title: Effect of age on axonal regeneration following peripheral nerve injury: Assessment of myelin content by magnetic resonance imaging (MRI) and post-mortem analysis

Authors: *E. GIORGETTI[1], M. OBRECHT[2], M. PANESAR[2], M. RONCO[2], C. LAMBERT[2], N. ACCART[2], M. NASH[2], M. BIDINOSTI[2], N. BECKMANN[2]
[1]MSD-PN, [2]Novartis Inst. For Biomed. Res., Basel, Switzerland

Abstract: Myelin content can be an important indicator of nerve health and disruption of myelination is associated with several peripheral nerve pathologies, e.g. Charcot-Marie-Tooth Disease. Although extensive investigation has been conducted on axonal pathology in peripheral neuropathies, there is limited research on how nerve health and myelination deteriorates with aging and to which extent this affects regeneration following injury. Here we present a comprehensive analysis of the myelination status in young and old rodents, and following peripheral nerve injury, by longitudinal non-invasive Magnetic Resonance Imaging (MRI) and post-mortem histological assessment. In particular, we examined the potential of Magnetization Transfer Ratio (MTR) as a rapid readout to assess demyelination in two commonly used rodent models of acute nerve injury: sciatic nerve crush and lysolecithin-induced demyelination. Sciatic nerve MTR was reduced in old (18 months) compared to young (9 weeks) mice at baseline (-4.1%). For both groups, MTR declined (-16.5% in young, -11.7% in old animals) one week after nerve crush. Full recovery was observed after six weeks; however, the rate of MTR recovery was faster for young mice. An increased nerve signal intensity was also observed after the crush, suggesting inflammation and/or axonal injury. Changes in nerve MTR were accompanied by a reduction in calf muscle volume (-10.8% in young, -27.4% in old mice), that was still present at week six post-crush. Moreover, an increased T2 relaxation time was observed in the calf muscle one week after the crush in segments distal to the site of injury.
These MRI signal changes correlated with histological and gene expression analysis of post-mortem specimens. In particular, myelin content decreased in the sciatic nerve one week after nerve crush and fully recovered at six weeks in young mice. Parallel macrophage infiltration was also observed in the nerve, consistent with an inflammatory process elicited by the crush. Analogous results were obtained for topical lysolecithin administration to the sciatic nerve in rats. A reduction by 15% in nerve MTR was observed in both young (8 weeks) and old (10 months) rats one week after lysolecithin (0.1 mg). Three weeks following lysolecithin, the MTR had not yet returned to baseline levels, but the rate of recovery was faster in young rats.

Overall, our results underline age differences in recovery following peripheral nerve injury and indicate the usefulness of non-invasive imaging and histological analysis to investigate these models of demyelination in rodents, especially in the context of pharmacological studies.

Title: Unique functional digit representation in human motor cortex across columns and layers

Authors: *L. HUBER[1], E. FINN[2], D. GLEN[3], R. REYNOLDS[3], B. POSER[5], P. BANDETTINI[4]
[1]NIMH/LBC/SFIM, Natl. Inst. of Hlth. Office of Intramural, Bethesda, MD; [2]NIMH, Bethesda, DC; [3]NIH, Bethesda, DC; [4]NIH, Bethesda, MD; [5]MBIC, Maastricht, Netherlands

Abstract: The sensorimotor system consists of multiple brain areas, incl. M1 and S1. The neural connections between sensorimotor areas follows pathways that are uniquely distributed across cortical layers and columns. Recently, we found that the analysis of laminar resting-state fMRI fluctuations in M1 are indicative of afferent vs. efferent connectivity in M1 [Huber, Neuron(96), 2017]. In this study, we seek to characterize both the columnar and laminar topology of body-part representations across M1 and S1 using blood-volume-sensitive fMRI at ultra-high spatial resolutions. N=4 participants underwent up to seven 2h fMRI sessions (8h-14h scan time per participant) using resting-state and a variety of movement tasks. The fMRI resolution was 0.78x0.78 (in-plane) with 3D-EPI [Poser, NeiroImage(51), 2010] VASO.
Sensory areas depict a single clear digit organization, as expected. In the hand knob of M1, however, we unexpectedly observe multiple digit representations (Fig. A). Each individual hand representation matches a cortical patch that is differently activated during movements of grabbing vs. extension (Fig. A-B). The same patterns of fine-scale digit representations can be detected both during explicit movement and at rest (Fig. C-D). We find that digit representations in S1 are 3-4 times larger than in M1. Upper layers (II/III) have a higher columnar digit specificity than deeper layers (Vb/VI). While all participants' data revealed at least two hand representations, their topological size and shape was highly variable across individuals.
We conclude that the topology of digit representations in M1 is very complex, and that body-parts within-vertebra representations are not as linearly organized as across-vertebra. This work suggests that advanced high-resolution fMRI can reveal fine scale organizations in M1 that could

only be investigated in animal models so far.

Title: Neuroanatomical and functional substrates associated with a single muscle representation

Authors: *A. M. ALBISHI, B. FISHER, J. KUTCH
USC, Los Angeles, CA

Abstract: Background: A muscle can be recruited volitionally as a prime mover or automatically as a postural stabilizer. Any given muscle receives command signals from its representation in both primary motor cortex (M1) and supplementary motor area (SMA). Our goal is to determine if the SMA and M1 representations of an individual muscle that is used both volitionally and automatically (e.g. trunk muscles) are contained in different brain networks, such that one network would be focused on volitional and the other more focused on automatic signaling.
Purpose: To map brain networks including M1 and SMA representations of trunk and hand muscles and determine if trunk muscles are contained in differential brain networks compared to the hand.
Methods: Transcranial magnetic stimulation and task-based functional magnetic resonance imaging (fMRI) were used to map 3-dimensional coordinates (regions-of-interest, ROI) for the SMA and M1 representations of a trunk (external oblique, EO) and hand muscle (first dorsal interosseous, FDI). These ROI were used in a whole-brain functional connectivity analysis utilizing resting-state fMRI (rs-fMRI). For each muscle, the whole-brain functional connectivity map of SMA was compared to M1.
Results: Basal ganglia and cerebellum are more connected to SMA while primary somatosensory and parietal cortex are more connected to M1 for both muscles. Slight differences in lateralization were observed in FDI compared to EO.
Conclusion: Our results suggest the possibility that brain networks underlying more automatic muscle control may extend equally well to distal muscle given that the basic features of differential connectivity of SMA and M1 appeared to be muscle-independent.

Title: Evidence of neuromuscular junction remodelling during periods of prolonged muscle inactivity in amphibians

Authors: *D. GE[1], P. G. NOAKES[3], N. A. LAVIDIS[2]
[1]Sch. of biomedical sciences, [2]The Univ. of Queensland, Brisbane, Australia; [3]Univ. of Queensland, Brisbane, Australia

Abstract: At mammalian neuromuscular junctions (NMJs), prolonged inactivity leads to severe degeneration, however amphibian NMJs do not show such severe degeneration even though they can remain inactive for many years of drought imposed inactivity. We have previously reported on the extent of functional inhibition in neurotransmission imposed during the dry season, along with the possible involvement of dynorphin-A. In the present study, we compared NMJ morphology of *Bufo marinus* obtained from the wild during the wet (January to April) and dry (August to November) southern hemisphere seasons. Iliofarbularis muscles were isolated, and prepared for immuno-staining with anti-SV2, a monoclonal antibody that labels synaptic vesicle glycoprotein SV2. These muscles were also stained for the location of post-synaptic acetylcholine receptors (AChRs) using Alexa555 conjugated α-bungarotoxin. Confocal microscopy and 3D reconstruction were then used to examine and compare the pre- and post-synaptic morphology of *Bufo marinus* NMJs from the dry (inactive) and wet (active) seasons. During the dry season, NMJs with large nerve terminals revealed a greater number of branches and increased fragmentation, while medium nerve terminals had fewer branches, when compared to NMJs from the wet season. Further, we observed a lower pre- and post-synaptic apposition (i.e. SV2-AChR overlap) at large NMJs during the dry season, compared to the wet season. Together these observations show that during periods of relative NMJ inactivity (dry season), there exists some NMJ remodelling.

Title: Modeling the action potential-driven force production in fast skeletal muscles

Authors: *H. KIM[1], T. G. SANDERCOCK[2], C. HECKMAN[2]
[1]Daegu Gyeongbuk Inst. of Sci. & Technol., Daegu, Korea, Republic of; [2]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The goal of this study is to develop a physiologically realistic model that reflects nonlinear input-output properties of fast muscles over a wide range of physiologically relevant input conditions for stimulation rate and muscle length. To achieve this goal, we adapted our recently developed muscle-tendon model for the cat soleus muscle based on the NEURON platform, which allows direct interactions with simulations of neural circuits. Our target muscle was the cat medial gastrocnemius muscle, which is primarily fast twitch. The differences in muscle activation dynamics between the model and real fast muscle were first identified and characterized under the same rate and length protocols used for soleus. Then, the mechanisms that generated these differences were mathematically formulated and incorporated into the modeling framework. The main differences between the simulation and experimental data were found for unfused contractions, during which the force gradually declined over time. By compensating this sag phenomenon by modulating the dynamics of cross-bridge formation, the extended muscle model could accurately replicate the force production of fast muscles over a full physiological range of muscle length and stimulation rate during isometric and isokinetic contractions. The modeling framework developed in NEURON platform for this study may be useful not only for investigation of neuromusclar interactions but also for development of electrical stimulation treatments and neuroprosthetic devices for movement disorders.

Title: Role of fez1 in motor neuron function and associated locomotion function

Authors: *Z. WANG[1], V. J. T. KOK[2], J. J. E. CHUA[2], K. LIM[1,2]
[1]Natl. Neurosci. Inst., Singapore, Singapore; [2]Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Neurons, unlike other cells, have elongated processes that require complex intracellular transport machinery to maintain optimal function. It is therefore unsurprising that disruption of this process has been implicated in defective neuronal development and neurodegeneration. Studies have found that loss of FEZ1, an important adaptor for motor protein Kinesin-1, results in perturbed transportation of synaptic vesicles and proteins, and synapse loss. Nevertheless, how FEZ1 mediated transport affects synaptic function remains unclear. Therefore, this project seeks to investigate the effect of loss of FEZ1 function on synaptic morphology and associated behavioural phenotypes. Using *Drosophila* as a model organism, we demonstrated that the loss of UNC-76, the sole *Drosophila* homolog of FEZ1, results in a significant loss of synaptic boutons that is accompanied by locomotion deficits and increased mortality. Importantly, the effect of *unc-76* knockdown on locomotion appears to manifest specifically in motor neurons, indicating that the FEZ1 has a potential role in the maintenance of normal motor neuronal function. Taken together, these results suggest that loss of FEZ1 disturbs the normal formation and/or maintenance of synapses, resulting in behavioural phenotypes and affecting mortality of the organism.

Title: An integrated, mathematical model of excitation-contraction coupling and calcium-activated mitochondrial metabolism in skeletal muscle fibers

Authors: *S. SENNEFF, M. LOWERY
Electrical & Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: Mitochondrial abnormalities have been demonstrated in neurodegenerative disorders such as Parkinson's disease, Huntington's disease, and Amyotrophic lateral sclerosis. In addition to changes within the nervous system, experimental studies in skeletal muscle have quantified changes in mitochondrial activity suggested to impact excitation-contraction coupling (ECC), the signalling cascade controlling muscle contraction and relaxation. These include reductions in electron transport chain activity, mitochondrial ATP synthesis, and depolarization-evoked calcium release, linked to elevated mitochondrial ROS production.
Several mechanisms have been proposed to address the cause and effect of these changes within muscle, but testing each hypothesis experimentally is difficult. Integrated computational models of ECC and mitochondrial metabolism could provide a valuable means of exploring effects of these changes on both mitochondrial function and muscle force.
A mathematical model of ECC and calcium-activated mitochondrial metabolism was developed for fast and slow twitch skeletal muscle. A compartmental modelling approach was used where the fiber was split into equally sized 100 μm compartments, each containing a transverse-tubular system modelled as a radial cable. Stimulation at the center of the fiber elicited a bidirectional propagating action potential, initiating ECC and metabolism within each compartment. Changes in transmembrane potential were solved with the cable equation.
Model simulations were performed at a range of stimulation frequencies and temperatures for three case studies: a 25% reduction in depolarization-evoked calcium release, a 25% reduction in the rate of mitochondrial ATP synthesis, and a 50% reduction in electron transport chain activity, in accordance with experimentally observed values. A sensitivity analysis will be performed to determine how, and to what extent, components of the ECC pathway and mitochondrial metabolism are compromised by these changes, with a focus on alterations in muscle force production and mitochondrial membrane potential.
Computational modelling of skeletal muscle activation can be used to explore the effects of neurodegenerative diseases on muscle output. Three case studies were simulated to assess changes in tetanic force production as well as mitochondrial membrane potential, which has been demonstrated to play an important role in apoptosis. Further studies will be done to better understand the effects of mitochondrial abnormalities on skeletal muscle to support pre-existing, or suggest new, testable experimental hypotheses.

Title: *In vivo* expression of a designer ubiquitinase delays muscle paralysis and accelerates muscle recovery following botulinum toxin A intoxication

Authors: *B. M. WINNER[1], E. VASQUES-CINTRON[1], C. PHUNG[1], A. BRADFORD[2], C. ONDECK[1], P. BODNER[1], P. MCNUTT[1]
[1]USAMRICD, Aberdeen Proving Ground, MD; [2]Univ. of New Hampshire, Durham, NH

Abstract: Botulinum neurotoxins (BoNTs) cleave neuronal SNARE proteins, blocking synaptic transmission. Recent studies indicate that directed ubiquitination of the BoNT/A catalytic light chain using a recombinant E3 ligase can promote ubiquitination and degradation by the ubiquitin proteasome system. To further evaluate the therapeutic utility of directed ubiquitination, we designed transgenic mice expressing a bifunctional designer ubiquitinase consisting of a LC/A function-blocking VHH camelid antibody fused to an F-box protein E3 ligase under the control of the thy1.1 promoter. The transgene was robustly expressed in brain, spinal cord, and diaphragmatic neurons. To characterize effects of transgene expression on intoxication, we evaluated diaphragmatic function ex vivo using isometric twitch contraction following administration of BoNT/A. Diaphragms from wild-type (WT) mice were fully paralyzed within approximately 90 min after intoxication, whereas diaphragms from transgenic mice were paralyzed significantly later at 120 min after BoNT/A intoxication. In pilot dose-response studies, WT and transgenic mice were administered 1-5 LD_{50} doses of BoNT/A in gastrocnemius muscle. All WT mice in the two highest dose groups died within 5 days, whereas no transgenic mice died at any dose. The digit abduction score (DAS) assay, a sensitive index of gastrocnemius muscle paralysis, was further used to evaluate recovery of muscle function. WT mice recovered muscle function after 45 days, whereas recovery of muscle function in transgenic mice occurred within just 3 days. These studies demonstrate that in vivo expression of designer ubiquitinases represents a novel, therapeutically viable strategy to promote recovery from paralysis after BoNT intoxication.

Abstract: The H-reflex is recognized as an important neurophysiological tool to evaluate the sensitivity of spino-muscular circuitry. Studies have found that electro-magnetic stimulation on spinal segmental levels (SEMS) can result in an altered threshold intensity and the index of frequency-dependent depression (FDD) of H-reflex. Eight non-injured participants were tested in an IRB approved study at Stony Brook University and the Northport Veterans Affairs Medical Center, 4 from each Center were examined using the FDD index. A protocol was designed to study H-reflex by using tibial nerve electrical stimulation pre- and post- 30 minutes of SEMS on L5/S1 spinal levels with 60-70% coil intensity at 0.2Hz. FDD was measured at the intensity which evoked 30-50% of H-max at 0.2, 1.0 and 2.0 Hz frequencies over 3 sessions for each participant. Data for 11 sessions (n=19 legs) exhibited decreased threshold intensity after the SEMS specifically the FDD was 15% and 7% at 1.0 Hz and 2.0 Hz, respectively. The pre-post data included 4 sessions where the post- H-reflex had an average of 17% less depression at 1.0 Hz and 8% less depression at 2.0 Hz; and in 2 sessions 1 leg exhibited an increase of H-reflex threshold intensity after SEMS. These results provide preliminary normative data to which FDD, when measured in pathology such as spinal cord injury, could be compared.

Title: Neuromuscular transmission failure in an animal model of early onset spasticity

Authors: *J. E. BRANDENBURG[1], M. J. FOGARTY[2], G. C. SIECK[3]
[1]Dept. of Physical Med. and Rehabil., [2]Dept. of Physiol. & Biomed. Engin., [3]Physiol. & Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Pre- and post-synaptic glycine (Gly) mutations are associated with changes in central synapses (motor neuron (MN)) and peripheral synapses (i.e. neuromuscular junctions (NMJ)). Adult mice lacking Gly receptor (s*pa* [B6.Cg-*Glrb*^{spa}/J]) display marked symptoms of early onset spasticity. In *spa* mice, we have shown that MN pruning is increased, such that fewer MNs are present. With fewer MNs, axonal branching to individual muscle fibers may be increased to maintain innervation (increased innervation ratio), which may also contribute to greater neuromuscular transmission failure (NMTF) due to branch point failure. However, it is not known if *spa* mice have greater NMTF. In humans with early onset spasticity, such as cerebral palsy, death is most commonly due to respiratory disorders. One potential contributor to respiratory disorders may be greater difficulty with respiratory control due to increased NMTF. Thus, we hypothesize that *spa* mice will have greater diaphragm muscle (DIAm) NMTF and muscle fatigue when compared to wild-type (WT) mice. *Ex vivo* diaphragm-phrenic nerve preparations were stimulated with trains of 330 ms duration. Each train had supramaximal amplitude pulses of 40 Hz acting on nerve or muscle. Direct nerve-evoked train stimulations occurred every second for 2 mins. Indirect muscle stimulations was superimposed every 15 s and effective neuromuscular transmission and NMTF compared between *spa* and wild-type mice. The DIAm strip was stimulated across a range of frequencies (from 5 to 100 Hz) in 1 s duration trains with rest periods of 2 min between each frequency to assess the maximal tetanic force. Muscle strips were weighed and absolute measures of muscle specific force (normalized to DIAm cross-sectional areas) and relative measures were assessed. Continuous indirect muscle stimulation (40 Hz) of 330 ms pulses for 2 min was used to assess fatigue in DIAm strips. Effective neuromuscular transmission (initial nerve-evoked contractions compared to initial

muscle stimulations) was 10% less in *spa* mice compared to WT mice (P=0.038) with *spa* mice having greater NMTF than WT mice (P<0.001) over the 2 min duration of stimulation. At the end of stimulation, *spa* mice had a 40% greater NMTF than WT mice (P<0.001). With regard to muscle, s*pa* mice had a 26% reduction in maximal muscle tetanic force (P<0.002) with a 33% increase in muscle fatigue index (P<0.001) as compared to WT mice. Thus *spa* mice have greater DIAm NMTF, reduction in overall DIAm force, and increased muscle fatigue. Currently, we are determining the functional implications of these findings on DIAm force (i.e. transdiaphragmatic pressure (Pdi)) and respiratory function (i.e. plethysmography).

Title: Determination of cellular and molecular mechanisms of 1,1'-methylenebis{4-[(hydroxyimino)methyl]pyridinium} (MMB4) toxicity on rabbit neuromuscular junctions

Authors: *K. PAGARIGAN, J. MACHAMER, B. WINNER, A. BRADFORD, C. PHUNG, C. ONDECK, P. MCNUTT
Res., USAMRICD, Gunpowder, MD

Abstract: The acute toxicity of organophosphorus (OP) compounds is primarily a result of acetylcholinesterase (AChE) inhibition in the central and peripheral nervous systems. Severe OP poisoning causes convulsion, respiratory collapse, and death. Current treatment for OP poisoning includes the administration of the antimuscarinic drug atropine, the anticonvulsive drug benzodiazepam and the oxime pyridine-2-aldoximechloride (2-PAM) to reactivate AChE. However, 2-PAM is only modestly effective against a limited range of OP nerve agents and is toxic near effective concentrations, and therefore an improved oxime with rapid systemic distribution and lower toxicity is critically needed. 1,1′-methylenebis{4-[(hydroxyimino)methyl]pyridinium} (MMB4) is a leading candidate for next-generation nerve agent treatment and is more effective at reactivating AChE than is 2-PAM. Although MMB4 appears clinically nontoxic at effective concentrations in rodents, MMB4 depresses respiratory function in rabbits, causing death at doses exceeding 200 mg/kg. To determine the mechanisms of MMB4 toxicity, we first evaluated concentration-dependent effects of MMB4 on rabbit diaphragm function by measuring ex vivo nerve-elicited isometric twitch, subtetanic, and tetanic contraction strength in New Zealand white female rabbits. Preliminary results indicate a progressive use-dependent inhibition of muscle contraction strength by MMB4, which causes the

complete loss of diaphragmatic function at high concentrations. To determine the molecular mechanisms of MMB4-induced diaphragmatic collapse, we performed ex vivo diaphragm endplate recordings prior to and following perfusion of MMB4. As concentrations of MMB4 increased, endplate potential (EPP) and miniature EPP (mEPP) amplitudes were reduced, while quantal content was unaffected. Additionally at higher concentrations of MMB4, halfwidths of mEPPs and EPPs were increased. These results demonstrate that MMB4 has a multifactorial effect on cholinergic synaptic transmission in rabbits that collectively impairs diaphragmatic function. Future work will focus on the effects of MMB4 in rats to determine the basis for differential toxicity between rabbits and rodents.

Title: Fine motor control of a peripheral nerve injured arm achieved through an implantable muscle stimulator

Authors: *T. M. SIBINDI[1], G. G. L. GAMMAD[1], L. ONG[1], I. DEWANY[2], C. W. C. LIM[1], S.-C. YEN[1], C. D. LIBEDINSKY[1]

Abstract: ABSTRACT
OBJECTIVES
Central and peripheral nervous system injuries can result in loss of limb movements and the fine motor control of said limbs. To address this problem, we utilized functional electrical stimulation (FES) of peripheral muscles and nerves in the arm of non-human primates (NHPs). Here, we describe the properties of FES in NHPs to restore fine motor control (via an implantable muscle stimulator) required for self-feeding.
APPROACH
Muscle mapping using multiple electrodes were implanted at specific sites for the NHP thumb (flexor pollicis brevis) and the four digits (flexor digitorum superficialis) in healthy animals, as well as animals with peripheral nerve damage. The baseline parameters (50Hz, 4mA, 200μs, 200NoP) allowing the longest sustained contractions were established with healthy innervated

NHPs.
MAIN RESULTS
We were successfully able to generate individual finger movements and hand grasps, using subject-specific FES parameters. We found the denervated NHP arm to be less excitable than a healthy arm as the denervated arm required greater current intensities to elicit a visible contraction of the digits. Overall, denervated NHPs were able to grasp and hold objects of varying weights, ranging from 19.3g to 102.4g. Additionally, to reduce muscle fatigue, which is a major limiting factor of FES, we developed a closed-loop system integrating a force sensor. This allowed us to achieve an adaptive control over the muscle stimulation by modulating FES parameters (frequency and current intensity) to the gripping force of the denervated NHP arm. Using this feedback-controlled electrical stimulation, the denervated NHPs were able to hold the weights for a longer amount of time.
SIGNIFICANCE
We present here the stimulation properties that can lead to sustained grasping of everyday objects, such as a spoon or mug for self-feeding, whilst minimizing muscle fatigue. We endeavour to be able to control fine hand movements used in activities of daily living.

Title: Evidence for MuSK-mediated BMP signaling at the neuromuscular junction

Authors: *L. A. FISH[1], D. JAIME[2], A. YILMAZ[3], L. A. MADIGAN[2], J. R. FALLON[1]
[1]Neurosci., [2]Mol. Biology, Cell Biol. & Biochem., Brown Univ., Providence, RI; [3]The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The stability of the neuromuscular junction (NMJ) is critical for proper motor function and is a target for treating neuromuscular disorders. However, the mechanisms by which the NMJ matures and is maintained remain largely unknown. Muscle-specific kinase (MuSK) is a receptor tyrosine kinase with a well-established role in the agrin-LRP4 pathway mediating NMJ formation and stability (Wu et al., 2010). Recent work from our laboratory shows that MuSK, in

a manner not requiring its tyrosine kinase activity, is also a BMP co-receptor. MuSK binds directly to BMPs, via its Ig3 domain, as well as the BMP receptors ALK3 and ALK6. MuSK shapes BMP stimulated transcriptional output in myogenic cells, notably regulating genes important for NMJ formation including MuSK itself, Dok7 and Wnt11 (Yilmaz et al., 2016). Here, we explore MuSK's role as a BMP co-receptor in regulating NMJ structure. To selectively manipulate MuSK-BMP binding we used CRISPR/Cas9 genome editing to create a mouse line in which the MuSK Ig3 domain is constitutively deleted ('Delta-Ig3-MuSK'). Structural analysis indicates that the levels of synaptic MuSK in Delta-Ig3-MuSK animals are comparable to littermate controls but that the NMJs are abnormal. Confocal analysis revealed that the postsynaptic apparatus in Delta-Ig3-MuSK mice is significantly more segmented compared to wild-type littermates (n=70 sternomastoid NMJs of each genotype from 6 Delta-Ig3-MuSK and 3 wild-type 3-month old animals; Mann-Whitney U-test for difference in segment count, $p<0.0001$). Such fragmentation often indicates impaired NMJ maturation or stabilization (Amenta et al., 2012). Preliminary ultrastructural analysis indicates that the junctional folds in Delta-Ig3-MuSK mice are overall shallower and disorganized compared to wild-type. Additional characterization is in progress. Together, these results suggest that MuSK-BMP signaling plays a role in NMJ organization and stability.

Title: Antigen-specific immunotherapy of myasthenia gravis in domestic dogs - a pilot study

Authors: *J. LUO, O. A. GARDEN
Sch. of Vet. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Myasthenia gravis (MG) and its animal model, experimental autoimmune myasthenia gravis (EAMG), are caused by antibody-mediated autoimmune responses to acetylcholine receptors (AChRs) of skeletal muscles that cause complement-mediated destruction of the

AChRs and impairment of neuromuscular transmission, resulting in weakness and fatigability. The specificities of pathological autoantibodies and pathological mechanisms in EAMG and MG are similar. All of the pathological autoantibodies are directed at the extracellular domain of the AChR, especially the main immunogenic region (MIR). We have devised a specific immunosuppressive therapy for EAMG in rats using bacterially-expressed cytoplasmic domains of human AChR subunits in a therapeutic vaccine that prevents the development of chronic EAMG and rapidly suppresses ongoing EAMG. The therapy diverts autoantibody specificities away from pathological extracellular epitopes like the MIR, towards pathological irrelevant cytoplasmic epitopes. This therapy is safe, potent, robust, long-lasting, and avoids the side effects of nonspecific immunosuppressive drugs, which are the mainstay of treatment in human patients. We now translate our rat studies into a spontaneous canine model that recapitulates the human disease in clinical presentation, diagnostic testing, treatments, and immunopathology. We evaluated the safety of the canine-specific vaccine in healthy colony dogs. We are currently investigating the safety and potential efficacy (phase 1/2) of the canine-specific vaccine in a small cohort of client-owned dogs with seropositive generalized MG, serving as a pilot study for a subsequent clinical trial. Evaluation of our therapy in client-owned dogs will provide a better understanding of the likely outcome in human patients, providing a proof-of-principle that will inform and accelerate human clinical trials.

Abstract: Neuromuscular dysfunction is associated with many disorders, such as amyotrophic lateral sclerosis (ALS) and myasthenia gravis. During development, it is well-known that there is substantial crosstalk between neurons and muscle fibers required for proper development and function; however, many of the factors and mechanisms that mediate this crosstalk, as well as corresponding functional outcomes, have yet to be identified. A major reason for the relative lack of exploration into crosstalk mechanisms the lack of physiologically relevant neuromuscular junction (NMJ) models. Much of what is known about NMJs has been contributed from *in vivo* models, but these models tend to be expensive and too complex to examine things at a molecular level, while current *in vitro* models tend to lack sufficient three-dimensionality, compartmentalization, and/or functional endpoints. Here, we present a novel microfabricated culture platform that allows for compartmentalized three-dimensional co-culture of neural and muscle cells. Using this platform to culture optogenetically active embryonic stem cell-derived neurospheres and engineered muscle tissues, we observed preferential neurite outgrowth toward muscle tissues and ultimately innervation and the formation of optogenetically active NMJs. After innervation, the muscle tissues exhibited increased spontaneous and stimulated activity, as measured by both force and contraction frequency, presumably due to spontaneous neural activity. To examine this neural activity in more detail, we dissociated the same neurospheres and seeded them on microelectrode arrays (MEAs), allowing us to analyze neural network activity and development over time. While the cells spontaneously increase firing rate over time, treatment with muscle-conditioned medium significantly increased network activity and accelerated network development and maturation, as measured by network bursting and synchrony metrics. Taken together, the biased neurite outgrowth toward muscle, enhanced muscle contractility in the presence of neurons, and enhanced neural network activity and development in the presence of muscle-conditioned medium suggests that there is substantial reciprocal crosstalk between neural and muscle cells, resulting in significant functional outcomes. In addition, the platform developed here serves as a physiologically relevant method to analyze crosstalk and specific mechanisms underlying NMJ development, both in healthy and disease states. Differences in neuron-muscle crosstalk are likely to be implicated in various neuromuscular disorders and may provide therapeutic targets for future treatments.

Title: Altered muscle satellite cell distribution and phenotype in patients with spastic cerebral palsy

Authors: *S. K. YEAGER[1,2], K. G. ROBINSON[2], E. L. CROWGEY[2], R. E. AKINS[2]
[1]Wilmington, DE; [2]Biomed. Res., Nemours Alfred I duPont Hosp. for Children, Wilmington, DE

Abstract: Spastic cerebral palsy (CP) represents ~80% of CP cases and is characterized by muscle stiffness and contracture with disrupted movement, posture, and gait. Previous research indicates that muscles in individuals with CP have altered fiber type distributions, satellite cell (SC) function, extracellular matrix composition, gene expression profiles, and neuromuscular junction (NMJ) microanatomy. It has been suggested that these disruptions in CP muscle may be inter-related and associated with muscle pathology, but additional research is needed. The current study evaluated SC distribution in tissue, SC function in culture, RNA-Seq profiles, and NMJ organization in spastic CP.
Subjects with CP and controls were enrolled in an IRB approved study. Muscle biopsies were collected for quantitative immunofluorescense (IF) analysis and for SC isolation. We used the tissue location of cells and staining with the cell surface marker NCAM1 (neural cell adhesion molecule) and the transcription factor Pax7 to identify SCs. To evaluate the distribution of SCs, muscle sections were evaluated for the presence of these markers. Data evaluating NMJ organization were derived from IF co-localization of acetylcholine esterase, nicotinic acetylcholine receptor (nAChR), and laminin β2 and correlated with the SC data. SC cell lines isolated from patients with CP (n=6) and controls (n=6) were cultured under proliferation conditions until reaching 60-75% confluence and then switched to differentiation medium for 24 hours. RNA was collected and analyzed by RNASeq.
Results indicated that subjects with CP had fewer SCs overall. CP subjects had a greater proportion of NCAM1-positive / Pax7-negative cells occupying SC niches compared to controls (CP = 0.18 ± 0.001, Ctrl = 0.08 ± 0.0006; $p<0.01$). Among controls, there was a negative correlation between the proportion of NCAM1-positive / Pax7-negative SCs and total nAChR staining (CC=0.997, $p<0.01$); this correlation was not seen in patients with CP. Cultured NCAM-positive/Pax7-positive SCs exhibited diagnosis-related differences in proliferation. Preliminary RNAseq analysis revealed significant differences in the patterns of gene expression in the cohorts. In particular, cultured SCs from patients with CP had significantly altered RNA patterns related to cell growth, cell motility, matrix remodeling, cell differentiation, and NMJ maintenance. Further analysis will elucidate specific relationships between altered SC gene expression, SC phenotype, matrix deposition, neuromotor synapse dysmorphism, and muscle function in CP.

Title: Toward developing biorobots that walk

Authors: *C. KAUFMAN[1], S. C. LIU[1], G. NASERI[1], R. BASHIR[2], M. GILLETTE[3]
[1]Neurosci. Program, [2]Bioengineering, [3]Cell and Developmental Biol., Univ. of Illinois, Urbana-Champaign, Urbana, IL

Abstract: A biorobot is a hybrid machine that combines abiotic and biological components for a wide variety of possible functions. These may include the ability to sense their environment, process signals, and produce force. Recent work in the field of biorobotics has focused on developing a musculoskeletal biological machine that can produce motion in response to controllable external signaling. Here, we report the development of a muscle-cell actuator on a 3D-printed hydrogel skeleton under explicit neuronal control such that this multi-cellular system is able to locomote through its environment by harnessing the emergent properties of vertebrate nervous systems. The use of an intact spinal cord as a neuronal source provides the system with a degree of autonomy that will be critical for many future applications of this technology. Bioengineered soft robots might be used to test disease models, create a "peripheral nervous system-on-a-chip" device for drug safety and efficacy testing, and eventually forward-engineer life forms.

Abstract: Pelvic floor muscles (PFM), such as pubocoocygeus (Pcm) and iliococcygeus (Icm), assist importantly in micturition. Several clinical and basic studies support that some PFM are estrogen sensitive, which explains the prescription of estrogen-based therapies as treatment for women suffering stress urinary incontinence (IUS). Findings from our workgroup, gathered in female rabbits and rats, however, suggest PFM can respond differently to changes in circulating and local estrogen levels. In order to determine whether this presumptive estrogenic sensitivity can be extended to the myofiber cross-sectional area **(**CSA). We used Wistar female rats 1) at proestrus (P) and metaestrus (M) stages of the estrous cycle, 2) sham surgery or 3) ovariectomized (OVX) rats implanted with empty capsules or estradiol benzoate filled capsules; an additional OVX+EB group was administered with a blocker of aromatase activity (1,4,6-Androstatriene-3,17-dione, ATD) was done to approach the contribution of local estrogens. Hematoxilyn-eosin stained transverse sections of the Pcm and Icm were used to measure the myofiber CSA. Results showed an increase in the CSA for the Pcm, but not for the Icm at proestrus. Furthermore, ovariectomy increased the CSA for the Pcm, which was reversed by the EB; the treatment with ATD exacerbated the effect of OVX. No alterations were observed for the Icm. Our results support our hypothesis regarding PFM respond differentially to estrogens in female rats.

Abstract: The ability to produce motor neurons from induced pluripotent stem cells (iPSCs) provides the means to model several neuromuscular disorders using human cells. It is now possible to explore human-specific drug screening platforms with prospective treatment possibilities using iPS-derived motor neurons for disorders lacking therapeutic options such as amyotrophic lateral sclerosis (ALS). Here we demonstrate the generation of iPS-derived motor neurons using an optimized differentiation protocol generating a population with greater than 60% purity based on Isl1/2 and Tuj1 positive staining. Furthermore, we used this cell line to generate a TDP-43 line, equipping researchers with this valuable tool for ALS prognostics and treatment. We characterize our cells and co-cultured them with human skeletal muscle, capable of forming neuromuscular junctions in vitro. We are now exploring co-culture conditions with human iPSC-derived skeletal muscle based on our published protocol (Caron et al. 2016). Our media-based differentiation method efficiently generates contractile and fused myotubes without the need for any cell sorting or myogenic gene overexpression. Combined with our motor neurons, this co-culture platform will enable ALS drug discovery and facilitate complex disease modeling of other neuromuscular disorders.

Title: Plasma concentrations of alpha-pyrrolidinovalerophenone (PVP) predict the extent of motor activation after systemic administration of the drug to rats

Authors: *M. H. BAUMANN[1], H. M. WALTERS[1], J. S. ELMORE[2], D. WALTHER[1], D. M. ANDRENYAK[3], D. E. MOODY[3]
[1]Designer Drug Res. Unit, IRP, NIDA, NIH, DHHS, Baltimore, MD; [2]Johns Hopkins Med. Inst., Baltimore, MD; [3]Univ. of Utah, Salt Lake City, UT

Abstract: The synthetic cathinone alpha-pyrrolidinovalerophenone (PVP) is a widely-abused new psychoactive substance with psychomotor stimulant properties. Preclinical studies show that PVP exerts its effects by potently inhibiting high-affinity plasma membrane dopamine transporters (DAT) and norepinephrine transporters (NET), thereby elevating extracellular concentrations of dopamine and norepinephrine in the brain. No study has examined pharmacokinetics and metabolism of PVP *in vivo*. Here we examined plasma pharmacokinetics of PVP and its major metabolite 2”-oxo-PVP in male Sprague-Dawley rats fitted with surgically-implanted jugular catheters. Rats received sc injection of PVP (0.25, 0.5, 1.0 & 2.0 mg/kg) or its saline vehicle and were placed into chambers equipped with photobeams for the detection of locomotor activity. Serial blood samples were withdrawn via the catheters at 15, 30, 60, 120, 240 and 480 min post-injection and plasma was assayed for PVP and 2”-oxo-PVP using liquid chromatography coupled to mass spectrometry. We found that plasma concentrations of PVP peaked rapidly (Tmax = 15 min post-injection) and rose linearly with increasing dose (Cmax range = 13 - 149 ng/mL). The drug was quickly cleared from the circulation with a plasma half-life of about 90 min. The 2”-oxo metabolite displayed a pharmacokinetic profile similar to that of PVP, but concentrations were 30-fold lower. Motor activity induced by PVP administration was positively correlated with plasma concentrations of parent and metabolite, but *in vitro* transporter assays demonstrated that 2”-oxo-PVP does not interact with DAT or NET. Collectively, our findings demonstrate that PVP and 2”-oxo-PVP exhibit rapid pharmacokinetics in rats but the

metabolite is present at much lower concentrations and is not bioactive. Thus, behavioral activation produced by PVP is most likely due to effects of the parent compound with no involvement of its major metabolite.

Title: The effect of self-generated movement on lateral line sensitivity in the toadfish, Opsanus tau

Authors: *L. S. ROGERS, JR[1,2], J. C. VAN WERT[2], A. F. MENSINGER[1,2]
[1]Univ. of Minnesota Duluth, Duluth, MN; [2]Marine Biol. Lab., Woods Hole, MA

Abstract: The mechanosensory lateral line in fishes functions to detect water displacement via the deflection of hair cells within the superficial and canal neuromasts. Previous experiments have shown that the lateral line aids in schooling behavior, rheotaxis, hearing, and predator/prey interactions. However, the effect of self-generated movement on the sensitivity of the lateral line has remained largely unknown. Prevailing hypotheses have suggested that either sensory hair cells are efferently modulated or that filtering occurs in higher order centers of the brain, thus reducing the effect of self-generated movement on the neuromasts. To test these hypotheses, microwire electrodes were inserted into the anterior lateral line nerve of Oyster toadfish (*Opsanus tau*) using an implantable micromanipulator, which allowed neural activity to be monitored for up to two weeks post-implant. Experiments measured the neural response to external stimulus, which was provided by a 50 Hz vibrating sphere or a robotic fish, during forward movement. During these experiments, the lateral line of free swimming toadfish remained sensitive to external stimuli without efferent modulation. Additionally, lateral line units did not exhibit a decrease in firing rates during movement, which indicates that the lateral line is still capable of sensing external stimuli. While efferent modulation or central filtering of self-generated movements had previously been postulated as mechanisms to allow free swimming fish to continue to detect outside stimuli, the current experiments show that at the swim speeds observed, the mechanosensory lateral line remains sensitive to external stimuli without efferent modulation or central filtering.

Title: Serotonergic SK channel modulation promotes adaptive optimized coding of natural stimuli

Authors: *M. G. METZEN, C. G. HUANG, M. J. CHACRON
Dept. of Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Growing evidence suggests that sensory systems optimally encode natural stimuli with given statistics. As stimulus statistics vary with context, coding mechanisms must be adaptive to be efficient. Adaptation is seen ubiquitously across systems and species, and neurons can adapt their response properties to “simple”, as well as to “complex” stimulus attributes. However, the underlying mechanisms are generally poorly understood. We investigated adaptive optimized coding of electrosensory stimuli experienced by the weakly-electric fish *Apteronotus leptorynchus* in their environment. Previous results have shown that pyramidal cells optimally encode natural sensory stimuli. We thus studied whether optimized coding was adaptive to changes in stimulus statistics due to the activity of conspecific fish (Fig 1A). We presented the animal with stimuli with different statistics typically found under natural conditions and measured neuronal and behavioral performance (Fig 1B). Specifically, we varied the power law exponent describing the relationship between spectral power and temporal frequency. Neural tuning and behavioral responses were assessed using sinusoidal stimuli. We found that neurons adapted their tuning to optimally encode the new stimulus (Fig 1C, top & middle). Changes in tuning were accompanied by shifts in behavioral sensitivity to better match the new stimulus statistics (Fig 1C, bottom). Further experiments revealed that the descending signal required for adaptation reaches pyramidal neurons through serotonergic fibers emanating from the raphe nuclei (Fig 1E). This is because both neural tuning and behavioral responses did not adapt (Fig 1F) after application of the 5HT2 receptor antagonist ketanserin (Fig 1D). Our results thus reveal a novel functional role for the serotonergic system, which is very well conserved across vertebrates. Thus, the action of 5HT on tuning is likely through up- and downregulation of SK channels. Important parallels between the electrosensory and other systems imply that our results will very likely be generally applicable.

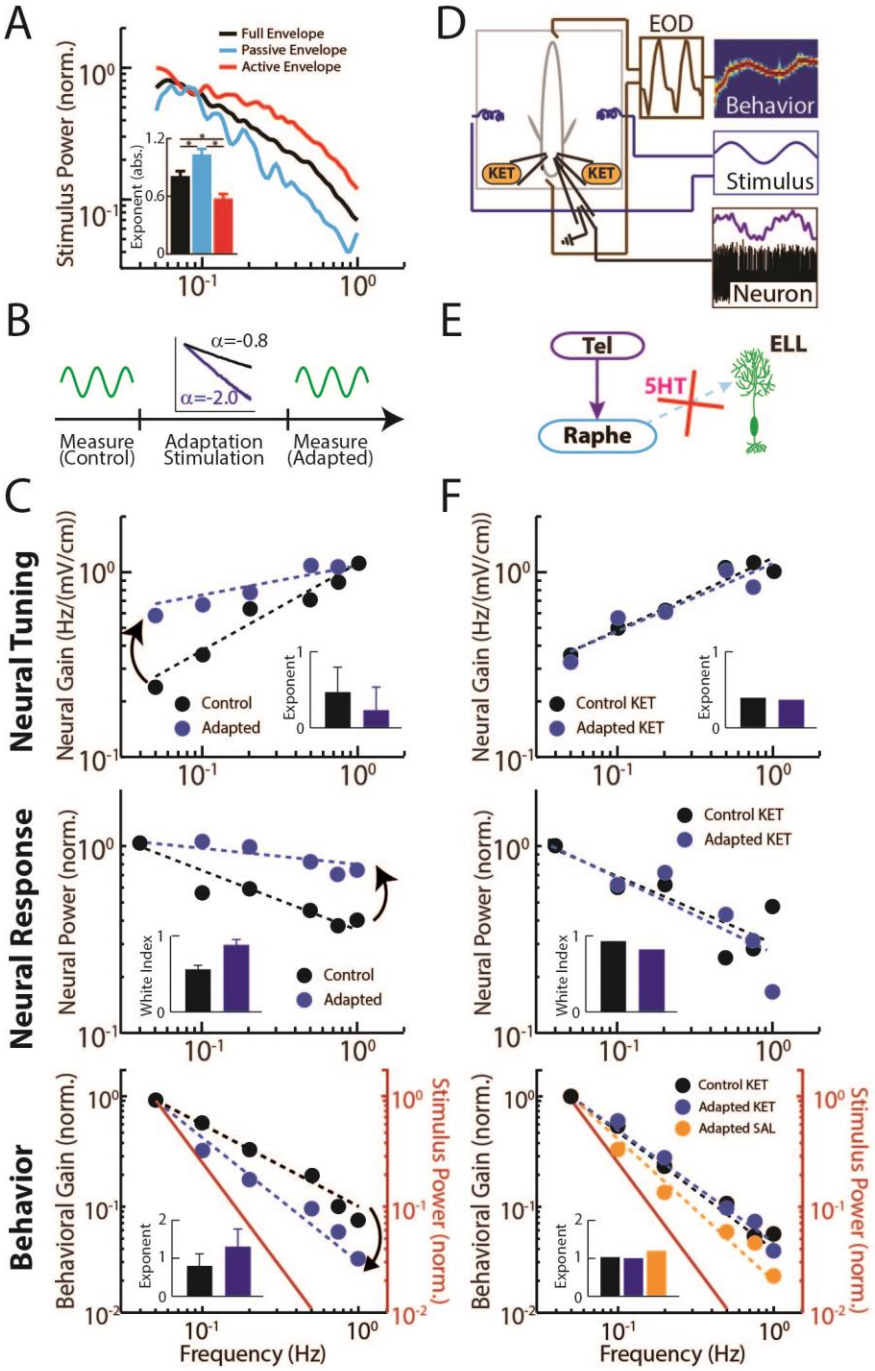

Figure 1: Optimized adaptive coding occurs in the electrosensory system. A) Power spectrum of the full movement envelope (black), during high (red) and low (cyan) activity. Inset shows the power law exponents. **B)** Stimulation paradigm showing control measurements with sinusoidal envelopes at the beginning and every 2h after stimulating with a natural movement envelope containing statistics with power-law exponent α=-2.0. **C)** Shifts in neural tuning (top), neural response via whitening (middle), and behavioral adaptation (bottom) over the course of 6h where the fish was presented with a natural stimulus with exponent α=-2.0. **D)** Schematic of experimental paradigm with ketanserin injection. **E)** Circuitry showing 5HT blockade after ketanserine application. **F)** Neural tuning (top) and response power (middle) did not shift after ketanserin (blue) injection compared to control (black) and abolishes the behavioral (bottom) adaptation (compare black and blue), while behavioral adaptation does occur for saline positive control (yellow). Title: Correlation based stimulus encoding in electrosensory processing

Authors: *V. HOFMANN, M. J. CHACRON
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Perception and behavior are usually determined by the collective activity of large neural ensembles. Our efforts to understand population coding is however complicated by the fact that the activities of multiple neurons are not independent but correlated, a phenomenon found almost ubiquitously in the brain.
Two components contribute to correlated activity: Signal correlations quantify co-variation of the average responses of two neurons presented with different stimuli. Noise correlations quantify correlations in the response trial to trial variabilities when presented with the same stimulus repeatedly. The relation between signal and noise correlations strongly impacts information transmission. However, as noise-correlations were found to be plastic and change depending on the animal's state, attention of stimulus statistics, comprehensive knowledge of both, the functional implications on information coding and the mechanisms mediating correlation plasticity is scarce to date.
We use the weakly electric fish *A. leptorhynchus* to investigate correlation-based stimulus encoding. Our data from pairs of medullary pyramidal neurons shows that correlations (raw) decrease significantly with increasing stimulus contrast. This observation could neither be explained with changes in firing rates nor when analyzing signal correlations - both showed slight increases. Noise correlations (i.e. correlated variability) however decreased strongly thereby driving a correlation-based encoding of stimulus contrast.
Using a combination of experimental and theoretical techniques, we found that the differential activation of pyramidal neuron receptive field sub-portions can mediate changes in the balance of correlated and anti-correlated inputs thereby creating an asynchronous state. Our results are expected to have general applicability given the many parallels between the electrosensory system and mammalian visual and auditory systems.

Title: Sensorimotor activity in midbrain circuits of freely swimming electric fish

Authors: *I. UYANIK[1], N. J. COWAN[2], E. S. FORTUNE[3]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Mechanical Engin., Johns Hopkins Univ. Dept. of Mechanical Engin., Baltimore, MD; [3]New Jersey Inst. of Technol., Newark, NJ

Abstract: A challenge in understanding sensorimotor systems is that they operate in a dynamic closed loop in which motor outputs stimulate sensory receptors, which, in turn, provide feedback for subsequent motor output. Our strategy to reveal mechanisms for feedback control used by animals relies on the dynamic modulation of reafferent feedback (i.e. feedback generated as a consequence of the animal's own movements). To modulate reafferent feedback, we recently built an augmented reality system for refuge tracking in weakly electric fishes. These fish swim back and forth to maintain their position within a moving refuge. The new experimental system measures the position of the fish in real time, allowing us to modulate reafferent feedback by

moving the refuge in relation to the fish's own movements.
To reveal the neurophysiological mechanisms underlying sensorimotor control in the brain, we made chronic recordings of midbrain neurons while the animal performed tracking behaviors in the augmented reality system. We implanted tetrodes into the torus semicircularis (Ts) and optic tectum (OT). Recordings in the Ts examine electrosensory activity whereas OT recordings reveal sensorimotor and multi-sensory interactions. This combination of behavioral and neurophysiological measurements allow simultaneous system identification of the sensorimotor performance of individual fish while observing the neurophysiological computations for its control.
Behavioral results show that adult *Eigenmannia* tunes its CNS controller in relation to reafferent feedback gain to maintain a constant magnitude of sensory slip between the refuge and its own sensory receptors. Our goal is to understand how this "tuning" process manifests itself through the activity of midbrain neurons.

Title: Reproductive state dependent visual sensitivity in an African cichlid fish

Authors: *J. M. BUTLER[1], S. M. WHITLOW[1], L. S. ROGERS[2], R. L. PUTLAND[2], A. F. MENSINGER[2], K. P. MARUSKA[1]
[1]Louisiana State Univ., Baton Rouge, LA; [2]Univ. of Minnesota Duluth, Duluth, MN

Abstract: Visual communication is used widely across the animal kingdom to convey crucial information about an animals' identity, motivation, reproductive status, and sex. Although it is well-demonstrated that auditory and olfactory sensitivity can change with reproductive state, fewer studies have tested for plasticity in the visual system, a surprising detail since courtship and mate choice behaviors in many species are largely dependent on visual displays. Here, we tested for reproductive state-dependent plasticity in the eye of a cichlid fish *Astatotilapia burtoni*, using behavioral, gene expression, neural activation, and electrophysiology techniques. Ovulated females had higher mRNA expression levels of reproductive neuromodulatory receptors (sex-steroids; gonadotropins) in the eye than non-ovulated females, but males had similar expression

levels independent of reproductive/social state. This increase in neuromodulatory receptors was also seen in prostaglandin F2a-induced ovulated females, but not females injected with DMSO vehicle. In addition, ovulated females were more responsive to male courtship displays, and these mate choice-like behaviors positively correlate with expression of gonadotropin system receptors in the eye. Natural and PGF2a-induced ovulated females have higher neural activation in the ganglion cell layer of the retina compared to non-ovulated females when exposed to a courting male. Using electroretinography to measure visual sensitivity in dark-adapted fish, we also found that gravid females have increased visual sensitivity at several wavelengths associated with male courtship displays compared to non-gravid females. When injected with PGF2a, gravid females ovulated and increased their spectral sensitivity compared to pre-PGF2a injection measurements. This increased sensitivity after PGF2a injections was absent in non-gravid females and males, suggesting an ovulation-triggered increase in visual sensitivity. Collectively, these data indicate that plasticity in the eye is dependent on female ovulation status, not overall female gravidity, and provides crucial evidence linking endocrine modulation of visual plasticity to mate choice behaviors in females.

Title: Social regulation of dopaminergic modulation of spinal motor circuit activation in zebrafish (Danio Rerio)

Authors: *K. CLEMENTS, F. HEAGY, T. MILLER, F. ISSA
Biol., East Carolina Univ., Greenville, NC

Abstract: Adaptive motor behavior is integral for survival as animals navigate their social and physical environment. Here, we investigated how social dominance affects adaptive motor behavior while probing the neuromodulatory mechanisms that mediate activation of spinal motor circuits. Using zebrafish, we show that social status influences the activation pattern of two competing motor circuits: the Mauthner mediated escape (M-cell) and swim circuits. When paired, males form a social relationship consisting of dominants and subordinates. Using a non-invasive electrophysiological approach, we recorded field potentials generated as the escape and

swim circuits were active. Subordinates swim less and escape more than their dominant counterpart. Because of its known role in social regulation and motor control, we studied whether dopaminergic signaling underlies this behavioral shift. Using a pharmacological approach, we systemically injected L-DOPA, D1R, D2R, or D3R agonists and antagonists. Interestingly, blocking the D1R enhanced startle escape and suppressed swimming activity in dominants, mimicking subordinate behavior. Subordinates were not affected by D1R agonist or antagonist. These results correlate with brain gene expression analysis where subordinates displayed a significant decrease in D1R levels. To corroborate these findings we tested the escape and swim behaviors of homozygous D1R knockout zebrafish, which exhibited subordinate-like startle and swim activity pattern. These results suggest that dopaminergic modulation of motor activity is socially regulated and mediated via D1R. D1R is known for its excitatory signaling, yet blocking the D1R enhanced the escape response in dominants suggesting that dopaminergic modulation of the M-cell is mediated indirectly via a disinhibitory mechanism. The primary inhibitory inputs that regulate the excitability of the M-cell are GABA and Glycine. To determine which inhibitory input the D1R signaling is mediating, we administered bicuculline and strychnine. Bicuculline led subordinates to decrease their response sensitivity while dominants showed no change. If D1R was acting through GABA, it was expected that the escape sensitivity would increase in dominants, mimicking the D1R antagonist action. However, our results suggest that dopaminergic regulation of M-cell sensitivity is not mediated through GABAergic input. After strychnine administration, dominants showed an increase in escape sensitivity while subordinates showed no significant change; suggesting that D1R influences the M-cell through Glycine. Our results highlight the impact of social interactions on CNS function.

[5]IBENS INSERM U1024, Paris, France; [6]Inst. de Biologie de l'ENS, Paris, France; [7]Biol. Sci., NJIT, Newark, NJ

Abstract: Vertebrates can pick up cues from their environment through their sensory systems and integrate this information to produce relevant, context-dependent behavior.
While we are able to map the representation of sensory inputs and motor commands in the brain by looking at the correlation between the occurrence of stimuli or behavior and neural activity, the way sensorimotor integration is performed still remains an open question.
To address this question, we used two-photon calcium imaging in intact, behaving zebrafish larvae expressing the genetically encoded calcium indicator GCaMP5. We monitored neural activity elicited by pure tones (150 to 1000 Hz) across large portions of the brain with near single-cell resolution, while simultaneously recording motor activity with a high-speed camera.
We observed stimulus-related neural responses in the octaval nuclei and torus semicircularis, in agreement with previous studies. We found 4 classes of neurons with different tuning properties. Stimuli with frequency between 150 and 450Hz were able to elicit motor activity, which was not restricted to the mauthner-mediated escape response.
We classified the neurons according to their correlation with stimulus presentation and behavioral output and identified regions which could mediate the sensorimotor transformation via a gating mechanism.

Title: Altruistic allogrooming in subordinate male mice

Authors: *T.-H. KUO, Y.-S. SU
Inst. of Systems Neuroscience, Natl. Tsing, Hsinchu, Taiwan

Abstract: Animals perform a wide range of social behaviors for survival and reproduction. Understanding these behavior may provide a framework of social interactions in human and eventually help us to elucidate abnormalities in social behaviors under various psychiatric disorders. Allogrooming, or social grooming, is defined as grooming behavior between members

of the same species and can be widely observed throughout animal kingdoms. This behavior plays an important role in social bonding and is generally believed to be an altruistic behavior because groomers face several immediate costs to benefit recipients. Although allogrooming has been documented in mice, the functions and mechanisms have never been well characterized due to intensive male-male aggression, which limits the observations of other social behaviors during resident-intruder assay. By comparing dominant and subordinate males under resident-intruder assay, we found that subordinate males lose their aggression but mainly perform allogrooming during interaction with intruders while there is no change in other social behaviors. Covering exotic materials, like mineral oil, on an intruder significantly enhanced the allogrooming behavior from a groomer (resident), supporting the function of allogrooming for hygienic purpose. We also observed increase of immobile time of intruder during allogrooming interaction, suggesting that grooming recipients are directly benefited from this social interaction. Our study showed that allogrooming in mice is altruistic and can be easily observed in subordinate animals. This study established a new platform to investigate the biological mechanisms of altruistic behaviors for future study.

Title: Multiple running wheels with ID sensors for group-housed mice

Authors: *C. K. JUNG[1], O. JANKE[2], J. FÜNER[2], Y. WINTER[3]
[1]Phenosys Gmbh, Berlin, Germany; [2]Preclinics GmbH, Potsdam, Germany; [3]Humboldt Univ. - Inst. Biologie, Berlin, Germany

Abstract: Mouse models of neurological disorders, such as multiple sclerosis and Parkinsons disease, and models of pain exhibit marked deviations in several parameters of voluntary wheel running activity. Thus, wheel running assays serve to diagnose disease progression and treatment outcome. Typically, mice are kept singly in their wheel cages even for extended periods of time. For ethical reasons group housing of mice would be highly preferable. We present a novel system where wheel running cages are mounted in a regular cage rack. The cages are interconnected so that mice can move between them. Mice carry subcutaneous RFID chips for individual identification. ID sensors placed outside the cages but next to a cage‘s wheel detect

the identity of the mouse that uses the wheel. Thus, any wheel running can be assigned to an individual mouse. Wheel running of individual mice can be scored irrespective of the specific wheels used by a mouse. This novel system allows keeping mice in groups but still obtain individual records of running activity. We demonstrate the great potential of this novel method with data from a mouse model of muscle paralysis.

Title: Looming threat as an ethological stimulus for use in anxiety studies

Authors: *B. L. AGUILAR[1,2,3], J. TOIB[1,4], L. MALKOVA[2,3], P. A. FORCELLI[2,3]
[2]Dept of Pharmacol., [3]Interdisciplinary Program in Neurosci., [4]Dept of Biol., [1]Georgetown Univ., Washington, DC

Abstract: Rapidly approaching visual stimuli (looming objects) are known to evoke unconditioned defense responses across species. From lampreys to monkeys, such responses to predator approach are important for species survival and appear to be highly evolutionarily conserved. A subcortical visual threat processing pathway containing the superior colliculus (SC) has been described in rodents as a structure important for visual loom response. The SC receives multimodal sensory information, including visual information via retinal relay, and mediates reflex-like behaviors, orienting, avoidance, cowering, escape, and defensive vocalizations. Response to visual loom falls under the umbrella of threat reactivity in which the SC appears to play a critical role. Although components of the circuitry underlying unconditioned response to a looming stimulus have been elucidated, pharmacological studies showing modification of the behavior itself have yet to be completed. Similarly, aside from a single study investigating an

autism-like mouse mode, no behavioral outcomes from disease or disorder models have been described. Here we describe a modified version of the looming threat task, Forced Loom, where no escape route is available using Sprague-Dawley (SD) rats. We characterized several variables of interest: stimulus specificity (loom vs. reverse loom), habituation (repeat loom exposure), context-dependence (reinstatement of freezing), pharmacological sensitivity (anxiogenic/ anxiolytic drug effects in naïve and habituated rats), and ethological priming effects (cat odor, female rat odor). We observed strong freezing in response to an expanding disk, but not to control stimuli [I.e., a grey screen, a contracting disk] during the loom period ($P<0.01$, 2-way ANOVA, pairwise comparisons) and during the post-loom period ($P<0.01$), fast habituation to the stimulus (by 2nd loom, $P<0.01$), and a lack of context-dependent reinstatement (1st v. 4th loom, $P=0.68$). Interestingly, we found that while administration of diazepam to naïve SD rats significantly reduced freezing ($P<0.01$), administration of GABA inverse agonist FG-7142 displayed not change to behavior ($P=0.08$). We report sex differences in their responses in this task. Studies are currently underway to examine both the plasticity of this behavior using ethological priming stimuli and any strain-specific differences between SD and Long Evans rats.

Title: Why animal wiggle their sensors when following signals

Authors: *C. CHEN[1], M. A. MACIVER[2]
[1]Biomed. Engin., [2]Biomed. and Mechanical Engin., Northwestern Univ., Evanston, IL

Abstract: Movement and sensing work fundamentally in synergy. Animals move around to gather information and the new information guides the animal to initiate new movements. Sensory organs such as eyes, ears, and noses -- and the bodies they are attached to -- are constantly on the move as animals progress from exploring, searching, tracking, and finally, physical engaging with targets of interest. Surprisingly, an animal searching for either a stationary or a moving target not only orients its sensory organs to the target, but also wiggles them around the axis to the target. These controlled movements have been observed across a diverse range of animal lineages, from marine snails to humans. What is the underlying objective of these movements? We re-analyzed past movement data from mammalian olfactory tracking, along with new data on electrosensory tracking, to quantify key features of sensor wiggle. With

our analysis, we demonstrate a new finding that sensory wiggle amplitude decreases as sensory signals transition from weak to strong while animals close in on their target. Here we propose an ergodic information harvesting strategy, a novel theoretical framework that naturally reproduces these wiggle motions as well as their variation with changes in signal strength. The proposed model uses an information-theoretic approach to close the movement and sensing loop by planning trajectories for the information gathering organs to sample space proportionate to the expected information gain. The behavioral signatures of ergodic information harvesting -- including small oscillatory movements of sense organs sometimes interpreted as contributing error to subsequent neural processing -- are markedly different from alternative models proposed for active sensory movements such as infotaxis. In addition, by examining the effect of attenuating the wiggles generated by the algorithm on simulated tracking, we provide quantitative evidence that sensor wiggle enhances tracking performance. These results demonstrate that exploratory motions prior to signal detection and exploitative motions following detection do not require different mechanisms, but rather can be explained by the emergent features of ergodic information harvesting. Our normative framework provides a new perspective in the effort to understand sensorimotor integration in animals behaving in complex environments with uncertainty.

Title: The mousecam: A miniature head-mounted camera system for freely moving mice integrates detailed behavioural monitoring with multichannel electrophysiology

Authors: *M. SAHANI[1], J. POORT[2], A. F. MEYER[1], J. O'KEEFE[3], J. F. LINDEN[4]
[1]Gatsby Computat. Neurosci. Unit, [2]Sainsbury Wellcome Ctr., [3]Sainsbury Wellcome Ctr. and Dept. Cell & Devel. Biol., [4]Ear Inst. and Dept. Neurosci. Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: A major goal in neuroscience is to understand how neural circuits integrate a wide range of inputs to produce flexible and adaptive behaviours in natural settings. This requires detailed monitoring of both neural activity and behavioural variables while animals interact with their environment. An extensive toolkit for neural circuit recordings and manipulations makes the mouse a powerful model organism for systems neuroscience. However, detailed monitoring of behaviour in freely moving mice remains a major challenge.
Here, we report the development of a lightweight head-mounted camera system that we combine with motion sensors and multichannel neural recording devices to simultaneously monitor eye position, pupil dilation, and whisking along with head motion and neural activity in unrestrained, freely behaving mice. The system generates stable video output with image movements of less than 1 pixel (40 microns) in ~99% of the frames, even during active behaviours such as running and grooming. Moreover, the system has minimal effect on mouse behaviour, thereby enabling studies of natural ethology.
We demonstrate the potential of the system in a series of experiments in freely moving mice. First, we show that whisking frequency and pupil size vary systematically with behavioural state and that these changes are correlated with neural activity, thereby generalizing to freely moving mice and natural behaviours results previously obtained in head-restrained animals (e.g., McGinley et al. *Neuron* 2015). Second, we demonstrate that a large fraction of variability in eye position in freely moving mice is explained by head movements, as has also been observed in rats (Wallace et al. *Nature* 2013). Our data further indicate that mice stabilize their gaze with respect to the horizontal plane, and that this stabilization does not depend on visual input. Third, we demonstrate that neural activity in primary visual cortex is strongly modulated by self-generated head movements, even in the absence of visual input. This effect was not explained by whisking or variability in eye movements. These results illustrate how the new system can give novel insights into the interactions between different behaviours and their relation with neural activity.
The head-mounted camera system is open-source and we provide all required software and design files. Furthermore, the system is modular and therefore could be integrated with alternative methods for recording neural activity and/or combined with technologies for optogenetic manipulation of neural circuits during behavioural monitoring.

Title: Understanding the role of sensory feedback on a robotic platform during peristaltic locomotion

Authors: *A. KANDHARI[1], H. J. CHIEL[3], R. D. QUINN[1], K. A. DALTORIO[2]
[1]Mechanical and Aerospace Engin., [2]Mechanical Engin., Case Western Reserve Univ., Cleveland, OH; [3]Case Western Res. Univ., Cleveland, OH

Abstract: Earthworms locomote using traveling waves of segment contraction and expansion. Because of the hydrostatic coupling, as the diameter of a segment increases, its length decreases. Segments can also bend. The mechanics of the body result in a large range of body shapes that both comply with the environment and contribute to directed locomotion. During the crawling movements of earthworms, sensory feedback provides the animal with an ability to adapt to different types of environmental perturbations. Mechanosensory organs and stretch, touch, and pressure receptors are the feedback sources in earthworms that allow the body to contort and adapt to its surrounding environment. Here, we present a robotic platform for exploring the role of sensory feedback to control peristaltic locomotion in constrained environments. Inspired by earthworms, we designed and constructed a new robot: Distributed-Sensing Compliant Worm (DiSCo-Worm) Robot. DiSCo-Worm is equipped with 36 Force Sensing Resistors (6 per segment) that allow the robot to detect external constraints and 12 flexible stretch sensors (2 per segment) that allow for tracking the shape of the robot. We contrast the ability of the robot to navigate in constrained spaces using an open-loop, time-based controller and a closed-loop sensory feedback controller. The results indicate that when the robot can sense its environment and its internal state (longitudinal extension of each segment), it uses this information to determine whether to expand, contract or anchor each segment. Using the closed-loop controller, the robot is able to adapt to its environment and reduce forward slip, which accounts for 58% of the total motion in open-loop control.

Title: Preserved gene coexpression networks between human cortex and songbird pallium

Authors: *G. GEDMAN[1], B. HAASE[2], O. FEDRIGO[2], E. D. JARVIS[3]
[1]The Lab. of Neurogenetics and Language, The Rockefeller Univ., New York, NY; [2]Vertebrate Genome Lab., [3]The Lab. of Neurogenetics of Language, Rockefeller Univ., New York, NY

Abstract: The six-layered mammalian neocortex and the nuclear avian pallium bear little structural resemblance, presenting a challenge for comparing the neuroanatomical substrates of complex behavioral traits across species. A major step towards understanding the avian-mammalian neuroanatomical relationship has been resolving the cell-type homologies between these lineages. Using shared neural connectivity, gene expression, and physiology, some studies suggest a one-to-one homology between the different mammalian cortical layers and different avian pallial subdivisions (nuclear-to-layer hypothesis), while others argue that the mammalian neocortex is wholly different from the avian pallium (independent evolution hypothesis)[1]. A limitation of these studies is that a small number of genes have been analyzed leading to underpowered interspecies comparisons. Here we used next-generation RNA sequencing (RNASeq) to assess the entire transcriptome within and between songbird pallial regions (zebra finch) laser captured in our lab and human cortical layers isolated by the Allen Institute for Brain Science. Using clustering analyses of significantly differentially regulated genes, we showed that the avian ventral mesopallium is nearly identical in its transcriptome profile to what is known as the dorsal mesopallium. Further, we found that the hyperpallium and nidopallium are nearly identical, suggesting shared developmental origins of these subdivisions. In the human brain, layer 4 transcriptome data were not easily distinguished from the other cortical layers, presumably due to inaccurate dissections, but we did find distinct profiles for the upper and lower layers. For comparisons between species, we used weighted gene coexpression network analysis (WGCNA)[3] and identified ~10-20 coexpression modules per species, each containing ~100 genes, with evidence of module preservation across species. The module with the highest significantly preserved expression ($Z_{summary}$ = 26.11) was composed of ~2500 genes that associated the avian arcopallium and deep cortical layers 5 and 6 in humans. Gene ontology analysis found this module is enriched for genes involved in anatomical organ development and cell-fate determination. The next highest module, with fewer genes, associated the avian mesopallium regions with upper cortical layers 2/3 of humans. Together, these results support the nuclear-to-layer hypothesis of vertebrate brain evolution. This work highlights the presence of shared gene networks across songbird and human, species separated by more than 300 million years, and provides hundreds of candidate genes for testing conserved functionality.

Title: Modeling visual perception, learning, and memory of wood ant navigation in naturalistic environments

Authors: *A. J. MENDOZA, D. D. LENT
Biol., California State Univ. Fresno, Fresno, CA

Abstract: A number of experiments have revealed how different visual features are used to guide familiar foraging routes in wood ants. Using these data, we have developed algorithms to extract visual features that ants use for guidance from panoramic scenes. We created a computational foraging model in the MATLAB computer program to simulate navigation in procedurally generated environments where the visual cues could be precisely characterized. In these environments, our algorithms extracted and stored the visual cues that were available during a single Levy-walk foraging event. Following a random foraging event, the success on subsequent return bouts using the stored information was examined. To explore how to best store information we simulated the Levy-walk foraging events over various sampling points (1000-10000) and implemented linear or exponential decay in the networks storing the information. Our data suggests that the optimal strategy is to sample and store between 1000 and 2000 points along the walk, with a network subjected to exponential decay. These parameters resulted in a stored representation that allowed the simulated ant to best find the goal on subsequent foraging bouts. We then produced several novel random foraging walks to the same goal location. The subsequent walks for these foraging events had similar success while taking different paths back to the goal, demonstrating idiosyncratic routes were formed and that sufficient information was stored regardless of where in the environment the random path searched before reaching the goal location. Additionally, we explored how repeated subsequent walks updated and modified memory to produce more robust walks over time. Our model has also been used to predict how changes in the environment would disrupt navigational success by producing subsequent walks after a portion of the objects in the virtual world are removed. The results of these simulations have provided insight into the mechanisms involved in prioritization and perception of visual information, it supports that ants need only processes relevant cues intermittently and they do not continually process visual information. Additionally, it has let us investigate how learning and storage of spatial information can be optimized in simple networks and nervous systems.

Title: What does it mean to be a tactile specialist? Lessons from peripheral anatomy and central processing in 7 species of waterfowl

Authors: *E. R. SCHNEIDER[1], C. R. LATTIN[2], E. O. ANDERSON[1], M. MASTROTTO[1,3], J. E. BROWN[2], E. O. GRACHEVA[1,3], S. N. BAGRIANTSEV[1]
[1]Cell. and Mol. Physiol., [2]Dept. of Radiology and Biomed. Imaging, [3]Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Waterfowl of the Anatidae family exist in a variety of habitats, changing their diet during development, migration, and breeding. Depending on time and location diving ducks prefer different foods from dabbling ducks, and rely to differing extents on tactile or visual foraging strategies. It has been shown that across orders of birds the size of brain regions that process tactile or visual information correlates well with reliance on touch or vision for foraging (Gutiérrez-Ibáñez et al., 2009; Dubbeldam, 1990). Likewise, bony "pits" in the bill are also present in bills of many tactile specialist birds. This led us to ask whether anatomical and functional differences in the trigeminal system innervating the bill can be detected in closely related species of Anatidae with different foraging strategies. Since ducks are precocial we performed these tests shortly before hatching. Our sample consisted of embryos at the "exterior pip" stage from seven species including dabbling ducks from genera Aix and Anas, and diving ducks from genera Aythya, Mergini, and Oxyurini. We measured the number of bony pits in the bill using microCT, the percentage of trigeminal ganglia (TG) neurons expressing the mechanosensitive ion channel Piezo2 using *in situ* hybridization, and the number and sensitivity of acutely-dissociated TG neurons responding directly to mechanical stimulation by patch-clamp electrophysiology (n=2-3 embryos, 40-178 cells per species). We compared these parameters with the relative size of brain regions receiving tactile input from TG from the literature. The number of bony pits was not significantly correlated with the number of mechanosensitive neurons, neuronal sensitivity, or Piezo2 expression, suggesting that in these species bony pits are not a good predictor of tactile acuity. We hypothesized that neurons obtained from dabbling ducks from the genus Anas would be more numerous and sensitive than those of diving ducks from genus Mergini. However, the number and sensitivity of mechanosensitive TG neurons varied widely within species obtained from both genera. For instance, *A. pekin* was more sensitive than *A. rubripes* on both measures, confirming our prior reports (Schneider et al., 2017, Schneider et al., 2014). Surprisingly, TG neurons from Ruddy ducks (*O. jamacensis*) were most sensitive to touch but had the smallest number of neurons expressing Piezo2, suggesting the presence of an alternative mechanotransducer. Overall our findings reveal that across these species anatomical organization is not highly predictive of functional sensitivity, suggesting adaptation to tactile foraging in Anatidae can occur by a variety of strategies.

Title: Bite force in the naked mole-rat (Heterocephalus glaber)

Authors: B. W. CAIN[1], D. KUKLA[2], J. KODURI[3], *D. K. SARKO[4]
[1]Anat., Southern Illinois Univ. Sch. of Med., Carbondale, IL; [3]Computer Engin., [2]Southern Illinois Univ., Carbondale, IL; [4]Dept. of Anat., Southern Illinois University, Sch. of Med., Carbondale, IL

Abstract: Naked mole-rats (*Heterocephalus glaber*) are subterranean rodents from the family Bathyergidae. The naked mole-rat has emerged as a leading model for studies of dentition due to behavioral reliance on the incisors for object manipulation, grasping, exploration, and navigation of the environment. Naked mole-rats utilize their incisors for feeding, for chisel-tooth digging of complex tunnel systems, and for social interactions (or defense) in their eusocial colony structure. In addition, the naked mole-rat exhibits remarkably expanded central nervous system representations with modular organization devoted to tactile inputs from the dentition. Although previous studies have shown that naked mole-rats have relatively wider and taller skulls (attributes associated with greater bite force; McIntosh and Cox, 2016), in addition to impressive masticatory musculature (Cox and Jeffery, 2011; Cox and Faulkes, 2014), no studies to date have directly measured bite force in this species. In the current study, we assessed naked mole-rat bite force in relation to skull and body measures as well as each animal's position within the social hierarchy (i.e., the dominant queen and subordinate males and females). Individual animals were placed in an enclosure similar to their home cages and connected to a tunnel-like tube that provided access to the bite force sensor. Animals were permitted to freely interact with the sensor, which they were more motivated to bite when it was blocking a potential exit route. Bites were recorded using a piezo-resistive force sensor (Tekscan Flexiforce sensor coated in Plasti Dip) connected to a Raspberry Pi (Model B) for data recording of each behavioral session and subsequent analyses. We hypothesized that the naked mole-rat's bite force would exceed that predicted by its body size due to the behavioral importance and specialization of the naked mole-rat incisors. Altogether, these studies provide insight into the differences in bite force across species, and the role that social and ecological factors might play in the evolutionary relationship between bite force performance and underlying anatomical structures.

Title: Short-term inflammatory pain in the African naked mole-rat is driven by P2Xr and can be attenuated by the endocannabinoid system

Authors: *B. M. BROWE, C. RAMIREZ, T. J. PARK
Biol. Sciences- Neurobio., Univ. of Illinois At Chicago, Chicago, IL

Abstract: African Naked Mole-Rats (NMR) are highly social long-living mammals (lifespans reaching >30 years) whose fossorial lifestyle comes with a multitude of challenges. One predominant hurdle to adapting to life underground in large colonies (as many as 200 animals) is that the habitat becomes hypoxic and CO2 levels increase. Previously, our lab has shown that NMR have developed mutations in their Nav1.7 voltage gated Na+ channel, to become impervious to the painful acidosis caused by increased CO2. In addition, NMR have a mutated peripheral substance P promoter region, eliminating the chemical messanger from the presynapse of sensory nerve C-fibers making them impervious to capsaicin. These mutations completely eliminate pain response from capsaicin and CO2; however, they do not affect mechanical pain such as the tail pinch and, most interestingly, only partially reduce short-term inflammation from assays including the formalin test. This study aimed to characterize the remaining functionality of the peripheral pain pathway for short-term inflammation in the NMR. Here, we show that the NMR's attenuated pain response to formalin can be rescued with Substance P replacement to the spinal cord triggering activation of TRPV1 receptors. Additionally, the inflammatory response to formalin is significantly reduced after P2X3r antagonism. P2X3r has been implicated as a target for cannabinoids in pain attenuation. The endocannabinoid system is a major regulator of synaptic signals through retrograde
inhibition and manipulation of the cannabinoid system has shown promise in medical treatments of pain. However, cannabinoids have also been shown to have a high affinity to TRPV1. The NMR offers a unique ability to test the effect of Cannabinoid Receptor 1 (CB1r) activation in pain attenuation for the P2X3r pathway in a wild type animal without interference from the peripheral TRPV1 pathway. We found that there is a significant attenuation to formalin pain when given WIN55, an agonist to CB1r. Moreover, this pain attenuation is to a greater degree than that of WT mice indicating that this pathway is an important component of NMR pain reduction. Our results indicate that, while NMR are completely unaffected by capsaicin they retain a functioning P2X3r pathway that can be modified by cannabinoids.

Title: Neural mechanisms for discrimination of communication and echolocation calls in the big brown bat (Eptesicus fuscus)

Authors: *A. SALLES[1], S. MACIAS[2], H. SUNDAR[3], M. ELHILALI[3], C. F. MOSS[3]
[1]Psychology and Brain Sci., [2]Dept. of Psychological and Brain Sci., [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Auditory scene analysis is crucial for species that rely on sound to navigate their environment. Bats are auditory specialists that use echoes from their own vocalizations to build a scene of their surroundings. At the same time, these social animals live in roosts and use their vocalizations to communicate with conspecifics. Important advances have been made in understanding the neural underpinnings of echolocation, but far less is known about the mechanisms supporting acoustic communication. In big brown bats (*Eptesicus fuscus*) call structure, along with behavioral context, appears to determine the function of acoustic signals. Specifically, FM bouts are emitted by males in a competitive foraging environment and are hypothesized to have a food claiming function. Though these calls differ in behavioral relevance with conspecific echolocation calls, they overlap in spectro-temporal features. This raises the question of how stimulus content is processed to support discrimination of communication calls and echolocation calls. We are investigating the neural mechanisms that enable the discrimination of natural stimuli that overlap in spectro-temporal features. Using 16-channel silicon probes in awake restrained animals, we compare responses of single neurons in the Inferior colliculus (IC) to playbacks of acoustic signals used by bats for spatial orientation and social communication. FM Bouts elicited strong responses in a subpopulation of neurons, while the same neurons showed weak or no responses to sequences of echolocation calls that matched the timing of the communication calls. This result was consistent in both female and male bats, supporting previous data that showed no sex difference in behavioral responses to these social calls. STRF analysis was performed to further understand the stimulus features that contribute to the selectivity of these midbrain neural responses.

Title: Inactivation of the superior colliculus alters orienting behavior in the echolocating bat

Authors: *B. L. BOUBLIL[1], M. J. WOHLGEMUTH, III[2], C. F. MOSS[2]
[1]Psychological and Brain Sci., [2]Johns Hopkins Univ., Baltimore, MD

Abstract: The midbrain superior colliculus (SC) is a multimodal, laminated structure implicated in sensorimotor integration and goal-directed orienting movements of the eyes, head and ears. Past work has identified specializations in the SC of the echolocating bat for audiomotor integration, namely 3D tuning of auditory neurons and vocal-motor activity preceding each sonar call. The success of bat echolocation depends on adaptive orienting behaviors in response to information carried by echo returns. For example, a bat adjusts sonar call duration and interval as it tracks, approaches, and prepares to capture prey. The capture phase, characterized by a call rate of ~150 Hz, is commonly referred to as the terminal buzz. Here, we investigated the role of the SC in the echolocating bat's temporal coordination of adaptive vocal behaviors for precise sonar target tracking. In this experiment, big brown bats (*Eptesicus fuscus*) were trained to track a moving tethered insect from a platform. The target approached the bat with one of two different trajectories, simple linear motion directly towards the bat or complex back and forth motion, before arriving at the bat's position. Additionally, two stationary clutter objects were positioned symmetrically on either side of the moving target at a distance of 70 cm and an angular offset of 10º from the target's path. The bat's echolocation behaviors were studied under simple or complex target motion trajectories, and in the presence or absence of clutter objects. Muscimol, a GABA agonist, or saline was infused bilaterally into the SC. We found a significant increase in the rate of vocal production following SC inactivation with muscimol. We also found that the terminal buzz onset occurred earlier (i.e. when the target was further from the bat) in muscimol treatment trials, suggesting a disruption in the bat's coordination of sonar call parameters with target distance. And lastly, we found an increase in the duration of the terminal buzz, preceding target capture. Taken together, these data suggest that the SC plays a role in

temporal coordination of sonar orienting behaviors.

Title: Claustrum and endopiriform nucleus in the fruit bat

Authors: *R. ORMAN[1], R. KOLLMAR[2], M. STEWART[1]
[1]Physiology&Pharmacology, [2]Cell Biol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: The Seba's short-tailed bat, Carollia perspicillata, a fruit bat, is an interesting animal to offer insights into the question of whether claustrum and endopiriform nucleus are anatomically and functionally close enough to each other to warrant sub-naming of a single structure or if they show enough structural or functional independence to preserve their separate naming. A strong argument that claustrum and endopiriform nucleus are closely related enough to be considered as subregions themselves of a parent structure comes from immunohistochemistry with relatively claustrum-specific markers, such as latexin. However, in anatomical studies with non-specific neuronal markers such as NeuN, the sizes, shapes, density, and orientation of cells differentiate the claustrum from the endopiriform nucleus. In NeuN-stained material, the natural boundary between the claustrum and endopiriform nucleus is evident as an abrupt shift from densely packed claustral cells located dorsally to the distinctly lower density packing of endopiriform neurons located ventrally. Dorsomedial and ventrolateral subregions based on size, shape, and cell density can be visualized in endopiriform nucleus. The most impressive definition of claustrum as separate from the endopiriform nucleus in Carollia brain comes from labeling cells of both regions for calcium binding proteins such as parvalbumin, calretinin, and calbindin. In adult Carollia, parvalbumin-expressing neurons are found in the claustrum, but not in the endopiriform nucleus. In claustrum, parvalbumin-immunoreactive (ir) and calbindin-ir neurons are the most common for calcium binding proteins (among parvalbumin, calretinin, calbindin), and account for close to 10% of all cells based on DAPI labeling of cell nuclei. By contrast, calretinin-ir neurons are absent from claustrum. Calretinin-ir neurons are located in significant numbers along the ventral edge of the endopiriform nucleus, forming a partial ring around the ventrolateral portion of the endopiriform nucleus. Much of the connectivity data available from other species is not yet available for the

bat, but based on the histological and physiological data that are available, we believe the bat brain offers a strong case for separate identities of claustrum and endopiriform nucleus.

Title: Sensorimotor activity in the superior colliculus of the echolocating bat as it moves freely in 3D space

Authors: *M. J. WOHLGEMUTH, III[1], N. B. KOTHARI[2], C. F. MOSS[2]
[2]Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: As animals move about the world, they navigate through 3D space, localizing objects, and steering around obstacles. Visual and auditory localization of objects, and attention to their features, has been studied primarily in restrained subjects performing simplified tasks. If we are to gain an understanding of brain function in more real-world settings, we must study animals moving through space, sensing objects in their environment, and reacting to dynamic stimuli. Our research investigates sensorimotor events in the central nervous system of animals engaged in natural and adaptive behaviors. Specifically, we have recorded from the midbrain of flying, echolocating bats as they navigated through a 3D environment, sensing and reacting to physical obstacles along their flight path. We performed wireless neural recordings in the superior colliculus, a midbrain structure conserved across vertebrates (optic tectum in non-mammals), which is integral to the representation and use of egocentric sensory cues to drive orienting behaviors. In animals that use vision, such as primates, the SC guides eye movements to visual targets. The SC is also involved in auditory orientation and shows activity in the echolocating bat related to its sonar orienting behaviors. In our experiment, bats flew freely in a multimedia test room, and we recorded from three different functional classes of neurons in the SC: sensory neurons that showed increased spiking probability in response to echoes arriving from objects in 3D egocentric space; pre-vocal-motor neurons that fired before sonar call production; and sensorimotor neurons that exhibited pre-vocal-motor activity before sonar call onset and responded to the arrival of echoes. Our data also show that the bat's sonar vocal production

patterns can dynamically alter the tuning properties of neurons. These results demonstrate dynamic changes in midbrain neural activity in an animal moving naturally through space, interacting with objects along its path.

Title: Assessment of vascular amyloid pathology in brain microvessels isolated from persons with mild cognitive impairment or Alzheimer's disease

Authors: *P. BOURASSA[1], C. TREMBLAY[1], D. A. BENNETT[2], F. CALON[1]
[1]Ctr. De Recherche Du CHU De Québec, Quebec, QC, Canada; [2]Rush Alzheimer's Dis. Center, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Compelling pieces of evidence suggest that blood-brain barrier (BBB) dysfunction is implicated in the pathophysiology of Alzheimer's disease (AD). Cerebral amyloid angiopathy (CAA), faulty Aβ peptide clearance and pericyte deficiency are all suspected to contribute to BBB dysfunction. Brain microvessels are typically investigated using immunostaining approaches on brain sections, with often limited possibilities for quantification. In this study, we sought to evaluate vascular amyloid pathology and pericyte loss in microvessels isolated from human parietal cortex samples (n= 60) from participants of the Religious Orders Study, a longitudinal clinical-pathological cohort study on aging and AD. We first validated human microvessel-enriched extracts (HME) generated from frozen tissue by Western blot and immunofluorescence experiments. We confirmed the enrichment of endothelial markers (claudin5 and occludin), and basal lamina marker (collagen IV) in the vascular fraction while neuronal markers were more abundant in the post-vascular fraction. To assess vascular amyloid pathology, ELISA showed that Aβ40 and Aβ42 levels in HME were increased in subjects with a neuropathological diagnosis of AD (+100% for Aβ40 and +200% for Aβ42, versus controls subjects), in ApoE4 carriers (+150% for both Aβ40 and Aβ42, versus ApoE4 non carriers) and in those with moderate to severe CAA (+400% for Aβ40 and +100% for Aβ42, versus individuals without CAA). In addition, Aβ40 and Aβ42 levels in HME were negatively correlated with ante mortem visuospatial ability, but not with global cognitive score. Western blot analyses showed that ABCB1 (p-glycoprotein) levels were reduced in AD subjects (-50%), positively correlated to

cognitive function and inversely correlated with Aβ40, but not with Aβ42. In contrast, apoE and β-secretase (BACE1) were increased in AD subjects, associated negatively with cognitive function and positively with Aβ40 and Aβ42 levels. Measurements of PDFGR-β and CD13, also called ANPEP, levels in HME by Western blot showed that both pericyte markers were reduced in individuals diagnosed with AD. Linear regression analyses showed that pericyte markers were correlated positively with cognitive scores and inversely with Aβ peptides concentrations. Overall, our data show that microvessel-enriched extracts generated from frozen human brain samples can be used to selectively analyze BBB cells and vascular Aβ pathology in the cerebrovasculature.

Title: Identification of novel internalized cell surface proteins in human brain capillary endothelial cells by SWATH-MS

Authors: *S. ITO[1,2], M. OISHI[2], T. MASUDA[1,2], T. FURIHATA[3], S. OHTSUKI[1,2]

Abstract: The blood-brain barrier (BBB) regulates and restricts the transport of therapeutic drugs, antibodies, and nanoparticles that are used to treat central nervous system (CNS) disorders. Drug delivery to the brain still remains one of the major challenges that needs to be overcome. Efficient receptor-mediated transcytosis (RMT) across the BBB is an important strategy for drug delivery to the CNS. Although the transferrin receptor (TFR) is a promising molecule within the brain-targeted drug delivery system, concerns regarding its safety limits its application in humans. Thus, the purpose of the present study was to identify novel cell surface proteins that are selectively expressed and internalized into human brain capillary endothelial cells in vitro in order to identify novel RMT molecules at the BBB. To find BBB-selective RMT molecules, we used the hCMEC/D3 and HBMEC/ciB cell lines as BBB model and HUVEC as a peripheral blood vessel model. The proteins expressed in the plasma membrane of the cells were biotinylated with or without EZ-Link NHS-Biotin solution in PBS for 30 min at 4°C (cell surface fraction), and then treated with 20% human serum in PBS for 5 min at 37°C. To remove biotin from the biotin-labeled residual surface proteins, the cells were washed with or without a

MESNA wash buffer (internalized fraction). Biotinylated proteins in the samples were captured using streptavidin-immobilized magnetic beads. The biotinylated proteins were then eluted from the beads using DTT in PTS buffer. Silver staining showed that biotinylated proteins were detected in the cell surface and internalized fractions. Using SWATH-MS analysis, 563 hCMEC/D3, 314 HBMEC/ciB, and 399 HUVEC proteins were identified in the cell surface fractions. In the plasma membrane, approximately 378 hCMEC/D3 (57%), 197 HBMEC/ciB (63%), and 225 HUVEC (64%) biotinylated proteins were expressed after excluding the cytosolic proteins annotated via Gene Ontology analysis. Furthermore, 109 hCMEC/D3, 28 HBMEC/ciB, and 85 HUVEC internalized cell surface proteins were extracted using our original criteria. Among these, 73 proteins were BBB-selective internalized proteins. Considering the expression levels of these proteins in the isolated hCMEC/D3 plasma membrane fraction using SWATH-MS, 20 proteins (including TFR) were speculated to be candidate molecules for RMT at the BBB. These results suggest that we identified proteins internalized into human brain capillary endothelial cells in vitro using a cell surface biotinylation-based internalization method. Our present study provides novel information regarding the development of a BBB-permeable, brain-targeted drug delivery system.

Abstract: Progressive research in pharmacology and neurology has recently centered around the molecular constituents of the blood-brain barrier (BBB) whose restrictive properties are required information for development of effective treatments for neurological disorders such as migraine headaches. Recent studies show implication of the membrane solute carrier Na+/H+ exchanger (NHE) in migraine physiology. Clinical studies show a tripled rate of migraine onsets in women

over men in America and an approximately doubled rate worldwide, indicating sex hormones as a regulator of NHE expression and function. To determine the integrity of the BBB in migraine with aura models, expression of the tight junction proteins known to hold the BBB intact were probed for. We carried our experiment via molecular and behavioral techniques utilizing rat models grouped by gender and treatment. Our investigations targeted the sodium/hydrogen exchanger 1 (NHE1) isoform of NHE and the tight junction proteins Occludin, Claudin-5 and Zonula occludens-1. Our three areas of interests were the brain and brainstem in the CNS and the trigeminal nerve in the PNS. Funded by Provost and a grant from the Arizona Area Health Education Centers (AHEC) Program. Title: The effect of circulating angiotensin II on blood-brain barrier vascular permeability in the hippocampus of normotensive rats

Authors: *S. HAMASAKI, T. MUKUDA, Y. KOYAMA, T. KAIDOH
Tottori Univ., Yonago, Japan

Abstract: Blood proteins such as hormones cannot penetrate from systemic circulation into the brain including the hippocampus, owing to the presence of the blood−brain barrier (BBB). However, hypertensive model rats show an increased BBB permeability, in which angiotensin II (Ang II) participates in its regulation mechanisms. In contrast, effect of Ang II on BBB permeability in normotensive rats has not yet been examined. We inspected effects of physiological oscillation of circulating Ang II on BBB permeability in normotensive rats. To induce a transient elevation of circulating Ang II within the physiological ranges, rats were deprived of water for 16 hours per day during a 7-day experimental period. To detect BBB permeability histologically, rats were injected intravenously with a fluorescent dye, Evans blue (EB), which cannot cross the BBB, 15 min before transcardiac perfusion for fixation on the last day of the experimental period. EB is often used to evaluate an increased BBB permeability in the brain by detecting its extravasation into the parenchyma histologically and biochemically. In this study, we adopted a novel histological methodology for highly sensitive detection of EB; we

found that hippocampal neurons take up EB, presumably through endocytosis, and accumulate it in the somata even when the extravasation of the dye was difficult to detect. Using this technique, we can quantify BBB permeability by counting neurons stained with EB in the brain. Unexpectedly, EB-positive neurons were found in the hippocampal dentate gyrus in controls, suggesting a constitutively increased BBB permeability in the hippocampus. Moreover, the number of EB-positive neurons in the water−deprived rats increased compared with that in controls. This result suggest a possibility that a transient elevation of circulating Ang II induced by water deprivation increases BBB permeability in the hippocampal dentate gyrus of the normotensive rats. To determine the types of neurons stained with EB, immunostaining for several neurochemicals including a marker protein for the interneuron, parvalbumin, was made. Some EB-positive neurons (>15 μm) localized in the hilus of the dentate gyrus were immunoreactive for parvalbumin, indicating that these are interneurons. Taken together, an increased BBB permeability induced by Ang II would not only increase opportunities for circulating proteins to contact neurons, such as interneurons, in the hippocamapl dentate gyrus, and but also modulate neuronal activities.

Title: Association between blood-brain barrier transport system alterations and brain parenchymal abnormalities in a mouse model of diet-induced insulin resistance assessed using quantitative proteomics

Authors: *S. OGATA[1], S. ITO[1,2,3], T. MASUDA[1,2,3], S. OHTSUKI[1,2,3]
[1]Grad. Sch. of Pharmaceut. Sci., [2]Fac. of Life Sci., Kumamoto Univ., Kumamoto, Japan; [3]AMED-CREST, Tokyo, Japan

Abstract: The blood-brain barrier (BBB) transport system plays a key role in the maintenance of brain parenchymal functions. Insulin resistance has been reported to contribute to BBB breakdown, the details of which are important for understanding the development of dementia because insulin resistance in type 2 diabetes mellitus is a risk factor for dementia, including Alzheimer's disease and vascular dementia. The purpose of the present study was to investigate the association between BBB transport system alterations and brain parenchymal abnormalities in a mouse model of diet-induced insulin resistance using quantitative proteomics. A high-fat

diet (HFD) was fed for 2 or 10 weeks to 8-week-old mice, which exhibited mild or severe insulin resistance, respectively. The expression levels of BBB transporters [Glut1 (39%), Mdr1 (36%)] and tight junction proteins [claudin-5 (53%), occludin (36%)] were significantly reduced in the brain capillary-rich fraction (Bcap) of 2-week HFD-fed mice, but these were not altered in that of 10-week HFD-fed mice. The expression of Mct1 protein was increased 2.4-fold in the Bcap of 10-week HFD-fed mice, but this was not altered in that of 2-week HFD-fed mice. In 2-week HFD-fed mice, immunohistochemical analysis showed no reduction of brain capillary density but a reduction in Glut1 and Mdr1 protein expression, similar to that measured by SWATH-MS. In addition, functional analysis showed reduced Glut1 and Mdr1 activity in 2-week HFD-fed mice. In the cerebral cortex of these mice, the expression of neurofilament-L (38%) and -M (29%) was significantly reduced. In the hippocampus, neurofilament-L (32%), -M (34%), -H (25%), and CaMKII (31-38%) levels were significantly reduced in 2-week HFD-fed mice. No significant reduction of neurofilament-L, -M, -H, or CaMKII levels was observed in the cerebral cortex and hippocampus of 10-week HFD-fed mice. The association analysis revealed that the changes of Glut1 and Mdr1 protein expression were closely related with that of neurofilament and CaMKII in both 2- and 10-week HFD-fed mice. The present results suggest that mild insulin resistance causes BBB transport system breakdown in the early phase of type 2 diabetes mellitus. This alteration in the brain may trigger the development of cognitive dysfunction.

Title: Contributions of the glycocalyx, endothelium, and extravascular compartment to the blood-brain barrier

Authors: *N. KUTUZOV[1], H. FLYVBJERG[2], M. LAURITZEN[1]
[1]Univ. of Copenhagen, Kobenhavn N, Denmark; [2]Tech. Univ. of Denmark, Copenhagen, Denmark

Abstract: Drug design for brain delivery usually focuses on the drug's ability to cross the vascular endothelium of the blood-brain barrier; thus, the glycocalyx and the astrocyte endfeet remain under-studied. We employed two-photon microscopy of single cortical capillaries to

record the passive transport of sodium fluorescein and fluorescently labelled dextran from the blood into the brain in anesthetized mice. We found that fluorescein penetrated nearly the entire glycocalyx volume, but dextran penetrated less than 50% of the volume. We found that the extravascular compartment, a region outside the vessel, which colocalizes with astrocyte endfeet, restricted passive transport of the two fluorescent dyes. The diffusion coefficients of the dyes were an order of magnitude lower in the perivascular compartment than in the brain parenchyma. Finally, we formulated a transport model to estimate the permeability of the healthy and the mannitol-disrupted blood-brain barrier. Our results suggested that the blood-brain distribution of small and large hydrophilic molecules was determined by three separate barriers: the glycocalyx, the endothelium, and the perivascular compartment.

Title: Transport activity impairment of creatine transporter (G561R), a novel mutation associated with creatine transporter deficiency, by abnormal N-glycosylation and cellular locaization

Authors: *T. UEMURA[1], S. ITO[1,2,3], T. MASUDA[1,2,3], Y. OTA[4], M. TACHIKAWA[4], T. WADA[5], M. HIRAYAMA[1,2,3], T. TERASAKI[4], S. OHTSUKI[1,2,3]
[1]Grad. Sch. of Pharmaceut. Sci., [2]Fac. of Life Sci., Kumamoto Univ., Kumamoto, Japan; [3]AMED-CREST, Tokyo, Japan; [4]Grad. Sch. of Pharmaceut. Sci., Tohoku Univ., Sendai, Japan; [5]Grad. Sch. of Med. Sci., Kyoto Univ., Kyoto, Japan

Abstract: Creatine transporter deficiency (CRTD) is the second-most common cause of X-linked intellectual disability, and caused by loss-of-function mutations in the creatine transporter (CRT) gene (*SLC6A8*). We previously reported that CRT majorly contributes to supplying creatine to the brain across the blood-brain barrier (BBB), in rodents. We also reported a novel CRT gene missense mutation (c.1681G>C, Gly561Arg) in Japanese CRTD patients, who had low cerebral creatine levels. However, the mechanism by which G561R-CRT mutation causes a reduction in cerebral creatine levels remains unclear. The purpose of the present study was to clarify the contribution of CRT to creatine transport across the human BBB *in vitro* and the mechanism of functional attenuation of G561R-CRT. Quantitative proteomics showed that the CRT protein was expressed in the plasma membrane of the human brain endothelial cell line

(hCMEC/D3) as a human BBB model. [^{14}C]creatine uptake by hCMEC/D3 cells was decreased by unlabeled creatine, a specific CRT inhibitor (β-guanidinopropionic acid), and CRT-targeted siRNAs. The uptake analysis also revealed that G561R-CRT mutation reduced the [^{14}C]creatine uptake by the skin fibroblasts, which are derived from patients harboring the G561R-CRT mutation, and by G561R-CRT expressing 293 cells. Immunohistochemical analysis showed that G561R- CRT protein was localized in the intracellular compartment, while the wild-type CRT (WT-CRT) protein was predominantly localized at the plasma membrane of 293 cells. Western blot analysis revealed that WT-CRT protein was detected at 68 kDa in the plasma membrane fraction of WT-CRT expressing 293 cells, whereas G561R-CRT protein was predominantly detected at 55 kDa in the crude membrane fraction of G561R-CRT expressing 293 cells. Both bands shifted to 50 kDa following treatment with N-glycosidase. These results suggest that functional attenuation of G561R-CRT mutation was caused by defective protein trafficking to the plasma membrane, due to protein misfolding and altered N-glycosylation. As a result, G561R-CRT mutation causes to impair creatine supply into CNS across the human BBB.

Title: Two-photon fluorescence imaging *in vivo* as a platform to investigate cell-penetrating peptides and liposome-based nanocarriers for drug delivery across the blood-brain barrier

Authors: *K. KUCHARZ[1], M. KRISTENSEN[2], K. KRISTENSEN[3], M. LUND[3], T. ANDRESEN[3], B. BRODIN[2], M. LAURITZEN[1,4]
[1]Inst. of Neurosci., [2]Dept. of Pharm., Univ. of Copenhagen, Copenhagen, Denmark; [3]Dept. of Micro- and Nanotechnology, Tech. Univ. of Denmark, Copenhagen, Denmark; [4]Glostrup Hosp., Copenhagen, Denmark

Abstract: INTRODUCTION: Successful development of new trans-BBB drug delivery systems to the brain relies on the feedback from *in vitro* models. These, however, do not represent the full extent of the complexity of the brain with all its structural and functional constituents, e.g. blood flow, glycocalyx or perivascular space. Furthermore, the properties of the

BBB differ in distinct regions of the vascular tree (i.e. in pial, penetrating, pre- and capillary vessels). The assessments *in vivo* are sparse and often limited to post-mortem evaluation or to crude brain imaging that lacks spatio-temporal resolution to resolve the fate of tested compounds at the BBB interface. Consequently, even promising carrier candidates fail in *in vivo* trials.
METHODS: Here, we used two-photon microscopy in living mice to characterize two distinct trans-BBB drug delivery approaches: (a) Tat cell-penetrating peptide (CPP) delivery system currently employed in clinical trials and (b) fluorescently labeled antibody-conjugated (i.e. targeted) liposome nanocarriers. The imaging data was supplemented with concurrent real-time functional readout of *in vivo* electrophysiology, i.e. systemic blood pressure, exhaled CO2 and neuronal activity.
RESULTS: We show that
a) Fluorescently labeled Tat successfully penetrates the BBB and accumulates in the brain, with slower kinetics of accumulation and clearance of the compound from the blood when conjugated to a therapeutic drug. However, regardless of cargo presence a significant fraction of Tat becomes trapped within specific elements of the BBB, i.e. endothelium in pial and penetrating arteries and in pericytes at the level of precapillary vessels and capillaries.
b) We formulated a novel class of fluorescently labeled endothelial transferrin receptor antibody-conjugated liposomes to track a single carrier nanoparticle at the BBB interface in the living brain. We show that targeted liposome nanocarriers associate over time at the BBB interface, primarily in pre- and capillary vessels, where they exhibit limited lateral motility. Although more stable in the blood than Tat-based compounds, a small fraction of liposomes becomes partially scavenged by circulating leukocytes.
SUMMARY: Understanding how drug delivery systems interact with the BBB, whether these interactions differ within the vascular tree, and characterizing dynamic properties of these interactions is of vital importance for development of novel drug delivery systems to the brain. High spatio-temporal resolution two-photon imaging *in vivo* may be instrumental for optimization of existing approaches and may help to identify new strategies for trans-BBB drug delivery *in vivo*.

Title: Single-domain antibody against insulin-like growth factor-1 receptor (IGF1R) undergoes receptor-mediated transcytosis and delivers pharmacologically efficacious levels of pain-suppressing neuropeptide galanin across the blood-brain barrier

Authors: *W. ALATA, A. YOGI, E. BRUNETTE, U. IQBAL, K. KEMMERICH, M. MORENO, D. STANIMIROVIC
Natl. Res. Council (NRC), Ottawa, ON, Canada

Abstract: The blood-brain barrier (BBB) is one of the biggest challenges for the treatment of neurological diseases, as the majority of biologics do not cross the BBB sufficiently to achieve a pharmacological response. Therefore, it is crucial to develop new delivering technologies suited for delivery of biologics. This can be achieved using receptor-mediated transcytosis pathways that physiologically deliver large molecules across the BBB. In this study, a single domain antibody raised against the extracellular domain of the human insulin-like growth factor-1 receptor (IGF1R) by llama immunization (IGF1R4 V_HH) was evaluated for its: i) ability to transmigrate across an *in vitro* rat BBB model, ii) *in vivo* brain uptake by fluorescence- based *in situ* brain perfusion technique (ISBP), iii) ability to deliver galanin (Gal, non-crossing BBB analgesic neuropeptide) to the brain and induce a central pharmacological response. In contrast to negative control V_HH A20.1, IGF1R4 V_HH antibody showed a saturable BBB transcytosis *in vitro*. ISBP demonstrated that mice perfused with 500 µg of fluorolabeled IGF1R4-Fc-CF790 exhibited a significantly higher total brain fluorescence intensity ($p < 0.05$) and increased distribution volume (Vd, ~4-fold, $p < 0.01$) compared to those perfused with A20.1-Fc-CF790. Brain perfusion with increasing doses of IGF1R4-Fc-CF790 (50 – 800 µg) resulted in a linear accumulation plateauing at approximately 400 µg (~ 1 µM), confirming a saturable mechanism of transport. To evaluate the ability of IGF1R4 V_HH to deliver a drug payload into the brain, IGF1R4 chemically conjugated to Gal (IGF1R4-Gal) was tested in a Hargreaves model of inflammatory pain. As expected, iv injection of Gal alone did not result in any analgesic effect as it does not cross the BBB. In contrast, animals injected with equimolar concentration of IGF1R4-Gal (7 mg/kg) showed a potent suppression of thermal hyperalgesia. A repeated dose (7mg/kg) of IGF1R4-Gal 1 h after the first injection failed to induce additional analgesic effect; however, the analgesic response was recovered when IGF1R4-Gal was injected 24 h post-first injection. Similarly, the brain uptake of IGF1R4-Fc-CF790 perfused 1 h after injection of 7 mg/kg IGF1R4 V_HH was reduced by~ 27% compared to that in saline injected animals; however, the brain uptake was recovered 24 h post injection of IGF1R4 V_HH, suggesting reduced IGF1R capacity to engage new antibody molecules (due to down-regulation or rate of recycling) for a period of time between 1h-24h. In conclusion, IGF1R4 V_HH is a novel single domain antibody targeting IGF1R that shows receptor-mediated transport and ability to deliver pharmacological cargo across the BBB.

Title: Poldip2 depletion blocks COX-2 expression and protects against LPS-induced blood-brain barrier disruption

Authors: D. KIKUCHI[1], A. CAMPOS[3], R. SADIKOT[2], B. LASSÈGUE[1], K. GRIENDLING[1], *M. S. HERNANDES[1]

Abstract: Introduction:
Sepsis is a systemic inflammatory response characterized by endothelial permeability which can be modeled by lipopolysaccharide (LPS). Septic encephalopathy (SE) is a frequent complication of sepsis and a major factor in sepsis mortality and morbidity. The blood-brain barrier (BBB) is compromised in SE, however, the signaling pathways that underlie this disruption require further study. Nuclear factor-κB (NF-κB) modulates the expression of proinflammatory mediators involved in sepsis, including cyclooxygenase-2 (COX-2). COX-2 catalyzes the first committed step of prostaglandin synthesis. In the brain, prostaglandin E2 (PGE2) induces endothelial permeability and facilitates BBB disruption. Polymerase δ-interacting protein 2 (Poldip2) depletion has previously been reported to abrogate BBB disruption following ischemic stroke. Here we investigated Poldip2 as a novel regulator of COX-2 and its downstream signaling.
Methods:
Intraperitoneal injection of LPS (18 mg/kg) was used to induce BBB disruption in Poldip2$^{+/-}$ and Poldip2$^{+/+}$ mice. BBB disruption was assessed by Evans blue extravasation 18 hours after LPS administration and measured spectrophotometrically after formamide extraction of the dye from whole brains. The cerebral cortices of Poldip2$^{+/+}$ and Poldip2$^{+/-}$ mice were isolated 6 hours after LPS injection and expression of inflammatory markers was evaluated by immunoblotting and ELISA. Primary rat brain microvascular endothelial cells were used to investigate the effect of Poldip2 depletion by siRNA on LPS-mediated COX-2 induction and adenovirus was used to study the effect of Poldip2 overexpression on COX-2 expression.
Results:
LPS induced BBB disruption in Poldip2$^{+/+}$ mice (Evans blue: 18±4 μM/g vs. 168±42 μM/g, $p<0.001$). BBB permeability was reduced in Poldip2$^{+/-}$ compared to Poldip2$^{+/+}$ mice 18 hours

after LPS injection (67±13 μM/g vs. 168±42 μM/g, $p<0.05$). In Poldip2$^{+/+}$ cortices, Poldip2, COX-2, and NF-κB expression was upregulated (45%, $p<0.05$, 79%, $p<0.01$ and 33%, $p<0.05$, respectively) after 6 hours of LPS. No induction was observed in Poldip2$^{+/-}$ mice, which had lower levels of COX-2 ($p<0.05$), NF-κB ($p<0.01$) and PGE2 (3744± 834 pg/mL vs. 6173± 488 pg/mL, $p<0.05$) than Poldip2$^{+/+}$ after LPS treatment. Consistent with our in vivo findings, depletion of Poldip2 blocked LPS-mediated COX-2 induction in cultured cells (n=2) and overexpression of Poldip2 induced COX-2 expression (n=1).

Conclusions:

Our data suggest that Poldip2 induces COX-2 and PGE2, thus mediating LPS-induced BBB disruption.

Title: A novel human cell based model for evaluating brain iron uptake of pharmaceutical compounds and ferritin

Authors: B. CHIOU[1], E. NEAL[2], A. B. BOWMAN[3], E. LIPPMANN[2], I. A. SIMPSON[4], *J. R. CONNOR[1]
[1]Neurosurg., Penn State Col. of Med., Hershey, PA; [2]Chem. and Biomolecular Engin., Vanderbilt Univ., Nashville, TN; [3]Pediatric Neurol. Res. Lab., Vanderbilt Univ. MC, Nashville, TN; [4]Penn State Univ. Col. of Med., Hershey, PA

Abstract: Iron delivery to the brain is essential for multiple neurological processes such as myelination, neurotransmitter synthesis and, as it is for all organs, critical for the utilization of oxygen for energy production. Consequently, factors that influence iron transport across the blood brain barrier (BBB) can significantly impact neurological function. Understanding the mechanism by which iron transport across the BBB is regulated is crucial in developing treatments for brain iron deficiency. Using a novel model comprised of human BBB endothelial cells differentiated from induced pluripotent stem cells, we demonstrate the ability for apo-transferrin, holo-transferrin, hepcidin, and DMT1 to impact iron transport across the BBB.

Furthermore, we demonstrate that release of iron from the endothelial cells is similarly impacted by these proteins. Our model further shows a novel function for H-ferritin to transport iron across the BBB by binding to the T-cell immunoglobulin and mucin receptor 1 (Tim-1). We also provide evidence for a novel function of endothelial cells to synthesize and secrete transferrin and H-ferritin, providing another layer of regulation. As a clinical correlate, we also examine 5 pharmaceutical iron formulations given intravenously during clinical treatment of iron deficiency for their ability to cross the BBB. We report that, compared to the positive controls of transferrin and H-ferritin, the pharmaceutical iron formulations do not cross the BBB or significantly load the endothelial cells with iron. Finally, given the novelty of ferritin transport of iron, we provide in vivo evidence for ferritin as an iron transport protein and demonstrate a sex and genotype effect on uptake during development. Our data demonstrate the ability for the brain to modulate and exert exquisite control over iron transport and identifies ferritin as a novel and potent iron delivery protein.

Title: A human stem cell derived blood brain barrier model that provides a translational method to predict adeno-associated virus barrier penetration for therapeutic gene delivery to the brain

Authors: *T. P. GRAY
Translastional Biol., Biogen, Cambridge, MA

Abstract: Adeno-associated virus (AAV) serotype 9 has recently emerged as capsid featuring enhanced blood-brain barrier (BBB) penetration, making it an attractive gene-therapy vehicle to treat neurodegenerative diseases. Based on a recent publication (Merkel et. al J Neurochem), it is a serotype-specific characteristic, as it has been shown that AAV2 does not transport, but transduces the BBB. Of note, to date the AAV9 derivative PHP.B (described in Deverman et al. Nat Biotech 2016) has only demonstrated enhanced penetration in the C57BL6 mouse strain. To resolve the gap of interspecies translation we have designed a ‘human-first’ approach to examine the potential of different AAV serotype candidates for gene delivery across a transwell in vitro BBB model.
Using an array of primary, immortalized, and induced pluripotent stem cell (iPSC)-derived brain microvascular endothelial cells (BMEC) from various species, we have optimized BBB transwell

models for a variety of functional assays, including validation and characterization of AAV serotype-specific penetration, transduction, and species translatability. Human iPSC-derived BMECs are an ideal choice for BBB modeling due to their adult human origin and ability for bulk production to ensure reproducibility. The iPSC-BMECs produced from our optimized differentiation, dissociation and sub-culture conditions (protocol based off Lippmann et al. Nat Biotech 2012) display relevant BBB surface markers including CD31, Glut-1, ZO-1, and occludin. Notably, for iPSC-BMEC in monoculture, we demonstrate transendothelial electrical resistance (TEER) values up to 4000 $\Omega*cm^2$ and extend the functional assay window by sustaining $\geq$1000 $\Omega*cm^2$ TEER for a week post dissociation, significantly above our cutoff of 500 $\Omega*cm^2$ for functional assays to ensure no passive diffusion of large molecules and AAV across the BBB.
We have started validating our BBB models with AAV2, AAV9, and PHP.B loaded with a fluorescent payload and found serotypes to behave differently in transcytosis and transduction, of both endothelial cells and human iPSC-derived neurons cultured in the basolateral compartment. Importantly, the latter demonstrates that capsids that have undergone transendothelial transcytosis are still fully functional and able to transduce cells "behind the BBB". We conclude that our model shows potential to be an efficient way to predict which serotypes and engineered capsid modifications may improve endothelial cell barrier penetrance, transduction, and facilitate the translation between animal models and human, altogether holding promise to increase the probability of success in gene therapy research and development.

Title: Intranasal delivery of full-length immunoglobulin G antibodies to the central nervous system in APP/PS1 and non-transgenic mice: Feasibility, permeation enhancement and implications for Alzheimer's disease immunotherapy

Authors: *G. NEHRA[1], N. N. KUMAR[1], K. VANG[1], T. XIE[1], R. G. THORNE[1,2,3,4]
[1]Sch. of Pharm., [2]Clin. Neuroengineering Training Program, [3]The Ctr. for Neurosci. and Neurosci. Training Program, [4]Cell. and Mol. Pathology Grad. Program, Univ. of Wisconsin-Madison, Madison, WI

Abstract: The intranasal route can non-invasively deliver large macromolecules into the central nervous system (CNS), bypassing the blood-brain barrier, via olfactory and trigeminal nerve pathways that exist in the nasal mucosae (Thorne et al. *Neuroscience.* 2004; Lochhead & Thorne. *Adv Drug Deliv Rev.* 2012). Further widespread distribution occurs along perivascular spaces surrounding major cerebral blood vessels (Lochhead et al. *J Cereb Blood Flow Metab.* 2015). We have previously shown that intranasal delivery of immunoglobulin-G (IgG) can be enhanced by modulating nasal epithelial permeability with intranasal matrix metalloproteinase-9 (MMP-9) pre-treatment in rats. Here, we investigated this effect across species by intranasally administering non-targeted mouse IgG following MMP-9 pre-treatment in 7-10 month old, female APPswe/PS1dE9 and non-transgenic mice. We first quantified acute CNS distribution profiles for a tracer dose of ^{125}I-labeled IgG following saline pre-administration in anesthetized mice (n = 6), showing rapid CNS delivery within 30 minutes in non-transgenic as well as in APP/PS1 mice. Following pretreatment with activated mouse MMP-9 (100 nM; activity validated in-house using a fluorometric assay), we observed a trend for enhanced IgG exposure in multiple CNS regions (n = 6). Confocal imaging of sections obtained from APP/PS1 mice having intranasally administered AF594-labeled IgG following MMP-9 pre-treatment confirmed signal in the brain associated with a compartment adjacent to but not co-localizing with PECAM-1/CD31-positive endothelial cells, i.e. the perivascular space. IgG signal was also evident near insoluble plaques, suggesting the possibility of amyloid-antibody interactions if a targeted IgG were used. We have now initiated a chronic study with 4-month old, awake APP/PS1 mice involving intranasal delivery of a targeted-antibody against the beta-amyloid N-terminus (6E10) over 14 weeks; insoluble plaque burden and olfactory behavior differences will be compared across treatment groups. Overall, our findings offer insights into whether intranasal antibody delivery to the brain is viable and potentially modifiable in APP/PS1 mice. The results suggest the intranasal route may ultimately be useful for future Alzheimer's disease immunotherapy approaches.

Title: Hypoxia-induced vascular responses in the adult mouse brain

Authors: *M. D. SWEENEY, M. T. HUUSKONEN, A. MONTAGNE, C. MURPHY, K. KISLER, Z. ZHAO, B. ZLOKOVIC

Abstract: Mild continuous hypoxia is a phenomenon observed in several central nervous system (CNS) conditions including diabetic retinopathy, chronic hypoperfusion, and Alzheimer's disease (AD). Pericytes, mural cells that enwrap capillaries, become dysfunctional and degenerate in ischemic stroke, diabetic retinopathy and AD. Pericytes are vital orchestrators of key neurovascular functions including blood-brain barrier (BBB) integrity, cerebral blood flow (CBF), and angiogenesis. Increased CBF and angiogenesis are physiological responses in brain elicited by a mild hypoxic state. The transcriptional regulation of these structural/functional hypoxic responses has never before been investigated in the adult brain, nor has its corresponding impact on brain microvascular health. Adult mice exposed to mild continuous hypoxia up to 21 days show both an acute increase in capillary diameter and red blood cell velocity in the somatosensory cortex using longitudinal multiphoton imaging. Additionally, several imaging techniques reveal a progressively increased regional rate of microvascular density accompanied by transient BBB permeability. Moreover, RNA-sequencing analysis of brain microvascular pericytes and endothelial cells during different timepoints of mild continuous hypoxia reveals significant differentially expressed genes of pathways regulating angiogenesis (differentiation, proliferation, migration) and BBB permeability, determined via Ingenuity Pathway Analysis. Altogether, elucidating the transcriptional, structural and functional responses to mild continuous hypoxia in the adult brain is vital to inform therapeutic efforts to combat hypoxic insults and/or microvascular dysfunction in numerous CNS disorders.

Abstract: Brain pericytes are the vascular mural cells located within the basement membrane of blood microvessels. Pericytes maintain blood-brain barrier integrity, regulate cerebral blood flow (CBF) and participate in the clearance of brain toxic byproducts. Much of the knowledge has been gained from studies in mice with inherited pericyte deficiency caused by aberrant signaling between endothelial-derived platelet-derived-growth factor B (PDGF-B) and PDGF-receptor β (PDGFRβ) in pericytes. Here, we report the development of a new murine pericyte-specific Cre line using a double-promoter strategy and show Cre-dependent expression dtTomato reporter only in brain pericytes, but not in oligodendrocytes, oligodendrocyte progenitor cells, vascular smooth muscle cells, brain endothelial cells, astrocytes or microglia. Next, we developed a model with inducible pericyte ablation after diphtheria toxin (DT) administration in adult mice expressing the Cre-dependent human DT receptor (DTR) in pericytes. We show that acute ablation of pericytes leads to neurovascular dysfunction and a series of pathophysiological events that begin with dysregulated cerebral blood flow responses and blood-brain barrier breakdown causing rapid neuronal dysfunction and functional deficits. These data suggest that pericytes importantly keep the integrity of the neurovascular unit and that their loss leads to disruption of the neurovascular unit causing cerebrovascular disorder and white matter and neurodegenerative changes.

Title: Acquisition of BBB properties by the developing brain vasculature is controlled by a retinoic acid-WNT signaling axis

Authors: *S. BONNEY, B. J. C. DENNISON, E. PETERMAN, M. WENDLANDT, J. A. SIEGENTHALER
Pediatrics, Univ. of Colorado Denver, Aurora, CO

Abstract: The formation of a functional blood-brain barrier (BBB) is crucial for the brain vasculature to properly support central nervous system (CNS) health. During development, endothelial cells that form the brain vasculature quickly obtain BBB properties which include the formation of tight junctions and recruitment of BBB support cells called pericytes. Acquisition of these BBB properties is required for vascular stability, thus understanding the developmental signals that regulate this process are important. Endothelial WNT signaling is a known driver of brain vascular development and BBB properties however it is unclear how endothelial WNT signaling is regulated. We recently showed that mouse embryos with disruptions in retinoic acid (RA) synthesis (*Rdh10* mutants) and endothelial RA signaling (*Pdgfbi*^{cre}; *dnRAR403*$^{fl/fl}$) have ectopic WNT signaling in the brain vasculature. Here we show that increased vascular WNT signaling in *Pdgfbi*^{cre}; *dnRAR403*$^{fl/fl}$ and *Rdh10* mutant embryos is associated with elevated expression of the WNT transcriptional effector, β-catenin, in the brain endothelium. These RA mutants also have increased numbers of pericytes along the brain vasculature. However the WNT-regulated tight junction protein, Claudin-5, appears unaltered. Using *in vitro* studies in brain endothelial cells, we show that RA may inhibit WNT signaling by targeting β-catenin for proteasomal degradation. Our data suggests that the inhibition of WNT signaling by RA is important for regulating pericyte recruitment during brain vascular development and this may be mediated through proteasomal degradation of β-catenin. In addition, we find that the downstream WNT target, Sox17, is required for pericyte recruitment to the developing brain vasculature, potentially by directly regulating the expression of the pericyte mitogen PDGFB. Our studies highlight the importance of regulating vascular WNT signaling by RA to ensure proper development of the BBB, most notably through pericyte recruitment. This inhibitory regulation of WNT signaling by RA could be needed to prevent over-recruitment of pericytes that might impair endothelial-pericyte interactions crucial for BBB formation and maintenance.

Title: ApoM deficiency induces an increase in the BBB permeability via the sphingosine-1-phosphate signaling pathway *in vivo*

Authors: *M. M. JANIUREK[1], K. KUCHARZ[1], C. CHRISTOFFERSEN[3,2], L. NIELSEN[4], M. LAURITZEN[1,5]
[1]Dept. of Neurosci., [2]Dept. of Biomed. Sci., Univ. of Copenhagen, Copenhagen, Denmark; [3]Dept. of Clin. Biochem., Rigshospitalet, Copenhagen, Denmark; [4]The Fac. of Hlth., Aarhus Univ., Aarhus, Denmark; [5]Dept. of Clin. Neurophysiol., Rigshospitalet-Glostrup, Copenhagen, Denmark

Abstract: Introduction. Modulation of endogenous signaling pathways that regulate the blood-brain barrier (BBB) permeability represents a potential strategy for increased drug delivery to the brain. Sphingosine-1-phosphate receptors (S1PRs) are surface membrane receptors located on vascular endothelial cells. In a healthy organism, the majority of the S1PR agonist, i.e. sphingosine-1-phosphate (S1P), is transported in the blood by the molecular chaperone, apolipoprotein-M (ApoM), which is a critical part of HDL. Disruption of ApoM-S1P signaling is associated with a permeable endothelial barrier in the lungs. This led us to examine the role of S1P signaling for the BBB integrity.
Aim. To determine the importance of the S1P/S1PR signaling pathway for BBB integrity and function in ApoM knockout mice.
Methods. We used *in vivo*two-photon fluorescence microscopy in ApoM deficient ($ApoM^{-/-}$) mice and in wild-type litter-mates. To monitor BBB permeability in a living brain, water-soluble fluorophores of varying sizes were injected intravenously, and BBB integrity was assessed via a craniotomy over the somatosensory cortex. The accumulation of the fluorophores was measured in real time at cortical depths ranging from 0 to 120 μm relative to the brain surface. Furthermore, transmission electron microscopy (TEM) was applied for a quantitative ultrastructural analysis of the BBB.
Results. Loss of ApoM-mediated S1P transport led to increased permeability towards blood-circulating fluorescent molecules. Compared to wild-type litter-mates, the BBB in $ApoM^{-/-}$mice exhibited a 5-fold increase in the accumulation of small fluorophores (with MW less than 0.65kDa) within 30 minutes post injection. This effect was not observed with larger molecules. Moreover, pharmacological modulation of the S1P/S1PR pathway with an S1PR agonist led to reversal of the phenotype and partially reinstated the BBB integrity. Preliminary data from TEM show a difference in the morphology of the junctional complexes in $ApoM^{-/-}$ mice, with no difference in vesicular components of the endothelium. These results indicate that the loss of the ApoM-mediated S1P transport results in an increased paracellular permeability, while transcellular transport remains intact.
Conclusion. The BBB integrity towards blood circulating molecules can be altered by targeted modulation of the ApoM/S1P/S1PR signaling, implying that this pathway plays an important role in maintaining the integrity of the BBB. Disruption of ApoM/S1P/S1PR signaling may be a

novel method for bidirectional modulation of BBB integrity for increased trans-BBB drug delivery to the central nervous system.

Title: Sphenopalatine ganglion stimulation disrupts tight junction protein architecture and increases blood-brain barrier permeability

Authors: *R. F. SCHMIDT, M. J. LANG, G. P. STRICSEK, R. H. ROSENWASSER, A. D. SHARAN, L. IACOVITTI
Dept. of Neurosurg., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Introduction: The sphenopalatine ganglion (SPG) provides parasympathetic innervation to the anterior intracranial circulation in mammals. Early investigations suggest that SPG stimulation increases blood-brain barrier (BBB) permeability. We demonstrate the effects of SPG stimulation on the BBB by quantifying fluorescent tracer extravasation into brain after specimen homogenization and present a putative mechanism of action by demonstrating disruption of tight junction proteins in stimulated rat brain. Methods: Female Sprague-Dawley rats (235-240g, n=8 rats) underwent intermittent SPG stimulation at 10Hz for 40 minutes with concurrent femoral vein injection of 70kDa FITC-dextran. Five 3mm sections from each cerebral hemisphere were obtained from each rat and homogenized in 7.5% trichloroacetic acid (n=80 specimens). Control rats (n=5 rats, 50 specimens) underwent tracer injection without SPG stimulation. Fluorescence uptake was calculated as the percentage of tracer concentration in the supernatant of homogenized brain to serum concentration. Tight junctions were evaluated in separate control (n=3) and stimulated rats (n=3) that did not undergo tracer injection. 20µm brain sections were fixed in 100% methanol and stained for rat endothelial cell antigen (RECA-1) and the tight junction proteins occludin or ZO-1. 20X images (n=120 each group) were obtained and the percent overlap of occludin or ZO-1 with RECA-1 was quantified using a computerized colocalization algorithm. Results: There was a 6-fold increase in fluorescence uptake in 10hz stimulated specimens compared to controls (0.28% vs 1.66%, t-test, &lt<0.0001). Additionally, there was a statistically significant decrease in the overlap of occludin and ZO-1 staining with

endothelium in stimulated rats (74.6% vs 39.7% and 67.1% vs 60.5%, respectively, &lt<0.0001 for both).Conclusions: Prolonged SPG stimulation at 10Hz increases BBB permeability, demonstrated by increased fluorescent tracer extravasation seen in homogenized rat brain specimens. Stimulation also appears to disrupt tight junction proteins, providing a possible mechanism for increased BBB permeability. Bypassing the BBB with SPG stimulation could open the door for new paradigms of therapeutic delivery for disorders of the CNS.

Abstract: Carbogen was introduced nearly a century ago as a treatment for psychiatric disorders. We report here that carbogen induced BBB disruption indicated by extravasation of an intravenous protein tracer. When the tracer was injected immediately or 1-24 h post-carbogen inhalation, little or no detectable tracer was detected in the rat brains, suggesting the rapid reversibility of this response after carbogen exhalation. Despite marked BBB disruption, inhalation of carbogen for 30-90 min had no long-term effects on body weight, food intake, locomotor activity, or learning and memory performance. Our study introduced carbogen as a potential inhaled agent for BBB disruption.

Title: Cellular response following focused ultrasound mediated blood-brain barrier opening: A two-photonmicroscopy study

Authors: *C. POON[1], K. HYNYNEN[2]
[1]Physical Sci., Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada; [2]Med. Biophysics / Physical Sci., Univ. of Toronto / Sunnybrook Res. Inst., Toronto, ON, Canada

Abstract: Background: Focused ultrasound (FUS) is a non-invasive technique that can be used to deliver therapeutic agents, such as chemotherapeutics and stem cells, to targeted brain regions by temporarily opening the blood-brain barrier (BBB). Safety studies have shown that under controlled FUS parameters and with the addition of an ultrasound contrast agent, FUS can transiently open the BBB without causing erythrocyte extravasation. Two independent groups have provided evidence that FUS-mediated BBB opening itself, without the use of therapeutics, reduces Aβ plaque load and improves memory functions in mouse models of AD.
Rationale: The cellular response following FUS is currently unknown. An acute inflammatory response has been reported at six and 12 h following FUS. Transient inflammatory responses have been shown to promote Aβ plaque clearance and may be a mechanism by which FUS decreases Aβ plaque load.
Methods: To follow the cellular immune response following FUS-mediated BBB treatment, EGFP Wistar rats [Wistar-TgN(CAG-GFP)184Ys], which harbour GFP-positive leukocytes, were used in this study. A 5-mm craniotomy was prepared on the parietal bone for two-photon fluorescence microscopy. FUS was delivered using a ring transducer positioned over the craniotomy; increased BBB permeability was assessed by the leakage of a fluorescent dextran from the intra- to extravascular space. Cell identity was determined using immunohistochemistry.
Results: FUS treatment causes an activation of the neurovascular unit, leading to glial cell activation and recruitment of peripheral immune cells. Blood flow is also transiently affected.
Conclusion: FUS treatment to open the BBB is currently already in clinical trials for AD. However, much of the biological mechanisms behind its effects are unknown. These studies will determine the cell types involved and elucidate possible molecular pathways that are activated.

Title: Monosodium glutamate-induced neonatally excitotoxicity modifies regionally the blood-brain barrier properties in the adult male rat

Authors: *B. F. FAJARDO-FREGOSO, J. L. CASTAÑEDA-CABRAL, C. BEAS-ZÁRATE, M. E. UREÑA-GUERRERO
Cell. and Mol. Biol., Univ. de Guadalajara (CUCBA), Zapopan, Mexico

Abstract: The Blood-Brain Barrier (BBB) is essential to maintain the central nervous system homeostasis. Plasmalemmal vesicle associated protein-1 (PV1) is considered a marker of BBB immaturity and claudin-5 is an essential component of the tight junctions. Several pathological states that course with excitotoxicity also show an increased vascular permeability in the acute phase, but it is unknown yet, if these changes are lasting. The goal of this work was to evaluate the long-term effects of monosodium glutamate (MSG)-induced neonatally excitotoxicity on BBB properties. Male newborn rats were randomly assigned to intact or MSG-treated group. MSG [4 g/kg of body weight (b.w.)] was subcutaneously administered at postnatal day (PD) 1,3,5 and 7. At PD60, the BBB permeability was evaluated through sodium fluorescein (2.5 ml/g of b.w. of 10% solution) penetrability to the motor cerebral cortex (MC), striatum, hippocampus, entorhinal cortex (EC) and hypothalamus in both normoosmolar and hyperosmolar conditions. Hyperosmolar condition was induced by 10 ml/kg of b.w. of 2.95 M NaCl solution intraperitoneally injected. The levels of protein expression of claudin-5 and PV1 were measured by western-blotting referred to β-actin in MC and hippocampus. Brain studied regions showed the followed fluorescein penetrability gradient: MC<striatum<hippocampus<EC<hypothalamus. No differences were found in normoosmolar condition between groups in any studied region. However, in hyperosmolar condition, fluorescein penetrability was higher in all regions of MSG-treated group, reaching a more significant change in the hypothalamus. The protein expression level of claudin-5 was decreased by MSG treatment, showing a marked decrease in the hippocampus. While PV1 displayed a slight increased expression level in the hippocampus of MSG-treated group. Results indicate that MSG-induced neonatally excitotoxicity has significant long-term effects on the BBB properties: 1) affecting the expression of structural proteins that are determinant in the barrier function, and 2) increasing its susceptibility to a hyperosmotic condition. Then our results suggest that the BBB is more susceptible to disrupt after an excitotoxic process, which it must be widely studied.

Title: What are the molecular mechanisms of blood-brain barrier dysfunction in disease?

Authors: *C. P. PROFACI[1], K. BAJC[1], S. H. FU[1], J. P. MILLER[2], T. Z. ZHANG[1], R. DANEMAN[1]
[1]Univ. of California San Diego, La Jolla, CA; [2]Univeresity of California San Diego, La Jolla, CA

Abstract: The blood-brain barrier (BBB) is a set of properties unique to central nervous system (CNS) endothelial cells (ECs) that comprise the inner walls of blood vessels. In contrast to peripheral vessels, which allow extensive exchange of molecules and ions between the blood and tissue, CNS ECs exert tight control over what can enter the parenchyma. BBB dysfunction is a key component of many neurological conditions, including multiple sclerosis, stroke, epilepsy, and traumatic brain injury. Despite the vastly different triggers of these diseases, in each case vascular permeability causes an influx of blood-borne molecules, disruption of ionic homeostasis, and an increase in immune cell extravasation. These events contribute to the dysfunction, damage, and even degeneration of neurons, ultimately worsening clinical outcomes. Identifying common molecular changes in ECs during disease could point towards a therapeutic target for reducing BBB dysfunction in wide range of neurological diseases.
To investigate the molecular changes occurring in CNS endothelial cells during disease, we isolated endothelial cells from four disease models during BBB dysfunction and performed RNA sequencing. A set of 198 genes was upregulated across multiple conditions, suggesting a common pathway for BBB dysfunction regardless of the trigger of disease. To further probe this BBB dysfunction pathway, I took a two-pronged approach, investigating which other cell types might induce these endothelial changes as well as the mechanism by which these common transcriptional changes lead to BBB permeability.

Title: Factors influencing therapeutic antisense oligonucleotide distribution in the CNS following intrathecal administration: Implications for neurodegenerative diseases

Authors: *B. WILKEN-RESMAN[1], M. E. PIZZO[1], R. G. THORNE[1,2,3,4]
[1]Div. of Pharmaceut. Sci., [2]Inst. for Clin. and Translational Res., [3]The Ctr. for Neurosci. and Neurosci. Training Program, [4]Cell and Mol. Pathology Grad. Program, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Antisense oligonucleotide (ASO) therapies administered intrathecally for CNS indications have moved forward in recent years, e.g. FDA approval for an ASO used for spinal muscular atrophy and several clinical trials for other neurodegenerative diseases such as Huntington's disease and ALS in progress. ASOs are attractive therapeutic candidates for diseases caused by known genetic abnormalities because they can manipulate target mRNA to modify or block protein production.

ASOs are unable to cross the blood-brain barrier, so they must be administered centrally. Despite the use of the intrathecal route in most studies testing ASOs for brain and spinal cord diseases, the CNS distribution of ASOs after intrathecal administration and the factors that help or hinder this distribution have not been well described in the literature. Here, we investigated ASO transport in the CNS, focusing on the effects of different ASO chemistries and the two mechanisms thought to govern the distribution of macromolecules in the brain: diffusion through extracellular spaces and convective flow through perivascular spaces (Pizzo et al. *J Physiol*, 2018).

We compared the diffusion and CNS distribution of two different clinically relevant ASO chemistries: a 1st generation phosphorothioate-modified ASO and a 2nd generation ASO with a 2' sugar modification. Both ASOs were covalently attached to AF488 fluorophores for detection. ASO free diffusion was measured in dilute agarose using integrative optical imaging, yielding free diffusion coefficients (37°C) of 1.88 ± 0.03 x 10^{-6} cm^2/s (mean ± sem; n=29) and 2.14 ± 0.02 x 10^{-6} cm^2/s (mean ± sem; n=14) for the 1st generation ASO and the 2nd generation ASO,

respectively, and apparent hydrodynamic diameters of approximately 3-4 nm for each monomer, as expected.
Intrathecal administration of the same ASOs was conducted in rats and the resulting distribution was visualized using *ex vivo* fluorescence and confocal microscopy. Our preliminary results showed a substantially more limited distribution for the 1st generation ASO as compared to the 2nd generation ASO. This comparison suggests that ASOs may experience additional sources of hindrance aside from size (e.g. binding or electrostatic interactions) that may limit their distribution in the brain.

Title: Altered cerebral capillary densities and cognitive performance in neuronal HIF-1α/HIF-2α knockout mice

Authors: J. C. LAMANNA, V. MISTRY, A. ABDOLLAHIFAR, *K. XU
Dept Physiology/Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: Hypoxia-inducible factor-1α (HIF-1α) and hypoxia-inducible factor-2α (HIF-2α) are transcription factors critical to the neurobiological response to hypoxia, a condition when the body is low in oxygen, by inducing short-term vasodilation and long-term angiogenesis. Angiogenesis is also strongly related to cognitive improvements. In this study we investigated the effect of neuronal knockout of HIF-1α/HIF-2α on cerebral capillary densities and cognitive performance and in mice. We use floxed HIF-1α/HIF-2α (HIF-1α$^{F/F}$ /HIF-2α$^{F/F}$) as controls. For neuronal knockout (KO), calcium/ calmodulin-dependent kinase (CAMKII)-Cre were used. Mice were 2-3 months of age. Y-maze tests were used to evaluate cognitive function. Microvascular density (N/mm^2) was determined by GLUT-1 immunohistochemistry. The capillary density in neuronal HIF-1 KO mice (451 ± 56, n = 6) was similar to that of the control mice (413 ± 57, n =8). Compared to the control mice, the neuronal HIF-2α KO mice had significantly higher capillary density in cortical brain (422 ± 64, n =8 vs. 498 ± 60, n = 7). The HIF-2α KO mice and HIF-1α/HIF-2α KO mice showed a decrease in cognitive Y-maze performance (presented as decreased alternation rate or decreased activity for exploring). Our data suggest that knockout of neuronal HIF-1α/HIF-2α altered the baseline brain capillary density and cognitive performance, HIF-1α and HIF-2α may play different roles in controlling capillary density in brain.

Title: A constrained model of extracellular space using literature parameters and Monte Carlo simulation

Authors: *C. NICHOLSON
Physiol. & Neurosci., New York Univ., New York, NY

Abstract: I present a constrained 3D model of the ECS in rodent cortex using literature data derived from studies of molecular diffusion in the extracellular space (ECS) combined with Monte Carlo simulation. Measurements using the Real-Time Iontophoresis method with tetramethylammonium give a typical tortuosity value of 1.6 and a volume fraction of 0.2 [1]. This may be decomposed into a contribution of tortuosity = 1.2 for the interstitial viscosity [2], and a contribution of tortuosity = 1.33 from geometrical constraints. Packed convex cells separated by a uniform ECS width are known to only contribute tortuosity = 1.18 for this volume fraction [3] meaning that dead-space microdomains must make up the missing geometrical tortuosity. Measurements with the Integrated Optical Imaging method using macromolecules of different sizes together with application of restricted diffusion theory suggest that the typical width of the ECS is 40 nm [4] [5]. This set of constraints determines a basic cellular structure (BCS), which is arrived here at by Monte Carlo simulation. The ECS models consisted of 32 x 32 x 32 BCS each comprised cubes of side 2*a* with either cubic voids of side *b* ("sheets and voids model") or tunnels with square cross-section of side *b* ("sheets and tunnels model" [6]) to form the dead spaces. The BCS were separated by 40 nm. An instantaneous point-source of 25000 point molecules was placed in the ECS in the center of the BCS ensemble and a Monte Carlo simulations performed with MCell software [7] using a range of *a* and *b* values and the resulting tortuosities measured. It was found that there were unique values of *a* and *b* that resulted in tortuosity = 1.33.

Title: Sleep in crayfish: Relation between brain electrical activity and autonomics variables

Authors: M. OSORIO-PALACIOS, I. OLIVER-DOMÍNGUEZ, L. MONTIEL-TREJO, *K. MENDOZA-ANGELES, J. HERNÁNDEZ-FALCÓN
Univ. Nacional Autónoma de México, México, Mexico

Abstract: In vertebrates like mammals and birds two types of sleep have been described: rapid eye movement (REM) sleep and no-REM sleep. Each one has a specific brain electrical activity, and is accompanied of changes in cardiac and respiratory frequencies. Slow wave sleep has been described in some invertebrates. Crayfish sleep fulfills behavioral and electrophysiological criteria defined for vertebrates. In this animal, heart and respiratory frequencies are modified by diverse changes in its environment during wakefulness. However, we do not know if this animal has sleep phases and what is the behavior of cardiorespiratory activity during sleep. The main goal of this work was to search for sleep phases in crayfish, and if there is any correlation with cardiorespiratory activity. We used adult male crayfish *Procambarus clarkii* in intermolt, synchronized to light-dark cycles 12:12. In cold anesthetized animals we implanted electrodes on deutocerebrum, both gill chambers, and cardiac sinus. After two days of recovery, we recorded, simultaneously, behavioral and electrical activity during 8 continuous hours. For behavioral records, we defined three conditions of the animal: wandering, immobile or lying on one side, and associated each one with the time of recording. To analyze brain electrical activity for each condition we used wavelet transform. We measured cardiac and respiratory rates during all recording conditions. We found that crayfish can sleep lying on one side or when it is motionless. The depth of sleep (measured as the power of electroencephalographic activity) change over time and is accompanied by oscillations in cardiorespiratory frequency. In conclusion, we propose that in crayfish there are phases of sleep.

Title: Validation of developmental sleep disruption using an orbital shaker in the prairie vole (microtus ochrogaster)

Authors: *M. E. KAISER, C. E. JONES[1], R. A. OPEL[2], M. M. LIM[3,4]
[1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Portland VA Res. Fndn., Portland, OR; [3]Veterans Affairs Portland Hlth. Care Syst., Portland, OR; [4]OHSU, Portland, OR

Abstract: Early life sleep may play a critical role in development of adult behaviors. Research in our lab suggests that prairie voles (*Microtus ochrogaster*) subjected to early life sleep disruption (ELSD) have a reduced preference for a mate, increased neophobia, and locomotor hyperactivity as adults. Sleep disruption was accomplished by housing litters of voles on a standard laboratory orbital shaker for one week with both parents present in the home cage. In two experiments, we validated the specificity of this method for early life sleep disruption by 1) characterizing sleep stages in juvenile prairie voles housed both on and off the shaker, and 2) observing parental care during ELSD (to eliminate the possibility that the altered behavior observed in ELSD prairie voles later in life is caused by a change in parental care due to sleep disrupted parents). Nine young prairie voles underwent sleep EEG recordings for three days on the orbital shaker and three days at baseline, with order pseudo-randomized. EEG results showed that the orbital shaker caused fragmentation of NREM sleep and reduction of REM sleep. Next, 12 litters of voles (age 14-21 days) were recorded in the morning and afternoon and scored for parental care behaviors such as nursing, huddling, stereotypy, and lack of interaction with pups. Sleep disrupted parents did not significantly alter the total amount of care provided over the 7 day sleep disruption paradigm. In summary, our orbital shaker protocol significantly disrupts sleep in developing pups, while not significantly diminishing total parental care in either male or female parents, indicating that ELSD effects on behavior are likely specific to sleep disruption rather than disruption in parental care received.

Title: Dendritic spine density and morphology on prefrontal pyramidal neurons is altered in adult prairie voles after early life sleep disruption

Authors: *A. Q. CHAU[1], C. E. JONES[2], P. TEUTSCH[1], R. OLSON[1], M. M. LIM[1,2]
[1]Veterans Affairs Portland Hlth. Care Syst., Portland, OR; [2]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Synaptic pruning during development allows for maintenance of proper connections and the elimination of aberrant ones. Rapid eye movement (REM) sleep is critical for pruning and maintaining new synapses formed during both development and learning. We hypothesize that disrupting REM sleep early in life will result in long lasting changes in synaptic density in cortical brain regions. The prefrontal cortex (PFC) is a late-maturing region that modulates higher order social and cognitive functions. Abnormally high dendritic spine density in the PFC is implicated in neurodevelopmental disorders. Emerging research in our lab suggests that selectively suppressing REM sleep early in life in the socially monogamous prairie vole (Microtus ochrogaster) impairs social development and increases inhibitory interneurons in the PFC. Using Golgi-Cox staining in adult prairie vole post-mortem tissue, we quantified dendritic spines in the prefrontal cortex in adult animals that underwent early life sleep disruption (ELSD). In males, ELSD increased spine density and decreased spine width selectively in the apical oblique distal (> 90 μm) segments of pyramidal neurons in prelimbic cortex layers II/III. Distal dendrites reflect long range inputs from further cortical and thalamic regions, suggesting that ELSD may lead to an impaired ability to integrate sensory information. Ongoing work will examine dendritic spine density and morphology earlier in development and in additional brain regions, including other brain regions and layers of the PFC. Results from these studies will

enhance our understanding of how modulation of sleep early in life contributes to the neuropathology of developmental disorders.

Title: Early life sleep disruption increases cortical parvalbumin and impairs social and behavioral development in prairie voles

Authors: *M. M. LIM[1,2], A. Q. CHAU[1], D. L. COCKING[1], J. R. QUINTANA[3], E. A. HAMMOCK[3], C. E. JONES[2,1]
[1]Veterans Affairs Portland Hlth. Care Syst., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Across species, juveniles sleep more compared to adults, with disproportionately more time spent in REM sleep stages in the young. One function of REM sleep may be to facilitate the timing of GABAergic parvalbumin interneuron expression in the developing brain, a function critically important for tuning of excitation and inhibition. Here, we show that one week of REM sleep deprivation during a sensitive postnatal window of development increases parvalbumin-immunoreactivity in the cortex of prairie voles (*Microtus ochrogaster*), a highly social rodent species that forms lifelong pair bonds with other individuals. Prairie voles subjected to this protocol of early life sleep disruption failed to form pair bonds, showed locomotor hyperactivity, and showed more neophobia when presented with novel objects, compared to control subjects. There was a strong effect of sex on both parvalbumin-immunoreactivity and behavior testing, with impairments predominating in male animals. Taken together, these results may be reminiscent of the pathology and phenotype seen in autism spectrum disorder, a developmental

disorder characterized by disrupted sleep, altered cortical parvalbumin, and social impairment. We propose that sleep in early life plays a crucial role in the tuning of inhibitory neural circuits and the subsequent development of species-typical social behavior, and that sleep itself may play a causal role in the pathogenesis of neurodevelopmental disorders.

Title: Acute footshock stress increases ethanol preference in adult prairie voles after early life sleep disruption

Authors: *C. E. JONES[1,3], P. TEUTSCH[3], A. E. RYABININ[1], M. M. LIM[2,3]
[1]Behavioral Neurosci., [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR; [3]VA Portland Healthcare Syst., Portland, OR

Abstract: Early postnatal experience is important for shaping the development of the stress response. Across species, juveniles sleep more compared to adults, and early life sleep may represent an environmental factor associated with later life dysregulation of the behavioral and physiological response to stress. We show that one week of early life sleep disruption (ESLD) during a sensitive postnatal window of development interferes with the development of cortical GABA-ergic interneurons and impedes normal social development in the prairie vole (*Microtus ochrogaster*), a translational rodent model of social attachment. In addition to social impairments, adult prairie voles subjected to ELSD showed increased ethanol preference and ambulation in an open field after an acute footshock stressor, compared to control animals. This is reminiscent of neurodevelopmental disorders in humans that include comorbid anxiety and enhanced stress reactivity. We propose that early life sleep has a crucial role in the development

of neural circuits that underlie species-typical social behavior and stress reactivity, and that disrupted sleep may play a causal role in the pathogenesis of neurodevelopmental disorders.

Title: Taar1 agonism promotes wakefulness without impairment of cognition in cynomolgus macaques

Authors: *A. V. GOONAWARDENA[1], S. R. MORAIRTY[1], R. DELL[1], T. WALLACE[1], A. WILLOUGHBY[1], M. C. HOENER[2], T. S. KILDUFF[1]

Abstract: Trace amine-associated receptor 1 (TAAR1) is a GPCR with affinity for the trace amines. TAAR1 agonists have pro-cognitive, antidepressant- and antipsychotic-like properties in both rodent and non-human primates (NHPs). TAAR1 agonism has also been shown to increase wakefulness and suppress REM sleep in both mice and rats and to reduce cataplexy in two mouse models of narcolepsy. We investigated the effects of TAAR1 agonism in Cynomolgus macaques, a diurnal species that exhibits consolidated night-time sleep. We also extended our evaluation of the cognitive-enhancing potential of TAAR1 agonists in macaques by testing the acute effects of a TAAR1 partial agonist in a delayed match-to-sample (DMTS) test of working memory (WM). Adult, male Cynos (n=6) were implanted with epidural electroencephalograph (EEG) electrodes above left and right frontal cortex referenced to occipital cortex (Fp1-Oz and Fp2-Oz), and electromyogram (EMG) electrodes in the trapezius. Animals were kept under LD12:12; all studies were within-subject designs. For the sleep study, the partial TAAR1 agonist RO5263397 (0.1, 1 and 10 mg/kg; p.o.) was administered 30 min prior to lights off. EEG/EMG activity was scored in 30s epochs using guidelines of the American Academy of Sleep Medicine for scoring human sleep records and polysomnographic and spectral power measures were assessed during the initial 6h [Zeitgeber hour (ZT)13 to 18] following lights off. For cognition, animals were trained on a visual DMTS test to assess WM using 2 and 10-sec delays between the sample and choice phases; correct choices were rewarded with a food pellet. The same doses of RO5263397 were administered 30 min prior to testing DMTS. When compared to vehicle (VEH) treatment, R05263397 (10mg/kg) produced significant increases in Wake from ZT15 to ZT18,

reductions in both REM (ZT16 and ZT18) and NREM (ZT16 to ZT17) sleep, increases in wake after sleep onset (WASO) and decreases in sleep efficiency, NREM/REM cycles and REM/NREM ratio. EEG power analysis revealed significant increases in delta and theta power and reductions in alpha, sigma and beta power during Wake and significant increases in delta power and decreases in alpha, sigma, beta and low gamma power during REM sleep following the 10mg/kg dose compared to VEH. No significant change in DMTS accuracy (% correct) was observed at either delay at any dose of R05263397 compared to VEH, a paradigm previously shown to produce deficits with diazepam. These results indicate that effects of the TAAR1 partial agonist R05263397 has wake-promoting and REM-inhibiting effects on NHP sleep as previously described in rodents, properties that are desirable in a narcolepsy therapeutic.

Title: Sleep rebound after acute stress exposure in high- and low- yawning sublines of rats

Authors: *A. FIERRO-ROJAS[1], C. CORTES[1], J. EGUIBAR[1,2]
[1]Lab. of Behavioral Neurophysiol. and Motor Control. Inst. of Physiol, [2]Res. Office, VIEP. Benemérita Univ. Autónoma de Puebla., Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The sleep rebound is a homeostatic response that varies in base of the susceptibility of the subjects (Ss). Stress exposure during wake time can lead to a change on sleep-wake pattern. Specifically acute stress exposure produces sleep rebound, which consists on an increase on sleep duration and sleep bouts due to a decrease in sleep-induced by stress. The sleep rebound can be observed during waking phase, 9 h after acute stress exposure and can last more than 6 h. We selectively bred two sublines from Sprague-Dawley rats which differ on their spontaneous yawning frequency, high-yawning (HY) rats has a mean of 20 yawns/h and the low-yawning (LY) just 2 yawns/h. The LY rat also showed anxious responses when are evaluated on standardized tests compared to the HY. The aim of this study was to assess the changes in the sleep-wake pattern after acute stress on both sublines.

We used 8 male of HY and LY sublines at 3 months of age. All Ss were implanted to record EEG, EMG and EOG to characterized sleep-wake phases. Baseline EEG of 24 h were obtained on the first day beginning at 0800. The following day placed on acrylic restrictor for 60 min at 0700. During restrain we recorded every 5 min the behavior display including strong mobility, struggling, rotation, biting and audible vocalizations, and also light mobility such as: chewing, yawning, grooming, gnawing and number of fecal boluses. Then, an additional 24 h sleep-wake recording was made. All procedures followed the NIH rules and the protocol was approved by BUAP-IACUC.
Acute restraint induced strong mobility displayed in the first 5 min that decreased over time ($P<0.5$) in both sublines. Light mobility was higher after 45 min in the HY rat compared to the LY rat ($P<0.5$). After the acute restraint there was an increase of the number and duration of non-rapid eye movement sleep (NREM) in the HY 6 h after restraint stress ($P<0.5$), and there was also an increase on the number of rapid eye movements sleep (REM) bouts 9 h after restraint. However, LY rat during restrain displayed more strong behaviors and higher REM sleep rebound respect to HY ($P<0.5$).
In conclusion, LY rats are higher responders to acute stress that affect the homeostatic mechanisms of sleep supporting its anxious trait.

Title: GABAergic neurons in substantia nigra promote sleep

Authors: *D. LIU[1,2], C. MA[1,2], W.-C. CHANG[1,2], Y. DAN[1,2]
[1]Mol. and Cell Biol., Univ. of California Berkeley, Berkeley, CA; [2]Howard Hughes Med. Inst., Berkeley, CA

Abstract: Falling asleep is normally associated with the inhibition of arousal systems and decrease in voluntary motor activity. Lesion of the substantia nigra, an important nucleus for motor regulation, can cause hyperactivity and insomnia, suggesting that it could also play a role in sleep regulation. Here we show that GABAergic (γ-aminobutyric-acid-releasing) neurons in the substantia nigra pars reticulata (SNr) are causally involved in sleep regulation. Activation of these neurons, either optogenetically or chemogenetically, promoted both non-REM and REM sleep, while inactivation greatly increased wakefulness. Further examination of mouse behavior

showed that optogenetic activation of SNr GABAergic neurons modulated the naturally occurred behavior state transition. Anterograde and retrograde tracing showed that in addition to direct innervation of medial thalamus (mTH), superior colliculus and brainstem motor centers, SNr GABAergic neurons also project to wake-promoting neurons in arousal centers, allowing them to coordinate the modulation of motor activity and brain states. Activating the SNr projection to mTH significantly increased NREM sleep, possibly through its direct inhibition of thalamo-frontal activities. Finally, enhancing the excitatory inputs to SNr GABAergic neurons by activating the neurotensinergic neurons in subthalamic nucleus (STN) also promoted NREM sleep. Together, these results revealed the involvement of a motor suppression circuit - STN-SNr-mTH - in sleep regulation.

Title: Contextual fear conditioning produces robust sex differences in non-freezing behaviors and hippocampal EEG activity

Authors: *P. A. GEIST, S. DATTA
Univ. of Tennesee, Knoxville, TN

Abstract: Pavlovian fear conditioning has been routinely used as an animal model of human stress and anxiety disorders. However, fear conditioning studies have produced results with limited translational value to human research. In this study, we used holistic behavior categorization, hippocampal EEG recordings, and defecation as a sign of sympathetic activation to more closely approximate human fear. To accomplish this, ten male and ten female Sprague-Dawley rats with chronically implanted hippocampal EEG recording electrodes underwent a four-day contextual fear-conditioning paradigm. After each experimental condition, EEG activity was continuously recorded for twenty-one hours of their sleep-wake activities. Contextual fear-conditioning (CFC) behaviors were categorized as exploration, grooming, fleeing, apprehension, or freezing. We used Fast Fourier Transforms (FFT) to analyze EEG activity. The results of this study revealed a sex-dependent change in time spent in each behavior. Males spent more time performing apprehensive behaviors while females predominantly froze. Females also showed a significant increase in defecation over males. Males and females also displayed different patterns

of fear-related behaviors that would have been overlooked if only freezing responses were measured. These results suggest differences between sexes in contextual fear training and fear extinction (CFE) processes. In addition, hippocampal EEG activity showed sex dependent effects. Males showed a decrease in delta power while females displayed an increase. Both males and females displayed an increase in theta power, but males displayed a significantly greater increase and displayed changes earlier than females. Examining the relationship between the EEG activity and fear behaviors, hippocampal EEG activity and time spent in fear behavior were significantly correlated only when apprehensive behaviors were included with freezing behavior. These results demonstrate that combining more robust non-freezing behavioral and physiological fear responses can improve fear conditioning studies. Due to the highly conserved nature of physiological fear responses across species, this has important implications for the improved translation of animal research to human therapies.

Title: Brain derived neurotrophic factor mediates regulation of sleep and cognition via changes in synaptic transmission

Authors: *R. D. THAKKAR[1], P. A. GEIST[4], J. GARNER[2], S. DATTA[3]
[1]Dept. of Psychology, [3]Anesthesiol. and Psychology, [2]Univ. of Tennessee, Knoxville, TN; [4]Univ. of Tennesee, Knoxville, TN

Abstract: Brain derived neurotrophic factor (BDNF) is a widely expressed neurotrophic factor in the brain. Its role in growth, differentiation, and maintenance of neurons is well known. We have recently shown that heterozygous BDNF global knockdown (KD) leads to memory deficits and alterations in cortical and hippocampal EEG power in male and female rats. We further confirmed that this KD also led to significant reduction in REM sleep in both male and female rats. However, the molecular mechanisms underlying these cognitive and sleep changes remain to be understood. In the present study, we used protein analyses to examine the expression of molecular markers that regulate synaptic transmission in the cortex and hippocampus of wild-type and BDNF KD rats. The results of this study revealed that the expression of post-synaptic density marker, PSD95, was significantly reduced in male and female BDNF KD rats. However,

the expression of pre-synaptic markers like, synaptophysin and vesicular glutamate transporter 2 (vglut2), was increased in the BDNF KD male and female rats. These results suggest that BDNF-mediated regulation of these markers is lost, leading to disruption in synaptic transmission, following BDNF KD. These changes in synaptic markers, in both male and female rats, are correlated to BDNF-mediated changes in sleep and cognition. Collectively, our studies show that BDNF may drive cognitive plasticity, coordinate EEG activity, and modulate REM sleep via regulation of synaptic markers. Our study contributes to the understanding of altered BDNF pathways and the impact of downstream molecular signaling on sleep and cognition. This novel understanding may be useful for the development of therapeutic targets for neurodegenerative disorders as well as several psychiatric disorders that present sleep and cognitive deficits.

Title: A novel insight into the relationship between depression and sleep: The transitional sleep period between non-REM and REM sleep is altered in a depressive rodent phenotype

Authors: *A. BARNES[1], S. DATTA[2]
[1]Anesthesia Res., Univ. of Tennessee Hlth. Sci. Ctr., Knoxville, TN; [2]Anesthesiol. and Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Sleep alterations are well-documented phenomena in depressive disorders. The two most common observations are altered sleep spindles and reduced REM (Rapid Eye Movement) sleep latency. Interestingly, sleep spindles are observed in Stage 2 non-REM sleep and in the transitional sleep stage (tR) between non-REM and REM sleep. However, the biological mechanisms involved in tR are not well understood, and depression-related changes in tR have not been investigated. These unexplored changes in tR could reveal a relationship between depression-related alterations in non-REM and REM sleep, as well as provide insight into the biological mechanisms of tR. Here, we hypothesize that a long photoperiod model of depression in rodents produces changes in tR, and these changes are associated with changes in non-REM sleep architecture. Twelve control (n=6 male, n=6 female) and twelve experimental (n=6 male, n=6 female) rats were implanted with electrodes to enable the recording of sleep-wake (S-W) activity. Then, control animals were housed in a normal (12L:12D) light cycle, and experimental

animals were housed in a long photoperiod (21L:3D) light cycle. S-W activity was recorded for 24 hrs every four days for two weeks, and recordings were scored for wakefulness, non-REM, REM, and tR sleep. After two weeks, animals were tested for anxious, anhedonic and helpless behaviors. The results of this study revealed that long photoperiod rats showed increases in tR compared to control rats, and the largest increases occurred within the first hours of the altered light cycle. This increase in tR was not related to an increase in REM sleep. However, in long photoperiod animals, a reduction in REM sleep latency from Day 1 to Day 13 was observed. Additionally, the relationship between non-REM and REM sleep architecture was visibly altered in the long photoperiod condition compared to controls. No sex differences were observed. The results of this study suggest that changes in tR could be involved in the neurobiological underpinnings of depression-related sleep changes. Additionally, these results imply that there may be overlap between the biological basis of depression and the neural mechanisms involved in transitioning from non-REM to REM sleep.

Title: Sleep deprivation increases the duration of ketamine anesthesia and selectively potentiates latency of post-anesthesia rapid eye movement sleep

Authors: *B. MITCHELL[1], P. A. GEIST[3], S. DATTA[2]
[1]Psychology, [2]Anesthesiol. and Psychology, Univ. of Tennessee, Knoxville, TN; [3]Univ. of Tennesee, Knoxville, TN

Abstract: Neuronal mechanisms which have evolved to generate traits of sleep are postulated to be involved in mediating the loss of consciousness produced by general anesthesia. Prior studies suggest that propofol anesthesia facilitates recovery from rapid eye movement (REM) and non-REM (NREM) sleep deprivation, but the relationship between dissociative anesthesia and sleep remains incompletely explored. In this study, we examined the effects of ketamine anesthesia on the sleep-wake (S-W) cycle and the extent to which this relationship is modulated by sleep deprivation. To achieve this, electrodes were chronically implanted in adult Sprague-Dawley rats to enable recording of S-W activity using cortical electroencephalogram (EEG), hippocampal EEG, and nuchal electromyography (EMG). After surgical recovery and habituation to recording

sessions, we administered an anesthetic dose of ketamine (100mg/kg, IP) to both non-sleep deprived and sleep deprived rats. Inspection of S-W activity revealed that ketamine anesthesia and subsequent dissociative symptoms suppressed the sleep (both NREM and REM) of all rats for about 6-7 hours. Upon recovery, both non-sleep deprived and sleep deprived rats exhibited a significant rebound in sleep during the dark phase. Analysis of sleep latency across condition revealed that sleep deprivation before ketamine selectively decreased the onset of the first REM sleep episode but did not affect the latency of NREM sleep. We also tested whether sleep deprivation potentiates the onset and duration of ketamine anesthesia—an effect reported in other intravenous and volatile anesthetics—and found that sleep deprivation did not speed up the onset of ketamine anesthesia but significantly extended its duration, suggesting that different categories of anesthetics have distinct interfaces with sleep profile. Taken together, these findings help to clarify the bidirectional relationship between sleep and dissociative anesthesia, and offer insight into shared neuronal mechanisms that generate traits of both states. Most importantly, our study helps determine whether ketamine is relevant for the clinical care of patients with sleep disorders by understanding its effects on sleep architecture in the perioperative setting.

Title: Differential effects of sex, estrous cycle and estradiol on the manic-like behaviors of locomotion, rearing and 50-kHz ultrasonic vocalizations induced by sleep deprivation in Wistar rats

Authors: *C. P. DE SOUZA[1], A. S. DORNELLAS[1], M. WÖHR[2], R. K. SCHWARTING[3], R. ANDREATINI[1]
[1]UFPR, Curitiba, Brazil; [2]Philipps-University of Marburg, Marburg, Germany; [3]Exptl. and Biol. Psychology, Philipps-University of Marburg, Marburg-Biedenkopf, Germany

Abstract: The manic state in Bipolar Disorder (BD) is composed of several complex signs including hyperactivity, pressured speech, hypersexuality, low need for sleep, and impulsivity. Although prevalence does not differ between sexes, symptomatology and comorbidities seem to differ in the clinic. There also seems to be an important influence of hormonal fluctuation and the reproductive cycle on the frequency and severity of manic episodes. Despite this, preclinical

studies with females and the evaluation of hormone fluctuation in mania animal models are scarce in the literature. Therefore, the objective of this study was to investigate the role of sex, estrous cycle and acute estradiol administration in manic-like behavior induced by 24h sleep deprivation (SD) in Wistar rats. Hyperlocomotion and rearing in the open field and the emission of 50-kHz ultrasonic vocalizations (50-kHz USVs), which are related to a state of positive affect, were evaluated. It was observed that female and male rats express different profiles of manic-like behaviors induced by SD. While female animals present higher hyperlocomotion and rearing, males present higher emission of 50-kHz USVs. In addition, it was observed that the estrous phase influences the emission of 50-kHz USVs, which led to an increased number of USVs in females in the peak hormonal phase (proestrus), compared to other estrous phases. This effect was not observed on rearing or locomotor activity. Lastly, it was observed that acute estradiol administration induces an increase in 50-kHz USVs, rearing and locomotor activity in ovariectomized female rats. Thus, we observed sexual differences in manic-like behavior induced by SD, as well as the influence of hormonal fluctuation, specifically the effect of estradiol. The analysis of 50-kHz USVs appears to be more sensitive to hormonal fluctuation in females than hyperlocomotion and rearing and therefore 50-kHz USV appears to be an important and sensitive behavioral parameter to assess the affective state in the mania models. These results support the idea that sex and sex hormones are important factors that need to be taken into consideration in animal modelling of psychiatric disorders.

Title: Effects of an anesthetic dose of ketamine and sleep deprivation-induced rebound sleep on behavioral outcomes

Authors: *K. BURFORD[1], B. MITCHELL[2], R. D. THAKKAR[3], S. DATTA[4]
[1]Univ. of Tennessee-Knoxville, Knoxville, TN; [2]Psychology, Univ. of Tennessee, Maryville, TN; [3]Dept. of Psychology, [4]Anesthesiol. and Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Ketamine, a non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist, has been shown to produce long-lasting behavioral effects at sub-anesthetic doses. However, the

relationship between an anesthetic dose of ketamine and exploration behavior has not been fully investigated. Parallel studies from our lab have indicated that an anesthetic dose of ketamine accrues sleep debt, resulting in a substantial rebound of sleep during the subsequent dark period. In the present study, we examined the effects of an anesthetic dose of ketamine combined with sleep-deprivation induced rebound sleep on exploratory behavior within an open-field paradigm. To achieve this, Sprague-Dawley rats were recorded for baseline cortical EEG and baseline exploratory behavior in the open-field box. Animals with normal sleep or rebound sleep were then subjected to an open-field trial before and after ketamine administration (100mg/kg, IP). The results of this study revealed that rebound sleep prior to testing led to more exploratory behavior in the open-field as compared to animals with a normal sleep profile. Interestingly, animals that received ketamine alone also displayed more exploratory behavior than those who did not receive ketamine, and combination of sleep deprivation and ketamine further potentiated this effect. However, there were no changes in the total locomotion, quantified as total distance traveled, in all three conditions. Taken together, these results suggest that sleep profile modulates the degree to which an anesthetic dose of ketamine increases exploratory behavior. These data suggest that an anesthetic dose of ketamine reduces basal anxiety, which may have implications for behavioral research in rodent models. Finally, our study provides greater insight into the effects of clinically relevant doses of ketamine on cognition and emotion.

Title: Reduced compensatory mechanisms following homeostatic sleep preasure in an animal model for MSA reflect impaired sleep quality in patients

Authors: *T. FENZL[1], L. HÄRTNER[2], V. LEIS[3], M. KREUZER[1], G. WENNING[2], N. STEFANOVA[2]
[1]Tech. Univ. Munich, Clin. For Anesthesio, Munich, Germany; [2]Med. Univ. Innsbruck, Innsbruck, Austria; [3]Leopold Franzens Univ., Innsbruck, Austria

Abstract: Objective and Rationale: Multiple system atrophy (MSA) is a rapidly progressive, fatal neurodegenerative disease. Clinical symptoms include parkinsonism, cerebellar ataxia and

autonomic failure. Sleep related symptoms, such as rapid eye movement sleep behavior disorder (RBD), breathing disorders and restless legs syndrome are also very common in MSA patients and precede MSA diagnosis. The PLP-αSYN mouse model for MSA (MSAm) is very well established with a strikingly similar behavioral phenotype, when compared to the clinical situation. Our recent findings of MSA-related sleep symptoms in MSAm strongly increased face validity and set the stage for a potential predictive validity for the first time. In the present study we challenged the homeostatic equilibrium between sleep and wakefulness to access and to evaluate general sleep quality in MSAm. Methods and Results: We performed chronic EEG recordings on six consecutive days in freely behaving, 24-week old, adult MSAm (n=6) and age-matched C57Bl6 (WT, n=6) control mice. At day 4 of the recording session each animal underwent a sleep deprivation (SD) for 6 hours, starting at experimental time 0 (lights on at 10am, light cycle 12h/12h). We induced sleep deprivation by gentle handling. Two experienced scorers that were blind to each other analyzed the EEG recordings with a semi-automatic scoring routine and a manual rescoring. We performed the temporal and spectral analyses based on these scores. Both, WT and MSAm showed a sleep rebound immediately after the 6h SD. MSAm had a stronger non rapid eye movement sleep (NREMS) rebound, whereas WT showed a stronger (and delayed) rapid eye movement sleep (REMS) rebound. SWA power was higher in the WT during the 2h after SD. In the first lights-off phase after SD, WT and MSAm showed a second NREMS rebound. This rebound happened later in the WT group. The WT animals also expressed higher SWA power during the active period (lights off). Further, WT also developed a second REMS rebound that we did not observe in the MSAm. Conclusions: The response of WT to SD resembles established findings from the relevant literature. In contrast, the circadian shift of compensatory mechanisms during NREMS and lack of rebound effects during REMS on a homeostatic challenge in MSAm clearly demonstrate impaired compensation mechanisms. Together with other EEG-based results in MSAm, previously established in our sleep research group, these profound findings may serve as potential biomarkers for early MSA diagnosis. Given that the development of MSA is combined with a progressive loss in neuronal and synaptic function, our findings in SWA after SD may also support the theory of synaptic homeostasis.

Br., Army Res. Lab., Aberdeen, MD

Abstract: Network analysis has provided new and important insights into the function of complex systems such as the brain by examining the topology of both structural and functional networks constructed from diffusion MRI, functional MRI (fMRI) and electro/magnetoencephalography (E/MEG) data. However, these studies are often limited to the analysis of a single recording or scanning session for each subject, or only compared between two subsequent sessions, raising questions about inter-session reproducibility. Given the prevalence of inter-subject variability in network statistics calculated across multiple subjects for data from a single session, it is important to characterize the reproducibility of network statistics across sessions to assess the sensitivity and stability of network measures to between subject variation. Here, we investigate the reproducibility of network statistics measured in human brain networks by comparing inter-subject and inter-session variability across multiple measures of network structure. We study structural and functional brain networks derived from diffusion imaging, fMRI, and EEG from 30 subjects with 8 sessions of rest and task recordings. The diffusion imaging networks were constructed using a probabilistic tracking algorithm. The functional fMRI networks were constructed using Wavelet-Coherence across five frequency bins from 0.06-0.1Hz. For EEG data, networks were constructed using the de-biased weighted Phase Lag Index (dwPLI) across five frequency bands: δ (1-3Hz), θ (3-7Hz), α (8-13Hz), β (15-30Hz), and γ (30-50Hz). For the resulting networks, we calculated the degree, clustering coefficient, path length, small-world topology, synchronizability, local and global efficiency, spectral radius, and eigenvalue centrality. The Interclass Correlation Coefficient (ICC) was used to assess inter- and intra-subject variability across each network measure. We find that intra-subject reproducibility is higher than inter-subject reproducibility, indicative of the ability to detect individual differences in network structure in human brain networks. Interestingly, for fMRI networks, intra-subject reproducibility increases with the level of cognitive demand associated with tasks. Furthermore, EEG, unlike fMRI, exhibits a dependence upon the frequency band studied, with α (8-13Hz) having consistently higher reproducibility across rest and task.

Abstract: Sleep is essential for maintaining optimal physiology, behavior, and health. Sleep deprivation studies of 24 or more hours reveal impairments to neurocognitive performance. However, this knowledge is derived from substantial sleep loss in laboratory settings where performance is examined directly following sleep loss. In the real world, moderate and consistent sleep loss across days, weeks, or even months can occur, but it is not well understood how longitudinal effects of inadequate sleep influence performance. One central challenge for studying naturalistic sleep is that there is no clear consensus on what sleep parameters are critical for capturing decrements in neurocognitive performance. To address this gap, we use a longitudinal design to study how individual differences in naturalistic sleep influences bi-weekly neurobehavioral performance on a visual working memory (VWM) task.
For 16 consecutive weeks, participants (N=30) wore an Readiband Actigraph SBV2 wristwatch and completed daily sleep diaries to capture both objective and subjective metrics of sleep history. Daily sleep metrics were computed, including sleep duration, sleep efficiency, number of awakenings, and subjective reports of sleep quality. Participants came to the laboratory bi-weekly and completed a VWM task while BOLD responses were monitored using fMRI. Participants were asked to compare the location and color of a single square stimulus (easy) or six simultaneously presented stimuli (difficult) to a previously presented set of stimuli. BOLD data were averaged within 264 regions of a whole-brain atlas (Power et al., 2011), and functional connectivity was computed via wavelet coherence between all region pairs. A linear mixed-effects model was used to assess the relations among daily sleep metrics, pairwise functional connectivity between regions, and VWM performance across the 8 bi-weekly sessions.
Results indicated that sleep metrics derived from actigraphy explained the most variance in

VWM performance. Higher sleep efficiency (sleep duration divided by amount of time in bed) in the two-week period prior to each scan session was related to better VWM accuracy, while higher levels of intra-individual variability in sleep efficiency across the two-week period were related to lower VWM accuracy. Functional connectivity within task-active and aggregated across functional systems was also included as a moderator between sleep and VWM performance. In sum, these results provide evidence that naturalistic sleep fluctuations, especially sleep efficiency, produce systematic effects on cognition that are influenced by global brain dynamics.

Abstract: Individuals have different strengths, and these individual differences help explain a person's overall performance on a given task over time, but performance in any given session can vary. Even experts sometimes perform badly, and can be equal or worse than novices under some circumstances (Beilock et al., 2002). These fluctuations are thought to reflect variability in physiology where modulations in the efficiency of brain dynamics might underlie variable task performance (Raichle, 2010). This relationship is often described in terms of brain state effects on performance. Here, we examine whether recent methodological developments from network

neuroscience (Telesford et al., 2016) can detect changes in brain network connectivity that may determine state-based fluctuations on task performance. Importantly, we utilize a longitudinal study to examine the robustness and stability of the relationship between connectivity and performance within-subject and across five diverse cognitive tasks.
Over four months, participants (N=30) completed eight bi-weekly experimental sessions where simultaneous fMRI/EEG brain data was recorded while they completed five cognitive tasks, including working memory, sustained attention, dynamic attention, emotional valence, and mental arithmetic. The brain was parcellated into 68 regions of a whole-brain atlas (Desikan et al., 2006), and background functional connectivity was computed separately for each imaging modality. The BOLD connectivity was calculated via wavelet coherence (averaged .06-.10Hz) between all region pairs, while the EEG connectivity was computed between pairs of band-passed EEG sources (cLORETA) using a phase locking value (Lachaux et al., 1999). The connectivity timeseries were then used in a community detection algorithm (Garcia et al., 2018) to identify data-driven communities that captured the strength of the relationship between all pairs of regions across time. A graph metric method was used to determine three measures of these communities: 1) network flexibility, how often a node switches between communities, 2) node disjointedness, the probability of a node switching communities on its own, and, 3) module allegiance, the probability that two nodes are in the same functional community (Bassett et al., 2015). Preliminary results found a robustness to the metrics within-task and across individuals, but some shared resources between tasks that may indicate an adaption to retain robust cross-task function. These results display the robust coordination of neural units across tasks, but also the sensitivity (or neural *fragility*) of these network dynamics to fluctuations in brain state.

Title: The relationship between sleep and autonomic health in college students

Authors: *M. D. OLIVER, D. R. BALDWIN, S. DATTA
Univ. of Tennessee, Knoxville, TN

Abstract: Restrictions in sleep are associated with increased stress-related neuroendocrine system activation, which may induce alterations in autonomic control. Investigations into both sympathetic and parasympathetic branches of the Autonomic Nervous System (ANS) have shown that autonomic imbalances are precursors to cardiovascular disease, cognitive impairment, and other health-related risks. However, the relationship between aspects of sleep and ANS functioning remains to be poorly understood. Therefore, the present study examined the relationship between aspects of sleep and indices of ANS functioning in 141 undergraduate students (52 males and 89 females; mean age = 20.716 years). Participants completed a demographic survey and the Pittsburgh Sleep Quality Index (PSQI). **Next, physiological variables** [i.e. Skin Conductance (SC) and Heart Rate Variability (HRV)] were measured simultaneously for 5-minutes in order to assess ANS functioning at rest. Results revealed that SC was positively associated with sleep quality ($r = 0.187$, $p = 0.027$), sleep latency ($r = 0.173$, $p = 0.040$), use of sleep medication ($r = 0.306$, $p < 0.001$), and global PSQI score ($r = 0.188$, $p = 0.026$). Indices of HRV and sleep components yielded a negative association between the standard deviation of the normal-normal interval (SDNN) and the amount of time that it takes to fall asleep each night ($r = -0.173$, $p = 0.041$). Finally, sleep efficiency was negatively correlated with low frequency HRV ($r = -0.262$, $p = 0.002$) indicating that more effective sleep is associated with less sympathetic nervous system (SNS) activity. Findings of this study suggest that both quality and quantity of sleep are associated with autonomic activity at rest and may be a protective factor against negative consequences of SNS over-activation. Additionally, students need to be educated regarding the pitfalls of reliance upon sleep medication. Moreover, although sleep medication may promote the process of going to sleep, it has a paradoxical effect in that it is not sufficient enough to alter the effects of autonomic imbalance due to increased arousal and/or stress. Finally, our results show that sleep is an effective tool for the assessment of autonomic balance and cardiovascular health in college students.

Title: Travel in collegiate varsity student-athletes: Relationship to mood across seasons and the factors that influence this relationship

Authors: *E. VILLEGAS, JR[1], D. MCCARTNEY[3], M. HOLLIDAY[2], A. BOHR[2], M. MCQUEEN[2], T. D. HERNANDEZ[4]
[1]Psychology and Neurosci., [2]Univ. of Colorado Boulder, Boulder, CO; [3]Univ. of Colorado, Boulder, CO; [4]Psychology and Neurosci., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Travel for collegiate varsity student athletes during competitive season is a necessity, and may also be a significant stressor. Gaining an understanding of the factors that contribute to the stressful nature of competitive travel is important, as it holds the potential to uncover targets of opportunity for interventions aimed at minimizing the adverse consequences of competitive travel. To this end, the present study utilized the Brief Assessment of Mood (BAM) to assess mood disturbance and energy indices throughout two competitive seasons (fall 2016 and 2017) of Division I NCAA women's volleyball student athletes at the University of Colorado Boulder. In addition to quantitative measures of mood (BAM), qualitative information was also utilized to provide additional detail associated with BAM scores. Differences within each season and between the two seasons relating to mood disturbance and energy levels were assessed, as were potential factors that contributed to the differences. The main findings from the study include a consistent increase in mood disturbance after travel and an overall decrease in mood disturbance from fall 2016 to fall 2017. Additional findings from the study will be discussed in the context of how to minimize the adverse impact of travel as much as possible in collegiate varsity student athletes.

Title: Age and gender-related associations between objective sleep measures and inflammatory markers in bipolar affective disorder

Authors: *E. E. LEE[1], C. KAUFMAN[2], L. T. EYLER[3]
[2]Psychiatry, [1]UCSD, La Jolla, CA; [3]Dept Psychiatry, UC San Diego, La Jolla, CA

Abstract: Objective:
To characterize the relationship between objective sleep measures and inflammatory markers in

persons with bipolar disorder (BD)**.**

Rationale:

Disrupted sleep is a hallmark symptom of BD, contributing to worse quality of life and psychopathology. BD patients also have elevated inflammatory markers. Studies have described a strong link between sleep disturbances and increased inflammation, though this has not been examined systematically in BD.

Methods:

We examined 35 subjects with BD and 57 healthy comparison subjects (HCs) (age 26-65 years), with mean age 48 years and matched on gender and race. During a 2-week burst, subjects had blood drawn 3 times for assays of cytokine and chemokine levels. Sleep parameters (total sleep time, sleep latency, sleep efficiency, number and length of awakenings, overall sleep fragmentation) was assessed nightly using wrist-worn actigraphy.

Results:

The BD group had significantly worse sleep measures and higher levels of inflammatory markers compared to the HCs. There were significant group x sleep measure interactions for IL-8 and IP-10 levels. Within the BD group, CCL-11, MCP-1, and MIP-1b levels were correlated with worse sleep measures. Focusing on the sleep during the night prior to the blood draw for inflammatory markers for all subjects, time-lag analyses showed that prior evening's sleep latency was significantly associated with CCL-11 and MCP-1 only in the BD group. Also, the prior night's sleep latency was significantly associated with MCP-1 and MIP-1b among women with BD but not men with BD; while sleep latency was associated with CCL-11 in both genders. Age was correlated with MCP-1 and TNF-alpha in both diagnostic groups. When controlling for age, the prior night's sleep latency remained significantly associated with MCP-1 in the BD group.

Conclusions:

There is some evidence of a link between sleep and inflammation in BD, which varies with gender and age. It is likely that other factors, i.e., depressive mood, physical activity, and diet, contribute to both sleep and inflammation and warrant further assessment. Furthermore, the directionality of the relationship between sleep and inflammation is not clear. Longitudinal data collected in this ongoing study will allow us to address directionality in the future.

Institute, David Geffen Sch. of Med. at UCLA, Univ. of California at Los Angeles, Los Angeles, CA; [5]Div. of Pulmonary and Critical Care, Natl. Jewish Hlth., Denver, CO

Abstract: Introduction: Impaired cognition is a common symptom of obstructive sleep apnea (OSA), possibly due to neural injury in such cognitive areas as the hippocampus. The extent of injury varies between females and males, and the degree and type of cognitive impairments are also likely to vary by sex.
Methods: We studied 72 subjects which included 26 untreated (15 male) and 19 CPAP-treated (12 male) OSA patients, and 27 healthy controls (11 male). Cognitive function was measured using the Montreal Cognitive Assessment (MoCA), a 10-minute test assessing 7 cognitive sub-domains, providing scores for each category, and an overall score out of 30 (<26 indicates cognitive impairment). We described the MoCA findings by group for overall and subdomain scores: visuospatial, naming, attention, language, abstraction, delayed recall, and orientation. Group differences were assessed by ANOVA ($P<0.05$ threshold).
Results: Two sub-domains that showed significant effects ($P<0.05$) were delayed recall (more impaired in untreated female OSA vs. all other groups) and attention (higher in untreated male OSA vs. all other groups). Male and female controls had the highest overall scores (25.8±3.8 [mean±std]), while the untreated male (25.2±2.7) and female (24.8±2.9) OSA groups scored the lowest, and the male and female CPAP groups scored 25.6±1.6 and 25.7±4.8 respectively. However, these group differences were not significant ($P>0.05$). Naming and visuospatial sub-domains showed trends towards significance.
Conclusions: The findings show that OSA, in this sample, was not associated with major cognitive impairment, but some alterations in attention occurred, as did deficits in memory, consistent with findings by others. These cognitive differences were sex-specific, supporting the hypothesis that neural injuries underlie the symptoms. The findings also suggest that, as shown previously, females with OSA suffer from specific cognitive symptoms, such as impaired verbal recall.

Title: Linking naturalistic sleep fluctuations to the energy landscape in dynamic brain modules

Authors: *J. O. GARCIA[1,2], A. ASHOURVAN[2], S. M. THURMAN[1], N. WASYLYSHYN[1], S. H. TOMPSON[1], N. LAUHARATANAHIRUN[1,2], M. CIESLAK[3], J. C. ELLIOTT[3], G. OKAFOR[3], B. GIESBRECHT[3], S. T. GRAFTON[3], E. FLYNN-EVANS[4], D. S. BASSETT[2], J. M. VETTEL[1]

Abstract: Sleep plays a critical role in everyday biological functions, and the lack of adequate sleep has been widely linked to performance impairments in a variety of task domains (Van Dongen et al., 2004). To account for these impairments, the wake-state instability theory (Doran et al., 2001) posits that variability in performance reflects competition between two

neurobiological systems working to reciprocally inhibit the other: one system promoting sleep as homeostatic pressure accumulates, and the other fighting to maintain wakefulness (Killgore, 2010). Yet, this neurobiological process is still not well understood due to limitations of prevailing analytical techniques in measuring and tracking momentary changes in dynamic mental states.
To overcome this hurdle, we propose that state instability may be modelled by estimating the energy landscape of network transitions via a maximum entropy model (MEM) built upon dynamic network properties of the brain (Ashourvan et al., 2017). Borrowed from statistical mechanics, a MEM framework describes transitions between evolving states as a series of stays and transitions between different attractors in the system, successfully modelling ensemble neuronal activity (Tang et al., 2008), predicting perception (Watanabe et al., 2014a), and estimating sleep stage transitions (Watanabe et al., 2014b).
In a 16-week longitudinal study, participants (N=30) wore an actigraphy wristwatch and completed daily sleep diaries to capture objective and subjective measurements of their naturalistic sleep history (Thurman et al., 2018). During these 4 months, participants also completed a series of cognitive tasks and a resting state scan while brain activity was measured with biweekly fMRI/EEG recordings. We estimated the energy landscape (Ashourvan et al., 2017) in 4 steps: (1) calculated functional connectivity in discrete time bins in both the fMRI BOLD timeseries and band-passed EEG sources (cLORETA), (2) performed community detection of dynamic networks by optimizing a modularity quality function (Garcia et al., 2018), (3) fitted a pairwise MEM to the state of co-occurrence timeseries of each ROI, and (4) extracted features surrounding local energy minima. Our analysis found that increasing levels of sleep debt increased the energy requirements to change among the data-derived network communities from both the rest and task brain activity. Our findings suggest broad network dynamics in both the energy landscape estimated within BOLD-fMRI and oscillatory sources measured with EEG are associated with naturalistic fluctuations in sleep, suggesting a higher sensitivity of network dynamics to the impact of sleep.

Title: Circadian regulation of sleep in a mouse model of Dravet syndrome

Authors: *R. E. SANCHEZ[1], I. BUSSI[2], M. BEN-HAMO[2], H. O. DE LA IGLESIA[3]
[1]Grad. Program in Neurosci., The Univ. of Washington, Seattle, WA; [3]Biol., [2]Univ. of Washington, Seattle, WA

Abstract: In mammals, daily rhythms of physiology and behavior are synchronized to the 24-hour light-dark (LD) cycle via retinal input to the suprachiasmatic nucleus (SCN), the master circadian clock. The SCN is divided into two subregions, the dorsomedial SCN (dmSCN) and ventrolateral SCN (vlSCN), and relies on a GABAergic coupling mechanism to maintain neural network synchrony. The SCN has been demonstrated to play an important role in sleep timing and quality. These aspects of sleep are frequently impaired in epilepsies, which are among the most common neurological disorders in the world. Previous work in our lab has characterized circadian behavior in a mouse model of epilepsy called Dravet syndrome (DS), which is caused by a loss-of-function mutation in the *Scn1a* gene coding for the pore-forming subunit of the $Na_V1.1$ sodium channel, found primarily in GABAergic interneurons. DS mice display circadian behavioral deficits including a longer endogenous period of activity and slowed entrainment to abrupt shifts in the LD cycle simulating jet lag. Additionally, ex vivo calcium imaging demonstrated impairment in intercellular communication between the vl- and dmSCN of DS mice. Based on these results, we predicted that DS mice would also display impaired circadian regulation of sleep. Here we present a model of jet lag in which we combine activity monitoring with electrocorticographic (ECoG) and electromyographic (EMG) recordings to assess circadian regulation of sleep-wake rhythms in DS and wild-type (WT) mice. Mice were first subjected to a 6-hour delay, followed by a 6-hour advance of the LD cycle, while ECoG/EMG data were recorded continuously for a month. We report that for both WT and DS mice, jet lag induces a transient misalignment in the circadian timing of non-rapid eye movement (NREM) and rapid eye movement (REM) sleep stages. For both genotypes, we also find differences in the kinetics of re-entrainment following jet lag between the primary bout of sleep and the “siesta”, an abbreviated sleep bout under control of the circadian clock. We hypothesize that differences in entrainment time between DS and WT mice are due to impaired intercellular communication between vl- and dmlSCN. Ongoing work is probing the role of the $Na_V1.1$ channel in the SCN in sleep timing and quality by knocking out the *Scn1a* gene in a region-specific manner. Our work contributes to the understanding of mechanisms underlying sleep disturbances in both epilepsy and jet lag, and provides a novel experimental paradigm for probing circadian sleep regulation in the mouse.

Title: Sleep disturbance in the model rats of cerebrovascular dementia

Authors: *M. NAGAO[1], K. KUBOTA[2,1], S. KATSURABAYASHI[2], K. IWASAKI[2,1]
[1]Ins. Aging and Brain Sci., Fukuoka Univ., Fukuoka-Shi, Japan; [2]Fac. Pharmaceut. Sciences, Fukuoka Univ., Fukuoka-Shi, Japan

Abstract: The symptoms of patients with dementia are classified into core symptoms such as cognitive dysfunction and behavioral and psychological symptoms (BPSD) including sleep disturbance, anxiety, and depression. Sleep disturbance is known the main BPSD in the patients with light dementia. However, there is no specific insomnia drug for sleep disturbance in patients with dementia, because the mechanisms are still unknown. These facts may also be due to problem that there is no suitable animal model for sleep disturbance. We have previously reported that cerebral ischemia in rats showed significant impairments of spatial memory in the eight-arm radial maze task for a model of the cerebrovascular dementia. In the present study, we investigated whether cerebral ischemia rats show sleep disturbance by evaluating the sleep-wakefulness states. Cerebral ischemia was induced for 10 min by occluding both of the common carotid arteries, and this was repeated once after 1 hour. The rats were implanted with electrodes for electroencephalogram (EEG) and electromyogram (EMG) recording. Wakefulness, non-rapid eye movement (NREM) sleep, and rapid eye movement (REM) sleep were classified by an EEG/EMG recording during 24 hours 7 days after cerebral ischemia. The total time, average duration, number of episodes, and EEG power density of each wake/sleep state were computed during the light and dark phases. Cerebral ischemia rats significantly increased the total time of wakefulness and decreased the total time of NREM sleep during the light phase compared with sham-operated rats. However, the REM sleep was showed the no change. Furthermore, cerebral ischemia rats significantly decreased the average duration of NREM sleep and the number of NREM sleep episodes (more than 5 min), and increased the number of wakefulness episode (less than 5 min) during the light phase. However, the EEG power density of the delta (0.5 - 4.0 Hz) range in NREM sleep did not decrease in cerebral ischemia rats during the light phase. These results suggest that cerebral ischemia rats showed a decrease in the amount of NREM sleep and an increased number of awakenings without poor sleep efficiency. Therefore, we consider that cerebral ischemia rats would be an useful animal model for the new drugs especially remedying sleep disturbance in the patients with cerebrovascular dementia.

Title: Activation of basal forebrain cholinergic neurons reverses sevoflurane anesthesia and induces a wake-like state in rats

Authors: *J. DEAN[1], M. BRITO[2], T. LIU[3], A. FRYZEL[3], G. A. MASHOUR[3], D. PAL[3]
[1]Mol. and Integrative Physiol., Univ. of Michigan Dept. of Mol. and Integrative Physiol., Ann Arbor, MI; [2]Neurosci., [3]Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Recent work from our laboratory demonstrated that carbachol-mediated cholinergic stimulation of prefrontal cortex (PFC) increased local acetylcholine (ACh) levels and reversed general anesthesia [1]. PFC has reciprocal connections with cholinergic neurons in basal forebrain [2,3], which are known to increase activity during wakefulness [4,5]. Therefore, it is possible that cholinergic basal forebrain neurons were responsible for modulating arousal states and increasing cortical ACh levels after carbachol activation of PFC. To test this hypothesis, we conducted chemogenetic stimulation of basal forebrain cholinergic neurons in anesthetized rat. Under surgical anesthesia, male ChAT:Cre Long Evans rats (n=5) received bilateral microinjection (500nL) of AAV5:pAAV-hSyn-DIO-hM3D(Gq)-mCherry into substantia innominata region of the basal forebrain, and were instrumented to 1) record electroencephalogram (EEG) from across the cortex, 2) quantify local ACh levels through microdialysis, and 3) deliver Compound 21 [hM3D(Gq)-specific agonist] through a chronic catheter in jugular vein. After allowing five weeks for the maximal expression of hM3D(Gq), the rats were anesthetized with sevoflurane. General anesthesia was titrated (1.9-2.0%) to maintain loss of righting reflex (a surrogate of unconsciousness in rodents) and continuous slow wave EEG. Excitation of cholinergic basal forebrain neurons during sevoflurane anesthesia through intravenous administration of Compound 21 (5mg/kg) increased the respiration rate and caused EEG activation at a short latency (~10 s). The changes in respiration and EEG were accompanied by an increase in PFC ACh levels to those observed during pre-anesthesia baseline waking state. Importantly, all rats made active attempts at righting themselves and three out of five rats were able to fully right themselves despite continued presence of sevoflurane anesthesia. These results show that activation of cholinergic basal forebrain neurons is sufficient to reverse sevoflurane anesthesia in rats and induce a wake-like state.

Abstract: Sleep is thought to play a key role in memory consolidation; however, the relationship between alterations in sleep patterns and memory remain elusive. Previous studies have shown that both cognition and sleep undergo several age-related changes. Here, we examined the effects of sleep deprivation on sleep patterns, hippocampal place activity, and memory in young and aged C57bl6 mice. All animals were trained in a hippocampus-dependent object-place recognition task. On day 1, mice were habituated to a novel environment in which they subsequently explored an array of 3 objects over the course of 3 consecutive training sessions. Immediately after the last training session, animals were sleep deprived (SD) for 5 hours using an automated sleep deprivation system. The following day, animals were reintroduced to the environment for a single test session in which one object was displaced. Sleep patterns were analyzed before sleep deprivation and during sleep recovery using a Bayesian algorithm method. Prior to the sleep deprivation session, old mice displayed more fragmented sleep in comparison to young mice, as previously reported in other studies. Following the SD session, both young and old SD mice exhibited a trend toward less time awake and increased time in NREM. Interestingly, old SD mice also displayed reduced number, but longer length NREM bouts compared to old controls, which indicated that NREM not increased but was also more consolidated. The changes in sleep patterns correlated with alterations in memory and cellular

representations. Young SD animals exhibited lower preference for the displaced object, along with less place cell remapping during the test session relative to controls. Surprisingly, these trends were reversed in aged adult mice, which exhibited enhanced memory of the moved object and place cell remapping during the test session, a phenotype similar to that observed in young control mice. These data suggest that age-related sleep fragmentation contributes to some of the cognitive deficits associated with aging. However, consolidation of NREM sleep serves to ameliorate these changes by facilitating memory retrieval and allowing representations in the hippocampus to adapt to changing environments.

Title: Sleep and depressive-like behavior in rat: Differential effects between early life stress exposure and adulthood acute stress exposure

Authors: *A. VALDÉS-CRUZ, A. E. DÍAZ-FUENTES, M. G. MARTÍNEZ-MONTALVO, S. ESCALERA-OLVERA, S. ALMAZÁN-ALVARADO
Inst. Nacional de Psiquiatría RFM, México, Mexico

Abstract: Depressive disorder has different effects on sleep, as hypersomnia, insomnia, short duration of sleep stages, increase or reduction sleep latency, etc. Depression sleep disturbances could depend on factors such as depression onset age, and severity. In animal models, early life stress exposure by maternal separation and early social deprivation (MSESD) induce depressive-like behaviors that are present since childhood and are maintained to adult age. 15 minutes forced swimming is a method to induce depressive-like behaviors and has been considered a form to acute stress (AS), mainly when it is applied in adult age. Nevertheless, there is a controversy about depressive effect duration of this procedure. The aim of the present study was to compare the effect of MSESD and AS on depressive-like behaviors and on sleep architecture. Male Wistar rats were used. MSESD rats (n = 6) on postnatal day 21 were isolated from both their mother, and their littermates, also housed in an individual cage throughout all experiment. AS rats (n = 6) were housed in groups of three subjects until experimental procedure was started. In adulthood (postnatal day 85-95), all animals were implanted with electrodes in right and left hippocampus, both prefrontal cortices, and neck muscles to record the electromyogram. Four six-

hour polysomnographic records were done on consecutive days. On the second day, in AS group 15 minutes forced swimming was carried out. To quantify the depressive-like behavior 24 hours after forced swimming test (FST) 5 minutes duration was applied. In MSESD group solely FST was applied in the second day. In polysomnographic records the total time (TT) and number of phases (NP) of wakefulness, slow waves sleep (SWS) and rapid eye movement sleep (REM) stages were analyzed. In FST immobility, swimming, and climbing were analyzed. MSESD group showed lower TT in wakefulness ($p < .002$) and SWS ($p < .001$), and higher NP in SWS ($p < .01$) and REM ($p < .01$) than the AS group in the first record. Also in third record MSESD exhibited lower TT in SWS ($p < .001$) and higher NP in SWS ($p < .001$) and REM ($p < .03$). Repeated measures analysis showed that TT and NP in SWS of MSESD group were similar in the four polysomnographic records, while the AS group reach a similar level after the 15 minutes forced swimming and recovered in subsequent records. FST showed no difference between groups. Effects of the AS on sleep are transitory; only show impact in the stress exposition day. However, the results suggest a permanent effect of the MSESD on SWS and REM sleep, than could have a direct association with the expression of depressive-like behaviors.

Title: Comparison of sleep loss and recovery between binge cocaine and standard acute sleep deprivation

Authors: *T. E. BJORNESS[1], R. W. GREENE[2]
[1]Mental Hlth. Res., VA Med. Ctr. of North Texas, Dallas, TX; [2]Dept Psychiatry & Dept Neurosci., UTSW & VAMC, Dallas, TX

Abstract: As a psychostimulant, cocaine disrupts sleep under both active use and abstinence conditions with additional alterations in sleep stage composition. We have previously characterized the sleep/waking response in mice to several cocaine doses commonly used in addiction-related research. Here, we compare the sleep disruption and rebound recovery of standard acute sleep deprivation to binge cocaine administration. Adult male C57BL/6 mice were implanted with EEG and EMG electrodes. After recovery from surgical procedures, acclimation to the recording tethers, and baseline EEG and EMG collection, mice underwent

acute sleep deprivation or a binge cocaine protocol. Sleep deprivation consisted of 4 h of forced slow walking via a treadmill. For binge cocaine, animals first were exposed to the binge protocol (1 injection/h for 3 consecutive h) with saline (IP), followed by binge cocaine (15 mg/kg) the next day. Sleep deprivation and binge injections began at the start of the light phase. Mice receiving injections were weighed immediately prior to the first injection of the day each day. Sleep latency was increased compared to binge saline following both acute sleep deprivation and binge cocaine with a longer latency following SD, while REM latency was significantly longer following cocaine compared to sleep deprivation. At 4 h into the light cycle (i.e. within the sleep deprivation and binge administration time range) there was no difference in sleep time between baseline and binge saline or binge cocaine and sleep deprivation. Both sleep deprived and binge cocaine groups showed SWA rebound as defined as an increase in SWA from the same circadian time under baseline conditions, with slightly different time courses of recovery. At the end of the 24 h period, both sleep deprivation and binge cocaine groups showed a non-significant trend of decreased slow wave sleep slow wave energy suggesting that slow wave energy was not fully recovered during the 21 h post-injection or 20 h post-sleep deprivation period. Interestingly, mice that were sleep deprived showed a large increase in slow wave energy during waking suggesting that recovery from sleep deprivation alters both subsequent sleep and waking EEG activity. In sum, binge cocaine resulted in a similar loss of sleep time as acute sleep deprivation with REM sleep particularly effected. Additionally, the time course of SWA recovery was sharper following sleep deprivation, perhaps in part due to the increase SWA during waking. This increase in SWA during waking was likely not seen in binge cocaine animals due to high monoaminergic tone which would preclude SWA expression.

Title: Role of weekend recovery sleep in neurobehavioral deficits in chronic sleep deprivation paradigm of night shift work in mice

Authors: *S. SHIYANA[1,2], K. KONDEPUDI, 160014[3], M. BISHNOI[3], K. CHOPRA[2]
[1]Univ. Inst. of Pharmaceut. Sci., Panjab Univ., Chandigarh, India; [2]Univ. Inst. of Pharmaceut. Sci., Chandigarh, India; [3]Natl. Agri-Food Biotech. Inst., Mohali, India

Abstract: Methods
Female Laca mice of age 2-3 months, were chronically sleep deprived from 9:00 am to 5:00 pm from Monday to Friday using modified multiple platform method for 4 weeks as per the approval

from institutional animal ethic committee. The mice were grouped into three groups: control, sleep deprived without weekend recovery (SD) and sleep deprived with weekend recovery sleep (SD+R) having n=12 in each group. The protocol design mimicked the night shift work condition. The neurobehavioral deficits were assessed using open field test, actophotometer and hyperactivity scoring. Neurobiological changes were assessed with serum melatonin, cortisol, insulin, lipopolysaccharides (LPS) and C reactive protein (CRP) levels along with prospective physiological assessment of body weight and body temperature.

Results

Hyperlocomotion was depicted by increased ambulatory counts, rearing counts, number of line crossings in SD and SD+R group. The hyperactivity scoring indicated the pronounced stereotype behaviour in SD group. However, the stereotype was also seen in SD+R when tested immediately after sleep deprivation.

The serum melatonin and CRP levels were increased in SD group. Furthermore, there was significant decrease in blood glucose in both the groups. However, the serum insulin was increased in SD+R group only. The serum cortisol and LPS was not altered. Moreover, there was significant loss in body weight in SD group as compared to SD+R. The alterations in body temperature was more evident in SD group. These findings highlighted that the weekend recovery sleep plays role in neurobiological functions not in alleviating the mania like behavior.

Conclusion

Weekend recovery sleep is insufficient to counter the circadian insult induced by continuous night shifts during the weekdays. The study has implications for night shift workers.

Title: Coupling arousal and motor behavior: A dopamine hypothalamic circuit

Authors: *J. J. FRAIGNE, S. K. PINTWALA, M. HAMIEH, J. H. PEEVER
Cell & Syst. Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Motivated behaviors such as exploring, drinking and grooming only occur during wakefulness and therefore rely on the coordination of circuits that promote arousal and motor activity. We hypothesize that A11 dopamine cells play this role. These cells are specifically

active when arousal and motor behavior are coupled ($p<0.01$, ANOVA, n=6). Optogenetic activation of A11 dopamine neurons simultaneously triggers brain arousal and increases postural muscle tone ($p<0.01$, ANOVA, n=6), while optogenetic silencing of A11 cells produces behavioral and motor quiescence ($p<0.01$, ANOVA, n=8). Here, we used electrophysiology, optogenetics, genetically-assisted circuit mapping and behavioral assays to determine through which circuits the A11 dopamine cells operate to couple arousal state and motor activity. We showed that A11 dopamine neurons synapse on and directly activate hypothalamic orexin neurons. Optogenetic activation of A11 dopamine terminals in the orexin field promotes cortical arousal ($p<0.01$, n=5, t-test) without producing any motor behavior ($p=0.89$, n=5, t-test). Whereas, optogenetic activation of A11 dopamine terminals in the trigeminal motor pool engages movement ($p<0.01$, n=5, t-test) without causing cortical arousal. We propose that A11 dopamine cells form a control circuit that functions to couple arousal state and motor activity by directly connecting to and synchronizing the activity of hypothalamic orexin cells and motor neurons.

Title: Adolescent sleep disruption induces long-lasting impairment in social novelty preference

Authors: *W.-J. BIAN, L. DE LECEA
Dept. of Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Sleep takes one-third of our lives, yet its function is largely unknown. A large proportion (50~80%) of children with autism spectrum disorders (ASDs) were reported to have sleep problems, including delayed sleep onset, shortened sleep duration and fragmentation of sleep continuity, and a correlation has been found between sleep impairment and defects of social interaction, a core symptom of ASDs. However, the causal relationship between sleep disruption and social deficits as well as the underlying mechanisms have not yet been established but are likely to be critical for understanding the etiology of ASDs and for developing potential therapeutic means. Here we found that developmental sleep disruption in adolescent mice caused significantly reduced preference towards the socially novel conspecific in adulthood in the three-

chamber social interaction test without affecting the overall sociality. These social defects were persistent to at least 1 month after the initial test, suggesting the effects caused by adolescent sleep disruption are long-lasting. Interestingly, sleep disruption in the adulthood did not induce any social defects, indicating a critical period in adolescence during which sleep shapes social novelty preference. Dopaminergic (DA) neurons in the ventral tegmental area (VTA) and their projections to the prefrontal cortex (PFC) and nucleus accumbens (NAc) are important players in social reward processing and motivation, and they are active during waking but mostly silent during sleep. We found that in adolescent mice, over-excitation of the VTA DA neurons, specifically in the light phase when sleep mostly occurs, led to long-lasting social defects similar to those caused by sleep disruption. In contrast, developmental over-excitation of the DA neurons in the substantia nigra pars compacta (SNc) had no significant effect on social novelty preference. Collectively, these results suggest a critical role of adolescent sleep and normal activity level of VTA DA neurons in the developmental shaping of social novelty preference.

Title: Sleep in mice resilient and susceptible to social defeat stress

Authors: C. L. GRAY, J. SANCHEZ, *J. EHLEN
Neurobio., Morehouse Sch. of Med., Atlanta, GA

Abstract: Sleep disorders are a pervasive feature of a wide variety of neuropsychiatric conditions, and social stress is known to cause or exacerbate both sleep and neuropsychiatric disorders. It is also known that persons with sleep disorders prior to trauma have increased susceptibility to PTSD. In order to understand this relationship between sleep and stress we have employed a mouse model wherein sustained social avoidance occurs following social defeat stress. Preliminary data from this model are the first to demonstrate that development of social avoidance can be predicted by differences in sleep regulation that exist before exposure to social stress. Furthermore, these data demonstrate that increased sleep occurring after social-defeat stress is associated with resilience to social avoidance. These findings prompted us to examine local field potentials in a brain region linked to both social defeat susceptibility and sleep, the

medial prefrontal cortex (mPFC). We hypothesized that in vivo differences in the response of mPFC neurons to sleep are responsible for differences in susceptibility to social avoidance. Detailed analysis of slow-wave sleep and waking sleep pressure indicate electrophysiological differences in sleep occurring in the mPFC of susceptible and resilient mice. This suggests that the mPFC is a neural locus where sleep alters behavioral responses to social defeat stress.

Title: Search for neural circuits of narcolepsy-cataplexy

Authors: *E. HASEGAWA[1], T. MAEJIMA[2], T. YOSHIDA[3], M. YOSHIOKA[3], M. YANAGISAWA[1], M. MIEDA[2], T. SAKURAI[1]
[1]Intl. Inst. For Integrative Sleep Medi, Tsukuba, Japan; [2]Univ. of Kanazawa, Kanazawa, Japan; [3]Hokkaido Univ., Sapporo, Japan

Abstract: Mice lacking orexin peptides, orexin neurons, or orexin receptors recapitulate human narcolepsy phenotypes, further highlighting a critical role for orexin signaling in the maintenance of wakefulness. However, although the lack of orexin signaling causes the sleep disorder narcolepsy, the precise neural mechanisms by which orexin neurons prevent narcolepsy remain unclear. In a previous study, we found that targeted restoration of orexin receptor expression in the dorsal raphe (DR) and in the locus coeruleus (LC) of mice lacking both of orexin receptors inhibited cataplexy and pathological fragmentation of wakefulness (i.e., sleepiness), respectively. These results suggested that DR serotonergic and LC noradrenergic neurons play differential roles in orexin neuron-dependent regulation of sleep/wakefulness. As a next step, we used optogenetic and chemogenetic approaches to demonstrate that DR serotonin neurons suppress cataplexy by reducing the activity of the basolateral/lateral amygdala that plays an important role in emotional processing, as consistent with the fact that strong emotion often triggers cataplexy. Our results suggest that the orexin neuron-DR serotonin neuron-amygdala pathway is a critical circuit for preventing cataplexy. Furthermore, we identified a neuronal pathway that induces cataplexy when activated by optogenetic manipulation. We will discuss the role of this pathway in emotional processing as well as in REM-related muscle atonia.

Title: Activity of Amygdala GABA neurons during cataplexy

Authors: Y. SUN[1], E. BENDELL[1], B. ZOU[1], C. BLANCO-CENTURION[1], S. LUO[1], A. VIDAL-ORTIZ[1], P. J. SHIROMANI[1,2], *M. LIU[1]
[1]Psychiatry and Behavioral Sci., Med. Univ. of SC, Charleston, SC; [2]Ralph H. Johnson VA Med. Ctr., Charleston, SC

Abstract: Cataplexy, a distinctive symptom of sleep disorder narcolepsy, is usually triggered by strong emotions. The central nucleus of the amygdala (CeA) has been implicated in emotions and the GABA neurons in the CeA could regulate cataplexy. However, the real-time neuronal dynamics of identified GABA neurons during cataplexy is not known. In this study, we use fiber photometry to record calcium transients as a proxy of the activity of CeA GABA neurons during cataplexy. We generated narcoleptic VGAT-ires-Cre mice (VGAT-Cre+/-/orexin-/-) and identified narcoleptic symptoms. AAV-DIO-GCaMP6S was microinjected into the CeA and 21 days later sleep and calcium transients in CeA GABA neurons were recorded. We found that 30.95% of the cataplexy episodes were preceded by a GABA neuron activation event, indicating that other neurons in the CeA may also trigger cataplexy. Cataplexy and calcium events increased when mice were exposed to palatable food or predator odor. Surprisingly, we found that about 79.31% of the sleep attack episodes, which is another symptom of narcolepsy distinct from cataplexy, were accompanied by a concurrent activation of CeA GABA neurons. These results are the first to implicate CeA GABA neurons in triggering or maintaining sleep attacks. The circuit involving cataplexy is partially understood. However, sleep attacks are a more debilitating symptom of narcolepsy but the circuit is not known. We suggest that loss of orexin destabilizes amygdala neurons to trigger both cataplexy and sleep attacks.

Title: Vigilance dynamics are translated by head nodding in a mouse model of drowsiness

Authors: *A. SHIN[1], J. WOO[2], J. KIM[1], D. KIM[1]
[1]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of; [2]Chungnam Techno Park, Cheonan, Korea, Republic of

Abstract: In the drowsy state, the wake and sleep drives compete to yield a dynamic fluctuation of vigilance. It has proven challenging to study the mechanisms underlying vigilance dynamics, in part because of the lack of a robust animal model. Here, we established a mouse model of drowsiness. In this model, mice are starved for 1 day and then allowed to overeat high-fat food (to promote sleep) while positioned in an open-field box (to promote vigilance). They fall into a long-lasting drowsy state, as reflected by repeated and open-eyed nodding of the head while in a standing position. Simultaneous recording of electroencephalogram (EEG) and neck electromyogram (EMG) readouts revealed that this drowsy state had multiple stages in terms of the relationship between the vigilance level and head movements: the delta oscillations decreased in power prior to the head-rising period and increased during the head-falling period. CaV3.1-knockout mice, which have reduced delta oscillations, had a longer head-falling period with no difference in head-up latency compared to wild-type mice. This suggests that their balance is shifted from sleep to wakefulness, likely due to their previously proposed decrease in sleep-promoting functions. Our findings indicate that delta oscillations play a dominant role in controlling vigilance dynamics during sleep/wake competition, and that our novel mouse model may be useful for studying drowsiness and related neurological disorders.

Title: Spatial, functional, and translational profiling of the brain during sleep/wake behavior

Authors: *Y. HAN[1], P. LUU[2], A. NADTOCHIY[3], T. V. TRUONG[4], S. E. FRASER[5], D. K. DICKMAN[6]
[1]Neurosci. Grad. Program, [2]Mol. and Computat. Biol., [3]Biol. Sci., [4]Translational Imaging Ctr., [5]Mol. & Computat. Biol., [6]Neurobio., USC, Los Angeles, CA

Abstract: Synapses and neural circuits must maintain a dynamic balance of electrical activity in order to stabilize brain functionality throughout life, yet still permit the plasticity necessary to form and consolidate new memories. This exquisite balancing act is hypothesized to require the homeostatic control of synaptic strength during sleep-wake behavior, where synaptic strengthening accumulated through experiential wake activity is systematically down regulated during sleep, and experiences are consolidated and integrated into stable, long-term memories. Using the Drosophila adult central nervous system, we investigate the gene *insomniac*, a ubiquitin ligase adaptor that was recently demonstrated to be required for proper sleep behavior and homeostasis. Our approach utilizes the development of two complementary technologies: 1) New probes to visualize calcium activity and active gene translation in *insomniac*-expressing neuronal cell types, and 2) Use of multi-photon light sheet and light field microscopy to image sleep-related adaptations to neural activity in *insomniac*-positive neurons at unprecedented resolution, speed, and 3-dimensional coverage. These technologies are leveraged to complete three objectives: 1) Spatial profiling of genetically defined neurons and glia in relation to *insomniac* expression in the adult fly nervous system; 2) Calcium imaging in *insomniac* neurons at rest and following sleep deprivation; and 3) Translational profiling of *insomniac* neurons at rest and following sleep deprivation. Our findings illuminate previously undefined populations of neurons potentially involved in the homeostatic control of sleep behavior and adaptations in these cell types in the context of sleep/wake activity.

Title: Changes in sleep architecture, respiratory behavior, and indices of pain correlate after thoracic spinal cord contusion

Authors: *H. KLOEFKORN[1], S. IDLETT[2], M. HALDER[3], B. GOOLSBY[2], L. M. AIANI[2], N. P. PEDERSEN[4], S. HOCHMAN[5]

Abstract: Spinal cord injury (SCI) patients often experience disrupted sleep and chronic pain, and autonomic dysfunction[4], however these relationships are not well understood. In this study, we explored the relationship between sleep architecture, respiratory behavior, evoked secondary hyperalgesia, and spontaneous afferent population firing in a mouse model T10 contusion SCI. Prior to injury, measures of sleep architecture, resting respiratory behavior, and hind paw mechanical sensitivity were measured twice weekly in 11 female adult c57/bl6 mice for two weeks. Sleep architecture and resting respiratory behavior were measured using non-contact electric field sensors. These sensors have been validated against whole body plethysmography to reliably capture resting respiratory rate[2] and validated against electroencephalogram to measure sleep architecture from changes in respiratory behavior. Mechanical sensitivity of both hind paws was measured using von Frey filaments[1]. SCI was modeled in 7 mice using a moderate T10 contusion SCI (50 kDyne impact) with the remaining 4 serving as naïve controls. After 6 weeks following SCI, animals were euthanized and *in vitro* electrophysiologic recordings of spontaneous afferent population activity were obtained from isolated lumbar dorsal root ganglia (DRG) similar to previous work in rats correlating this increased firing to spontaneous pain[3]. Data were analyzed using 1-way ANOVAs and Tukey's post-hoc test for significance. Linear regressions were calculated to assess correlation between data.
Relative to baseline, SCI animals after 6 weeks developed 1) fragmented sleep behavior (reduced sleep event duration, $p=0.012$), 2) erratic breathing behavior (increased respiratory rate variability, $p=0.035$), 3) heightened mechanical sensitivity (evoked allodynia, $p<0.001$), and 4) increased spontaneous afferent population firing rate ($p=0.041$). Mechanical sensitivity correlated with both erratic breathing ($p<0.001$, $R^2=0.88$) and fragmented sleep ($p=0.016$, $R^2=0.64$). Fragmented sleep also correlated with afferent firing rate ($p=0.029$, $R^2=0.0.57$) and nearly with erratic breathing ($p=0.051$, $R^2=0.0.49$).
In summary, strong correlations between indices of pain, poor sleep quality, and erratic breathing were found after SCI. This is the first study, to our knowledge, to explore these relationships in SCI and further studies are planned to identify the neuroplasticity and causality between these measures.

Title: The Role of corticothalamic input in sleep regulation

Authors: *J. HONG, E. CHEONG
Yonsei Univ., Seoul, Korea, Republic of

Abstract: Sleep-wake control has been attributed to many brain regions, including the brain stem, hypothalamus, basal forebrain, basal ganglia, and thalamus. Sleep is composed of the non-rapid eye movement (NREM) and rapid eye movement (REM) sleep states, which are categorized by characteristic brain rhythms in electroencephalography (EEG) recordings and distinctive eye movements. The transition from wakefulness to a NREM sleep state at the onset of sleep involves a transition from low-voltage, high-frequency irregular EEG waveforms to large-amplitude, low-frequency EEG waveforms accompanying synchronized oscillatory activity in the thalamocortical circuit. The thalamocortical circuit consists of reciprocal connections between the thalamus and cortex. The thalamus is further dissected into thalamic reticular nuclei (TRN), which are composed of inhibitory neurons, and thalamocortical (TC) nuclei composed of excitatory neurons which reciprocally project each other. TC neurons send long axons to cortical neurons, and the cortical neurons in layer VI send strong excitatory feedback back to both TRN and TC neurons, which completes the loop of thalamocortical circuit. Within this circuit, the cortex sends strong excitatory feedback to the thalamus, however the function of which is unclear. In this study, I investigated the role of corticothalamic input to TC neurons in sleep architecture and sleep rhythms using genetically targeted inhibition of TC neuron in response to corticothalamic inputs.

Title: The roles of sleep oscillations in sensory and memory processing: New insights using transgenic and auditory stimulation approaches in mice

Authors: *C. BLANCO DUQUE[1], R. PURPLE[2], T. YAMAGATA[2], G. ANG[1], L. E. MCKILLOP[1], M. M. KAHN[1], D. M. BANNERMAN[3], V. V. VYAZOVSKIY[1]

Abstract: Spindles are oscillations (10-15 Hz) occurring during NREM sleep, which have been implicated in sensory processing and memory consolidation. Deficits in spindles have been reported in brain disorders associated with alterations in the GluA1 AMPA receptor subunit, which is encoded by the GRIA1 gene. Here, we investigate the role of spindles in sensory gating and memory processing in mice using transgenic and sensory stimulation approaches. First, we investigated the effect of knocking-out the GRIA1 gene in mice on local spindle properties, and studied the association between these oscillations and memory performance. Chronic in-vivo electroencephalography (EEG), electromyography (EMG), local-field potentials (LFP) and multi-unit activity (MUA) recordings from the primary somatosensory cortex (S1) were collected in GRIA1$^{-/-}$ (n=6) and wild-type (WT) littermates (n=6) male mice during both natural sleep and training on a spatial reference memory task. Frontal EEG spectral power during NREM sleep was significantly reduced in the spindle-frequency range (10-15 Hz) in GRIA1$^{-/-}$ relative to WT mice ($p<0.05$). Furthermore, individual EEG spindle events were readily detected in WT mice with an automated algorithm, while they were absent in GRIA1$^{-/-}$ mice ($p<0.05$). Interestingly, despite the absence of EEG spindles in GRIA1$^{-/-}$ mice, analyses of LFP signals revealed an occurrence of local spindle events in the S1 in both genotypes ($p>0.05$). A repeated measures analysis revealed significant learning across training (main effect of day; $F(6,36)=17.01, p<0.001$). However, there was no significant difference between genotypes in memory performance (main effect of genotype and interaction by day; $F<1; p>0.20$). This is consistent with previous evidence indicating that long-term memory formation is preserved in GRIA1$^{-/-}$ mice. Second, we assessed whether auditory stimuli could modulate spindles. In vivo

EEG, EMG, LFP and MUA recordings were collected in GRIA1$^{-/-}$ (n=4) and WT (n=4) male mice, over 24-hour periods, during both spontaneous sleep and sensory stimulation. Auditory stimuli appeared to disrupt sleep spindles and reduce MUA in local areas within S1 where spindles were especially prominent. This reduced MUA faded with repetitive presentation of acoustic stimuli in WT but not GRIA1$^{-/-}$ mice, consistent with earlier observations associating GluA1 deletion with impairments in habituation. These results have important implications for understanding the spatio-temporal dynamics and function of cortical spindles. More generally, our study provides novel insights into the biological role of sleep oscillations in sensory and memory processing.

Title: Control of non-REM sleep by a thalamo-amygdala circuit

Authors: *C. MA, S. AN, Z. K. BARGER, W.-C. CHANG, D.-Q. LIU, Y. DAN
Dept. of Mol. and Cell Biol., UC Berkeley, Berkeley, CA

Abstract: A crucial step in understanding the neural circuits controlling sleep is to identify the sleep neurons. In principle, a neuron could promote sleep by inhibiting wake-promoting neurons or by exciting other sleep-promoting neurons. Based on this simple logic, we performed anatomical screening for candidate sleep neurons followed by functional validation of the candidates. Rabies virus (RV)-mediated retrograde trans-synaptic tracing identified a subpopulation of neurons in the central nucleus of the amygdala (CeA) as a major source of GABAergic inputs to multiple wake-promoting neuronal populations. Optogenetic activation of these CeA neurons strongly promoted non-REM (NREM) sleep and suppressed both wakefulness and REM sleep, whereas their inactivation had the opposite effects. Optrode recording showed that the vast majority of these neurons are maximally active during NREM sleep. Furthermore, RV-mediated retrograde tracing from these CeA neurons revealed inputs from a subgroup of glutamatergic neurons in a posterior region of the thalamus. Optogenetic activation and inactivation of these thalamic neurons also increased and decreased NREM sleep, respectively. Together, these results reveal a novel thalamo-amygdala pathway for NREM sleep generation.

Title: A mouse model of neuroinflammation resulting from sleep disruption at high altitude

Authors: *N. P. CRAMER[1], A. GRILLAKIS[2], X. XU[1], Y. EUDY[1], K. WHITING[2], Z. GALDZICKI[1]

Abstract: Hypobaric hypoxia experienced by travelers at high altitude can cause significant disruptions to normal sleep. In turn, prolonged sleep disruptions promote systemic inflammation including elevation of proinflammatory cytokines which may interact with those driven by prolonged exposure to hypoxia to synergistically drive neuroinflammation. We developed a mouse model of sleep disruption under high altitude conditions to determine the mechanisms underlying the resulting neuroinflammation and associated behavioral deficits. Mice were group housed at sea level or a simulated altitude of 5000 meters for three weeks followed by two weeks of either normal or fragmented sleep. Sleep fragmentation occurred at the respective altitudes and consisted of a bar which swept across the bottom of the cage every two minutes during the light cycle. Mice exposed to high altitude showed significant deficits in contextual and cued fear conditioning relative to sea level controls and these deficits tended to be more severe in mice which underwent additional sleep fragmentation at altitude. Peripheral blood cytokine profiles show elevated levels of IL-6 in mice which underwent sleep fragmentation regardless of altitude exposure. EEG/EMG analysis is ongoing to determine which components of sleep (NREM/REM) may be more affected by either altitude or sleep fragmentation. These results will help elucidate the mechanisms underlying neuroinflammation resulting from sleep disruption under hypobaric-hypoxia and potential interventions to prevent or minimize long-term neurological consequences.

Title: Acute kynurenine challenge reduces rapid eye movement (REM) sleep duration and impairs hippocampal-dependent contextual memory in adult male and female rats

Authors: *S. A. BUCK[1], A. BARATTA[1], S. BEGGIATO[3], J. A. MONG[2], A. POCIVAVSEK[1]
[1]Maryland Psychiatric Res. Center, Dept. of Psychiatry, [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Life Sci. and Biotech., Univ. of Ferrara, Ferrara, Italy

Abstract: Increases in kynurenic acid (KYNA), a metabolite of the kynurenine pathway of tryptophan degradation and an antagonist at N-methyl-D-aspartate (NMDA) and α7 nicotinic acetylcholine (α7nACh) receptors in the brain, impair cognitive function. Recent evidence suggests that these disruptions may be causally related to impairments in sleep-wake behavior with KYNA elevation. Presently, we further explored the novel hypothesis that elevated KYNA adversely impacts sleep quality and cognition in adult cohorts of both male and female Wistar rats. Animals were treated with either vehicle or kynurenine (100mg/kg; intraperitoneally), the direct precursor to KYNA, at the beginning of the light cycle, zeitgeiber time (ZT) 0, or at the beginning of the dark cycle, ZT 12. *In vivo* microdialysis confirmed significant formation of KYNA in the dorsal hippocampus with kynurenine challenge at both time points. Separate animals were implanted with telemetric devices to acquire polysomnographic recordings that combine electroencephalogram (EEG) and electromyogram (EMG). Analysis of vigilance state-related parameters categorized as wake, rapid eye movement (REM) and non-REM (NREM) were assessed for 24 h after treatment. Kynurenine treatment at ZT 0 significantly reduced REM duration compared to vehicle treatment ($P < 0.05$), and we also found a main effect of sex ($P < 0.01$). Alternatively, when animals were treated at ZT 12, REM duration was impacted by a significant treatment x sex interaction ($P < 0.05$), but no main effect of treatment alone. Separate animals were tested in the passive avoidance paradigm, assessing contextual memory. Animals were treated with vehicle or kynurenine at ZT 0 or ZT 12 and trained in the task at ZT 2 or ZT 14, respectively. The next day, during the retention trials, animals treated with kynurenine at the start of the light phase were significantly impaired in the hippocampal-dependent task ($P < 0.05$), whereas animals challenged with kynurenine at the start of the dark phase were not impaired. Taken together, these findings and future complementary experiments will provide significant mechanistic value to understanding the role of KYNA in modulating a relationship between sleep and cognition.

Title: Modulation of startle response in rem sleep behavior disorder

Authors: *R. FRAU, F. TRACCIS, M. FIGORILLI, M. PULIGHEDDU
Univ. of Cagliari, Cagliari, Italy

Abstract: REM sleep behavior disorder (RBD) is a parasomnia featuring loss of normal muscle atonia, vivid dreams and complex behaviors during REM sleep. Patients with idiopathic RBD are susceptible to develop neurodegenerative diseases such as Parkinson's disease (PD). About 50% of PD patients exhibit RBD, typically in association with higher severity of PD symptoms, and increased risk for neuropsychiatric problems. RBD results from imbalances of excitatory and inhibitory inputs across several brainstem areas, such as the sublaterodorsal tegmental nucleus (SLD), medullary gigantocellular reticular nuclei and laterodorsal-pedunculopontine complex (LTD-PPN). Interestingly, the same structures are involved in the execution and modulation of startle reflex, a defensive response consisting in muscular contraction in reaction to sudden sensory stimuli. Here, we tested whether the alterations of REM sleep induced by lesions of the key areas involved in RBD pathogenesis (including SLD and LTD-PPN) were paralleled by (and correlated to) abnormalities of startle reflex and its modulatory processes in rat models. Adult Sprague-dawley rats were subjected to electrolytical lesions of SLD and LTD/PPN, or sham surgery and implanted with electrodes for 24-hour polysomnography (PSG) testing. Rats were then tested for either PSG or startle reflex paradigms, including startle habituation and pre-pulse inhibition (PPI). Our preliminary results showed that the lesion of SLD and LTD-PPN significantly reduced startle amplitude and habituation, but not PPI. Furthermore, animals subjected to LTD/PPN lesion exhibited more robust startle alterations than SLD and these alterations were accompanied by sleep behavioral abnormalities. Our results suggest that specific startle alterations in association with sleep disorders may provide a complementary early diagnostic index in PD development.

Sch. of Med., Baltimore, MD; [5]Ctr. for Sleep and Circadian Neurobio., Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Depression is a debilitating disorder that is a major economic and public health burden. First line antidepressants are only 40-50% effective, and require weeks of treatment before patients respond. Most depressed patients have disrupted sleep, yet one night of total sleep deprivation paradoxically has robust and rapid antidepressant properties. Sleep deprivation is an effective therapy for up to 60% of patients who experience antidepressant effects within hours following the night of sleep deprivation. This antidepressant response is lost after one night of recovery sleep, thus sleep deprivation cannot be adopted as a long-term treatment strategy. Understanding and exploiting the mechanisms underlying the fast and effective antidepressant response to sleep deprivation could lead to novel therapeutics to treat depression. Adenosine Monophosphate-activated Protein Kinase (AMPK) is the major energy sensor in the brain and is phosphorylated following sleep deprivation as well as by other rapid acting antidepressants such as ketamine. We used two methods of sleep deprivation to investigate the role of pAMPK in mediating antidepressant effects of sleep deprivation. Male and female mice were exposed to either spontaneous exploratory wakefulness or gentle handling for 6 hours. The gentle handling method of sleep deprivation increased corticosterone levels compared with spontaneous exploratory wakefulness and non-sleep deprived controls. Our preliminary data indicate an increase pAMPK in the spontaneous exploratory wakefulness paradigm in the hippocampus of males but not females, although a downstream target of AMPK, nuclear Sterol Regulatory Element-Binding protein (nSREBP), was increased in females. Female mice did not show an antidepressant response to acute sleep deprivation in the forced swim test (FST). However, sleep deprivation as an antidepressant therapy is only effective in depressed humans. Therefore, future

studies will use 12 days of chronic unpredictable stress, to further investigate the extent to which AMPK is necessary for a rapid antidepressant effect after sleep deprivation.

Title: SUVN-G3031, H3 receptor inverse agonist produces wake promoting activity in rats with hypocretin-2-saporin lesions of the lateral hypothalamus

Authors: *S. DARIPELLI, G. BHAYRAPUNENI, C. TIRUMALASETTY, V. BENADE, R. SUBRAMANIAN, S. PETLU, N. PRAVEENA, P. JAYARAJAN, A. SHINDE, R. BADANGE, V. BHATTA, R. NIROGI

Abstract: Numerous studies have demonstrated that brain histamine plays a crucial role in maintenance of wakefulness, attention, learning and other cognitive processes. SUVN-G3031, a potent H3 receptor inverse agonist is being developed for the treatment of narcolepsy and other sleep related disorders. SUVN-G3031 is one of the lead molecules with hKi of 8.7 nM and has more than 100 fold selectivity against the related GPCRs. SUVN-G3031 exhibited desired pharmacokinetic properties and brain penetration. SUVN-G3031 blocked R-α-methylhistamine induced water intake and increased *tele*-methylhistamine levels in brain and cerebrospinal fluid. A single oral administration of SUVN-G3031 produced significant increase in acetylcholine, histamine, dopamine and norepinephrine levels in the cortex. SUVN-G3031 produced wake promoting activity in male Wistar rats. In the present study, effects of SUVN-G3031 on sleep/ wake profile were evaluated in rats with lateral hypothalamic lesion using neurotoxin hypocretin-2-saporin. Narcoleptic-like sleep behavior was observed in rats injected with hypocretin-2-saporin in lateral hypothalamus. SUVN-G3031 produced significant increase in wakefulness with concomitant decrease in rapid eye movement (REM) sleep in these animals. These results are in agreement with electroencephalography (EEG) studies carried out in healthy male Wistar rats. Results from the current study and the neurotransmitter modulations produced by SUVN-G3031 provide a strong basis for the potential of SUVN-G3031 in treatment of sleep related disorders. First in human, Phase 1 studies for SUVN-G3031 are completed underUS IND and SUVN-G3031 has shown desirable pharmacokinetic profile with safety and tolerability in healthy human volunteers. Phase 2 study for narcolepsy is currently being planned.

Title: Validation of a sensory feedback system for selective sleep restriction in rodents

Authors: D. M. HUFFMAN[1], A. A. AJWAD[1], A. AGARWAL[4], B. F. O'HARA[2], K. D. DONOHUE[3], *S. SUNDERAM[1]
[1]Dept. of Biomed. Engin., [2]Dept. of Biol., [3]Dept. of Electrical & Computer Engin., Univ. of Kentucky, Lexington, KY; [4]Signal Solutions, LLC, Lexington, KY

Abstract: Sleep plays a vital role in physiological and homeostatic processes, with each state of sleep (Rapid Eye Movement (REM), non-REM (NREM)) mediating unique aspects of learning, memory, and cognition. A common approach to investigating these state-specific contributions is by restricting the state in question and observing the consequences. However, experimental tools to identify and selectively interrupt sleep are still underdeveloped: most are stressful to the animal, infringe on normal behavior, or are open-loop in operation. To this end, we sought to accomplish the common goal of REM Sleep Restriction (RSR) by means of automated, non-invasive vibro-tactile stimulation, which was applied via a tactile transducer mounted under the floor of the cage (MouseQwake; Signal Solutions, LLC.), and could be activated with predetermined stimulation parameters (frequency/amplitude) to yield more subtle or intense intervention. Eight C57BL/6 mice (4M, 4F) were instrumented with EEG/EMG headmounts

according to IACUC-approved protocols. Following recovery, signals were fed into an unsupervised computational model which predicted vigilance state in real time, and triggered stimulation upon detecting REM sleep. Each animal underwent four trials (each using a unique frequency/amplitude combination), which consisted a 12-hour baseline, as well as a time-locked 12-hour trial of RSR (stimulation triggered when REM detected) on the following day. Data was then manually scored by human raters, and the effect of stimulation on REM sleep was assessed. While more subtle stimulation showed no clear effect, more intense stimulation drastically affected REM sleep - reducing mean REM bout duration by 50-70% depending on stimulation parameters. The overall proportion of REM sleep was also reduced by as much as 40% during the first 4 hours of RSR, which eventually led to a homeostatic rebound to compensate for lost REM. In conclusion, this system provides a non-invasive alternative to currently available systems for sleep restriction in rodents. The stimulation parameters can be tuned to suit a particular animal or experimental condition, and can be adapted to compensate for persisting sleep resulting from homeostatic- or circadian-dependent changes in arousal thresholds. Future work is directed toward automated selection of stimulation parameters, and the incorporation of non-invasive sensors to alleviate the need for surgical implantation of EEG/EMG. These improvements will result in a completely non-invasive system that could be implemented with limited or no experience in surgical methods or sleep scoring and analysis.

Title: A new method for recording rodents' physical activity using an implantable accelerometer

Authors: D. FUNABASHI, I. KITA, *T. NISHIJIMA
Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: [Background] Physical activity is a key to sustaining physiological and mental health. However, population worldwide are increasingly becoming physically inactive. To overcome the physical inactivity-related health problems, it would be important to understand neural mechanisms that regulate physical activity level in rodents. So far, home-cage activity of rodents is usually examined in a single housed condition, because the recording apparatuses based on a beam-interruption, a telemetry, and a video-tracking system require animal isolation. Here, it would be notable that social isolation is a type of stress and has been demonstrated to affect emotional behaviors, impair spatial learning, and suppress hippocampal neurogenesis in rodents. Obviously, home-cage activity of rodents should be recorded in a group housed condition, which is feasible by using an implantable accelerometer, nanotag® (15 × 14.2 × 7.1 mm, 2.5 g, Kissei Comtec Ltd, Japan). [Purpose] As the first step, the purpose of this study was to examine a validity of the nanotag® in mice, i.e., whether an intraperitoneal implantation of nanotag® do not decrease home-cage activity and impair hippocampal neurogenesis. [Methods] Male C57BL6J mice (10 weeks old) were randomly allocated to following three groups; control (C, n = 5), sham-operated (SO, n = 5), and operated mice (O, n = 6). In this experiment, we needed to record the home-cage activity of C and SO mice that were not received nanotag® implantation, all the mice were singly housed, and their home-cage activities were recorded by a near infrared beam interruption system (LOCOMO LS-5, Melquest, Japan). Twenty-three days after the nanotag® implantation, mice were deeply anesthetized and the brain were removed for immunohistochemical examination of hippocampal neurogenesis (cell proliferation by Ki-67, and immature neuron by doublecortin). [Results and Discussion] Home-cage activities of both O and SO mice were transiently decreased due to the surgical invation for a few days, but no significant differences were observed between groups at 7 days after operation. We also found that there were no significant differences in densities of Ki-67-positive cells and of doublecortin-positive immature neurons between groups. [Conclusion] Theses results suggest that the intraperitoneal implantation of nanotag® do not influence ambulatory activity and hippocampal neurogenesis in mice. This device enables us recording physical activity of group-housed mice in any environmental situation.

Title: ONEIROS, a new telemetric and logger device to record sleep electrophysiology, physiology, temperatures, behavior, arousal threshold and sleep homeostasis

Authors: *P.-A. LIBOUREL[1], S. ARTHAUD[1], B. BARRILLOT[1], J. ROUX[1], G. UNGUREAN[2,1], P.-H. LUPPI[1], C. PEYRON[1], N. C. RATTENBORG[2], B. MASSOT[3]
[1]CRNL, Lyon, France; [2]Avian Sleep Group, Max Planck Inst. for Ornithology, Seewiesen, Germany; [3]INL, UMR5270 CNRS, INSA Lyon, Villeurbanne, France

Abstract: Sleep is a behaviorally inactive state of reduced environmental awareness shared by all animals. When compared to wakefulness, sleep behavior is associated with changes in physiology and activity of the central nervous system. The nature of these changes varies considerably across species, and therefore is a rich resource for gaining insight into the evolution and functions of sleep. A major obstacle for capitalizing on this resource is the lack of a small device capable of recording a high number of biological parameters for extended periods of time both in the laboratory and the field. We developed ONEIROS to this aim. This new tool is designed for sleep research on small freely moving animals. The system is a standalone, miniature, long-lasting (several days) that couples electrophysiological (up to 26 electroencephalogram (EEG), electromyogram (EMG), electrooculogram (EOG), electrocardiogram (ECG) and/or local field potentials (LFPs) channels), metabolic (3 temperature channels), and behavioral measurements (3D accelerometry). In addition, the device is equipped with a lightweight vibrating motor which can be used to assess arousal thresholds and to disrupt sleep. The system is available in a wireless or a datalogger configuration useable in the field. To demonstrate the efficacy of this tool, we simultaneously recorded for the first time, EEG, hippocampal LFP, electromyogram (EMG), electrooculogram (EOG), brain, body and ambient temperature, and 3D accelerometry. Moreover, we performed a selective paradoxical sleep deprivation by triggering the vibrating motor after online recognition of the state. Finally, we successfully recorded a pigeon (*Columbia livia*) in an 8 meters cube aviary in a social context with the logger mode, demonstrating the feasibility of using the device in the field.

Title: Ghrelin signaling targets segregated clusters of neurons within the nucleus of the solitary tract

Authors: *M. P. CORNEJO[1], P. N. DE FRANCESCO[1], G. GARCIA ROMERO[1], E. PORTIANSKY[2], J. M. ZIGMAN[3], M. REYNALDO[1], M. PERELLO[1]

Abstract: Ghrelin is a stomach-derived peptide hormone and its receptor, the growth hormone secretagogue receptor (GHSR) is highly expressed in the brain. The nucleus of the solitary tract (NTS) is a major sensory nucleus in the dorsal medulla that receives cardiovascular, visceral, gustatory and orotactile information. NTS neurons express GHSR but the identity and the physiological role of GHSR-expressing neurons of the NTS are uncertain. In this study, we used a GHSR reporter mouse (GHSR-eGFP) to perform a detailed neuroanatomical and functional characterization of GHSR-expressing neurons of the NTS. We first mapped the neuroanatomical distribution of eGFP neurons within the NTS. Then, we explored the phenotype of eGFP neurons using IHC against different neuronal populations. We also explored the physiological role of GHSR-expressing neurons of the NTS exposing GHSR-eGFP animals to experimental protocols known to activate the NTS and to involve ghrelin signaling and examining the pattern of expression of c-Fos in eGFP positive cells. Overall, we found that GHSR-expressing neurons were located throughout the extension of the NTS forming three clusters: one pair of rostral clusters, mostly comprising the ventral subnucleus, and one caudal cluster, mostly involving the parvicellular subnucleus. We also found that a population of GHSR-expressing neurons is GABAergic. Finally, eGFP neurons of the rostral clusters of the NTS showed an increase in c-Fos in response to hyperphagic protocols, while the caudal cluster of eGFP cells increased c-Fos levels in response to sensory stimuli from the gastrointestinal tract. Our results indicate that ghrelin signaling targets segregated clusters of NTS neurons that respond to different stimuli depending on their location.

Title: The minor spliceosome is required for proper hypothalamic development resulting in overeating and obesity in U11 cKO mice

Authors: *A. WHITE, K. C. HYATT, R. KANADIA
Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: In mammals, feeding is regulated by the neuroendocrine system, atop which sits the hypothalamus, which not only integrates these signals but also actively regulates feeding behavior. The hypothalamus develops from the Nkx2.1 progenitor population of the ventral diencephalon. Proper hypothalamic development relies upon controlled production of neuronal subtypes and the ratio of these subtypes is determined by regulated gene expression. Here we explore the role of minor intron splicing in hypothalamic development. The minor spliceosome is comprised of 5 small nuclear RNAs (snRNAs) U11, U12, U5, U4atac, and U6atac and is responsible for the splicing of minor introns, which are present in ~500 genes, called minor intron-containing genes (MIGs). Despite being responsible for the splicing of less than 0.5% of introns, mutations in components of the minor spliceosome have been implicated in developmental disorders including MOPD1 and IGHD. Here we use *Nkx2.1*-cre to ablate *Rnu11*, which encodes the U11 snRNA, a crucial component of the minor spliceosome, whose loss results in perturbed minor spliceosome function in the developing hypothalamus. Upon birth, U11-null *Nkx2.1-cre+* mice are indistinguishable from control littermates. However, these mice upon shifting to *ad libitum* food at P21, while underweight, begin gaining weight such that they became obese. Weight gain analysis showed that the females surpass their littermates' weight by 5 weeks and males by 8 weeks. Body composition analysis, shows a significant shift in the lean-to-fat mass ratio, preceding the adult-onset obesity in the mutant mice. Together these findings show the influence of minor spliceosome in hypothalamic development and its effect on adult-onset obesity.

Title: Pacap from the ventromedial hypothalamic nucleus is necessary for both energy balance and glucose homeostasis

Authors: *J. N. FLAK[1], B. LOWELL[2,4], R. A. ROSS[3,4,5]
[1]MEND, Univ. of Michigan, Ann Arbor, MI; [3]Psychiatry, [2]Beth Israel Deaconess Med. Ctr., Boston, MA; [4]Harvard Univ., Boston, MA; [5]McLean Hosp., Belmont, MA

Abstract: Obesity results from energy imbalance, due, at least in part, to suppressed energy expenditure. While it is understood that the brain controls energy expenditure, the neurocircuits, and essential components within these circuits, that can accelerate and decelerate energy consumption have not yet been revealed in great detail. The ventromedial hypothalamic nucleus (VMN) is a critical neural site for the control of energy expenditure. While the VMN contains, almost exclusively, glutamatergic neurons, neuropeptides are also expressed within the nucleus. Pituitary adenylate cyclase activating polypeptide (pacap) is the most abundant neuropeptide in the VMN. Since previous studies have implicated pacap^{VMN} in controlling metabolic tone in response to energy status, we hypothesized that pacap^{VMN} is necessary for body weight regulation by promoting energy expenditure. We acquired a pacap^{flox} mice that, in the presence of cre, results in a truncated protein, preventing communication downstream by pacap. Because pacap is expressed in the periphery, we administered a local injection of AAV^{cre} into the VMN of pacap^{flox} mice. Bilateral AAV^{cre} administration completely ablated dmVMN *pacap* expression. We found that, in both male and female mice, loss of pacap^{VMN} results in massive obesity, adiposity, and hyperglycemia. Surprisingly, food intake only increased in these mice once body weight had almost doubled. In support of this notion, pacap^{VMN}KO suppressed VO2 and not activity, despite massive obesity. Together, these data indicate that pacap^{VMN} is necessary for the control of energy expenditure. In addition to the control of energy balance, Pacap^{VMN}KO also induced hyperinsulinemia and suppressed glucose clearance to brown adipose tissue, heart, and muscle during hyperinsulinemic/euglycemic clamp. Our data demonstrate that pacap is an essential component for the promotion of energy expenditure by the VMN. Future studies will reveal both the VMN cells that use pacap for these functions and the downstream cells necessary for the control of energy balance and glucose homeostasis.

Title: Acute exposure to a high fat diet during the juvenile period: Effects on cognition and post translational modifications in adulthood

Authors: *T. M. MILEWSKI[1], K. A. BUCKHAULTS[2], A. J. LARA[3], P. T. ORR[2,1], K. A. STUMPO[3]
[1]Neurosci. Program, [2]Psychology Dept., [3]Chem. Dept., Univ. of Scranton, Scranton, PA

Abstract: Obesity is a worldwide epidemic and is closely related to diet-induced diabetes. Diabetes and hypoglycemia brought on by a high fat diet interfere with memory in human and mice as well as induce post-translational modifications such as phosphorylation and glycosylation of certain proteins, but little is known about these effects during the juvenile period. During this study, mice were exposure to a high fat diet (HFD) for eight weeks starting at 24 days postnatal. Mice receiving the HFD did not weigh significantly more prior to exposure ($t(11) = .954$, $p = .36$), but were significantly heavier at 3 ($t(11) = 2.61$, $p = .024$) and 6 weeks ($t(11) = 4.803$, $p = .001$). During the sixth week of exposure, behavioral testing began. Mice were tested on rotarod, open field, and Morris Water Maze to investigate motor coordination, anxiety, and memory. Motor coordination was assessed by a two day rotarod test. Mice exposed to HFD during the juvenile period spent significantly less time on the rod during day one ($F(1,10) = 11.473$, $p = .007$) and day two ($F(1,11) = 15.095$, $p = .003$) when compared to control mice. In general, mice in both groups did not demonstrate learning in the Morris Water maze. Additionally, there was no difference between groups on performance on day two ($F(1, 10) = 2.337$, $p = .157$) of testing. However, HFD mice took significantly more efficient paths to the platform on day three ($F(1,11) = 9.756$, $p = .01$). Moreover, mice exposed to the HFD did not display significantly more thigmotaxis of the open field ($t(11) = 1.214$, $p = .25$). Subsequent to behavioral testing, brain samples were taken for analysis of phosphorylation and glycosylation patterns induced by the HFD. Overall, these preliminary data suggest that juvenile exposure to HFD can affect motor behavior but may not affect learning or anxiety. Further, these exposures may result in differential post-translational modifications.

Title: Binge eating induction does not modify sensitivity to the reinforcing properties of sucrose

Authors: *W. ZEPEDA-RUIZ[1], D. N. VELÁZQUEZ-MARTÍNEZ[2]
[1]Univ. Nacional Autonoma De Mexico, Mexico, Mexico; [2]Psicofisiología, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Binge eating behavior is characterized by overconsumption of palatable food during brief periods of time in absence of energy deficits. It has been suggested that subjects with binge eating behavior assign a greater incentive value to food and that this is reflected in the amount of work that subjects is able do to obtain the palatable food; according to this view, Wojnicki *et al*. (2010) reported that after inducing binge, his subjects achieved higher break points when vegetable shortening was employed as reinforcer. However, we were unable to see an increase in the breaking points of a progressive ratio schedule after binge induction with sucrose. We thought that through training the constant exposure to sucrose during the operant session may induce a reduction of the reinforcing properties of sucrose. Therefore, the objective of the present experiment was to evaluate the performance of subjects with binge eating behavior in a progressive ratio schedule, employing different sucrose solutions as reinforcer. Twelve male Wistar rats (250-300 g) were trained in a progressive ratio schedule, after achieving behavioral stability (no more than 15% of variability in the break point during the last ten sessions); thereafter, subjects were divided according to their break point in two groups: control and experimental, and binge eating induction started following the protocol described by Corwin *et al*. (2006). Both groups had *ad libitum* access to water and standard food; access to a 10% sucrose solution was continuous for the control group and restricted (2 h per day, three days a week) to the experimental group. After binge induction, subject's performance was evaluated in the progressive ratio schedule, employing as reinforcer three sucrose solutions (5.62%, 10% y 17.78%) that were presented in a counterbalanced way. We found that subjects of control and experimental group decreased their break point after binge eating induction. Furthermore, all subjects achieved higher break points with the 17.78% sucrose solution and lowest break points with the 5.62% sucrose solution than with the training concentration of 10%. These results suggest that binge induction do not alter the reinforcing effects of sucrose or the subject's ability to discriminate between different sucrose solutions.

Title: Juvenile and adolescent acesulfame potassium consumption induces hippocampal-dependent learning deficits and anxiety in young adulthood

Authors: *L. TSAN[1,2], V. W. LEE[1], L. A. SCHIER[3], S. E. KANOSKI[3]
[2]Neurosci. Grad. Program, [3]Dept. of Integrative and Evolutionary Biol., [1]USC, Los Angeles, CA

Abstract: Non-nutritive artificial sweeteners (NAS) have become increasingly common in an attempt to maintain the taste of sweetness while reducing carbohydrate and overall caloric intake. Given that consumption of NASs has increased by nearly 200% in children over the past 20 years, it important to understand the extent to which exposure to these substances during critical periods of development in early life affects neurocognitive function. The present study tested the hypothesis that consumption of three common NAS—acesulfame potassium (AceK), stevia, or saccharin—during the juvenile and adolescent periods (postnatal day 26-77) influences cognitive outcomes in rats when tested during young adulthood. Importantly, NAS ingestion was limited to the FDA's acceptable daily intake range (based on mg/kg/day). Our results revealed that consumption of AceK, but not stevia or saccharin, impaired spatial memory in the Barnes maze and increased anxiety-like behavior in the zero maze relative to controls. Overall, these results suggest that early life daily consumption of AceK during the juvenile and adolescent periods of development produces hippocampal-dependent memory deficits and elevated anxiety-like behavior in male rats. Moreover, these neurocognitive outcomes appear to be specific to AceK and do not generalize to other commonly used NASs.

Title: Early exposure to high fat diet affects feeding related behavior

Authors: *H. SONG, M. KIM, H. CHOI
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The prevalence of obesity has increased and it is well known that obesity can cause many health problems. Moreover, the consumption of the palatable foods like high-fat diet (HFD) can cause obesity. Also, exposure to over nutrition environment leads to not only alter the

metabolism but also the mental state. Previous studies has reported that the maternal HFD can increase the risk of being obesity in offspring. However, the effect of eating HFD during childhood and adolescent is not well studied in the perspective of the behavior. We hypothesized that early exposure to the palatable foods after weaning state may cause obesity and modulate neuronal developmental process to increase feeding behavior. We measured the food-reward behavior by three tests : operant conditioning test (motivation level for appetitive pellet), conditioned place preference test (CPP) using palatable food, and three chamber test using social cue and food cue. Locomotive function and anxiety was tested using open field test. Memory function was tested using novel object recognition test. Locomotive function and anxiety was not significantly different between control diet group and HFD group. HFD mice showed significantly decreased motivation level for appetitive pellet compared with control group. HFD mice significantly drank less sucrose water compared with control group. When both control group and HFD group was combined, motivation level for appetitive pellet was in inverse correlation with bodyweight. These results suggest that early exposure to high fat diet may affect neural circuits and feeding related behavior.

Title: Genetic dissection of a lateral septum circuit that regulates feeding behavior

Authors: *K. KIM, H.-E. PARK, J. PARK, S.-Y. KIM
Inst. of Mol. Biol. and Genet., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Feeding, a fundamental behavior of animals, underlies homeostatic control of energy balance by providing caloric input. Although neural mechanisms controlling feeding behavior is extensively studied in hypothalamic regions, emerging evidences suggest that feeding behavior is regulated in complicated manner by multiple, redundant circuits innervating various brain regions. A recent study revealed the role of the septal complex in feeding behavior. However, specific cell population in the septal complex contributing to food consumption is not established yet. Here, by monitoring *in vivo* calcium dynamics and optogenetically stimulating lateral

septum neurons, we show that a subpopulation of GABAergic neurons in the caudal lateral septum are related to regulation of feeding behavior. We found that the septal GABA neurons are acutely inhibited upon food intake, whereas optogenetic stimulation of the same neurons showed trends towards decreased caloric consumption only in starved animals. Based on these preliminary data, we are investigating the structure and function of the septal neurons and their projections in feeding behavior.

Title: The subtle effects of dietary glucose and fructose on the ultrastructure of the hippocampus

Authors: *G. M. MARCELLO[1], E. ANDRÁSOFSZKY[2], V. E. MARKEVICIUS[1], P. SOTONYI[1], J. Z. SZABO[2], B. RACZ[1]
[1]Dept. of Anat. and Histology, [2]Dept. of Animal Nutr., Univ. of Vet. Med. Budapest, Budapest, Hungary

Abstract: The brain's resolute need for sugar elicits exploration of the effects of different carbohydrate sources on cognitive function. Increased fructose intake is of particular interest in light of increasing public awareness of obesity. Consumption of sustained high amounts of high fructose corn syrup in industrially processed foods and beverages has supported interweaving metabolic and neurological effects on human health. Short-term (8 weeks) of increased fructose versus glucose or starch intake as the sole carbohydrate source was investigated for its influence on well-documented hippocampal synaptic organization. Quantitative electron microscopy of CA1 stratum radiatum with a subsequent series of morphological measurements of synaptic profiles sheds light on the post-synaptic functional effect of fructose on hippocampal synapse structure. Surprisingly, increased fructose consumption in Wistar rats was found not to have a

notable impact on post-synaptic ultrastructure in the hippocampus. Differences in morphological measurements of spines in fructose feeding rats, except for spine size between fructose and starch treatment groups, were found to be not significant as compared to glucose or starch test group values. As compared to glucose and starch, fructose did not show significant ultrastructural changes in CA1 spines. Fructose was found to have a negligible influence on hippocampus-dependent synaptic plasticity.

Title: Nicotinic acetylcholine receptors in the arcuate nucleus and their implications for feeding behavior

Authors: *C. A. CALARCO[1], Z. LI[3], S. R. TAYLOR[4], S. LEE[5], W. ZHOU[2], J. FRIEDMAN[6], Y. S. MINEUR[7], C. GOTTI[9], M. PICCIOTTO[8]
[1]Psychiatry, [2]Yale Univ., New Haven, CT; [3]The Rockefellar Univ., New York, NY; [4]Neurobio. Section, Biol. Sci., UCSD, La Jolla, CA; [5]Univ. of Chicago, Chicago, IL; [6]Rockefeller Univ/ HHMI, New York, NY; [7]Psychiatry, [8]Dept Pyschiat, Yale Univ. Sch. Med., New Haven, CT; [9]CNR, Neurosci. Inst., Milano, Italy

Abstract: Despite the known health risks associated with smoking, up to 20% of the US population persist in this behavior. Many individuals smoke to control their weight or are resistant to quitting due to fear of post-cessation weight gain. In clinical populations, nicotine and tobacco use is associated with lower body weight, and cessation yields an average weight gain of about 10 lbs, mostly within the first year. In rodent models, nicotine reduces weight gain, reduces food consumption, and alters energy expenditure, but these effects vary with duration and route of nicotine administration. Nicotine, acting through nicotinic acetylcholine receptors (nAChRs), increases the firing rate of both orexigenic agouti-related peptide (AgRP) and anorexigenic pro-opiomelanocortin (POMC) neurons in the arcuate nucleus of the hypothalamus (ARC), however, it is unknown exactly how this yields reduced food intake.
The subunit composition of nAChRs directly controls their regulation of neuronal excitability, and while it has been shown that the β4 subunit is expressed on POMC neurons in the ARC, it was not known whether this expression is selectively expressed in anorexogenic neurons or how

other nAChR subtypes are distributed in this nucleus. Using translating ribosome affinity purification (TRAP) on ARC tissue from mice with ribosomes tagged in either AgRP or POMC cells, we examined nAChR subunit mRNA levels using real-time PCR. Further, we used immunoprecipitation to probe the subunit composition of functionally assembled nAChR. Numerous common and rare nAChR subtypes are expressed in the ARC, and there are fewer differences in expression between AgRP and POMC neurons than previously hypothesized. Further, the functional nAChR in this region are unique with respect to other brain areas that express the β4 subunit.
AgRP and POMC neurons have opposing functions with respect to controlling food intake, yet these cells are anatomically intermingled within the ARC. Cell type selective virally-delivered small hairpin RNAs targeting either the β4 or α7 subunit were used to examine the contribution of each subunit in either AgRP or POMC cells to the behavioral response to nicotine. While β4 and α7 subunits have different roles in the ARC with respect to responding to the nicotinic drugs nicotine and cytisine, their roles in AgRP and POMC cells are not dramatically different, despite the different functions of these cell populations.
Taken together these experiments further inform our understanding of nAChR signaling in the ARC and provide the basis for a new hypothesis regarding the regulation of this circuit by nicotinic drugs.

Title: A new intracellular emetic signaling system: The pivotal role of Glycogen Synthase Kinase 3 (GSK-3) in vomiting evoked by a variety of emetogens in the least shrew (Cryptotis parva)

Authors: *W. ZHONG, N. DARMANI
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: GSK-3, is a mutifunctional kinase and is involved in a variety of diseases. Its two isoforms GSK-3alpha and GSK-3beta are both constitutively active and upon cellular stimuli turns into its catalytic inactivation by phosphorylation at ser 21 and 9. To investigate the role of GSK-3 in emesis, we examined GSK-3α/β phosphorylation at Ser21/9 via performing Western

blots on brainstem protein extracts from least shrews treated intraperitoneally with fully effective emetic doses of diverse emetogens such as selective and/or nonselective agonists of serotonergic 5-HT3 (e.g. 5-HT or 2-Me-5-HT, 5 mg/kg)-, tachykinin NK1 (e.g. GR73632, 5 mg/kg)-, dopamine D2 (e.g. apomorphine or quinpirole, 2 mg/kg)-, cholinergic M1 (e.g. McN-A343, 2 mg/kg)-receptors, the L-type calcium channel agonist (FPL 64176, 10 mg/kg), chemotherapeutics thapsigargin (0.5 mg/kg, 0.5 mg/kg). Brainstems were collected at multiple time points post emetogens administration. The increase of GSK-3α/β phosphorylation at Ser21/9 was observed following administration of all above discussed emetogens. The increase located in brainstem emetic nuclei (the dorsal vagal complex) was further confirmed through immunostaining brainstem sections of FPL64176-treated least shrews. Moreover, GSK-3 inhibitor SB216763 at a low dose 0.25 mg/kg exerted potent and broad-spectrum antiemetic efficacy against vomiting in response to fully efficacious doses of discussed emetogens. Our findings demonstrate a pivotal role for GSK-3 in vomiting and implies targeting signals up and/or downstream of GSK-3 enzyme may provide powerful new avenues for developing new and potent antiemetics.

Title: A model of binge eating with solid palatable food

Authors: *S. ORTEGA-TINOCO[1], W. A. ZEPEDA-RUIZ[2], D. N. VELÁZQUEZ-MARTÍNEZ[2]
[1]Fisiología, UNAM, Ciudad de Mexico, Mexico; [2]Psicofisiología, Facultad de Psicología, Mexico City, Mexico

Abstract: Binge eating behavior is characterized by overconsumption of palatable food in brief periods of time without energy deficits. Several animal models had been suggested to study the characteristics of this eating disorder, but the most employed is the limited access model (Corwin et al., 2004, *Appetite,*139-142*)*, on which subjects have restricted access to palatable food (vegetable shortening or sucrose) 3 times a week. But humans have more varied diets, therefore, we evaluate the binge eating induction employing a solid food (M&M´s) with a high content of fat and sugar following Corwin et al. (2006) protocol. Twenty-four male Wistar rats were assigned to a control or experimental (according to their body weight) group; both groups had

continuous access to standard food and water. Control group had unrestricted access to M&M´s while the experimental group had access only two hours per day three days a week. After 4 weeks on this food schedule, clear (and significant) differences emerged between the groups. Furthermore, subjects did not change their water or standard food intake and the body weight of both groups increased along the manipulation; such results suggest that is possible to induce binge using M&M´s as palatable food. Additionally, in future studies, the use of food that resembles the complexity of human diet could contribute to evaluate the simultaneous effect of fats and carbohydrates in the reward system.

Title: Functional characterization of a parabrachial microcircuit underlying satiety

Authors: *E. RODRIGUEZ, D. RYU, F. WANG
Neurobio., Duke Univ., Durham, NC

Abstract: Organisms consume nutritious food to maintain metabolic homeostasis and continue their survival. Evidence has shown that there are extrinsic and intrinsic processes, relayed via intricate neural circuitry, orchestrating the initiation and termination of food consumption, such as appetite and satiety. More specifically, there are functionally distinct neural circuits mediating both forms of homeostatic and aversive satiety. Although neural circuitry underlying aversive satiety is well characterized, the circuitry underlying homeostatic satiety is not fully understood. Interestingly, various appetite and satiety signaling nodes project directly onto a distinct caudal sub-region of the lateral parabrachial nucleus (PB_L), which is a node which regulates various emotional and visceral processes including both homeostatic and aversive satiety. Using a novel activity-dependent neuronal labeling technology called CANE, we identified and selectively labeled condensed milk (CM)-activated caudal lateral PB_L (PB_{cl}) neurons that are not $CGRP^+$. We further performed various behavioral assays. Optogenetic activation of these satiety-PB_{cl} neurons induced place preference and decreased CM consumption, whereas silencing increased CM consumption. The novel satiety-PB_{cl} circuit revealed here demonstrates a neural substrate for homeostatic satiation.

Title: Nucleus accumbens projections to the ventral tegmental area mediate primary reward behavior

Authors: C. BOND, R. TRINKO, E. FOSCUE, *R. J. DILEONE
Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: The nucleus accumbens (NAc) is a basal ganglia structure critically important for reward learning, drug addiction and ingestive behavior. Recent work has described the synaptic targets of NAc (shell) projections in the ventral tegmental area (VTA), and demonstrated the role of this pathway in drug seeking behaviors. We sought to determine the activity and function of accumbal VTA projections in natural reward seeking. Using viral anterograde tracing, we find robust projections from the dopamine receptor 1 (D1) medial NAc neurons to both dopamine and non-dopamine cells in the ventral VTA. Optogenetic activation of this pathway reduced food intake and seeking, without affecting motivation or valence state. To assess the activity of VTA-projecting NAc neurons during intake, we selectively labeled this pathway using a viral strategy with retrograde Cre injected into the VTA, and Cre-dependent GCaMP6s into the NAc. Calcium transients were monitored during operant food seeking via fiber photometry. Consistent with optogenetic manipulations, we find that VTA projecting MSNs are modulated during both food seeking and food receipt. Together, these anatomical, functional, and activity experiments demonstrate that NAc projections to the VTA are important for primary reward seeking and consumption.

Title: Leptin-sensitive raphe neurons send projections to hypothalamic nuclei

Authors: *N. D. MAXWELL[1], L. P. REAGAN[1,2], J. R. FADEL[1], F. Z. LOYO-ROSADO[1], C. A. GRILLO[1,2]

Abstract: Leptin is an adipocyte hormone that controls a myriad of homeostatic functions. Most notably, leptin acts on neurons in the hypothalamus through the JAK/STAT pathway to control energy homeostasis and appetite. Leptin has not only been shown to act on hypothalamic neurons, but also on other select areas of the brain such as the raphe nuclei, the primary source of serotonin (5-HT) in the brain. Given the well described effects of 5-HT on feeding, we are interested in studying the connections between the raphe and the hypothalamic nuclei. Although, these connections have been described anatomically, their functional roles remain to be elucidated. We hypothesized that there are leptin-sensitive serotonergic neurons in the raphe nuclei that send projections to different nuclei within the hypothalamus including the arcuate. Our objectives are (1) to define raphe neurons sensitive to leptin that send projections to the hypothalamic nuclei and (2) to verify whether these neurons are serotonergic or not. Accordingly, we bilaterally injected fluorescently tagged cholera toxin-subunit-B (fCTB, a retrograde tracer) into the arcuate nucleus of adult male sprague-dawley rats. One month following the tracer administration, the rats were injected with leptin into the lateral ventricle and perfused with paraformaldehyde 1 hour later. Immunohistochemistry and immunofluorescence were performed on these brain sections, primarily focusing on the raphe nucleus. In order to observe colocalization between our targets, we triple-labeled with antibodies against phosphorylated STAT3 (pSTAT3), a marker for leptin activated neurons, and tryptophan hydroxylase (TPH), a marker of 5-HT neurons along with the fCTB from the injection into the arcuate. Our immunohistochemical results showed that fCTB was co-localized with TPH in the raphe nucleus, indicating that serotonergic neurons project to the arcuate nucleus. More importantly, we observed that serotonergic and non-serotonergic raphe neurons that project to the arcuate nucleus are activated by leptin, showing pSTAT3 staining in response to the leptin injection. These data support our hypothesis that there is an existing leptin-mediated raphe pathway projecting to the hypothalamus. Moving forward, we aim to better understand this pathway and the role that it may play in energy homeostasis and appetite regulation. Additionally, we will further characterize projections to other hypothalamic nuclei that may be important in appetite regulation, as well as determining the other non-serotonergic neuronal subtypes that may play a role within this system.

Title: Genetic mapping of central glucose sensing circuits

Authors: *S.-B. YANG
Inst. of Biomed. Sci., Academia Sinica, Taipei, Taiwan

Abstract: Diabetes is one of the epidemic diseases in the world. Multiple organs are involved in the pathophysiological development of diabetes, including brain. To ensure a constant supply of energy source, primarily glucose, to the brain, some neurons in the hypothalamus receives peripheral information such as nutrient and hormones and adjust gluconeogenesis and insulin sensitivities a variety of peripheral tissues, including liver and muscles. Previous *in vivo* multi-electrode recording and *ex vivo* brain slice patch clamp recording studies have shown that some neurons are reside within the dorsomedial hypothalamus (DMH), ventromedial hypothalamus (VMH), the arcuate nucleus (ARC) and lateral hypothalamus (LH) are sensitive to glucose. Biochemical studies further revealed that those glucose-sensing neurons express prerequisite molecules such as glucose transporters, glucokinase and certain ion channels that enable them to tune their excitability at different glucose levels. Nevertheless, the physiological effects upon direct manipulating these glucose-sensitive neurons are still largely unknown and the roles of these glucose-sensitive neurons in the metabolic syndrome remain elusive. In this study, we combine mouse genetics and electrophysiology to establish the causal relationship between the activity of this glucose-sensing neural ensemble and the physiological states.

Title: Single cell transcriptomic analysis of the lateral hypothalamic area reveals molecularly distinct populations of inhibitory and excitatory neurons

Authors: L. E. MICKELSEN[1], M. BOLISETTY[2], B. R. CHIMILESKI[1], A. FUJITA[1], P. ROBSON[2], *A. C. JACKSON[1]
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs Mansfield, CT; [2]The Jackson Lab. for Genomic Med., Farmington, CT

Abstract: The lateral hypothalamic area (LHA) coordinates fundamental behavioral states such as sleep-wake patterns, feeding, metabolism, stress and motivated behavior. The wide spectrum of innate behaviors and physiological functions ascribed to the LHA may be explained by an exceptionally heterogeneous population of LHA cell types, the diversity of which is poorly understood. In this study, we implemented a single cell transcriptomic approach to classify molecularly distinct neuronal and non-neuronal cell types in the LHA. Specifically, we used a droplet-based single cell isolation method followed by RNA sequencing (scRNA-seq) of individual cells from the LHA, microdissected from juvenile male and female mice. Using unsupervised clustering and differential gene expression analysis to determine transcriptionally distinct cell types, we identified 11 non-neuronal cell types and 30 neuronal cell types. Neuronal cell types in the LHA could be parsed into 15 populations of glutamatergic (*Slc17a6*-expressing) and 15 populations of GABAergic (*Slc32a1*-expressing) neurons, each expressing a suite of discriminatory markers. Distinct neuronal populations were determined by a confluence of markers that includes neuropeptides, transcription factors, synaptic proteins, calcium-binding proteins among other gene categories. In addition to identifying novel cell populations in the LHA, we discovered the molecular basis for discriminating subpopulations of both known and novel cell types. Furthermore, we validated differentially expressed genes through fluorescence *in situ* hybridization (FISH) and single cell qPCR (sc-qPCR) profiling of a selection of genetically-labeled neuronal populations. This comprehensive, transcriptomic analysis of cell types in the LHA, at single cell resolution, lays the groundwork for understanding the molecular, cellular and circuit-level underpinnings of LHA orchestration of fundamental behavioral states, and their dysfunction in disease processes.

Title: Hypothalamic MeCP2 protein levels are altered in mice exposed to high fat diet *in utero*

Authors: A. O'BRIEN[1], J. FRAYRE[2], M. J. MORRIS[1], *E. NA[1]
[1]Psychology & Philosophy, [2]Texas Woman's Univ., Denton, TX

Abstract: Obesity is a nationwide epidemic that affects approximately 30% of the adult population and also adversely affects children, with 1 in 3 children considered overweight. This alarming trend has been associated with cardiovascular disease, type 2 diabetes, as well as psychological disorders such as depression and anxiety. While genetics is a contributing factor, monogenic causes for obesity tend to be extremely rare particularly in childhood cases of obesity. We hypothesize that other biological factors such as epigenetic factors may contribute to the development of obesity in mice exposed to different gestational diets. Methyl-CpG-binding protein 2 (MeCP2) is one such epigenetic factor that is putatively involved in producing obesity in Prader-Willi syndrome children, a key symptom of which is hyperphagia. Here we examined the effects of gestational exposure to a high fat diet (HFD) in mice as compared to mice who were gestationally exposed to a diet that contained adequate levels of fat (NC: normal chow). We find that MeCP2 protein expression is elevated in the hypothalamus of mice exposed to HFD compared to mice exposed to NC during gestational development. MeCP2 protein levels are not altered in the hippocampus suggesting that exposure to HFD during gestation might be specific to areas of the brain that are responsive to changes in energy balance. We also show that body weight is substantially increased in mice that are maintained on HFD after weaning compared to mice that are maintained on NC diet. These data replicate past findings that exposure to HFD can produce obesity in mice. We also show that MeCP2 levels can be influenced by gestational diet and that perhaps MeCP2 may play a significant role in the etiology of obesity.

Title: Nine candidate genes involved in postoperative nausea and vomiting: Transcriptome analysis in the nucleus of the solitary tract of the musk shrew

Authors: *D. KONNO[1], S. SUGINO[1], T. F. SHIBATA[2,3], K. MISAWA[2,3], Y. IMAMURA-KAWASAWA[4,5,6], K. KIDO[7], M. NAGASAKI[2,3], M. YAMAUCHI[1]

Col. of Med., Hershey, PA; [7]Anesthesiol., Kanagawa Dent. Univ. Grad. Sch. of Dent., Yokosuka, Japan

Abstract: Background: Postoperative nausea and vomiting (PONV) is a serious complication after emergence from general anesthesia. However, the molecular mechanisms underlying PONV have not been fully elucidated. Musk shrews are used for emetic research worldwide because standard laboratory mammals, such as rats and mice, are not capable of vomiting. The aims of this study were to establish a shrew model of PONV and to determine changes in gene expression in the nucleus of the solitary tract, which is considered to be the vomiting center in the human brain. **Methods and Results:** Twenty-one female musk shrews (Jic:SUN-Her/Kwl strain, 7-10 weeks of age, weighing 30-50 g) were assigned to four groups and treated as follows: incision and suture of the lower abdomen under 5% of isoflurane inhalation (Surgery group, n = 9), 5% isoflurane inhalation alone (Sham group, n = 6), no treatment (Naïve group, n = 3), and nicotine administration alone as a positive control (PC group, n = 3). After the treatment, the shrews were transferred into an observation chamber to assess emesis for 30 minutes. Episodes of retching and/or vomiting when the interval between retches and/or vomits exceeded 2 seconds were counted. The numbers of episodes were 6 (8), 6 (1), 0 (0), and 12 (8) in the Surgery, Sham, Naïve, and PC groups, respectively [median (interquartile range), Kruskal-Wallis test, p = 0.066)]. After counting the episodes, each shrew was decapitated and the brain stem was immediately removed. The nucleus of the solitary tract was dissected from a frozen section of the brain stem, and total RNA was extracted from the nucleus. Whole transcriptome sequencing was then performed from three RNA samples in the Surgery group and three RNA samples in the Naïve group by using a next-generation DNA sequencer (Illumina HiSeq 2500). A total of 40 million paired-end reads (100 bp) were sequenced in each RNA sample. These reads were mapped to the shrew reference genome (Ous:KAT-227c strain, Suncus murinus Genome Project in Japan, unpublished draft sequence) by using Bowtie2 software. The mapped reads were assembled and annotated by using TIGAR software (Nariai et al., Bioinformatics 2013). Differential transcript expression levels were compared between two groups by using edgeR software. The expression levels of 52,381 transcripts were compared at a p value $< 10^{-5}$ and false discovery rate < 0.01. Nine genes, KIF1C, Ralgds, SDC3, MYRF, SNAP91, Itm2c, EHMT2, KCNIP4 and HSD17B12 genes, showed significantly different expression levels in two groups. **Conclusions:** We quantified changes in the whole transcriptome in the shrew nucleus of the solitary tract. Our results indicated that 9 genes may be involved in PONV.

Title: Hindbrain-originating catecholaminergic projections to the paraventricular hypothalamic nucleus are dispensable for recruitment of ERK1/2 in the lateral part of the central amygdalar nucleus following glycemic challenge in the rat

Authors: *A. M. KHAN[1], E. M. WALKER[1], K. NEGISHI[1], A. N. CLARK[1], A. G. WATTS[2]
[1]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX; [2]Biol. Sci., USC, Los Angeles, CA

Abstract: Hindbrain catecholaminergic (CA) neurons innervate and collateralize across many forebrain regions, including the arcuate (ARH) and paraventricular (PVH) hypothalamic nuclei and the central amygdalar nucleus (CEA). Using immunotoxin-based lesion methods, we have reported that certain PVH and ARH neurons require intact hindbrain-originating CA afferents in order to mount cellular responses to glycemic challenges (Khan et al., *J Neurosci*, 2011; *Endocrinol*, 2014). Here, we extend our long-term study of these same subjects (with either intact or lesioned CA afferents) by asking whether these projections to the PVH/ARH are also required for the lateral part of the CEA (CEAl) to respond to such challenges. To this end, we examined hindbrain CA afferents to the CEAl, as visualized by dopamine-β-hydroxylase-immunoreactive (DβH-ir); and CEAl neuronal activation 30 min after glycemic challenge, as visualized by elevations in phosphorylated ERK1/2 (pERK1/2)-ir neurons.
All intact (sham-lesioned) rats displayed modest DβH-ir fibers within the CEAl, in keeping with previous reports of the sparse but consistent presence of CA terminals in this amygdalar sub-region. The intact subgroup receiving i.v. saline displayed very few, if any, pERK1/2-ir neurons in the CEAl, whereas the subgroup receiving glycemic challenge (e.g., 2-deoxy-D-glucose; 250 mg/kg/ml, i.v.) displayed elevations of CEAl pERK1/2-ir neurons. Compared to intact rats, lesioned rats showing a loss of PVH/ARH DβH-ir fibers also displayed markedly reduced CEAl DβH-ir fibers. However, in contrast to what we reported for the PVH/ARH in these same

lesioned subjects, robust numbers of pERK1/2-ir neurons persisted in the CEAl of lesioned subjects. Our results show that phospho-ERK1/2 is recruited in CEAl neurons after glycemic challenge. Importantly, they also show that the CEAl contrasts with the PVH and ARH by its ability to mount robust cellular responses to glycemic challenge without intact hindbrain-originating CA afferents. Our findings suggest that another, as yet unidentified, ascending afferent system may relay these signals directly to the CEAl. The elevated numbers of neurons in the CEAl that display pERK1/2-ir could reflect activation of a descending, pre-autonomic component of a visceromotor system, a possibility well-supported by evidence that the CEAl helps to control autonomic function. These findings highlight the complex network interactions that occur across distributed sets of neuronal populations in the brain in association with a peripheral metabolic challenge.

Title: High-spatial resolution analysis of α-melanocyte stimulating hormone immunoreactivity in the adult male rat using a canonical brain atlas

Authors: *B. E. PINALES, A. M. KHAN
Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: α-Melanocyte stimulating hormone (αMSH) has a prominent role in the regulation of energy expenditure. Despite research dedicated to understanding its anorexigenic effects, the precise distribution of αMSH-immunoreactive (ir) axonal fibers has yet to be delineated systematically. Here, we performed an immunocytochemical analysis of αMSH-ir chemoarchitecture in the rat forebrain and mapped the labeling patterns to a canonical rat brain atlas (L. W. Swanson, Brain Maps 4.0, 2018). Fixed coronal brain sections of an adult male Sprague-Dawley rat were incubated with a sheep polyclonal antibody (Millipore Cat# AB5087, RRID: AB_91683), and visualized with 3,3'-diaminobenzidine. Nissl-referenced cytoarchitecture and the use of camera lucida drawings allowed for the careful determination of plane of section. Data were mapped with the aid of a dark field microscope. A semi-quantitative

analysis of the labeled fiber distributions was undertaken with the use of Axiome C software (JD Hahn, SFN 2016, San Diego, #467.01. We found αMSH-ir fibers distributed within parts of the thalamus, amygdala, bed nuclei of the terminal stria (BST), and the hypothalamus. Areas of the highest density of αMSH-ir fibers include the lateral septum, medial preoptic nucleus, BST, paraventricular thalamic nucleus, paraventricular and periventricular hypothalamic nuclei, and the amygdala. Dense fibers were also seen in the dorsomedial and arcuate hypothalamic nuclei. Expression of moderate to sparse immunoreactive fibers was noted within the lateral hypothalamic area. αMSH-ir fibers were spread sparsely in the suprachiasmatic, anterior and ventromedial hypothalamic nuclei. Regions devoid of labeling included the cerebral cortex and certain subregions of the thalamus (including the anteromedial nucleus and ventral anterior lateral complex). In sum, we provide an initial series of high-spatial resolution digital atlas maps of αMSH distribution in portions of the rat forebrain. Together with our semi-quantitative analysis, these maps will help to streamline the precise targeting of experimental interventions in forebrain regions that receive αMSH innervation. Future analysis will extend to an examination of αMSH distribution in additional parts of the rostral forebrain.

Title: Automatic derivation of atlas plate correspondences between rat brain atlases using feature-based matching and dynamic programming

Authors: *J. G. PEREZ[1], O. FUENTES[1], A. M. KHAN[2]
[1]Computer Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: The rat brain is one of the most widely studied brains among all animals. Many experiments at multiple scales have been performed on it and numerous rat brain atlases have been published, several of which are now available online. However, correspondences between the several different atlases are not well defined. If these correspondences were available, neuroscientists who already mapped their data to one atlas could more easily translate their data to the other atlases. We developed an image-based algorithm that can automatically derive the

correspondences between all the plates of two different atlases. Our method works by first building a similarity matrix resulting from the comparison of the Nissl-stained tissue images of each plate from one atlas to the images in the other atlas using feature-based matching. These similarities are computed using the Scale Invariant Feature Transform (SIFT), allowing for a small degree of non-rigid transformation between images. Global correspondences between the atlases are then derived using the similarity matrix through a dynamic programming algorithm that enforces ordering constraints imposed by the atlas plate sequences. The dynamic programming algorithm is based on the traditional edit distance algorithm, with modifications made for usage on the domain of rat brain image matches instead of strings. We demonstrate the effectiveness of this algorithm by using it on the Swanson atlas (*Brain Maps, 3rd edition*, 2004) and the Paxinos & Watson atlas (*The Rat Brain in Stereotaxic Coordinates, 7th edition*, 2014) to derive correspondences between these two atlases. Four atlas levels that are fully in register between the two atlases by craniometric alignment were found to also match accurately using the dynamic programming algorithm, with an average accuracy to within one atlas level. These results show that this method is accurate and is comparable to correspondences derived by a neuroscientist through an image independent method; namely, that of craniometric alignments using stereotaxic coordinates. Through these correspondences, we provide a first step towards the development of a unified spatial model of the brain with registered and consistent datasets from diverse studies across multiple scales.

Title: Hypothalamic chemoarchitecture of the adult male rat: High spatial resolution mapping of copeptin, LIM homeobox 6, and melanin-concentrating hormone

Authors: *A. MARTINEZ[1], L. M. BARRAZA ESCUDERO[1], D. CASTRO[1], S. A. CHAVEZ[1], M. CORONADO[1], S. GALLEGOS[1], A. PINEDA SANCHEZ[1], M. S. P. RUIZ[1], V. G. RUIZ[1], K. NEGISHI[1], A. M. KHAN[2]
[1]Biol. Sci., [2]Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: The hypothalamus is a key player in the control of homeostatic systems. While many complex networks involving hypothalamic peptides have been identified, their distributions remain poorly characterized. As a continuation of an ongoing hypothalamic mapping project undertaken annually by the HHMI-funded laboratory-based course (Brain Mapping & Connectomics), a team of undergraduate freshmen were taught how to conduct anatomical analyses of the hypothalamus in the adult male rat using Nissl-stained sections for cytoarchitectural analysis. To better understand the distributions of melanin concentrating hormone (MCH), copeptin, and LIM homeobox 6 (Lhx6), students combined immunofluorescence staining with formal atlas mapping techniques to digitally map the distributions of these molecules to the Swanson rat brain atlas (LW Swanson, Brain Maps 4.0, *J Comp Neurol*, 2018). MCH distribution was used as a reference dataset for direct comparisons between MCH maps generated by previous student cohorts to account for individual variability in mapping. Preliminary results of copeptin distribution in the hypothalamus corroborate previously reported data — it is present in the magnocellular populations of the hypothalamus (SO, PVHpml, NC) with extensive innervation of intra-hypothalamic structures. Further, our results show complementarity in the distributions of Lhx6 between the mouse and rat with labeling largely present in the anterior hypothalamus, absent at mid-lying levels and re-emerging at the level of the dorsomedial hypothalamus; specifically, in the dorsal and juxtadorsal lateral hypothalamic area and zona incerta. The maps from this effort represent the highest spatial resolution maps of copeptin and Lhx6 expression registered to a standardized rat brain atlas. These data continue to build upon our previous chemoarchitectural datasets to provide a better understanding of peptide distribution in the adult rat brain and a deeper understanding of hypothalamic circuitry.

Abstract: The hypothalamus is an important area for homeostatic regulation, due to its diverse population of chemical phenotypes. Although several studies have been dedicated to localizing these phenotypes, their overall spatial organization in relation to each other remains poorly understood. Here, we examine the distributions of neurons and axonal fibers immunoreactive for α-melanocyte stimulating hormone (αMSH) and cocaine- and amphetamine-regulated transcript (CART), both anorexigenic peptides, in relation to neurons and axonal fibers immunoreactive for tyrosine hydroxylase (TH) or neuronal nitric oxide synthase (nNOS). A cohort of freshman undergraduates was taught formal atlas mapping techniques within an HHMI-funded laboratory-based course. Multi-labeled immunofluorescent studies were performd on a male rat brain harvested under basal conditions. Fluorescently labeled immunostaining patterns were cross-mapped with a Nissl-stained tissue reference series to help localize chemoarchitectonic patterns in relation to the underlying cytoarchitecture. Plane of section analysis was carefully performed to facilitate the creation of high-spatial resolution digital maps of the chemoarchitecture within a canonical rat brain atlas (L. W. Swanson, *Brain Maps 4.0*, 2018). Patterns of 4,6-diaminidino-2-phenylindole (DAPI) labeling and immunostaining against the neuronal marker, NeuN, were also used for our analysis.The results show a widespread distribution of αMSH and CART immunoreactivities along the periventricular (pv) and paraventricular hypothalamic (PVH) nuclei, extending to sub-regions of the lateral hypothalamic area (LHA). There, these anorexigens partially colocalize within some areas. A few TH+ and nNOS+ cell bodies are expressed among their immunoreactive fiber distribution patterns, specifically along the margins of the periventricular hypothalamus (pv), where some neurons also appear to be sites of co-localization for both markers. TH+ cell bodies expressed along the pv also appear to be within the vicinity of both CART- and αMSH-immunoreactive fibers; further analysis will help to determine if these fibers form appositions with them. Ultimately, these data will provide high spatial resolution maps of peptides involved in feeding control. This effort will allow for precise functional targeting of specific chemical phenotypes and their comparison with other chemoarchitectural data mapped to the same canonical rat brain atlas (SFN 2015, Chicago, #616.08; SFN 2016, San Diego, #453.07; SFN 2017, Washington DC, #604.03).

Title: Spatial analysis of melanin-concentrating hormone axonal fiber distributions in the medial prefrontal cortex of the adult male rat

Authors: *E. MEJIA[1], A. ENRIQUEZ[2], K. NEGISHI[2], A. M. KHAN[3]
[1]1997, El Paso, TX; [2]Biol. Sci., [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: Melanin-concentrating hormone (MCH) is well-known for its contributions to motivated behaviors. An emerging view describes MCH as an integrative neuropeptide which modulates general arousal state in mammals. In support of this, MCH-containing axonal fibers reportedly distribute rather uniformly and with moderate densities within portions of the isocortex. However, these observations have not been examined thoroughly and there remains the possibility of subtle distinctions among cortical regions. Moreover, isocortex is known to contain a variety of GABAergic interneurons which are differentially involved in controlling behaviors. We used a cytoarchitecture-based approach to examine MCH-immunoreactive (-ir) axonal fiber distributions in the rat across coronal sections containing the medial prefrontal cortex (mPFC), beginning from the rostral end of the cortex to the genu of the corpus callosum. MCH-ir was present in low to moderate densities across all layers of the mPFC but a markedly denser innervation of layer 6 was observed in caudal parts of the infralimbic area and prelimbic cortex. Double label immunoperoxidase reactions were performed to visualize putative appositions between MCH and the prominent classes of interneurons - those that express either parvalbumin (PV) and somatostatin (SSt). Putative contacts were observed to a greater extent on SSt neurons than on PV neurons, despite PV neurons being more abundant. Interactions were more frequent in superficial layers of cortex than in deeper ones. A comparison between different areas of cortex showed that MCH-ir axons mainly targeted PV and SSt neurons in primary and secondary motor cortices. Interestingly, putative MCH-ir appositions were sparse in ventral mPFC areas despite the presence of MCH-ir axons. The maps from this effort could prove instrumental for targeting ultrastructural analyses needed to confirm the presence of synaptic interactions among these immunoreactive elements. Our findings also facilitate the design of functional investigations into bottom-up hypothalamic control of mPFC functions.

Title: Mesoscale characterization of medial prefrontal afferents from the hypothalamus: A spatial analysis of hypocretin/orexin and melanin-concentrating hormone neurons

Authors: *K. NEGISHI[1], A. M. KHAN[2]
[2]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., [1]Univ. of Texas at El Paso, El Paso, TX

Abstract: Research on interactions between the prefrontal cortex and hypothalamus is typically focused on the top-down control of motivated behaviors. By comparison, less is known about the structural and functional underpinnings of bottom-up influences on cortical processes. Hypocretin/orexin (H/O) and melanin-concentrating hormone (MCH) are prominent among hypothalamic cell types. These neurons occupy overlapping fields concentrated in the caudal half of the lateral hypothalamic area (LHA). H/O and MCH are known to project throughout the CNS but it is unclear whether their cell bodies of origin are topographically organized or, conversely, if connections emerge stochastically. Furthermore, the proportions to which PFC-projecting LHA neurons express H/O and MCH is unclear. We begin to address these issues using injections of cholera toxin β subunit (CTB) into the medial prefrontal cortex (mPFC). We then used triple label immunohistochemistry to identify retrogradely labeled neurons which co-localized with MCH or H/O. An injection into the infralimbic area (ILA) produced labeling throughout the hypothalamus. Cell counts performed on coronal sections containing H/O and MCH revealed that 40.4% of retrogradely labeled neurons belonged to those groups. 28.8% of ILA-projecting neurons produced MCH (30/104) whereas 11.5% expressed H/O (12/104). An adjacent Nissl section was used to localize CTB-labeled cells. Most MCH-ir CTB neurons were concentrated in the ventromedial and dorsal (LHAd) parts of the LHA as well as the zona incerta (ZI) where, interestingly, all CTB-labeled cells expressed MCH. ILA-projecting H/O neurons were mainly found in the suprafornical region of the LHA and the posterior hypothalamic nucleus. In contrast to the ILA, an injection centered in the dorsal part of the anterior cingulate area produced sparse CTB labeling in MCH neurons of the LHAd and ZI. Collectively, these findings suggest that MCH and H/O populations could be further subdivided into projection-defined groups.

Title: Identification and atlas mapping of mouse hypothalamic neurons that co-express tyrosine hydroxylase and the vesicular GABA transporter in *in situ* hybridization and immunohistochemistry studies

Authors: *M. J. CHEE[1], K. NEGISHI[2], K. SCHUMACKER[1], R. M. BUTLER[1], G. WITTMANN[4], A. M. KHAN[3]
[1]Carleton Univ., Ottawa, ON, Canada; [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., [2]Univ. of Texas at El Paso, El Paso, TX; [4]Tufts Med. Sch., Boston, MA

Abstract: In order to study the chemoarchitecture of GABAergic neurons within the mouse hypothalamus, we examined GABAergic neurons that express the catecholamine-synthesizing enzyme, tyrosine hydroxylase (TH). We crossed the *Vgat-cre* mouse expressing Cre recombinase under the control of the vesicular GABA transporter (vGAT) promoter to a L10-EGFP reporter mouse to label the soma of vGAT neurons. To validate vGAT expression, we combined immunohistochemistry (IHC) and *in situ* hybridization (ISH) methodology to determine the presence of GFP-immunoreactivity (ir) in the vGAT-L10-EGFP hypothalamus. A careful examination of the combined IHC and ISH signals showed that nearly every EGFP-positive hypothalamic neuron expressed *Vgat* mRNA. We then performed dual-IHC against TH (mouse, 1:2000) and GFP (rabbit, 1:1000) on formalin-fixed vGAT-L10-EGFP brain tissue to map the distribution of TH/GFP. Furthermore, in order to contextualize the observed TH/GFP expression patterns, we used Nissl-stained datasets and nomenclature from the online Allen Brain Atlas (P56, coronal) to perform Nissl-based parcellation and plane-of-section analysis.
Several hypothalamic regions contained neurons that co-localized GFP+TH-ir. The zona incerta contained the most robust co-labeling of GFP+TH-ir neurons. Strikingly, this colocalization appeared specifically restricted to Level 67-68 of the Allen Brain Atlas. We also found a moderate density of GFP+TH-ir neurons within the anterior parvicellular part of the paraventricular hypothalamic nucleus (PVHap); the preoptic (PVpo) and intermediate (PVi) part of the periventricular hypothalamic nucleus; the anterior (DMHa), posterior (DMHp) and ventral (DMHv) part of the dorsomedial hypothalamic nucleus; and at various levels throughout the arcuate hypothalamic nucleus (ARH). Additionally, we found that GFP+TH-ir neurons do not

express dopamine beta-hydroxylase, suggesting that these neurons are not noradrenergic or adregnergic and hence are likely to be dopaminergic.
These results suggest the existence of a novel hypothalamic population that may signal through the release of GABA and/or dopamine. Further functional studies may confirm these structural findings and determine their physiological and behavioral roles.

Title: Central circuitry involved in the control of brown and white adipose tissue in normal rats and obese rats fed with high energy diet from early age

Authors: *G. CANO[1], S. L. HERNAN[1], H. R. ALLEN[1], A. G. RICHIE[1], D. R. UKASIK[1], D. TUPONE[2], A. F. SVED[1]

Abstract: Brown adipose tissue (BAT) regulates heat production to maintain body temperature, whereas white adipose tissue (WAT) functions as an energy reserve. Central control of BAT and WAT activity is exerted via direct sympathetic innervation. Obesity causes dramatic changes in BAT and WAT body distribution and reduces BAT thermogenic activity. We used a well-known model of diet-induced obesity (DIO) to examine whether early life obesity affects the central circuitry that controls BAT and WAT activity in rats. Preadolescent rats (28 days-old; n =24) were fed with high energy diet (31.8% kcal from fat; 25.2% kcal from sucrose) for 8 weeks, whereas control rats were fed with chow. The DIO model generates two subsets of rats based on body weight: obese (573.6 $\pm$ 17.1 g) and obese resistant (460.5 $\pm$ 14.1 g). Chow-fed rats were 491.4 $\pm$ 15.2 g. Each rat was injected with a strain of pseudorabies virus (PRV) that expresses RFP (PRV-614) into inguinal WAT and a PRV expressing GFP (PRV-152) into intrascapular BAT. Rats were perfused at different survival times (96-136 hours), and brains were removed and processed. At early survival times, WAT- and BAT-infected neurons were observed in brain regions involved in central sympathetic control. In chow-fed rats, dual-infected neurons were numerous in the rostroventrolateral medulla (RVLM) and the A5 group, whereas the raphe

pallidus (RPa) and the parapyramidal group (PPy) showed mostly BAT-infected neurons. In other regions such as the paraventricular hypothalamic nucleus (PVH) and ventral locus coeruleus (vLC), similar numbers of single and dual-infected neurons were intermixed. In obese rats, most infected neurons in RVLM and A5 were single-infected BAT neurons, whereas most dual-infected neurons were located in the gigantocellular formation. In RPa and PPy, single-infected BAT and WAT neurons were segregated. The PVH and vLC showed similar numbers of dual and single-infected neurons. At longer survival times, obese rats showed numerous dual infected neurons in regions involved in metabolic control such as the lateral hypothalamus (LH; Orexin-positive), arcuate nucleus (Arc) and Edinger-Westphal nucleus. Dual-infected neurons were also abundant in the preoptic area and the dorsomedial hypothalamic nucleus. Our results suggest that though the same brain regions control BAT and WAT in chow-fed and obese rats, there are some subtle differences in some brain regions (RVLM and A5). Brain areas with an important role in thermoregulation, such as the RPa and PPy, contain tissue-specific segregated neurons, whereas in brain regions involved in metabolic activity (LH and Arc) most neurons are connected to both WAT and BAT simultaneously.

Title: Low nanomolar concentrations of isradipine selectively reduce *in vivo* burst firing of dopamine neurons in the lateral substantia nigra

Authors: *J. SHIN[1], L. KOVACHEVA[1], D. THOMAS[2], S. STOJANOVICH[1], C. A. PALADINI[3], G. GEISSLINGER[2], J. ROEPER[1]
[1]Inst. of Neurophysiology, Neurosci. Ctr., Frankfurt am Main, Germany; [2]Pharmazentrum frankfurt / ZAFES, Inst. of Clin. Pharmacol., Frankfurt am Main, Germany; [3]UTSA Neurosciences Inst., UTSA, San Antonio, TX

Abstract: Isradipine, a clinically approved L-type calcium channel inhibitor, is currently used in a clinical trial testing its ability to slow down the progression of Parkinson disease (PD-Steady III). Although there is evidence that isradipine reduces activity-dependent calcium loading of dopamine (DA) substantia nigra (SN) neurons in vitro, it is unknown whether isradipine affects the in vivo activity of DA SN neurons in therapeutically relevant concentrations. We have

previously presented evidence for a selective role of isradipine-sensitive L-type calcium channels in boosting in vitro burst excitability in lateral but not in medial DA SN neurons of adult C57Bl6N mice (Shin et al., SfN 2017). To now probe for a role of isradipine in the therapeutically relevant, low nanomolar concentration range in controlling in vivo bursting of DA SN neurons, we carried out single-unit recordings of DA SN neurons combined with juxtacellular labeling in anesthetized C57Bl6N mice. Systemic applications of 3 mg/kg isradipine (i.p.) resulted in a selective (ca. 40%) reduction of in vivo bursting of lateral DA SN neurons (spikes fired in bursts: control, 41.84 ± 26.48 %, isradipine, 25.69 ± 23.03 %, n=18, p=0.0006), while firing properties of medial DA SN neurons remained unaffected (spikes fired in bursts: control, 14.63 ± 18.67 %, isradipine, 14.65 ± 16.08 %, n=17, p=0.94). The maximal in vivo effect on bursting was observed at about 15 minutes after systemic drug application, which corresponded to a free plasma concentration of ca. 3 nM isradipine (22.53 ± 3.26 ng/ml at 15 min. post-injection, assuming 95% plasma protein binding, n=5). In vitro bath application of 3 nM isradipine was sufficient to induce a partial (ca. 35%) inhibition of burst excitability in lateral DA SN neurons (gain: control, 758.3 ± 120.3 Hz*nS, n=24, 300 nM isradipine, 425.9 ± 106.5 Hz*nS, n=17, 3 nM isradipine, 641 ± 181.8 Hz*nS, n=14) consistent with our in vivo results. We are currently probing for behavioral effects of low nanomolar isradipine locally infused into the lateral SN of freely moving mice to identify behavioral consequences of acutely suppressing burst activity in lateral SN DA neurons. In summary, our data identified a surprisingly selective in vivo effect of low nanomolar isradipine on burst firing of lateral SN DA neurons. These results constitute a new candidate mechanism how isradipine treatment might affect the most vulnerable DA subpopulation in Parkinson disease.

Title: New players in reward ventral tegmental area circuitry in mice: Electrophysiological and anatomical characterization of somatostatin-positive neurons

Authors: *E. NAGAEVA[1], M. FORSS[1], I. ZUBAREV[2], L. ELSILÄ[1], E. DE MIGUEL[1], E. KORPI[1]

[1]Pharmacol., Univ. of Helsinki, Helsinki, Finland; [2]Dept. of Neurosci. and Biomed. Engin., Aalto Univ., Espoo, Finland

Abstract: The ventral tegmental area (VTA), a part of the midbrain, plays a crucial role in motivational and cognitive behaviors, natural rewards and the action of addictive drugs. All these behaviors require dopamine (DA) release from the VTA to other parts of the brain. Although the VTA serves as one of the main sources for DA neurons in the mammalian brain, it also contains about 25% inhibitory γ-aminobutyric acid-(GABA) and about 5% excitatory glutamate-releasing neurons.

Decoding of any neuronal circuitry requires detailed characterization of all its components. In last decade, anatomy and physiology of VTA dopamine neurons were extensively investigated, whereas much less is known about GABA neurons. Here, we took an attempt to describe heterogeneity of GABA neurons in mouse VTA.

First immunohistochemical experiments showed no parvalbumin neurons in VTA. Using somatostatin(Sst)-Cre mouse line, we were able to find positive neurons, which accounted around 7% of VTA cells population. Further whole-cell current-clamp recordings on Sst-neurons and objective clustering algorithm (principal component analysis + Gaussian mixture model) revealed 3 major electrophysiological subtypes: afterdepolarizing (ADP), high-frequency firing (HFF) and delayed neurons. These subtypes can be easily recognized not only by their firing patterns, but also by location within VTA. Thus, ADP neurons are the most abounded group (53%, N=335) and usually can be found in lateral part of VTA, preferably in parabrachial pigmented (PBP) nucleus. Although, HFF neurons repeat anatomical pattern of ADP neurons, amount of them is much less (19%). Delayed neurons (28%) are located exclusively in the medial-posterior part of VTA in parainterfascicular and paranigral nuclei (PIF, PN). All electrophysiological experiments were done on male/female mice with C57BL/6 background of age P17-P23. Anterograde tracing experiments of VTA Sst neurons showed long-range projections to lateral hypothalamus, central amygdala, paraventricular thalamic nucleus and bed nucleus of stria terminalis.

Overall, here we first time described VTA somatostatin neurons population. This allows including them as the players in the midbrain reward circuitry and form the basis for investigation of somatostatin role in this circuitry.

Title: Structural and functional changes of input-specific excitatory synapses on nigral dopamine cells caused by cocaine

Authors: K. WINDSOR[1], P. VOIT[1], A. TOLER[1], A. LITCH[1], S. HEMANI[1], A. KARLA[1], C. GUO[1], P. FERRER[1], *G. M. BEAUDOIN, III[2]
[2]Biol., [1]Trinity Univ., San Antonio, TX

Abstract: *In vivo* cocaine exposure has been shown to induce changes in excitatory synaptic responses to mesostriatal dopamine neurons. These neurons may be a part of the reward pathway and could be important for controlling motivation and addictive behavior. Previously, we have shown glutamatergic projections from the pedunculopontine tegmental nucleus (PPN) onto dopamine neurons in the substantia nigra pars compacta (SNc) have altered glutamatergic receptor ratios one day after a single injection of cocaine administered *in vivo*. We are now characterizing the underlying structural and functional changes at this synapse. Using optogenetics, we are able to label and activate PPN by injecting in mice a virus encoding a light operated cation channel called channelrhodopsin (ChR2) and yellow fluorescent protein (YFP). Thus, we have begun to characterize the postsynaptic responses of SNc dopamine neurons to excitatory projections from PPN to identify the receptor subunit composition at these glutamatergic subtypes. As expected, N-methyl-d-aspartate receptors (NMDARs), have a standard outward rectifying I-V relationship suggesting the presence of standard NMDAR1/2 heteromers. Additionally, distribution of NMDAR1 subunit localization is not globally affected by cocaine in SNc. We are using the YFP-labeled axons to identify changes in localization of glutamatergic subunits at these synapses on dopamine neurons. We have developed an automated image analysis routine to identify putative synapses between PPN and dopamine neurons from confocal images in order to assay changes in localization of specific glutamate receptor subunits. By measuring the synaptic response of dopamine neurons and imaging the synapse, we have been able to begin characterizing what is affected by cocaine at these synapses.

Title: Glutamate transporters on ventral tegmental area astrocytes orchestrate avoidance and approach behaviors

Authors: *J. A. GOMEZ[1], J. PERKINS[2], G. M. BEAUDOIN, III[3], N. COOK[1], S. QURAISHI[1], M. J. WANAT[4], C. A. PALADINI[5]
[2]Biol., [1]The Univ. of Texas at San Antonio, San Antonio, TX; [3]Biol., Trinity Univ., San Antonio, TX; [4]Neurosciences Inst., Univ. of Texas at San Antonio, San Antonio, TX; [5]UTSA Neurosciences Inst., UTSA, San Antonio, TX

Abstract: Approach and avoidance responses are critical behaviors for survival that signify adaptive responses toward rewarding cues and away from aversive cues, respectively. The ventral tegmental area (VTA) is a heterogeneous midbrain structure that integrates distributed signals for both rewarding and aversive cues, but mechanistic studies have focused exclusively on manipulations of neurons. Whether astrocytes influence local VTA circuit signaling to effect motivated behavior remains unexplored. Here we demonstrate that VTA astrocytes control approach and avoidance behavior by mediating glutamatergic excitation of local GABA neurons. Loss of the glutamate transporter, GLT-1, from VTA astrocytes reduced approach-avoidance conflict in favor of approach. We found that astrocytic GLT-1 in the VTA mediated an increase in excitation of local GABA neurons that elicited a subsequent increase in inhibition of VTA dopamine neurons. The GLT-1-mediated excitation of local GABA neurons resulted in learned avoidance of cues associated with aversion, and prevented expression of preference for cues associated with reward. These data establish an endogenous VTA mechanism wherein astrocyte GLT-1 kinetics control GABAergic tone in the local circuit to shift expression between approach and avoidance behavior. This work suggests VTA astrocytes may be a compelling substrate for studying maladaptive failures of avoidance.

Title: GluN2C-containing NMDA receptors relay the reward signal in the ventral tegmental area

Authors: *G. A. HERNANDEZ[1], E. POIRIER[2], W. M. KOUWENHOVEN[2], D. LÉVESQUE[2], P.-P. ROMPRÉ[2]
[1]Physiologie, [2]Neurosci., Univ. de Montreal, Montreal, QC, Canada

Abstract: Studies on how the reward signal is transmitted in the brain had identified glutamate neurotransmission as an important component in the reward circuitry. Glutamate (Glu) relays the reward signal from the dorsal raphe to ventral tegmental area (VTA) dopamine (DA) neurons. It controls the switch from tonic to phasic firing in active DA neurons, the latter being associated with reward signaling. Also, Glu plays a role in the maintenance of DA inhibitory drive. This myriad of roles suggests that different Glu receptors are involved in these different functions. Here we studied the effects of VTA down-regulation of GluN2C-containing NMDA receptor on the reward signal that arises from dorsal raphe (DR) electrical stimulation. After rats were implanted with an electrode aimed at the DR and bilateral cannulae aimed at the VTA, they were trained to self-stimulate, and reward thresholds were measured using the curve-shift paradigm. Once stable behavioral measurements were obtained, small interfering RNA (siRNA) against GluN2C subunit or a non-active RNA sequence was microinjected into the VTA (5 µg per side); 24 h after each of the 2 consecutive daily bilateral VTA microinjections, reward thresholds were obtained. After the last measurement, reward thresholds were reassessed once rats received a bilateral VTA microinjection (0.825 nmol/0.5 µl/side) of the NMDA receptor antagonist, PPPA. Brains were harvested, and tissue punches from the VTA were taken to determine via Western-blot the levels of specific NMDA receptor subunits (GluN2C and GluN2A). The siRNA treatment produced a selective down-regulation of the GluN2C subunit (~40%) and a significant reduction in reward pursuit. Interestingly, the NMDA antagonist PPPA enhanced reward pursuit only in those rats that received the non-active RNA sequence. Thus, the present results suggest that VTA Glu neurotransmission relays the reward signal initiated by DR electrical stimulation by acting on GluN2C-containing NMDA receptors.

Title: *In vivo* characterization of dopamine neuron subthreshold activity

Authors: *J. M. PERKINS[1], A. S. KULKARNI[1], K. M. COSTA[2], J. ROEPER[3], C. A. PALADINI[4]
[1]Univ. of Texas at San Antonio, San Antonio, TX; [2]Inst. for Neurophysiol., Goethe Univ., Frankfurt am Main, Germany; [3]Goethe Univ. Frankfurt, Frankfurt, Germany; [4]UTSA Neurosciences Inst., UTSA, San Antonio, TX

Abstract: Changes in dopamine neuron firing activity are the result of dynamic changes in synaptic input. Previous extracellular in vivo studies have not been able to measure subthreshold ionic conductances driven by constant activity from both excitatory and inhibitory afferents. Intracellular in vivo recording is the ideal method for measuring changes in firing activity resulting from changes in subthreshold ionic conductances. We have developed a method to consistently obtain in vivo whole-cell recordings from dopamine neurons. Using intracellular in vivo recordings, we are able to differentiate the excitatory and inhibitory subthreshold ionic conductances that elicit either an increase or decrease in dopamine firing activity. We found that the majority of ventral midbrain dopamine neurons have a larger proportion of inhibitory conductance than excitatory conductance.

Title: Glt-1 on astrocytes in the vta regulates cocaine-seeking behavior

Authors: *N. COOK[1], A. S. KULKARNI[3], J. A. GOMEZ[4], C. A. PALADINI[2]

Abstract: The ventral tegmental area (VTA) plays an important, yet complex role in processing a reward (e.g. cocaine). It is known that GLT-1 on astrocytes is mainly involved in regulating extracellular glutamate concentrations surrounding neurons. However, it is unknown if the level of GLT-1 expression in VTA astrocytes affects cocaine-seeking behavior. Here, we examine a connection between GLT-1 levels in mice and their infusion rates during self-administration of cocaine. First, in control mice, we show there are variable levels of self-administration. We will measure the correlation between infusion rates and GLT-1 expression. Second, to show the

impact of astrocytic GLT-1 in the VTA on behavior we used a GLT-1 conditional knock out (cKO) specific to astrocytes in the VTA. Our results demonstrate a decrease in the expression of GLT-1 levels in the VTA can alter cocaine-seeking behavior in mice. GLT-1 cKO mice demonstrate low infusion rates when self administering cocaine. Our results indicate GLT-1 on astrocytes regulate cocaine-seeking behavior in the VTA.

Title: Hypothalamic - habenular - midbrain communication differentially regulates food preference in lean and obese rodents

Authors: *R. M. O'CONNOR, M. V. M. DI BONAVENTURA, W. M. HOWE, A. G. DIFELICEANTONIO, K. DEVARAKONDA, P. J. KENNY

Abstract: Rates of obesity are on the rise worldwide, resulting in a growing threat to public health. Pharmacotherapies that safely reduce body weight in obesity remain elusive, partially due to our incomplete knowledge of the complex neuronal mechanisms that control food choice (palatable high-calorie versus less palatable low-calorie food). The lateral hypothalamus (LH) is considered a critical node in the maintenance of energy homeostasis. A major output of the LH terminates in the lateral habenula (LHb) which has been described as a “preference center” and exerts a negative influence over motivated behaviors through inhibition of midbrain dopamine neurons. We tested the hypothesis that LH projections to LHb play an important role in food preference and food-related motivation through downstream influences on midbrain dopamine neurons. Using monosynaptic rabies tracing we found prominent innervation of ventral tegmental area (VTA) projecting LHb neurons originating in LH. Using fiber photometry, we found neuronal activity of these VTA projecting LHb neurons decreased in hungry animals during the retrieval of regular rodent chow rewards (homeostatic feeding) and in sated animals during palatable food consumption (hedonic feeding). In lean animals the magnitude of decreased neuronal firing from baseline was greatest for homeostatic food seeking compared to hedonic. Interestingly, this pattern switched when animals became obese through exposure to a cafeteria style diet and hedonic seeking of highly palatable food now dramatically reduced VTA projecting LHb neuronal activity. DREADD-mediated stimulation of the LH inputs to the LHb

decreased consumption of palatable energy-dense food, whereas ablation of this pathway increases consumption of the palatable food; opposite effects of these manipulations were observed when only standard (less palatable) chow was made available. Based on these findings, we hypothesize that deficits in the LH - LHb - VTA circuit may emerge during weight gain and contribute to obesity-associated behavioral abnormalities. Modulation of activity at this circuit may represent a promising therapeutic strategy for reversing hyperphagic feeding patterns that generate and maintain obesity.

Title: β-arrestin2 in dopamine receptor-containing neurons modulates the behavioral effects of cocaine and morphine

Authors: *K. A. PORTER-STRANSKY[1], S. L. KARNE[1], C. JEROME[1], N. M. URS[2], M. G. CARON[3], D. WEINSHENKER[4]
[1]Emory Univ., Atlanta, GA; [2]Dept. of Pharmacol. and Therapeut., Univ. of Florida, Gainesville, FL; [3]Duke Univ. Hosp., Durham, NC; [4]Dept Human Genet., Emory Univ. Sch. Med., Atlanta, GA

Abstract: Psychostimulants and opioids increase dopamine release, thereby promoting neurotransmission through dopamine receptors. The protein β-arrestin2 (βarr2) is important for desensitizing and internalizing G protein-coupled receptors (GPCRs), including dopamine receptors, and can also initiate G protein-independent signaling cascades following GPCR activation. Previous work has shown that mice lacking βarr2 globally have altered responses to drugs of abuse, but the specific neurons and circuits mediating these effects are unknown. By crossing D1-Cre and D2-Cre transgenic mice with floxed βarr2 mice, we generated mice that lack βarr2 only in neurons containing either D1 ($D1^{\beta arr2\text{-}KO}$) or D2 ($D2^{\beta arr2\text{-}KO}$) dopamine receptors and then examined drug-induced locomotion and reward (using conditioned place preference; CPP) following multiple doses of D1- and D2-like agonists, cocaine, and morphine. While $D1^{\beta arr2\text{-}KO}$ mice had normal drug responses, $D2^{\beta arr2\text{-}KO}$ mice showed dose-dependent reductions in locomotor responses to cocaine, morphine, and the D2 receptor agonist quinpirole,

as well as a blunted CPP for cocaine. Interestingly, both $D2^{\beta arr2\text{-}KO}$ and $D1^{\beta arr2\text{-}KO}$ mice displayed an enhanced CPP for morphine. These results indicate that βarr2 is necessary in D2 neurons for the rewarding and locomotor-activating effects of psychostimulants, while both D1 and D2 neuron-derived βarr2 can modulate the rewarding effects of morphine.

Title: Deletion of β-arrestin2 in D2-expressing cells alters dopamine, but not morphine sensitivity in D2 nucleus accumbens neurons

Authors: *A. K. PETKO[1], C. JEROME[2], M. G. CARON[3], N. URS[4], D. WEINSHENKER[2], C. PALADINI, 78249[1]
[1]Univ. of Texas at San Antonio, San Antonio, TX; [2]Dept Human Genet., Emory Univ. Sch. Med., Atlanta, GA; [3]Duke Univ. Hosp., Durham, NC; [4]Cell Biol., Duke Univ., Durham, NC

Abstract: G-protein coupled receptors such as opioid and dopamine receptors are coupled to β-arrestin2 (βarr2), which is an important regulator of receptor function. Within the nucleus accumbens (NAc), D1, D2 and μ-opioid receptors expressed on medium spiny neurons (MSNs) are subject to modulation by βarr2. Global deletion of βarr2 alters behavioral sensitivity to drugs of abuse, such as cocaine and morphine, but the cellular subtype and underlying mechanisms responsible are not known. Here, we examined psychostimulant and opiate responses in mice with a conditional βarr2 knockout in either D1 or D2 cells. Using slice electrophysiology, we found that the dopamine-mediated decrease in firing rate of D2 NAc MSNs observed in wild-type mice was attenuated in D2 βarr2 knockout animals, while the typical dopamine-induced increase in firing rate of D1 NAc MSNs was preserved in the mutants. Furthermore, we have found that morphine application similarly decreases maximum firing rate in D1 and D2 MSNs in βarr2 KO and control animals, suggesting that the change in sensitivity to morphine in βarr2 KO mice are likely a component of the dopamine-dependent pathway. Combined, our findings demonstrate a unique role for βarr2 in D2 NAc MSNs.

Title: Neuronal cilia mediate neuromodulatory signaling in a food-motivated progressive ratio task

Authors: *J. MCINTYRE[1], K. R. JASSO[1], V. CAMPANO[1], B. LEWIS[1], S. PARKS[1], B. SETLOW[2]
[1]Neurosci., [2]Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: The neural mechanisms that underlie motivated behaviors and substance use disorders are complex, and impacted by numerous factors. These additional factors include several neuromodulatory peptides associated with physiological states such as hunger and satiety. Several of the receptors for these neuromodulators are enriched in the primary cilia of neurons. Primary cilia are microtubule-based organelles that project from the surface of nearly all mammalian cells, including neurons. The importance of cilia function in human health is highlighted by the number of diseases that result from primary cilia dysfunction, many associated with cognitive and behavioral abnormalities. Despite what we know about cilia, our understanding of how cilia regulate neuronal function and behavior is still limited. One potential mechanism is to provide a signaling platform for neuromodulatory peptides. Several g-protein coupled receptors (GPCRs), such as melanin-concentrating hormone receptor 1 (MCHR1), are enriched in the membrane of cilia compared to the cell body. MCH is a known modulator of feeding behavior, and also modulates behavioral responses to drugs of abuse. The primary objective of this study was to investigate the role of primary cilia in regulating the behavioral effects of MCH on food-motivated behaviors. Using genetic approaches, we selectively ablated cilia from dopaminergic or GABAergic neurons in mice. We then tested whether cilia loss on either of these neuron populations alters motivational state using a food-rewarded progressive ratio task. To assess the role of cilia in MCH signaling in this task, mice were tested following systemic injection of the MCHR1 antagonist SNAP-94847. Compared to wildtypes, mice lacking cilia on GABAergic neurons showed a significant reduction in progressive ratio breakpoint (i.e., reduced food motivation), whereas mice lacking cilia on dopaminergic neurons were unaffected. SNAP-94847 dose-dependently reduced breakpoint in both wildtype mice and mice lacking cilia on dopaminergic neurons, providing further evidence for MCH effects on motivated behavior and indicating that MCHR1 signaling on dopaminergic neuronal cilia is not critical for

modulating food-seeking. In contrast, SNAP-94847 had no effect on breakpoint in mice lacking cilia on GABAergic neurons. These results provide evidence that cilia on GABAergic neurons are important for regulating motivated behavior, and are necessary for MCHR1 modulation of food-seeking behavior. Future work will investigate the neuroanatomical locus of these effects, as well as the role of ciliary neuromodulation in responses to drugs of abuse.

Title: Nutritional programming during pregnancy and lactation sensitizes food addiction-like behavior in offspring of rats

Authors: *L. MONTALVO MARTINEZ[1], L. A. REYES-CASTRO[2], E. ZAMBRANO-GONZALEZ[2], R. ORTIZ-LÓPEZ, 64250[3], A. CAMACHO[4]

Sci., Technological Inst. and of Superior Studies of Monterrey, MONTERREY, Mexico; [4]Univ. Autónoma de Nuevo León, Nuevo León, Mexico

Abstract: Obesity associates to excessive hypercaloric food intake leading to increase in body mass index. Incentive motivation to hypercaloric foods is partly related to an addictive-like behavior phenotype. Addiction correlates with selective changes in gene expression in specific brain reward regions, including the Nucleus Accumbens (NAc), which might be potentially transmitted to the offspring by transgenerational inheritance. Here, we used a murine model of maternal nutritional programming to determine whether: 1) addiction-like behavior of mothers is transmitted to male offspring (F1), and 2) candidate genes for food addiction in the NAc of addicted F1 correlates to aberrant synaptic plasticity gene profile found in drug addiction. We used 9 groups of Wistar rats (8-10 weeks of age), including 2 groups of females (F0) exposed for 9 weeks (pre-mating, pregnancy and lactation) to hypercaloric diet (HD) (maternal programming) or control diet (CD) (control group). All groups were trained by operant conditioning protocols (FR1, FR5, PR; 12 days) using a Skinner-type box, following by chocolate pellets as a reward to determine its addiction-like behavior. Microarray analysis from

the NAcshell of the offspring was performed to identify candidate genes. Our results show no changes in addiction-like behavior of F0 males and F0 females fed with CD. By contrast, F0 females fed with CD show enhanced motivation to hypercaloric rewards compared to F0 females fed HD. Of note, addiction-like behavior from F0 females fed HD was efficiently transmitted to the F1 male offspring in compare to F0 females fed CD. Likewise, global expression microarrays analysis showed that addiction-like
behavior subjects exhibit alteration in the expression of several genes involved in drug addiction such as: DR2, GluA1, GluA2, GluA3, BDNF, CREB, FosB, SIRT1, HDAC1, HDAC4 and MEF2. Genomic interaction pathways demonstrated interactive nodes involved in synaptic plasticity and neuronal function. Our results demonstrate that maternal hypercaloric programming sets food addiction-like behavior susceptibility which positively is transmitted to F1 male offspring showing selective gene expression changes in NAc shares during drug addiction phenotype.

Title: Reward and punishment encodingencoding has shown divisive normalization in primary motor cortex

Authors: *Y. ZHAO[1], J. P. HESSBURG[2], J. T. FRANCIS[3]
[1]Biomed. Engin., [2]Physiol. and Pharmacol., [3]SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Neural activity in the primary motor cortex (M1) is known to correlate with movement related variables including kinematics and dynamics. Recent studies have shown that M1 units are also modulated by reward signals. Divisive normalization encoding has been seen in many neural systems, like invertebrate olfactory system, retina and primary visual cortex. In this study, we investigated the reward and punishment modulation in M1 using divisive normalization model. Two non-human primates (NHPs), which were implant M1, have done the cued grip force task manually with different reward and punishment levels. The results have shown that M1 units, which modulated kinematics information, can have either motivation or valence modulation. These two modulation can be explained using the same divisive normalization model. Motivation units have shown linear or sigmoid relationship with stimuli (reward and punishment). Valence units have shown hyperbola relationship with stimuli and can be interpreted as “pleasant” or “willingness” encoding. Both motivation and valence units have

shown that they are sensitive for some particular reward and punishment levels, like receptor fields in primary visual cortex. These findings support the circumplex model of affect and provide new understanding on decision making process and emotion encoding.

Title: "Unhealthy" diet high in fat or sucrose on negative valence behavior in mice

Authors: *E. I. FLANDREAU[1], D. EUDAVE[1], M. BELOW[1], A. BUCHHEIT[2]
[1]Psychology, [2]Grand Valley State Univ., Allendale, MI

Abstract: Stress increases risk for psychopathology, but most stress-exposed individuals do not develop deleterious effects; other genetic and environmental factors moderate the risk for stress-induced psychopathology. A “Western” diet has been linked to psychopathology in humans; animal studies also show that diet can influence negative valence behavior in the presence or absence of stress, but findings are inconsistent, highlighting the need for additional research. The present study exposed mice to 10 days of high fat or high sucrose diet concurrent with social defeat stress and examined behavior in the social interaction, open field, elevated zero, tail suspension, and acoustic startle tests at acute (less than five days) and long-term (more than 30 days) time points after stress/diet exposure. In contrast to our hypothesis, we primarily observed main effects of stress or diet rather than stress x diet interactions. Stress increased negative valence behavior in these tests at the acute time point. Most stress-induced behaviors normalized after a 30-day recovery period, but social avoidance was still highly significant for stress-exposed mice, supporting the hypothesis that avoidance of trauma-related cues persists beyond non-specific anxiety-like behaviors. Supporting the hypothesis that an unhealthy diet contributes to psychopathology, non-stressed mice fed high fat or high sucrose diets spent less time exploring the center of the open field.

Title: Chemogenetic activation of medial prefrontal cortex excitatory neurons alleviated the impaired fear extinction of an animal model of PTSD

Authors: *J. OMURA[1], M. FUCHIKAMI[1], M. ARAKI[1], T. MIYAGI[1], S. MORINOBU[2]
[1]Psychiatry and Neurosciences, Hiroshima Univ., Hiroshima-Shi, Japan; [2]Kibi Intl. Univ., Okayama, Japan

Abstract: Although the impaired *extinction of fear memory* (EFM) is one of the hallmark symptoms of posttraumatic stress disorder (PTSD), the precise mechanisms of impaired EFM are unknown and effective pharmacological interventions have not yet been developed. A growing evidence shows that the activation of infralimbic cortex (IL), subregion of the medial prefrontal cortex (mPFC), predicts successful fear extinction, whereas functionally disrupting this region impairs extinction. We used a single prolonged stress (SPS) paradigm, which mimics the pathophysiological abnormalities and behavioral characteristics of PTSD including the impaired EFM. This study was undertaken to examine whether chemogenetic activation (CA) of mPFC excitatory neurons alleviated the impaired EFM in SPS. The CA was conducted by administration of clozapine-N-oxide (CNO) to activate virally delivered CamKII alpha-hM3Dq-DREADD in mPFC excitatory neurons, and the behavioral effect was examined using contextual fear conditioning. In addition, the effects of CA on the neuronal activity in sham and SPS rats were measured by multi-unit extracellular recording. The CA of IL, but not PL, just before extinction training significantly decreased freezing during the extinction training and extinction test (24h after extinction training) in sham rats, whereas this enhancement of EFM was only seen during the extinction test in SPS rats. Electrophysiological study revealed that the induction of neuronal activation by CA in IL of SPS rats was smaller than that of sham rats, though basal activity (without CA) in SPS rats was almost equal to that in sham. Our results indicates that the decreased excitatory tone in IL might, at least in part, be involved in the mechanism of the impaired EFM in SPS, and the simultaneous treatment with neuronal activation and exposure therapy may be effective in the treatment of patients with PTSD.

Abstract: Calcitonin gene-related peptide (CGRP), which is produced in both peripheral and central nervous system, is well known as a potent vasodilator. Although CGRP plays an important role in central nervous system, its effect on hippocampus-dependent fear memory is still not clear. 8-week-old male C57BL6J mice were examined to passive avoidance test or contextual fear learning test. Mice were given a 0.2 mA foot shock when entered black compartment. In the contextual fear learning test, mice were given a 0.3 mA foot shock. After fear conditioning, mice were given saline or CGRP (0.5 nmol) by intracerebroventricular administration. CGRP injections shortened the avoidance latency in passive avoidance test, and also reduced freezing time in contextual fear learning test. To examine which gene is involved in CGRP-mediated extinction of fear memory, microarray assay was performed. CGRP injections significantly increased *Npas4* gene rather than saline treatment. We also found that CGRP increased dephosphorylation of nuclear histone deacetylase 5 (HDAC5), which is known to be involved in epigenetic regulation of NPAS4, in the mouse hippocampus. These results suggest that HDAC5 and NPAS4 might be involved in CGRP-mediated extinction of fear memory.

Title: The role of glucocorticoid receptor in the induction and the prevention of the hippocampal abnormalities in an animal model of PTSD

Authors: *M. ARAKI[1], M. FUCHIKAMI[1], J. OMURA[1], T. MIYAGI[1], S. MORINOBU[2]
[1]Psychiatry and Neurosciences, Hiroshima Univ., Hiroshima-Shi, Japan; [2]Kibi Intl. Univ., Okayama, Japan

Abstract: Posttraumatic stress disorder (PTSD) is a representative stress-related mental disorder associated with an intricate biological and psychological symptom profile. Although the detailed mechanisms are not fully uncovered, numerous clinical studies of PTSD demonstrates the functional and morphological abnormalities in the hippocampus after exposure to life-threatening trauma, such as the enhanced negative feedback of the hypothalamo-pituitary-adrenal axis, hippocampal atrophy, and fear memory extinction. In this context, it is worthwhile to examine the alteration of hippocampal gene expression through glucocorticoid receptor (GR) in an animal model of PTSD to elucidate the pathophysiology of PTSD.
We used a single prolonged stress (SPS) paradigm, which mimic the pathophysiological abnormalities and behavioral characteristics of PTSD including the impaired extinction of fear memory. We first examined whether SPS changed the nuclear levels of GR in the rat hippocampus by Western blot, and found a significant increase 2 h after SPS. Subsequent analyses by ChIP-qPCR and RT-PCR revealed that SPS increased the binding of GR to the glucocorticoid response element (GRE) at the promoter of the Bcl-2 gene. Correspondently, we found the decreased expression of Bcl-2 mRNA in the hippocampus of SPS rats.
Based on these findings, it is plausible that the activation of hippocampal apoptotic pathway through the increased binding of GR to the GRE binding site may be induced by severe trauma, and may be consequently involved in the pathophysiology of PTSD. We are now examining the apoptotic changes in the hippocampus of SPS rats using TUNEL staining. In addition, we will examine the preventive effect of GR antagonist mifepristone (RU486) on the impaired fear extinction, changes in the hippocampal expression of apoptosis-associated genes, and the hippocampal apoptosis in SPS rats. Additional data will be shown at the meeting.

Title: Pre-conception predator stress induces physiological and behavioral changes in offspring

Authors: S. BHATTACHARYA, A1B3X9[1], A. FONTAINE[2], P. MACCALLUM[2], K. JARVIS[2], Q. YUAN[3], G. MARTIN[3], F. BAMBICO[4], *J. J. BLUNDELL[2]
[1]Psychol, Mem. Univ., St. John's, NL, Canada; [2]Psychol, [4]Psychology, [3]Mem. Univ., St John's, NL, Canada

Abstract: It is well known that traumatic stress can have deleterious effects on an individual. Recent data suggests that these harmful effects can propagate into future generations, making offspring more prone to mental illness (i.e. anxiety, depression and/or posttraumatic stress disorder). While recent data from the animal literature supports transgenerational effects of stress, little is known regarding the consequences of pre-conception stress on adolescent offspring. Furthermore, whether these changes persist into adulthood and make offspring more susceptible to future stressors is not known. Male and female mice were exposed to a predator (live rat-predator stress) or control condition for five minutes. Ten days later, stressed male mice were bred to stressed female mice and control male mice were bred to control female mice. On postnatal day (PND) 24, all offspring underwent a behavioural battery to assess anxiety-, depressive-like behaviour, and hyperarousal. We show that pre-conception predator stress increases anxiety-like behaviour as measured in the elevated plus maze, light/dark box, social anxiety test, and increased hyperarousal in adolescent offspring. At adulthood (PND 60), mice were subjected to a mild stressor and assessed for anxiety-, depressive-like behaviours, and hyperarousal. Pre-conception parental stress increased anxiety-like behaviour and hyperarousal in adult offspring exposed to a mild stressor indicating enhanced stress-susceptibility in these adult offspring. Furthermore, pre-conception parental stress increased stress-induced neural activation (cFOS expression), as well AMPA receptors (GLUA1), but not NR1, in the hippocampus of adult male offspring. Overall, our data suggest that traumatic stress not only affects an individual, but it can alter the behavioural responses of future generations. Currently, we are assessing the effects of pre-conception stress on the long-term potential in the hippocampus, hippocampal and amygdala dendritic morphology, corticosterone levels, and glucocorticoid receptors in offspring. Ultimately, identification of the mechanisms that promote anxiety in children, as well as increased stress-susceptibility in adulthood, will represent a major advance in the field, and may lead to novel treatments for such devastating, and often treatment-resistant disorders.

Abstract: There is substantial evidence of comorbidity between stress disorders and substance use disorders (SUDs). Studies using a combined rodent model of stress and substance use reveal that previous exposure to stress predisposes animals to the behavioral effects of psychostimulants and opioids, including the development of behavioral sensitization and drug self-administration. Here we showed a remarkable overlap between the enduring neuroadaptations produced in nucleus accumbens core (NAcore) excitatory transmission after acute restraining stress and drug use. Specifically, we discovered that 3 weeks after a single acute stress (2 hr restraint) glutamatergic synapses on NAcore medium spine neurons (MSNs) show increased AMPA/NMDA ratio and dendritic spine density, and marked reduction in glial glutamate transporter (GLT-1) expression and function paralleling previous measurements made after withdrawal from cocaine. Besides, pairing a stressful event with a novel odor, we found that the stress-conditioned odor alone induced cocaine seeking, and potentiated seeking when paired with the cocaine-conditioned light/tone cue. Previous work revealed that cocaine seeking is prevented by restoring GLT-1 with N-acetylcysteine (NAC), and we found that 5-days treatment with NAC also prevented stress odor-induced cocaine seeking. Importantly, NAC treatment in humans alleviates cocaine craving and the symptoms of co-morbid SUDs/PTSD, indicating that the stress-induced adaptations we have identified may contribute to the neuropathology of comorbidity in humans.

Title: Sex differences in sensitivity to an unpredictable versus predictable stressor in a novel inhibitory avoidance-based rat model of comorbid alcohol and anxiety disorders

Authors: *M. Q. STEINMAN[1], D. KIRSON[1], S. A. WOLFE[1], S. R. SPIERLING[1], M. BAJO[1], S. SURESHCHANDRA[2], N. K. HOANG[1], A. SINGHAL[1], C. S. OLEATA[1], I. MESSAOUDI[2], E. P. ZORRILLA[1], M. ROBERTO[1]

Abstract: Alcohol use disorder is often comorbid with anxiety disorders. These distinct conditions likely share common physiological etiologies that if elucidated could improve treatments for both alcoholism and anxiety. We adapted a recently published "2-hit" rat model of posttraumatic stress disorder (PTSD) to alcoholism research. Unlike more common alcohol footshock models, this model uses inhibitory avoidance to capitalize on both operant and Pavlovian fear conditioning. This is valuable as both types of responses occur in clinical anxiety disorders. In the model, 2 unpredictable footshocks administered once per day over 2 days promote long-lasting PTSD-like behavior. For unpredictable stress, each shock occurs in a different context (shuttle box vs. fear conditioning box) while predictable stress can be administered using the same shuttle box twice. We examined effects of unpredictable and predictable stress on alcohol intake during intermittent access 2-bottle choice (2BC) in male and female Wistar rats. In Experiment 1 rats were trained on 2BC for one month before shock exposure and were given 24 hr-long 2BC sessions. Predictable stress increased drinking in a subset of males that showed impaired inhibitory avoidance behavior during fear memory reactivation. Conversely, unpredictable stress caused a dramatic decrease in male 2BC drinking. We also examined translationally relevant PTSD-like behaviors. Male unpredictable stress rats exhibited enhanced acoustic startle responses. Both forms of stress disrupted sleep patterns in both sexes, shortening the longest bout of sleep. In Experiment 2 rats did not receive alcohol prior to footshock and the 2BC sessions were 2 hr-long to promote binge-like drinking. Stress increased alcohol intake in both sexes with the more potent treatment being predictable stress in males and unpredictable stress in females. Predictable stress males displayed a consistent

"deprivation effect" where they increased drinking after weekend abstinence. In all, these findings are consistent with reports that alcohol prior to footshock can impede the unpredictable shock-induced escalation in drinking. Ongoing studies are using the model to interrogate the role of neuroinflammatory responses in comorbid alcohol and anxiety disorders.

Title: Beta-hydroxybutyrate attenuates anxiety-related behavior in rodent PTSD model

Authors: *T. YAMANASHI[1], M. IWATA[1], K. TSUNETOMI[1], N. KAJITANI[1], M. NAGATA[1], A. MIURA[1], R. MATSUO[1], T. NISHIGUCHI[1], R. S. DUMAN[2], K. KANEKO[1]

Abstract: Post-traumatic stress disorder (PTSD) occurs after experiencing traumatic events such as war, disaster or violence. PTSD symptoms usually include intrusive recollections of traumatic events, avoidance of event reminders, anxiety and hyperarousal. Accumulated evidences have suggested that elevation of neuro-inflammation and decreased brain-derived neurotrophic factor (BDNF) contribute to the pathophysiology of PTSD. Recent reports show that in a rat model of PTSD, BDNF and CREB expression are decreased, and interleukin-1beta (IL-1beta) and tumor necrosis factor-alpha (TNF-alpha) are increased in the hippocampus (Lee et al. 2018 J Nat Med). The absence of optimal treatments along with low response rates makes the investigation for novel pharmacological therapies a high priority. Beta-hydroxybutyrate (BHB) is a ketone body that supports mammalian survival during states of energy-deficit. Recent reports showed that BHB exerts an antidepressant effect in rodent models of depression by inhibiting neuro-inflammation (Yamanashi et al. 2017 Sci Rep) or increasing BDNF (Chen et al. 2017 Biochem Biophys Res Commun). In this study, we aimed to evaluate the possible beneficial effects of BHB in a rat PTSD model using single prolonged stress (SPS). On a single day, rats are subjected to a 2-hour immobilization followed immediately by a 20-min forced swim. Rats are given a brief period of recuperation and then subjected to diethyl ether until they are anesthetized

and unresponsive. After SPS, rats were administered BHB subcutaneously twice a day. After 1-2 treatment period, we evaluated anxiety behavior using an elevated plus maze test (EPM). We found that repeated BHB administration attenuates SPS-induced anxiety-related behavior. While additional studies are needed, these findings suggest that BHB may be a novel therapeutic candidate for the treatment of PTSD related anxiety symptoms.

Title: Transitional impairments in fear memory in rodent ptsd model that could be prevented by intranasal npy

Authors: *X. LIU, L. I. SEROVA, E. L. SABBAN
Dept. of Biochem. and Mol. Biol., New York Med. Col., Valhalla, NY

Abstract: Disruption of fear memory is one of the crucial features in posttraumatic stress disorder (PTSD). Neuropeptide Y (NPY) is an endogenous neuropeptide associated with resilience to PTSD. Using the single-prolonged stress (SPS) rodent PTSD model, we previously demonstrated that early intervention with intranasal NPY delivery to the brain prevented development of many neuroendocrine and behavioral abnormalities, included anxiety, hyperarousal, and depressive-like behavior. Here, we exposed rats to SPS stressors and immediately gave them intranasal NPY (SPS/NPY) or vehicle (SPS/V) and tested fear memory after one-week or two-weeks compared to unstressed controls.
One-week after SPS stressors, there was no difference among the groups in acquisition or extinction of contextual fear. But the retention session showed that the SPS/V, not the SPS/NPY group, had significantly enhanced retention of extinguished fear memory. In cued fear conditioning, the extinction retention also showed changes of freezing over time and the SPS/V rats exhibited significantly more freezing. Intranasal NPY prevented the enhanced fear memory in the SPS/V rats, and the SPS/NPY group exhibited similar freezing levels as the unstressed control group.
However, two-weeks after SPS stressors, the pattern of changes in fear memory was different and not elevated in the SPS/V group for retention of extinguished contextual fear. Similarly, with

cued fear conditioning, the SPS/V group did not show
enhanced freezing in the context used for extinguishing the tone. However, reinstatement by placing the rats back into the initial context paired with the tone stimulus without foot-shock revealed marked response in the SPS/V group. The data revealed two divergent SPS/V subgroups as determined by the D'Agostino and Pearson Omnibus Normality Test. One subgroup showed significantly enhanced fear memory and the other had reduced retention compared to unstressed controls.
Overall, our study demonstrated that SPS affected fear memory differently depending on progression of time subsequent to the exposure to the traumatic stress, and revealed individual differences in manifestation of the memory impairments after stress.

Title: Determination of the relative reinforcing effect of MDMA by fixed ratio (FR) and progressive ratio (PR) intravenous self-administration testing in rats

Authors: *S. L. SMITH, M. HALLAM, D. HEAL
Renasci Ltd, Nottingham, United Kingdom

Abstract: There are relatively few published studies describing the reinforcing effects of MDMA (ecstasy) in rats. FDA recently granted breakthrough status to 3,4-methylenedioxymethamphetamine (MDMA; "ecstasy") for the treatment of PTSD. If MDMA is approved for medical use, it will have to move from being a C-I controlled drug to different schedules, i.e. C-II to C-V. There are very few published studies describing the reinforcing effects of MDMA in rats and none to our knowledge that have explored its relative reinforcing effect in this species. Therefore, we have investigated the reinforcing properties of MDMA in heroin-maintained rats using FR and PR schedules of drug reinforcement. Mildly food-restricted, male, Sprague-Dawley rats were initially trained to lever-press for food rewards before being surgically implanted with in-dwelling jugular catheters. Rats were allowed to self-administer heroin (15µg/kg/inj) on a fixed ratio (FR5) schedule of reinforcement in 2hr training sessions. After establishment of consistent heroin self-administration, the rats were subjected to saline extinction. The reinforcing effects of MDMA (0.025, 0.05, 0.1 or 0.25mg/kg/inj) were then evaluated on FR5 and FR3 schedules in 2hr sessions. In the second part of the experiment, if MDMA served as a reinforcer (>6 inj/session) in an individual rat, a 4hr progressive ratio (PR)/break-point analysis was performed. Results are mean ± SEM. Heroin maintained

self-administration in rats (15.6±2.2 inj/session, n=10) at levels significantly greater ($p<0.01$) than saline (4.9±0.3 inj/session, n=10). Although self-administration of MDMA was acceptable on FR5, it served as a more reliable reinforcer on FR3. On FR3, all doses of MDMA (0.025, 0.05, 0.1 or 0.25mg/kg/inj) maintained self-administration at levels significantly greater than saline (0.025=13.8±2.3 [n=4], $p<0.05$; 0.05=18.6±1.9 [n=5], $p<0.01$; 0.1=16.0±3.1 [n=5], $p<0.01$; 0.25=17.3±3.2 [n=5], $p<0.01$). The break-points for responding (mean lever-presses/inj) for these doses of MDMA were 18.0±2.9; 22.8±3.3; 20.0±2.2 and 30.6±7.4, respectively. MDMA served as a positive reinforcer across a 10-fold dose range in heroin-maintained rats. Powerful reinforcers, eg heroin (61.8±17.7, 25ug/kg/inj, n=8) and cocaine (65.7±22.2, 290ug/kg/inj, n=10) (Smith et al, 2016, SfN abst p.549.10) typically support break-points greater than 50 lever-press/inj. The break-point results obtained with MDMA classifies it as having moderate reinforcing efficacy in rats.

Title: Behavioral effects of a novel α_{2C}-adrenoceptor selective antagonist, ORM-10921, in an animal model of posttraumatic stress disorder (PTSD)

Authors: *D. WOLMARANS[1,2], C. L. ERICHSEN[2], D. J. STEIN[3,4], B. H. HARVEY[2,5]
[2]Ctr. of Excellence for Pharmaceut. Sci., [1]North-West Univ., Potchefstroom, South Africa; [3]Univ. of Cape Town, Cape Town, South Africa; [4]MRC Unit on Risk and Resilience in Mental Disorders, Cape Town, South Africa; [5]MRC Unit on Risk and Resilience in Mental Disorders, Potchefstroom, South Africa

Abstract: Posttraumatic stress disorder (PTSD) is a severe trauma and stress disorder that follows exposure to a life-threatening event in some individuals. Supported by clinical and pre-clinical data, dysfunctional noradrenergic signaling in the aftermath of trauma has been implicated. Current treatments for PTSD are inadequate and an urgent need exists to study the neurobiological constructs underlying the condition. While not overly successful, modulation of the noradrenergic system has attracted interest in the treatment of PTSD. In this regard, studies have suggested that non-selective modulation of the α_2 adrenoceptor exert opposing actions via the α_{2A} and α_{2C} receptors. Thus, the aim of the study was to explore the putative therapeutic effects of ORM-10921, a selective α_{2C}-adrenoceptor antagonist, in an animal model of PTSD, i.e.

predator scent exposure (PSE). 60 adult male Wistar rats (150 – 200g; 3-4 animals per cage) were randomly selected. Subjects were housed in ventilated cages that were maintained at 21ºC at a relative humidity of 50% on a 12-hour light-dark cycle (6h/18h). Food and water were provided ad lib (Ethical Clearance Nr NWU-00438-16-S5). Before the onset of experiments, subjects were randomly divided into non-scented and predator scent exposure cohorts. A single exposure (10 min) to a predator scented (normal cloth used as bedding material for a house cat for 3 months) or control cloth (normal cloth only; both 10 x 10 cm; one animal per cage) was applied. Immediately after exposure, subjects were divided into separate treatment groups (non-scented CTRL: n=8; non-scented ORM-10921: n=16; PSE CTRL: n=12; PSE ORM-10921: n=24) and injected with either saline or ORM-10921 (i.p.; 0.3 mg/kg/day) for 21 days. Our results indicate that PSE, but not exposure to non-scented cloth, induced significant anxiety-like behavior as assessed in the elevated plus maze (EPM) on day 7 post-exposure. Moreover, in congruence with the clinical condition in as far between-patient variance in post-trauma prognosis is concerned, this response could only be observed in 25% of the PSE cohort and lasted until day 21 post-PSE. With respect to the involvement of the α_{2C}-adrenoceptor in this behavior, ORM-10921 abrogated PSE-induced anxiety compared to CTRL animals as reflected by improvements in risk taking behavior and negligible changes in the number of open arm entries on day 7 vs 21 post exposure. In conclusion, this study can be appreciated as putative proof of concept for further investigations into the neurobiological role of the α_{2C}-adrenoceptor in anxiety-related conditions.

Title: Female gonadal hormones during trauma may account for their higher risk of developing PTSD

Authors: *C. V. CHEN[1], I. LIBERZON[2]
[1]Univ. of Michigan, Ann Arbor, MI; [2]Psychiatry, Univ. of Michigan Hlth. Syst., Ann Arbor, MI

Abstract: Post-traumatic stress disorder (PTSD) is a deleterious mental health condition with a lifetime prevalence of 6-9% in the US, affecting twice as many women as men. Since gonadal hormones play a crucial role in many sex differences, they may contribute to sex differences in

the etiology and prevalence of PTSD in women. Using a PTSD rodent model, Single Prolonged Stress (SPS), our lab has shown that male rats exposed to SPS develop a deficit in retention of fear extinction, a postulated key deficit in PTSD. Here, we sought to determine how estrous cycle in female rats affect various aspects of fear associated learning like fear conditioning (FC), fear extinction (FE), and SPS-induced extinction recall (ER) deficits. The estrous cycle of adult intact female rats was tracked using vaginal swabs. Experimental groups were exposed to SPS during proestrus, estrus, diestrus 1 or diestrus 2; finally, all animals (controls included) were tested on FC, FE and ER. Findings indicate that, compared to controls, rats that experienced SPS acquire fear conditioning faster and, though they behave similarly during FE, show a deficit in retention of extinction. This deficit in SPS rats seems to be driven by animals that were in proestrus and estrus phases on the day of SPS. Estrus stage on the day of FC and FE did not seem to affect ER performance. In other words, being in proestrus or estrus on the day of trauma seemed to place female rats at a higher risk of developing extinction recall deficits, regardless of later hormonal stage during testing. Together, these data indicate that the higher prevalence in PTSD in women may be explained by the level of their endogenous gonadal hormones during a traumatic experience.

Title: Role of adult hippocampal neurogenesis in SPS-induced extinction retention deficit

Authors: *E. RODRIGUEZ[1], J. A. GRECO[2], J. ABELSON[3], I. LIBERZON[4]
[1]Univ. of Michigan, Detroit, MI; [3]Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI; [4]Psychiatry, Univ. of Michigan Hlth. Syst., Ann Arbor, MI

Abstract: Posttraumatic stress disorder (PTSD) has been functionally linked to impairments in context-dependent fear extinction retention (ER), a process that requires intact prefrontal cortex - hippocampal (Hpc) circuitry. PTSD patients show abnormalities in Hpc volume and function, and in contextual processing, generally. At the cellular level, adult Hpc neurogenesis plays a role in key Hpc functions, like pattern separation, and is sensitive to stress, but has not been examined in PTSD. Here we use an animal model of PTSD - single prolonged stress (SPS) - to examine adult Hpc neurogenesis and its involvement in context-dependent ER. We first demonstrated impaired ER in irradiated animals, associated with reduced Hpc neurogenesis (by

70%). Irradiated rats showed normal fear conditioning and fear extinction, but impaired ER (increased freezing) associated with the degree of immature cell loss within Hpc. Secondly, we examined the effects of SPS on neurogenesis, demonstrating decreased number of immature neurons in Hpc of SPS animals. To determine whether this effect was due to cell proliferation or survival, we injected BrdU (synthetic thymidine nucleoside, 5-bromo-2'-deoxyuridine) three weeks before SPS (cell survival) or one day after SPS (cell proliferation). In both cases, SPS reduced the number of BrdU+ adult-born dentate gyrus granule cells. Finally, we rescued SPS ER effects by enhancing Hpc neuronal survival - via environmental enrichment. Together, these data strongly support a role for adult Hpc neurogenesis in mediating an SPS-induced extinction retention deficit. These results identify neurogenesis as a potential mechanism underlying PTSD contextual processing deficits.

Title: Alterations in serum/glucocorticoid-regulated kinase transcript: Evidence for peripheral and CNS effects in PTSD

Authors: *B. LEE, M. J. GIRGENTI[1], B. HARE[1], M. S. MAZEI-ROBISON[2], R. S. DUMAN[1]
[1]Yale Univ. Sch. Med., New Haven, CT; [2]Physiol., Michigan State Univ., East Lansing, MI

Abstract: Post-traumatic stress disorder (PTSD) is a debilitating psychiatric disorder with a life-time prevalence of 7.8% in the general population. Numerous studies suggest that alterations in gene transcription are associated with onset of PTSD. The majority of these studies have focused on peripheral blood transcript changes. While it is likely that many changes observed in the periphery reflect changes in the CNS, there are currently few studies directly examining the transcript changes in brain. In a previous study, we reported on the transcriptome analysis of postmortem brains of a small cohort of PTSD subjects, and identified serum/glucocorticoid regulated kinase 1 (*SGK1*) as being regulated in the dorsolateral prefrontal cortex (PFC). We have extended this work in a larger cohort of postmortem PTSD subjects and find that *SGK1* expression is decreased in the subgenual PFC. In addition, we find that levels of FK506 binding protein 5 (*FKBP5*), another gene implicated in PTSD based on studies of patient blood are also decreased in the subgenual PFC. Both genes are known to regulate inflammatory and glucocorticoid signaling. More importantly, previous studies in our lab have demonstrated that

Sgk1 inhibition enhances memory of contextual cues associated with fear conditioning. GWAS studies have identified 4 risk alleles within the *FKBP5* gene for development of PTSD. To further test the role of these genes identified from human samples in animal model of PTSD, we used classical fear conditioning in rats and found down regulation of both *Sgk1* and *Fkbp5* expression in medial PFC after training consistent with it's pattern of regulation in human subgenual PFC. Treatment with the synthetic glucocorticoid dexamethasone, in combination with one day of extinction training normalized levels of both transcripts in medial PFC and enhanced fear extinction. To better elucidate the functional consequences of decreased *Sgk1* expression on fear extinction, we are employing viral vector to express a catalytically inactive SGK1 protein into mPFC and measure extinction levels after training. These preclinical studies have identified *Sgk1* as a functionally important factor in the extinction of fear conditioning and support a role for dysregulation of this gene in the pathophysiology of PTSD and as a potential new target for therapeutic intervention.

Univ., Portland, OR; [6]CNRM, USUHS, Bethesda, MD

Abstract: Ketamine is one of the most commonly used battlefield analgesics administered to traumatically injured service members in Afghanistan. However, the impacts of peri-trauma administration of ketamine on the development of post-traumatic stress disorder (PTSD) are largely unknown. Moreover, there is a gap between pre-clinical and clinical studies because they utilize different doses and routes of ketamine administration. Therefore, we investigated the

effects of intravenous ketamine infusion on fear memory and *in vivo* regional brain glucose metabolism (BGluM) in rats. Male Sprague-Dawley rats received a continuous infusion of ketamine (0, 2, 10, and 20 mg/kg, 2 hr) either immediately after or 1 day after auditory fear conditioning (3 tone and footshock [0.6 mA, 1-sec] pairing). Fear memory retrieval, extinction, and recall were tested on days 2, 3, and 4 after fear conditioning and ketamine infusion. The effects of intravenous ketamine infusion (0 and 10 mg/kg, 2hr) on BGluM were measured using 18F-fluoro-deoxyglucose positron emission tomography (FDG PET) and computed tomography (CT). The ketamine infusion, both immediately after and 1 day after the fear conditioning, dose dependently enhanced fear memory retrieval, delayed fear extinction, and enhanced contextual and cued fear recall in rats. The ketamine infusion (10 mg/kg) increased BGluM in the hippocampus, amygdala, hypothalamus, and midbrain, while decreasing it in the cerebellum of rats. The current findings suggest that analgesic doses of ketamine infusion following stressful events may facilitate fear memory processing via activation of multiple brain regions that are critical for fear and stress. An additional research is in progress to understand molecular mechanisms of ketamine infusion on fear memory and BGluM.

Title: Development of a mouse model of early life stress-enhanced fear learning

Authors: D. SCHLEICHER, J. J. QUINN, *A. K. RADKE
Psychology, Miami Univ., Oxford, OH

Abstract: Post-traumatic stress disorder (PTSD) is a serious and potentially debilitating disorder that can cause a range of cognitive, emotional, and behavioral issues. Previous studies have found that exposure to early life trauma increases an individual's likelihood of developing PTSD following subsequent trauma in later life (Kessler et. al., 2107). This study will attempt to model this phenomenon in a rodent population. To simulate early life trauma, this study adapted the early life stress-enhanced fear learning (SEFL) protocol of Quinn et. al 2014, which has proven successful in rats, to a novel mouse model. On postnatal day (PND) 17, male and female C57BL/6J mice were exposed to early life stress, which consisted of 15 foot shocks delivered

over the course of an hour, followed by a period of maternal separation. The mice were then allowed to reach maturity undisturbed. In adulthood (PND60-90), the mice underwent contextual fear conditioning (CFC) in a novel context. CFC consisted of a single foot shock delivered 180 seconds after the mouse had been introduced to the chamber. Freezing (a typical fear response of rodents marked by a lack of motion) was monitored and assessed during the first 180 seconds to establish a baseline fear level. The following day, the mice were re-introduced to the CFC context to test fear memory expression. During the test, freezing behavior was measured for a period of eight minutes, and no shocks were delivered. The test was performed each day for an additional three days, in order to measure the rate of extinction of the fear response. Following this, the same procedure was employed to evaluate fear memory expression in the original early life stress context. The results revealed that exposure to early life stress causes a significant enhancement of fear learning in male and female adult mice, significantly increasing the percent time spent freezing and prolonging the extinction process. Freezing was negligible during adult exposure to the early life stress context in all of the groups. This lack of memory for the early life stress context during adulthood suggests that enhancement of fear learning is not dependent on the associative memory of early life stress. The findings of this study agree with those of Quinn et. al 2014, providing evidence for the validity of the novel mouse model as well as the enduring and detrimental psychological impact of early life trauma.

Title: Single prolonged stress PTSD model triggers progressive severity of anxiety, sensitivity to NPY and alterations in gene expression in the hypothalamus

Authors: *E. L. SABBAN, L. I. SEROVA
Dept Biochem & Mol Biol, New York Med. Col., Valhalla, NY

Abstract: PTSD symptoms can be long-lasted or display delayed onset. Thus, it is important to take a staging approach which may reveal distinct therapeutic approaches according to the biological progression of the disorder. The single prolonged stress (SPS), widely used rodent model of PTSD, has been mostly studied one week after the traumatic stress. At this time point, we demonstrated that intranasal delivery of neuropeptide Y (NPY) to the brain could reverse the

anxiety and depressive-like symptoms. Here, we examined progression of PTSD related symptoms of anxiety and the ability for reversal by intranasal NPY as well as prolonged gene expression changes in the mediobasal hypothalamus. The percentage of rats with maximal anxiety index on EPM increased from 3.6% in controls, to 17.5% one week and 57.1% two weeks after the SPS stressors indicating delayed worsening of symptomatology and may provide a model of late-onset PTSD. A dose of intranasal NPY (150 μg/rat) which was able to reverse the symptoms after 1 week was ineffective after 2 weeks. At this time point, a single infusion with a double dose of NPY reversed anxiety and depressive-like behaviour to unstressed control levels. The temporal differences in sensitivity to NPY might be related to differences in activation of the HPA axis. Therefore, gene expression for NPY receptors, CRH, GR and FKBP5 were examined in the mediobasal hypothalamus 1, 2 and 4 weeks after SPS stressors. CRH mRNA levels were elevated the entire time. In contrast there was a flip in GR, FKBP5 and NPY receptor gene expression between 1 and 2 weeks post-SPS stressors. The mRNAs for GR and FKBP5 were increased over levels in unstressed rats after 1 week, but down regulated in the later stages with maximal alterations at 2 weeks. Y1R mRNA levels were unchanged, but mRNAs for Y2R and Y5R were markedly elevated after 1 week. At later times, only Y5R mRNA differed from unstressed levels, with barely half the levels in controls after 2 weeks and had returned to basal unstressed levels by 4 weeks. The results demonstrate that SPS elicits a time-dependent dysbalance between CRH/GR and NPY systems in the mediobasal hypothalamus. This may be involved in the delayed onset of severe anxiety which was overcome with higher dose of NPY.

Title: BDNF Val66Met single nucleotide polymorphism enhances fear generalization in auditory fear conditioning

Authors: *N. TSE[1], J. D. RYAN[2], F. LEE[3]
[1]Weill Cornell Med. Grad. Sch. of Med., New York, NY; [2]Feil Family Brain & Mind Res. Inst., Weill Cornell Med., New York, NY; [3]Weill Cornell Med. Col., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) is a key regulator in neuronal differentiation and synaptic plasticity. The human BDNF Val66Met single nucleotide polymorphism (SNP) leads to impaired activity dependent secretion of this growth factor, and

has been associated with an increased susceptibility to mood disorders such as depression and anxiety. In addition, BDNF Val66Met knock-in mice have been shown to have alterations in depression-like (forced swim test) and anxiety-like (open field, elevated plus maze) behaviors. However, no current studies have examined the BDNF Val66Met mouse in fear generalization, a behavioral process that is overactive in post-traumatic stress disorder (PTSD) and which inhibits the ability to distinguish between fearful cues and neutral cues. In this current study, we optimized a fear generalization paradigm and found that $BDNF^{Val/Met}$ mice display significantly increased fear generalization, as compared to wild-type controls. In particular, wild-type mice were able to distinguish between two distinct auditory cues, one of which is paired to a foot shock, while $BDNF^{Val/Met}$ mice displayed similar freezing times following both the fear and safety cues. These findings suggest that BDNF bioavailability is needed for the capacity to discriminate between cues associated with an aversive stimulus and neutral cues. Future studies will involve mechanistic gain of function studies to rescue this shift from discriminative to generalized fear in these variant BDNF SNP mice.

Title: Vulnerability to traumatic stress predicts increased ethanol consumption in male and female rats

Authors: *R. R. DENNY[1], E. M. UNTERWALD[2]
[1]Ctr. for Substance Abuse, Temple Univ., Philadelphia, PA; [2]Dept Pharmacol & Ctr. Sub Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Post-traumatic stress disorder (PTSD) begins with traumatic-stress exposure and is marked by frequent fear memory recollections and increased sympathetic nervous system arousal. Approximately 60% of males and 50% of females are exposed to at least one traumatic event during their lifetime. Only 15-30% of trauma-exposed individuals develop PTSD. PTSD is highly co-morbid with alcoholism and typically PTSD precedes the development alcoholism. The aim of the present study is to investigate the biological basis of susceptibility to this comorbidity using a rodent model. Male and female young adult Sprague-Dawley rats were exposed to a traumatic-stress using a single prolonged stress (SPS) model or control handling and were behaviorally phenotyped using responses on the elevated plus maze, open field test,

and cue reactivity. On the elevated plus maze, SPS-exposed males compared to controls had significantly lower % open arm time ($p < .05$) and SPS male and females had significantly lower % open arm entries compared to controls ($p < .05$), indicating higher anxiety-like behaviors in the SPS groups. Open field test and cue reactivity revealed no significant differences between group means of control versus SPS for males or females. Rats then underwent 6-12 weeks of intermittent two-bottle choice ethanol consumption. Correlation analyses between post-SPS behavioral endpoints and subsequent ethanol consumption in the male cohort revealed that cue reactivity (freezing to the tone) after SPS was a significant predictor of following ethanol consumption and mediated a large effect using the Pearson's r score ($p < .05$, $r > .5$). A significant predictor of female subsequent ethanol consumption was post-SPS elevated plus maze and mediated a large effect using the Pearson's r score ($p < .05$, $r > .5$). These data demonstrate that individual susceptibility to the traumatic stress as measured by higher anxiety-like behaviors in females and higher cue-reactivity in males predicts higher ethanol consumption. These findings will allow further investigation of the biological link between trauma-induced anxiety and ethanol consumption.

Title: Molecular and systems-level interrogation of the ventral hippocampus in mediating fear generalization

Authors: *J. D. RYAN[1], D. JING[2], N. TSE[3], F. LEE[2]
[1]Feil Family Brain & Mind Res. Inst., [2]Dept. of Psychiatry, [3]Grad. Sch. of Med. Sci., Weill Cornell Med., New York, NY

Abstract: Fear learning is an adaptive mechanism aimed at survival in the face of a potentially life-threatening threat that is conserved across species and is dependent on a classical conditioning process. Briefly, a cue (e.g., a tone) repeatedly paired with an aversive stimulus (e.g. electric shock) will induce a fear response independent of whether the shock is applied (which in rodents is exemplified by stereotyped immobility, or 'freezing'). Normally, animals display a robust ability to discriminate between cues associated with an aversive stimulus and neutral cues. If the aversive stimulus is particularly intense (to the degree that it might induce symptoms of PTSD in humans), then the animal will generalize and respond to both the fear cue

as well as neutral cues. However, the neural circuitry involved in mediating fear generalization remains unclear. Here, we use fiber photometry to measure population-level neural activity in the ventral CA1 (vCA1) region of the hippocampus in freely-moving mice during a fear memory retrieval task. We find that fear conditioning with a strong shock compared to a weak shock induces generalized freezing behavior and distinctive patterns of neural activity in the vCA1. We also find altered generalization behavior and neural signaling in BDNF Val66Met mice, indicating that altered activity-dependent BDNF secretion may contribute to fear generalization. Overall, this study provides insights into both the molecular mechanisms and neural circuits involved in fear generalization.

Title: Pax7 neurons in the interpeduncular nucleus regulate fear memory

Authors: *J. LIANG, Y. REN, Q. FENG, M. LUO
Natl. Insitute of Biol. Sciences, Beijing, Beijing City, China

Abstract: The medial habenula (MHb)- interpeduncular nucleus (IPN) pathway has been preserved throughout evolution in vertebrates, suggesting that these nuclei may involve in very fundamental progresses for survival. Recently, some studies pointed out that MHb may have a role in fear regulation which is crucial since a proper response to danger often determines living or death. However, the neural mechanisms which MHb mediates such behaviors remain elusive. As the only downstream of MHb, the interpeduncular nucleus may be the proxy to relay fear signals from MHb to other related brain structures. Here, we used Pax7-creER mice which can specifically label almost the whole cells in IPN to investigate the role of this nucleus in fear regulation. By using fiber photometry and fear conditioning test, we found that IPN Pax7 neurons are activated by foot shock (US) and could learn a positive response to auditory cue (CS). Activation of IPN Pax7 neurons with channelrhodopsin (ChR2) increases freezing in the fear conditioning test whereas their ablation leads to a reduction of freezing. Taken together, these results may pave the way to understanding the behavioral function of this conserved but mysterious pathway and provide new insights to treat fear related neuropsychiatric disorders.

Title: Selective manipulation of BDNF promoter IV-expressing cells in the hippocampus modulates fear expression and hippocampal-prefrontal synchrony in mice

Authors: *H. QUILLIAN[1], H. L. HALLOCK[1], Y. MAI[1], J. L. HILL[2], K. R. MAYNARD[1], K. MARTINOWICH[1]
[1]Lieber Inst. for Brain Develop., Baltimore, MD; [2]Astellas Res. Inst. of America, San Diego, CA

Abstract: Our laboratory has previously shown that mice with disrupted production of brain-derived neurotrophic factor (BDNF) from promoter IV (p4) have impaired fear expression and extinction that co-occurs with decreased oscillatory synchrony between the hippocampus (HPC) and medial prefrontal cortex (mPFC). These results suggest that activity-dependent BDNF signaling critically regulates HPC-mPFC communication, which is associated with a variety of fear and anxiety-related behaviors. To better understand how p4-expressing cells in the HPC-mPFC circuit regulate fear expression and HPC-mPFC synchrony, we designed a viral construct that selectively targets these cells for tamoxifen inducible Cre-mediated recombination (AAV8-p4Bdnf-ERT2CreERT2-PEST-P2A). Injection of this construct, along with a virus encoding for Cre-dependent expression of tdTomato, into the HPC of wild-type (WT) mice successfully induced tamoxifen-mediated labeling of p4-expressing cells. Using the p4CreERT2 construct, we next induced expression of an excitatory Designer Receptor Exclusively Activated by Designer Drugs (DREADD), hM3Dq, in p4-expressing cells located in the ventral HPC of WT mice. Synthetic activation of these neurons with clozapine-N-oxide (CNO) increased fear expression during both pre-tone context recall and within-session tone/context extinction, as measured by percentage of time spent freezing while in the conditioning chamber. *In vivo* recording of local field potentials (LFPs) in the ventral HPC and mPFC revealed reduced HPC-mPFC oscillatory synchrony and altered power spectra in hM3Dq+ mice during fear recall and extinction. These effects were not due to non-specific alterations in behavior or brain activity following activation of these cells, as no significant differences in behavior or LFP activity were observed between groups in the home cage following CNO injections. Our data reveal a critical role for BDNF p4-expressing cells in the ventral HPC and hippocampal-prefrontal synchrony during fear-related behavior. We propose that normal activation of p4-expressing HPC cells in the hippocampal-prefrontal pathway promote optimal fear expression. The data also demonstrate the utility of our

p4CreERT2 construct for selectively targeting genetically-distinct populations of cells to better understand their contribution to HPC-mPFC circuity and fear-related behavior.

Abstract: Fear dysregulation is a hallmark symptom of several neuropsychiatric disorders, including generalized anxiety disorder (GAD) and post-traumatic stress disorder (PTSD). Both the hippocampus and medial prefrontal cortex (mPFC) have been linked with expression of learned fear in rodents, but the mechanisms by which these brain regions regulate fear memory remain poorly understood. To identify the contribution of hippocampal-prefrontal signaling to the recall and expression of learned fear, we demonstrate that direct inputs from ventral hippocampal CA1 (vHC) to the prelimbic subregion of the mPFC (PrL) are selectively recruited during fear expression in wild-type (w/t) mice. We also show that activation of vHC-PrL projectors with an excitatory designer receptor exclusively activated by designer drugs (DREADD) reduces fear expression during both context recall and within-session extinction, and disrupts freezing-related population dynamics in PrL neurons. To probe the molecular events that regulate function in this circuit during fear expression, we tested fear recall in mutant mice with disrupted production of brain-derived neurotrophic factor (BDNF) from activity-dependent promoter IV (-e4 mice), and found that these mice had increased expression of learned fear relative to w/t controls. We next used a combination of viral targeting and single-molecule fluorescence *in situ* hybridization to show that a similar proportion of vHC-PrL projectors are activated during fear expression in both w/t and –e4 mice, and co-express high levels of both exon IV-containing *Bdnf* and *Ntrk2* (which encodes the TrkB receptor) transcripts following fear

recall in both genotypes. Whole cell patch clamping recordings in *ex vivo* slice preparations revealed that vHC-PrL projectors in –e4 mice receive a lower frequency of inhibitory post-synaptic currents (iPSCs), and have a more depolarized resting membrane potential at baseline, relative to w/t projectors. These results suggest that activation of projectors in the absence of promoter IV-derived BDNF may lead to increased fear expression. In support of this hypothesis, synthetic activation of these neurons in –e4 mice led to an opposite phenotype than that observed in w/t mice (increased fear expression during recall and extinction). Taken together, these data support the central hypothesis that activity-dependent BDNF signaling impacts the ability of vHC-PrL projectors to bi-directionally regulate fear expression. Targeting clinically-relevant signaling pathways in defined neural circuits could provide avenues for precision medicine approaches to treating disorders that feature fear dysregulation.

Title: Behavioral effects of early life stress in the predator confront model of PTSD

Authors: *N. COBRA BARREIRO BARROCA[1], E. H. LIMA UMEOKA[1], M. SANTOS DA SILVA[2], J. ANTUNES-RODRIGUES[2], M. F. JURUENA[1], N. CYSNE COIMBRA[1], N. GARCIA-CAIRASCO[2]
[1]Dept. of Neurosci. and Behavioral Sci., [2]Dept. of Physiol., Univ. of São Paulo, Ribeirao Preto, Brazil

Abstract: Stress during early life is associated with a higher risk of developing psychopathologies in adult life, for example, post-traumatic stress disorder (PTSD), a psychopathology triggered by a traumatic event and characterized by intense anxiety, avoidance and hypervigilance. It reflects stress-induced changes in neurobiological systems and an inadequate response of them against re-exposure to the context of the trauma. The aim of this study was to assess if stress experienced during early periods of postnatal development, is related to a greater defensive response later in life, in a PTSD model.Mice were subjected to the limited bedding and nesting model of early life stress (ELS) from P2 to P9, which induces abnormal and

fragmented maternal care. One batch of mice was sacrificed at P9, body weight and corticosterone (CORT) were determined. Another batch was allowed to reach adulthood, and at P120, submitted to predator confront paradigm, using exposure to a venomous snake (*Bothrops moojeni*) and re-exposure to its skin a week later, in the same experimental context. Frequency and time spent at risk assessment, escape, defensive immobility and interaction with predator (exposure) or with the skin (re-exposure) were determined.At P9 ELS mice, compared to controls, presented significantly reduced body weight (2.75 ± 0.13 g, n=21 and 3.89 ± 0.09 g, n=33; $p<0.001$) and increased CORT basal levels (5.41 ± 1.32 µg/dl, n=21 and 2.63 ± 0.18 µg/dl, n=26; $p<0.05$). At P120, during predator exposure, ELS mice spent significantly more time in scape (4.8 ± 2.19 %, n=9 and 1.93 ± 1.03 %, n=6; $p<0.05$) and interaction (0.66 ± 0.45 %, N=9 and 0.18 ± 0.30 %, N=6; $p<0.05$) behaviors compared to control group. During re-exposure, regardless of the ELS experience, females had significantly enhanced frequency of risk assessment and escape ($p<0.05$). Moreover, ELS males showed increased frequency and time for escape during re-exposure ($p<0.05$), when compared to those mice confronted with the predator. It was also observed main effect of ELS ($p<0.05$) on the number of risk assessment and interaction between prey and predator, in comparison to control mice, for those without previous exposure to the predator.ELS induced physiological changes leading to alterations in PTSD-like behaviors in the prey versus predator confrontation model during adult life. Detailed behavioral analysis associated with an anatomical determination of Fos+ neuronal activity in key brain structures should provide further insights on the role played by ELS on the neurobiology of psychiatric disorders, such as PTSD and panic attacks, as well as other unconditioned/conditioned fear- and anxiety-related conditions.

Title: Susceptibility and resilience to predator odor stress differs between male and female rats

Authors: *E. M. BLACK[1], Z. D. BRODNIK[2], N. W. SNYDER[3], J. R. BARSON[1], R. A. ESPAÑA[1]
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ., Philadelphia, PA; [3]A.J. Drexel Autism Inst., Philadelphia, PA

Abstract: Patients with posttraumatic stress disorder (PTSD) display symptoms such as hypervigilance and increased anxiety, as well as increased comorbidity with substance use disorder. Though many individuals are exposed to traumatic stress, only approximately 30% develop PTSD ("susceptible") while the other 70% demonstrate resilience to the stress ("resilient"). Further, data from human studies suggest that women are up to twice as likely as men to meet criteria for PTSD. Although many studies have examined behaviors in PTSD models in male rats, data is still lacking with regard to the behavioral and neurobiological response of female rats in these models. We employed our previously established predator odor stress model of PTSD to classify and define the neurobiological and behavioral correlates of female rats in response to predator odor exposure. The importance of such an approach was highlighted by the divergence from cut-off criteria established in male rats. Unlike male rats, segregation into susceptible and resilient groups in female rats was primarily influenced by hypervigilance as measured by acoustic startle response. Females in this model also demonstrated increased locomotion in anxiety-prone environments and alterations in corticosterone levels that differed from those observed in males, suggesting unique responses to predator odor stress. Interestingly, the prevalence of susceptibles is markedly similar between male and female rats. Thus, though males and females may differ in some anxiety-related physiological and behavioral responses in the predator odor stress model of PTSD, the overall likelihood of displaying the PTSD-phenotype is similar between the sexes. This research emphasizes the importance of establishing unique and appropriate segregation criteria for males and females in order to properly characterize sex differences in the field of stress research.

Title: True prophylactic treatment effect in a rat PTSD model on plasticity in ventral hippocampal, lateral amygdala, and medial prefrontal cortex and molecular targets

Authors: *R. M. MILLER[1], E. SAITO[2], B. DABNEY[2], R. HANSEN[2], G. MELENDEZ[2], S. M. PICKARD[2], C. EDWARDS[2], L. APONIK[2], T. CROFTS[2], S. MANGUM[2], J. G. EDWARDS[1]
[1]Physiol. and Developmental Biol., [2]Brigham Young Univ., Provo, UT

Abstract: Post-traumatic stress disorder (PTSD) is a complex anxiety/depression disorder that affects about 1 out of 4 individuals after a stressful/traumatic experience. Two commonly used models that we employed were single prolonged stress (SPS) and social defeat (SD) (both used with 2 weeks of chronic light). First, more naturally anxious rats were selected based on results of an open field test where cat fur and fox urine were placed in one quadrant. Rats were classified as anxious if they avoided that quadrant, froze for long periods of time, did not rear, and frequently urinated or defecated. The naturally anxious rats were used in either the SPS or SD protocols. Next, the elevated plus maze (EPM) and light-dark transition (LDT) tests were used to detect anxious behavior at the conclusion of SPS or SD protocols. We noted that both protocols were able to cause significant anxious behavior when compared to controls, with SD being more significant. Next, we performed field electrophysiology experiments in rat brain slices. The data illustrated that the SD protocol caused significant changes in ventral hippocampus plasticity while SPS did not. Therefore, we used the SD model to look at changes in other brain regions known to have altered plasticity in PTSD. SD caused a significant increase in long-term potentiation (LTP) in the ventral hippocampus (VH), lateral amygdala (LA), and medial prefrontal cortex (mPFC). To determine whether a prophylactic treatment could prevent the physiological changes of PTSD, we simultaneously administered propranolol and mifepristone at 10 mg/kg doses by intraperitoneal injection one week prior and during the entire duration of SD. These drugs significantly decreased LTP in the VH, LA, and mPFC of SD rats that received drug injections when compared to SD rats with no drug injections and controls. However, the SD drug treated rats did not show significant reductions in anxious behavior when tested on the EPM and LDT when compared to the SD rats with no drug injections and still exhibited significantly more anxious behavior than control rats. We then examined potential gene targets involved in plasticity and stress that could be altering the LTP in stressed and drug-treated rats. Significant alterations in the mRNA expression levels of glucocorticoid, mineralocorticoid, and beta 3 adrenergic receptors; AMPAR subunits, and NMDAR subunits were detected using RT-qPCR between all groups in all three brain regions. Overall, our data suggest that propranolol and mifepristone together may be a viable prophylactic treatment for preventing PTSD.

Title: Differential baseline and activity-dependent transcriptional profiles between modifiable and modification-resistant memories

Authors: *J. M. PERISH, A. SANDOVAL, H. ELAHI, J. PLOSKI
The Univ. of Texas at Dallas, Richardson, TX

Abstract: The repeated, involuntary recall of traumatic experiences in anxiety disorders such as post-traumatic stress disorder (PTSD) is tremendously distressing to patients and presents a technical challenge to neuroscientists. After initial storage, long-term memories can be retrieved, modified, and re-stabilized in a related process called reconsolidation updating. Existing research suggests reconsolidation updating is an adaptive process allowing formerly consolidated long-term memories to be modified. Numerous studies have demonstrated that circuits encoding weak fear memories become destabilized after retrieval necessitating the protein synthesis-dependent process of reconsolidation to re-stabilize the memory and, thus, allow its permanence. This period of lability presents a potential therapeutic window whereby memory re-stabilization can be pharmacologically disrupted to induce amnesia. Strong, pathological memories (as in PTSD), however, are resistant to reconsolidation initiation. This limits the potential clinical utility of reconsolidation therapy as a means to attenuate pathological memories. The largest obstacle to development of a targeted reconsolidation therapy is an insufficient understanding of the molecular mechanisms gating reconsolidation initiation for strong fear memories. Existing therapies have been largely ineffective in attenuating PTSD-related symptomologies. It is critical we study the molecular biological differences of modifiable versus modification-resistant fear memories to aid the development of an effective PTSD treatment. Here, utilizing Next Generation Sequencing technology, we demonstrate the baseline and retrieval-dependent transcriptional differences between amygdalae encoding modifiable and modification-resistant fear memories and propose experiments to further elucidate the molecular mechanisms impeding reconsolidation of strong fear memories.

Title: Sex differences in revealing susceptibility to a PTSD-like phenotype in rats (RISP model)

Authors: D. CRETHERS[1], K. ALEXANDER[1], R. NALLOOR[2], K. BUNTING[1], *A. I. VAZDARJANOVA[2]
[1]Augusta Univ., Augusta, GA; [2]Charlie Norwood VA Med. Ctr., Augusta, GA

Abstract: We have previously demonstrated that we can reveal individual susceptibility to a Post-Traumatic Stress Disorder (PTSD)-like phenotype (RISP model) in male rats. Revealing susceptibility requires exposure to a mild stressor and subsequent characterization of the rats' startle response to a series of loud white noise presentations (ASR) and anxiety-like behavior in the Elevated Plus Maze. According to the RISP model, rats high on both measures are classified as susceptible (Sus), while those low on both measures- resistant (Res). The RISP model has both face and predictive validity, as Sus male rats account for ~20% of the tested population similar to the percentage reported for men who develop PTSD after exposure to a traumatic event. Additionally, after exposure to an emotionally traumatic event (high footshock in a novel place or contextual fear conditioning) Sus, compared to Res, rats show impaired fear extinction, elevated startle for nearly a month after the trauma, generalized anxiety, and impaired performance on a task requiring cognitive flexibility. All of these behaviors map to diagnostic criteria for PTSD (DSM-V). Accordingly, Sus rats also have impaired hippocampal and medial prefrontal cortical function compared to Res rats, as revealed by task-induced expression of plasticity-associated genes (*Arc* and *Homer 1a*). These brain regions are required for successful fear extinction and cognitive flexibility and contribute to altered anxiety-like behavior. Importantly, their function is disrupted in people with PTSD. PTSD is a sexually dimorphic condition with females suffering at twice the rate of men. Therefore, we hypothesized the RISP model will identify a higher percentage of female rats as Sus. We discovered that identifying susceptibility in females requires a different set of criteria. While the pre-trauma ASR and anxiety-like behavior were positively correlated in males, in females, this correlation was negative. Furthermore, the post-trauma behavior in females was significantly different than males: impaired fear extinction was not correlated with post-trauma ASR. These data demonstrate that a PTSD-like phenotype as well as susceptibility to such a phenotype should be modeled differently in males and females. It also cautions that making translational inferences from animal research done only in males may apply better to men than women suffering from PTSD.

Title: Modulation of associative learning and reflexive behavior depends on timing of administration of the fatty acid amide hydrolase (FAAH) inhibitor URB597

Authors: *E. G. LOWERY-GIONTA[1], L. P. SIMMONS[2], E. BERGMAN[3], M. ETUMA[3], N. L. MOORE[4]

Abstract: Impairments in associative learning are found in post-traumatic stress disorder (PTSD). Previous reports of the involvement of the endocannabinoid system in associative memory processes suggest compounds influencing this system may assist in recovery from adverse behavioral responses to fear memories. To better understand the role of endocannabinoid tone in fear-associated learning and memory, we characterized the impact of the FAAH inhibitor URB597 in a rodent model of fear conditioning and conditioned suppression of food-maintained operant behavior. To better distinguish conditioned suppression from freezing behavior, an ongoing study is examining the effects of URB597 on freezing behavior alone. Male rats were initially trained and subsequently maintained on a variable-interval schedule of reinforcement (VI32) in food-maintained operant sessions. Following this, rats were conditioned to associate light-and-tone pairing to an aversive footshock (i.e., conditioning, "IES") and later tested for conditioned suppression of lever-pressing (i.e., extinction, "EXT"). URB597 (0.1 or 0.3 mg/kg, i.p.) or its vehicle was administered 30-min prior to either IES or EXT to assess effects of FAAH inhibition on the acquisition and expression/extinction of conditioned fear responses, respectively. One week after EXT tests, light-potentiated startle responses were measured. In a separate ongoing study, the effects of URB597 (0.1 or 0.3 mg/kg, i.p.) given during IES or EXT on fear-associated freezing behavior is being assessed. At the tested doses, URB597 administered in either the IES or EXT phase of the study resulted in non-significant decreases in the latency to the first active-lever press following a single light-and-tone cue delivery relative to control groups. This effect was most obvious on the first of five days for either IES or EXT phases, and all groups were indistinguishable by the third day. Interestingly, URB597 (0.3 mg/kg) administered in the IES phase resulted in significantly greater potentiation of light-potentiated startle relative to the EXT-administered group. This suggests that administration of URB597 could enhance conditioned fear learning if given when the conditioned fear association is acquired. Thus, careful consideration of the timing of administration of a cannabinoid compound should be made as the potential therapeutic value of such compounds are evaluated for the treatment of PTSD and related disorders. Ongoing studies of URB597's effects on freezing behavior will provide additional insights in to the effects of cannabinoid modulators on conditioned fear processes.

Title: Reflexive, exploratory, and learning behavior characterization of nociceptin/orphanin FQ (NOP) receptor antagonists in a rodent model of traumatic stress

Authors: *R. M. ENGA, E. M. BERGMAN, I. H. JEONG, M. D. MAY, M. C. VENTURA, N. L. T. MOORE
Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Current FDA-approved pharmacotherapies for treatment of post-traumatic stress disorder (PTSD) are limited in number and can be inefficacious, leaving a need for characterization and evaluation of other possible pharmacotherapies. Rodent models of traumatic stress have been established, including underwater trauma and predator (PRED) exposure. Recent evidence implicates the nociceptin/orphanin FQ (NOP) receptor system in PTSD, including a single-nucleotide polymorphism within the OPRL1 gene encoding the NOP receptor and effects of NOP agonist/antagonist on centrally-mediated processes known to be impaired in PTSD. Here, we first characterized the effects of two NOP antagonists on baseline behavioral performance in rats. Subsequent, ongoing studies are examining the effects of NOP antagonism on behavioral recovery after traumatic stress exposure as well as on Pavlovian fear conditioning. Male rats were administered J-113397 (2-20 mg/kg, i.p.), SB-612111 (0.1-4 mg/kg, i.p.), or vehicle once-daily and tested in behavioral performance in acoustic startle response (ASR), elevated plus maze (EPM), hot plate test, and open field (OF). Tests were performed on Days 1, 2, and 7 to assess acute and repeated administration effects. In a subsequent, ongoing study, these NOP antagonists are undergoing evaluation for their efficacy on behavioral performance recovery one or seven days following protected exposure to a single-day 3-species predator (snake, ferret, and cat) exposure regimen or sham exposure. Finally, an additional ongoing study is evaluating the efficacy of the NOP antagonist, JTC-801 (1-10 mg/kg, i.p.), on reducing fear-associated freezing behavior after an initial conditioning session in which a mild, brief footshock is paired with co-terminating light and tone cues. The NOP antagonists J-113397 and SB-612111 did not significantly affect baseline behavioral performance in ASR, EPM, hot plate test, or OF at any tested dose. This suggests a lack of behavioral effect of these NOP antagonists on the critical behavioral measures used to characterize our rodent models of traumatic stress in stress-

naïve rodents. Ongoing studies will determine the efficacy of NOP antagonism on behavioral recovery following predator exposure as well as on fear conditioning.

Title: Modulation of hippocampal gamma oscillations by amphetamine and guanfacine

Authors: B. H. DENNIS[1], F. WEISZ[2], A. BRITO DA SILVA[3], M. O. CUNNINGHAM[3], S. A. NEALE[1], *T. E. SALT[2,1]
[1]Neurexpert Ltd, Newcastle-upon-Tyne, United Kingdom; [2]UCL Inst. Ophthalmology, London, United Kingdom; [3]Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Neuronal circuit oscillations in the neocortex and hippocampus are thought to underly a number of functions related to learning, attention, and cognition. Within the hippocampus, gamma-frequency oscillations, are important in the routing of information and thus attention and memory formation. *Gamma* oscillations are thus thought to be an important biomarker of cognitive functions. Amphetamine and guanfacine are drugs that are known to modulate cognitive performance in animals and humans, albeit via different mechanisms, and have been used to treat conditions such as ADHD. We therefore investigated the actions of these drugs on hippocampal *gamma* oscillations in order to shed further light on their potential mode(s) of action.
Horizontal *in vitro* slice preparations (450μm thickness) were made from the brains of adult male Sprague-Dawley rats. Extracellular field recordings were made from the CA3 area of the hippocampus in an interface bath at ~33C. Addition of carbachol (Cch; 5μM) to the bathing medium resulted in the generation of stable *gamma* oscillations with peak power in the 32-60Hz region. Addition of D-amphetamine to the bathing medium (10μM, 15 minute application) in the continued presence of Cch resulted in changes in the power spectrum, such that there was an overall increase in power and the peak in the spectrum shifted to the 10-20Hz ("*beta*") range (from 34.8±3.1Hz to 7.8±8.5Hz, mean±Std Dev, *n*=7). This was associated with the occurrence of high-amplitude sharp wave activity. Similar, more pronounced, effects were also seen in the presence of 100μM D-amphetamine. By contrast, addition of guanfacine (10μM) to the bathing medium had little effect on the peak frequency in the power spectrum, but decreased the *gamma*-frequency power to 66±6.3% (*n*=5) of control.
Amphetamine is thought to exert its effects (at least in part) via dopaminergic mechanisms,

whereas guanfacine is an *alpha*2A- adrenoceptor agonist. Our finding that they have different actions on hippocampal circuit function emphasises this difference and may be important in characterising the actions and mechanism of action of other potential drugs developed for attention and cognitive disorders.

Title: Gene expression analysis of ASD patients using LCLs

Authors: *M. TORITSUKA[1], M. MAKINODAN[1], T. YAMAUCHI[1], Y. YAMASHITA[1], D. IKAWA[1], T. KOMORI[1], S. KIMOTO[1], K. HAMANO-IWASA[1], R. TAKADA[1], A. OMORI[1], E. SUMIDA[1], H. KITAOKA[1], M. HONDA[1], H. MATSUZAKI[2], T. KISHIMOTO[1]
[1]Dept. of Psychiatry, Nara Med. Univ., Kashihara, Japan; [2]Univ. of Fukui, Eiheiji-Cho, Yoshida-Gun, Japan

Abstract: Objective; Lymphoblastoid cell lines (LCLs) are nearly-immortalized B cells developed by infecting peripheral blood lymphocytes with Epstein-Barr virus, which provide a long-lasting supply of cells as a biological resource. These cells have been utilized not only for genome sequencing, but also for phenotypic analyses of cells from subjects with neuropsychiatric disorders, such as autism spectrum disorder (ASD). The pathobiology of ASD is considered to be associated with aberrant immune activation, such as increased levels of plasma pro-inflammatory cytokines, and excessively activated microglia as observed by positron emission tomography scanning. An immune cell in the brain is microglia having the same origin with peripheral macrophages, but direct analysis of microglia is impossible because of its inaccessibility. Our recent studies highlighted the usefulness of peripheral blood cells instead of the microglia, thus we aimed this study to identify biomarkers of ASD using LCLs as a substitute for microglia. Methods; We evaluated the gene expression of LCLs established from ASD patients and typically developed (TD) children by qRT-PCR. All study participants and their legal guardians provided written informed consent prior to enrollment. This study was approved by the appropriate Ethics Committee of the Nara Medical University and was performed in accordance with the Declaration of Helsinki. Results; To verify the stability of the cellular features of newly established LCLs, we first measured gene expression in LCLs of TD group with different passage numbers. The result showed that gene expression substantially changed

within 10 passages in LCLs, and, in particular, the expression of *GAPDH*, a common house-keeping gene used as internal control for qPCR, varied considerably during subculture. Next we compared gene expression of pro-inflammatory cytokines between ASD and TD. Surprisingly, the expression of some of them were lower in ASD group. Conclusion; Our data suggest that the use *GAPDH* as an internal control for qRT-PCR may be unsuitable when using early passage LCLs, and that LCLs can be a useful tool for searching biomarkers of neuropsychiatric disorders.

Title: An image reconstruction approach to characterizing the topography of emotional face space related to borderline personality disorder

Authors: *C.-H. CHANG[1], A. C. RUOCCO[1], N. DROBOTENKO[1], A. C. LEE[1,2], A. NESTOR[1]

Abstract: Difficulties in recognizing facial emotional expressions may cause interpersonal problems, such as those observed in individuals with borderline personality disorder (BPD). Previous studies have suggested that individuals with BPD tend to be less accurate at recognizing emotions and sometimes misperceive emotions. However, prior work on emotion recognition in BPD has relied primarily on a small range of prototypical emotional expressions, limiting the generality of the conclusions from this research. It is also unclear how individuals with BPD misperceive facial expressions. Additionally, it is unknown whether individuals with BPD have similar biases in their memory of emotional expressions. The current work, therefore, aims to address these issues with the aid of an image reconstruction approach as applied to a relatively large set of facial expressions. Specifically, the goal of this approach is to reveal the pictorial information of visual representations associated, in the current context, with perception and memory for facial expressions. To this end, participants with BPD and healthy controls provided similarity ratings of emotional expressions for pairs of visually-presented face stimuli or for pairs

consisting of one face stimulus and a face recalled from memory. These ratings were then used to construct a multidimensional facial expression space for each individual. Subsequently, the appearance of faces viewed or recalled from memory, were reconstructed separately for each participant through a combination of significant features and dimensions derived from the facial expression space. Our findings establish the feasibility of reconstructing images of facial expressions from perception and memory data. Reconstruction results provide evidence for differences in the structure of expression representations for individuals with BPD compared to healthy controls. Further, we evaluate the reconstruction accuracy of different expressions and we establish the differential sensitivity to negative bias across a range of emotional expressions. In summary, the present work provides a novel approach to examing the representation of facial expressions from perception and memory in healthy adults and in individuals with BPD.

Title: Interleukin 6 involvement in a rodent model of chronic fatigue syndrome

Authors: *R. D. CUEVAS OLGUIN[1], T. MARES-BARBOSA[1], R. VELÁZQUEZ-CONTRERAS[1], M. MIRANDA-MORALES[2], S. ROSE-JOHN[3], M. ATZORI[4]

Abstract: Chronic fatigue syndrome (CFS) is a disorder characterized by extreme fatigue unexplained by any underlying medical condition. CFS does not improve with rest, but can worsen with physical or mental activity. Since infection and immune challenge are possible triggers for CFS, a role for cytokines has been hypothesized in the etiology of CFS. The pro-inflammatory cytokine interleukin 6 (IL-6) has been positively correlated to the onset of numerous stress-triggered neuropsychiatric conditions including schizophrenia, depression, anxiety, and autism. We wondered whether IL-6 is involved in the expression of CFS. To answer this question, we compared the behavior of a group of wild type animals (WT), with that of genetically modified mice in which IL-6 central trans-signaling was blocked by overexpression of the IL-6 transducer glycoprotein 130 by the promoter of the astrocytic marker glial fibrillary

acidic protein (GFAP-sgp130Fc, TG). C57BL/6 mice where submitted to a protocol of 3 injections of Brucellla abortus (BA), one every 2 weeks during 6 weeks, as model for CFS. Motor activity was monitored during the whole duration of the experiment in four groups: saline- or BA-injected WT, and saline- or BA-injected TG. Motor activity was measured with an automated system allowing to monitor the number of turns of a spinning wheel and other motor parameters for individually lodged mice continuously during the whole duration of the experiment. Our results show that BA (vs. saline) injections significantly reduce motor activity (90 ± 14% vs. 44 ± 7%, n = 11, 10, respectively) in WT, but not in TG animals (82 ± 20% vs. 63 ± 7%, n = 10 each). Porsolt forced swimming, sucrose preference, and elevated plus-maze tests suggest that both WT and TG BA-injected animals display increased depression, anhedonia, and anxiety, while gripping strength was unaltered by BA-injections in all groups. Our data corroborate the hypothesis that central IL-6 trans-signaling is a critical factor in the induction of CFS.

Title: The interaction between muscarinic and mGlu2/3 in animal models of schizophrenia

Authors: *J. M. WIERONSKA[1], P. CIEŚLIK[2], M. WOŹNIAK[2], A. PILC[3]
[1]Dept. of Neurobiology, Inst. of Pharmacol., Krakow, Poland; [2]Inst. of Pharmacol. PAS, Krakow, Poland; [3]Inst. of Pharmacol., 31-343 Krakow, Poland

Abstract: The role of $GABA_B$ receptor in the antipsychotic-like action of mGlu4 receptor orthosteric agonist LSP4-2022.
Variety of our previous research showed that the action of the ligands of metabotropic receptors for glutamate is dependent on the others neurotransmitters in the central nervous system. We also showed that synergistic action between mGlu4 and muscarinic M4 receptors may be proposed as alternative therapy for schizophrenia. Here, we assessed the mutual action of M4 and mGlu2/3 receptors ligands in selected animal models of schizophrenia. DOI-induced head twitches test in mice, social interaction test in rats and novel object recognition test. VU152100 was used as positive allosteric modulator of M4 receptors and LY487379 was used as positive allosteric modulator of mGlu2/3 receptors. Both compounds induced clear and dose-dependent

antipsychotic-like action in all three tests at the doses 0.5, 1 and 3 mg/kg (LY487379) or 0.25, 0.5, 1, 2 and 5 mg/kg (VU152100). Our results show that the simultaneous administration of both compounds in subeffective doses induced clear antipsychotic-like effect similar to that observed for each active dose alone. The combinations did not disturbed motor coordination of animals when measure in rotarod test. Therefore, the antipsychotic treatment based on the activation of both mgLu2/3 and M4 receptors could be proposed as an alternative therapy to presently used neuroleptics.

Title: The impact of cortical interneurons on synaptic development in neuropsychiatric disorders

Authors: *A. KATHURIA[1], R. KARMACHARYA[2]
[1]Harvard Med. Sch., Boston, MA; [2]Harvard Univ., Boston, MA

Abstract: Schizophrenia (SCZD) is a crippling neurological disorder with a world-wide prevalence of 1%. Cognitive impairments is the most important predictor of functional outcomes in patients with schizophrenia. However, efficacious treatment of cognitive deficits in psychotic disorders remains a significant challenge in clinical practice. Even though, antipsychotic medications provide symptom relief by reducing hallucinations, they do not improve the cognitive deficits that is the core feature in schizophrenia. There is an urgent need for new therapeutic approaches that target the neurobiology of cognitive impairments. Our research focuses on developing stem cell-based models to study the molecular and cellular basis of schizophrenia using iPSCs (Induced pluripotent stem cells) generated from patients. We are investigating the functional connection between excitatory and inhibitory cortical neurons derived from patient and healthy iPSCs. Currently, we have identified decrease in synaptic co-localisation and spine density in the patient lines. Therefore, focusing our research on high-throughput screens of small molecule libraries to discover compounds that can normalize/modulate cellular disease signatures.

Title: Induction of hippocampal hyperactivity by dentate gyrus inhibition

Authors: *D. SCOTT[1], C. A. TAMMINGA[2]
[1]Psychiatry, UT Southwestern, Dallas, TX; [2]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: Although psychosis is the defining and the most recognizable symptom domain in schizophrenia, the biological mechanisms underlying psychosis remains unknown. Analysis of post-mortem human hippocampal tissue and in vivo human imaging studies in schizophrenia have detected abnormalities within hippocampal subfields: decreased GluN1 within the dentate gyrus (DG), along with increased synaptic plasticity markers in CA3 and increased *in vivo* basal activity within CA3/CA1 which correlates with psychosis severity. We have previously demonstrated in a mouse model that CA3 hyperactivity per se is sufficient to induce psychosis-like behaviors in mice. However, the mechanism underlying the induction of this hippocampal hyperactivity remains unclear. Recent work suggests that decreased excitatory drive onto CA3 pyramidal cells from the mossy fiber results in homeostatic upregulation of CA3 activity. We hypothesize that decreasing DG granule cell activity in mice would result in a replication of both the brain pathology associated with psychosis, i.e., increased basal activity and synaptic markers in CA3, and a psychosis-like behavioral phenotype. To address this, we infused male C57BL6/J mice (n >6/group) with AAVs containing either DREADDs or a control virus to specifically inhibit DG granule cells, allowing manipulation of activity with spatial, temporal, and cell-type specificity. Following surgery, we chronically treated mice with clozopine-N-oxide, assessed basal activity in the hippocampal subfields through expression of cFos, measured synaptic markers with Western blotting, and performed behavioral analysis, utilizing paradigms associated with a psychosis-like phenotype in mice: prepulse inhibition, fear conditioning, and social memory. Scientific rigor was ensured by repeating each experiment in multiple cohorts of mice, and analyses were performed using automated methodology when possible, to eliminate experimental bias. Results suggest that decreasing DG activity does result in hippocampal hyperactivity, and the magnitude of this resultant hyperactivity determines the presence of a psychosis-like behavioral phenotype. Experiments to determine levels of synaptic proteins are still underway.

Title: SK_3 KO in 5-HT neurons inhibits binge-like eating in mice

Authors: *Y. HE, X. CAI, P. XU, Y. YANG, C. WANG, H. LIU, I. HYSENI, Y. XU, 77030 Baylor Col. of Med., Houston, TX

Abstract: Neural networks that regulate binge eating remain to be illustrated, and effective treatments for binge eating are limited. Our previous data showed that local inhibition of a small conductance Ca^{2+}-activated K^+ (SK) current in the dorsal Raphe nuclei (DRN) markedly suppressed binge-like eating in female mice through the ER-alpha receptor mediates signal pathway. Here we first combined qPCR and immunohistochemistry to establish that SK3 highly expressed in serotonin (5-HT) neurons in the DRN while other two isoforms of SK channel are not expressed. Further we use genetic engineering techniques to specific knock out (KO) SK3 in DRN area in mouse brains. We demonstrated that after SK3 was KO in 5-HT neurons resulted in spontaneous action potential (AP) firing frequency increase and depolarization of the resting membrane potential (RP) in 5-HT neurons. These suggest that loss of SK3 in in 5-HT neurons will increase the neuronal activity. Further study in binge like eating behavior we found that mice with SK3 KO in 5-HT neurons showed reduced binge like eating compare to the WT control mice without change the anxiety behavior. I.C.V injection of SK3 selective blocker apamin suppress binge-like eating behavior in WT mice while not in SK3 KO mice. Thus, we identified the SK3 in 5-HT neurons as one potential target for anti-binge therapies.

Title: Autonomic imbalance in women with premenstrual syndrome: A model disease of allostatic load

Authors: Y. MENG[1], *R. ZHOU, SR[2]
[2]Dept. of Psychology, [1]Nanjing Univ., Nanjing, China

Abstract: Introduction Allostatic load occur while individuals are undergoing stressors frequently, have poor reaction and delayed recovery of related physiological responses. This is embodied in the dysregulation of autonomic nervous system (ANS) and hormone secretion. It is unclear whether the Premenstrual Syndrome (PMS) is caused by an allostatic load of premenstrual stress. The purpose of this study is explore whether or not the ANS of PMS female has a dull response and a delayed recovery to the stress.
Method By measuring heart rate variability (HRV, sympathetic and parasympathetic response of ANS) of PMS group(n=50) and health group(n=46), this study aimed to evaluate the response and recovery of the ANS and the related emotional experiences after stress during the menstrual cycle. The Biopac MP150 was been used to measure the HRV at rest and their changes during stress tasks (speech task and mental arithmetic task) and recovery phase. The emotional experience were measured before and after the tasks.
Results In the resting state, the sympathetic response (LF/HF) of the participants during the luteal phase was higher than that of the follicular phase ($F_{(1, 94)}$=40.22, p<0.05, ηp2=0.30), and the PMS was significantly lower than the healthy ($F_{(1, 94)}$=7.76, p<0.05, ηp2=0.076). The parasympathetic response (HF) does not change significantly throughout the process (p>0.05). During the stress tasks, the LF/HF results of the two groups was presented in Figure 1. The negative emotional experience of the PMS individuals during the luteal phase was significantly increased (p<0.05).
Conclusion No matter at rest or stress tasks, PMS group had a duller sympathetic response than healthy group during luteal phase, and they also had slow recovery time after tasks, which illustrated PMS women have autonomic imbalance during the premenstrual period. The autonomic imbalance also increases individual's negative feelings to stress. The function of the ANS was discussed starting from the theory of allostatic load, which helps to explain the mechanism of PMS and the causes of negative emotions.

Title: Anticipation of negative stimuli lead to blunted activation of negative emotion in females with premenstrual syndrome

Authors: *L. CHEN[1], R. ZHOU, SR[2,3]
[1]Dept. of Psychology, Nanjing Univ., Jiangsu Province, China; [2]Dept. of Psychology, Nanjing Univ., Nanjing, China; [3]Ctr. for Exptl. Social and Behavioral Res. of Jiangsu Province, Nanjing, China

Abstract: Introduction Premenstrual syndrome(PMS) consists of regularly recurring psychological or somatic symptoms, or both; the symptoms occur specifically during the luteal phase of the cycle and are relieved by the onset of, or during, menstruation(Yonkers, K. A., O'Brien, P. S., & Eriksson, E,2008). Patients with PMS had significantly enhanced reactivity during anticipation of negative emotional stimuli(Bannbers et al. ,2011;Gingnell et al.,2013). For healthy people, anticipatory emotion didn't influence emotion processing if they can make effortful anticipatory cognitive distraction(Erk, Abler, & Walter (2006). However, anticipation of negative stimuli attenuated emotion processing for the depression patients(Rosenblau et al, 2012).So this research aims to study if the anticipation will affect the subsequent emotion processing of PMS females. **Methods** 42 female university students were divided into two groups by scores of the Chinese Premenstrual Syndrome Scale: PMS group (n=22), and non-PMS group (n=21). There is significant difference between their scores for this scale ($t_{(41)}$=14.644, p<0.001), no difference in age, length of menstrual cycle and length of menstrual flow. The participates were asked to watch positive or negative emotion pictures(IAPS) after the clue of the green or the red patch, and they also watched the same pictures after no clues in the luteal phase and follicular phase while the ERPs were recorded. **Results** The mean amplitudes of P300 from 350-500ms at PZ were analyzed by a three-way mixed ANOVAs: 2 (group: PMS, non-PMS) × 2 (condition: positive pictures with clue, negative pictures with clue, positive pictures without clue, negative pictures without clue) ×2(menstrual phase: luteal phase, follicular phase). The results showed that the main effect of condition was significant ($F_{(3,39)}$= 24.87, p=0.029, η^2=0.657) and the interaction between the group and condition was significant ($F_{(3,39)}$= 3.342, p=0.029, η^2=0.204)while the other interactions were not significant. For the PMS group, the P300 of the negative pictures without the clue were significantly greater than these with the clue(p=0.004), but there were no remarkable differences between these two conditions in non-

PMS group (p=1.000). For non-PMS group, the P300 of the negative pictures with clue were larger than that of positive pictures with clue(p=0.014) while PMS females didn't have significant differences between these two conditions(p=0.097). **Conclusion** Compared with non-PMS female, anticipation of negative stimuli lead to blunted activation of negative emotion in PMS females and this blunted activation is not related to the menstrual phase.

Title: Investigating the neurobehavioral mechanisms of motivational control in Attention Deficit/Hyperactivity Disorder

Authors: *A. O. CECELI[1], J. Y. NATSHEH[2], D. CRUZ[3], E. TRICOMI[1]
[1]Psychology Dept., Rutgers Univ. - Newark, Newark, NJ; [2]Kessler Fndn., East Hanover, NJ; [3]Counseling Services, Rutgers Univ., Newark, NJ

Abstract: Attention Deficit/Hyperactive Disorder (ADHD) is characterized by pronounced distractibility and impulsivity. Additionally, reward processing deficits and paralleling aberrance in the brain's reward circuitry have been reported, suggesting sub-optimal decision-making. The neurobehavioral mechanisms of motivational control in ADHD remain elusive. Motivational control of action is governed by a balance between caudate- and prefrontal cortex-regulated goal-directed actions that are executed in pursuit of desirable outcomes, and posterior putamen-regulated habits that are outcome-insensitive. We tested whether ADHD is associated with an over-reliance on habitual control and posterior putamen hyperactivity. Twenty-three patients and 23 matched controls were trained on a free-operant reward-learning task while undergoing fMRI. Participants learned two novel stimulus—response—outcome associations where instrumental responses to fractal cues predicted either M&M or Goldfish outcomes in variable-interval reinforcement. After moderate training, we removed subjects from the MRI scanner and devalued one of the two snacks via selective satiety. A subsequent extinction task in the scanner tested whether subjects performed outcome-driven, goal-directed behaviors (i.e., diminished response rate to fractal predicting devalued snack), or cue-driven, habitual actions (i.e., persistent response rate towards devalued snack). Despite behavioral similarities between patient and control groups, ROI analyses suggest posterior putamen hyperactivity in ADHD patients. Furthermore, whole-brain analyses reveal a shift from anterior to posterior putamen recruitment

over training in ADHD. These findings highlight the potential role of striatal sub-regions in strengthening novel associations in ADHD. Further research directed towards understanding the motivational and neural underpinnings of ADHD may be imperative in developing biomarkers for improved diagnostic and interventive methods.

Title: Significant interaction between purinergic P2X4 receptors and dopamine D1 receptors in mediation of prepulse inhibition of acoustic startle reflex and underlying molecular mechanisms

Authors: *S. KHOJA[1], L. ASATRYAN[2], M. W. JAKOWEC[3], D. L. DAVIES[2]
[2]Titus Family Dept. of Clin. Pharm., [3]Dept. of Neurol., [1]USC, Los Angeles, CA

Abstract: Ivermectin (IVM), a dihydro lactone derivative obtained from the soil actinomycete, *Streptomyces avermitilis*, is a FDA-approved drug for treatment of parasitic infections. Mechanistically, IVM acts as an allosteric positive modulator of purinergic P2X4 receptors (P2X4Rs) that are ion channels gated by adenosine-5'-triphosphate (ATP). Recently, we found that IVM induced deficits in prepulse inhibition (PPI), enhanced thigmotactic behavior and increased levodopa-induced motor behavior in male C57BL/6J mice. We were interested in IVM's effects on PPI, since IVM induced PPI dysfunction and this effect was attenuated in P2X4R knockout (KO) mice, implicating a role for P2X4Rs in this behavior. PPI deficits are often associated with cognitive impairments and are linked to a wide spectrum of neurological disorders. Interestingly, the PPI deficits in P2X4R KO mice were rescued by dopamine (DA) receptor antagonists indicating an interaction between P2X4Rs and DA receptors in PPI regulation. On the basis of findings from P2X4R KO mouse model, we hypothesized that modulation of DA receptors can alter the effects of IVM on PPI. This was accomplished by testing the effects of DA D1 and D2 receptor antagonists, SCH 23390 (1mg/kg) and raclopride (3 mg/kg) respectively and D1 agonist, SKF 82958 (0.1mg/kg) in regulation of IVM-mediated effects on PPI. To elucidate the mechanisms by which dopaminergic drugs modulate IVM-mediated PPI deficits, we investigated the interaction between IVM and dopaminergic drugs on phosphorylation of signaling molecules linked to PPI regulation including dopamine and cyclic-AMP regulated phosphoprotein of 32kDa (DARPP-32), Ca^{2+}/calmodulin kinase IIα (CaMKIIα) and neuronal nitric oxide synthase (nNOS) in the ventral striatum, a critical region for PPI

regulation. We found that SCH 23390, but not raclopride, significantly attenuated the PPI disruptive effects of IVM. Furthermore, SKF 82958 tended to potentiate IVM-mediated PPI disruption. At the molecular level, SCH 23390 and raclopride significantly blocked IVM-mediated increase in DARPP-32 phosphorylation in the ventral striatum, whereas SKF 82958 significantly potentiated IVM's effects on DARPP-32 phosphorylation in the same brain region. Additionally, SCH 23390 blocked IVM-mediated effects on CaMKIIα phosphorylation, but there was no interaction between IVM and raclopride or SKF 82958 in regulation of this enzyme. Overall, these findings suggest an involvement for D1 receptors in IVM-mediated PPI disruption via modulation of DARPP-32 and CamKIIα phosphorylation, indicating a complex interaction between P2X4Rs and D1 receptors on PPI and underlying signaling pathways.

Network, Albuquerque, NM; [4]Yale University, Sch. of Medicine, Dept. of Psychiatry, New Haven, CT; [5]Central Connecticut State University, Dept. of Psychological Sci., New Britain, CT; [6]Autism & Neurodevelopmental Disorders Inst., George Washington Univ., Virginia Beach, VA; [7]Olin Neuropsychiatry Res. Center, Inst. of, Hartford, CT

Abstract: Background: Over the recent years there has been a growing debate regarding the extent and nature of the overlap in neuropathology between schizophrenia (SZ) and autism

spectrum disorder (ASD). Dynamic functional network connectivity (dFNC) is a recent analysis method that explores temporal patterns of functional connectivity (FC). We compared resting-state dFNC in SZ, ASD and matched healthy controls (HC), characterized the association between temporal connectivity and behavior, and preformed classification analysis based on dFNC parameters. **Methods:** Resting-state fMRI was collected from 100 individuals: 33 SZ, 33 ASD, 34 HC. High-order independent component analysis (ICA) was performed, followed by dFNC analysis (window=30s, step=1TR, k-means clustering) using the GIFT toolbox. Number of transitions (NT), number of states (NS), fraction time (FT), and dwell time (DT) were calculated per subject. These measures were compared between groups using ANOVA, correlated with symptoms, and entered into linear discriminant analysis (LDA). **Results:** Three re-occurring FC states were identified (Fig A): 1. cortico-cortical, 2. weak, intra-network, 3. strong cortico-cortical. *Both clinical groups* (Fig C,D) showed decreased NS [P=0.001] and increased $FT_{state\text{-}2}$ and decreased $FT_{state\text{-}1}$ [P<0.001]. *The SZ group* further showed decreased NT [P<0.001] and $FT_{state\text{-}3}$ [P<0.001], and increased $DT_{state\text{-}2}$ [P<0.001] compared to HC and ASD, and decreased $DT_{state\text{-}1}$ [P=0.001] compared to HC. $DT_{state\text{-}3}$ correlated with social functioning score (ADOS; Fig B) in SZ [P=0.043; r=0.416]), but not ASD. Classification results correctly identified SZ at high rates (specificity- 81.8%), while ASD and HC were correctly classified at low rates (50%, 41%; respectively). **Conclusions:** Results indicate a severe and pervasive pattern of temporal aberrations in SZ (specifically, being "stuck" in a state of weak connectivity), that distinguishes SZ participants from both ASD and HC, and is uniquely associated with social functioning.

Title: Exploration of novel dopaminergic circuitry regulating impulsivity

Authors: *B. KIM[1], S. YOON[1], R. NAKAJIMA[2], Y.-K. LEE[1], J.-S. CHOI[1], B.-J. YOON[1], G. AUGUSTINE[3], J.-H. BAIK[1]

Abstract: Dopamine is broadly implicated in important brain functions such as motor control, cognition, memory, motivation and reward. Dopamine D2 receptor (D2R) plays crucial roles for such dopaminergic functions. It has been reported that polymorphism of dopamine D2 receptor genes can lead to drug addiction associated with impulsivity, schizophrenia and attention deficit/hyperactivity disorder (ADHD). Using 5-choice serial reaction time task (5-CSRTT), we measured attention and impulsivity in wild type (WT) and D2R knockout (D2R -/-) mice. D2R -/- mice showed significantly lower accuracy and higher premature response than WT mice. Selective optogenetic activation of D2R expressing neurons via microinjection of channelrhodopsin (AAV-DIO-hChR2(H134R)-eYFP) into the central amygdala (CeA) of D2R-Cre mice induced a decrease of premature response. Further, we identified synaptic connectivity from D2R-expressing neurons of CeA to bed nucleus of the stria terminalis (BNST) via ChR2-assisted circuit mapping. Selective optogenetic activation of D2R-expressing neurons in CeA-BNST circuit caused a decrease of impulsivity. These studies revealed a novel dopaminergic circuit that plays a crucial role in impulsive behavior which is important component of reward-related psychiatric disorders.

Title: Changes in fMRI BOLD signal pre- and post- weight restoration in subjects treated for anorexia nervosa: Implications for the use of neuroimaging in eating disorders research

Authors: *D. DEVILLE[1], K. L. KERR[2], S. MOSEMAN[3], J. BODURKA[4], W. K. SIMMONS[5]
[1]Laureate Inst. for Brain Res., Tulsa, OK; [2]Human Develop. and Family Sci., Oklahoma State Univ., Tulsa, OK; [3]Laureate Psychiatric Clin. and Hosp., Tulsa, OK; [4]Stephenson Sch. of Biomed. Engingeering, Univ. of Oklahoma, Norman, OK; [5]Mood Disorders Biomarkers, Jannsen Res. & Develop., San Diego, CA

Abstract: Anorexia nervosa (AN) has been linked to functional and structural brain differences, and functional MRI has been increasingly utilized to examine the neurobiological processes underlying AN. However, indiscriminate use of BOLD imaging in underweight AN patient samples may pose methodological concerns due to physiological effects of malnutrition on the brain. While several studies have drawn conclusions about the psychological features of AN from fMRI research using patients who are significantly underweight, to date there is no published research on the reliability of the BOLD signal in acutely ill AN patients. We therefore sought to examine BOLD signal strength in response to a visual checkerboard task in AN patients over the course of weight restoration. Prior research demonstrates strong test-retest reliability and reproducibility of activation within occipital and posterior thalamic regions in response to the checkerboard task.
Fifteen right-handed female subjects (mean age = 16.1 years, SD = 2.32, range = 13-20 years) undergoing inpatient treatment for AN participated in the current study and completed fMRI scanning at two time-points: at the beginning of treatment (mean body mass index [BMI]= 15.8 kg/m^2, SD = 1.5, range = 12.6-17.6), and after weight restoration (mean BMI = 19.5 kg/m^2, SD = 0.6, range = 18.7-20.5). Subjects were unmedicated at both time points. During fMRI scanning, subjects viewed a flashing black and white checkerboard alternating with a fixation screen. The checkerboard and control blocks were presented 12 times each, lasting for 17.5 seconds at a time. We used a dependent t-test to compare task-related BOLD activation from each time point (i.e., pre- and post- weight restoration) and found that following weight restoration, subjects exhibited

significantly decreased activation in occipital and thalamic regions. Further, the magnitude of reduction in BOLD signal strength in these regions from pre- to post- weight restoration was significantly correlated with AN patients' underweight BMI, such that a lower BMI was associated with a greater change in BOLD signal strength (r = -0.51 and r = -0.43 for occipital and thalamic clusters respectively) from the first to second time-point. These findings suggest that investigators should be mindful when including underweight subjects in fMRI research, and that results of studies that include underweight individuals should be interpreted cautiously. The effects of significantly low body weight on the BOLD signal may be accounted for by several different factors related to the malnourished state, and future research should aim to elucidate these specific mechanisms.

Title: Cognitive impacts of fatigue induced in a mouse model of radiation therapy

Authors: B. S. WOLFF[1], L. R. FENG[1], *K. FUKUHARA[3], L. SALIGAN[2]
[1]Natl. Inst. of Nursing Res., [2]NINR/IR, NIH, Bethesda, MD; [3]Intramural Res., Natl. Inst. of Nursing Res., Bethesda, MD

Abstract: Fatigue is a common and distressing symptom following radiation therapy for cancer, and it can be frequently undertreated in clinical practice. It is commonly defined as a subjective feeling of exhaustion that is not alleviated by rest or sleep, and it is likely a symptom with very complex underlying biology. It is strongly associated with other symptoms, including cognitive deficits. To explore the relationship between fatigue and cognitive symptoms, we use our previously established mouse model of radiation-induced fatigue, in which mice developed fatigue-like behavior after receiving radiation targeted to a region in their lower abdomen. In this study, we compared the fatigue-like behavior measured by home cage running wheel activity with cognitive performance in the Y-maze, 0-maze, and open field tests in irradiated mice vs sham-irradiated controls. In separate experiments, we also compared fatigue-like behavior measured by spontaneous home cage ambulatory activity with cognitive performance in a home cage learning task in irradiated mice vs sham-irradiated controls. We found that peripheral irradiation, despite not targeting the central nervous system, reduces cognitive performance in

the Y-maze test and may have complex effects on behavior in the open field and 0-maze tests. These results support the idea that fatigue and cognitive symptoms can have similar biological origins, and animal models may help develop treatments targeted either to particular symptoms or to a broader symptom cluster.

Title: Normalization of VTA dopamine neuron activity activity by mGluR2/3 agonist pomaglumetad methionil in the methylazoxymethanol acetate model of schizophrenia

Authors: *S. SONNENSCHEIN[1], A. A. GRACE[2]
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Pomaglumetad methionil, a group 2 metabotropic glutamate receptor (mGluR2/3) agonist, showed promise as a novel antipsychotic in preclinical research but failed to show efficacy in clinical trials, though it has been suggested that it may be effective in certain patient populations. Although previous studies have shown that mGluR2/3 agonists have no effect on dopamine (DA) in normal rats, we used the methylzoxymethanol acetate (MAM) rat model of schizophrenia to determine whether pomaglumetad may regulate DA neuron activity in a model representative of the hyperdopaminergic state thought to underlie psychosis, compared to control (SAL) rats. MAM and SAL rats were treated with pomaglumetad methionil (1, 3, 10 mg/kg, i.p) or 1 mg/kg saline 30 minutes prior to anesthetized in vivo electrophysiological recordings. The population activity of VTA DA neurons was measured by passing an electrode in a grid-like pattern, counting the number of spontaneously firing DA neurons, and analyzing their firing rate and bursting activity. Pomaglumetad dose-dependently reduced the number of spontaneously active DA neurons in the VTA of MAM rats to control levels without affecting DA firing in SAL rats. In rats treated with 3mg/kg pomaglumetad for 14d, DA neuron activity remained reduced in MAM rats, without effect in SAL rats, suggesting lack of tolerance following repeated daily treatment. As in the MAM rats, DA neuron population activity can be increased in a hippocampal-dependent manner via acute restraint stress. Administration of 3 mg/kg pomaglumetad prior to 2h restraint stress prevented the restraint-induced increase in DA neuron activity, and this effect was blocked by pretreatment with an mGluR2/3 antagonist. Thus, the

ability of pomaglumetad methionil to reduce the hyperdopaminergic activity in both MAM rats and in normal rats following restraint stress suggests that it can indirectly regulate DA neuron activity, likely by reducing increased ventral hippocampal activity, which may contribute to its potential therapeutic effects.

Title: Titration-based BDNF dual effect underlies the opposed behavioral effect of CB1 and TRPV1 agonists

Authors: *C. A. DINIZ[1], C. BIOJONE[2], S. R. L. JOCA[3], E. CASTRÉN[2], F. S. GUIMARÃES[1], P. C. CASAROTTO[2]
[1]Pharmachology, Sch. of Med. of Ribeirão Preto - Univ., Ribeirao Preto, Brazil; [2]Neurosci. Center, Univ. of Helsinki, Helsinki, Finland; [3]Sch. of Pharmaceut. Sci. - Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Rationale: anandamide (AEA) or 2-arachidonoylglycerol (2AG), both CB1 agonists, induce CB1 coupling to transactivate TRKB (*Tropomyosin receptor kinase B),* thus regulating the neuronal migration and maturation in the developing cortex. However, at higher concentrations AEA also engages vanilloid receptor - TRPV1, usually with opposed consequences on behavior, especially concerning anxiety. Then, the aim of the present study was to investigate the interaction between CB1/TRPV1 and TRKB systems in a mouse model of anxiety/repetitive behavior, along with *in vitro* approach. **Methods:** male C57BL67j were used to behavioral protocols and cortex of E18 rat embryos were dissected and cultured. Marble burying test (box with 5cm sawdust layer and twelve marbles evenly spaced over the floor) was used to evaluate repetitive behavior. Mice were placed on box´s center and 25min later the number of buried marbles was counted. Western blotting or ELISA were used to quantify protein levels and stereotaxic surgery to cannulate the animals. **Results:** systemic infusion of WIN (CB1 agonist, 1mg/kg) decreased the number of buried marbles, while previous K252a (TRK blocker, 80ug/kg) treatment prevented it. Infusion into prefrontal cortex of AEA (o.5pmol) and ACEA (more selective CB1 agonist, 0.05pmol) decreased, while capsaicine (CPS, TRPV agonist;

5pmol) and BDNF (endogenous TRKB agonist, 200pg) increased the number of buried marbles ($F(3,32)= 11.74$). About *In vitro* results, treatment with AEA 100 and 200nM ($F(5,18)= 16.53$), CPS 200nM ($F(3,19)= 9.28$) and BDNF 20 and 50ng/ml ($F(3,16)= 134.40$) increased pTRK levels. AEA 100nM ($F(1,20)= 16.01$), but not BDNF 20ng/ml ($F(1,16)= 0.85$), increased pTRK levels by activating CB1 receptor. With a previous capsazepine (TRPV1 antagonist) 20uM treatment, the excess of pTRK levels guaranteed with AEA 200nM treatment was reversed to the same levels obtained with AEA 100nM ($F(2,30)= 17.04$). Previous treatment with TRKB.fc (BDNF scavenger) also brought the effect of AEA 200nM to the levels of pTRK found with AEA 100nM treatment ($F(2,18)= 15.01$). AEA 200nM increased pTRK levels by increasing BDNF levels released in the medium, since levels of pTRK and BDNF were positively correlated (Spearman's $r= 0.77$). Accordingly, capsaicine 200nM increased pTRK levels, effect which was also prevented with previous TRKB.fc treatment ($F(1,20)= 9.28$). All the data were considered significant with $p<0.05$. **Conclusion:** our data suggest a complex interaction between CB1, TRPV1 and TRKB, whose final balance modulates burying behavior. The amount of BDNF released might mean an additional modulatory mechanism by which CB1 and TRPV1 display opposite effects**.**

Title: Effects of chronic exercise training on fatigue: A meta-analysis & meta-regression analysis

Authors: *S. CHEN[1], N. THOM[2], M. P. HERRING[3], D. C. MONROE[4]
[1]Univ. of California-Los Angeles, Los Angeles, CA; [2]Biol., Wheaton Col., Wheaton, IL; [3]Physical Educ. and Sport Sci., Univ. of Limerick, Limerick, Ireland; [4]Neurol., UC Irvine, Irvine, CA

Abstract: Objectives: The neurobiological mechanisms of fatigue are poorly understood. And though it is a public health burden there are few effective, evidence-based treatment options. Studies suggest that exercise training reduces symptoms of fatigue, but the evidence from RCTs on the effect of exercise training on fatigue has not been synthesized since 2006. This study estimated the population effect size for exercise training effects on fatigue, and determined to

what extent participant and trial characteristics moderated these effects, in order to guide work seeking to uncover the neurobiological mechanisms of fatigue.
Methods: One hundred eighty-six effects were derived from 109 articles comprised of 12,470 participants (mean age = 52.37±15.01 y, 75% female/25% male). Studies included both randomization to exercise training (n = 6,355) or non-active control (n = 6,115), and a validated fatigue outcome measured at baseline and post-intervention. Hedges' *d* effect sizes were computed, and random effects models were used for analyses. Meta-regression quantified the extent to which participant and trial characteristics moderated the mean effect.
Results: Exercise training significantly reduced feelings of fatigue by a heterogeneous mean effect size delta (Δ) of 0.49 ($z=10.74$, $p<.0001$, 95CI:[0.40, 0.58], $Q_{T[182]}=987.07$, $p<.001$).
The overall meta-regression model was significant ($Q_{R7}=26.40$, $p=.0004$, $R^2=.14$; $Q_{E103}=168.25$, $p<0.001$). Sex (B=.32, z=2.84, p=.005), disease status (B=.32, z=2.24, p=.03), and intervention length (B=.33, z=3.33, p=.0009), accounted for significant variation in the overall effect of exercise on fatigue. However, age (B=-.01, z=-.10, p=.92), exercise mode (B=.22, z=1.47, p=.14), exercise intensity (B=-.06, z=-.45, p=.65), and exercise time (B=.34, z=1.52, p=.13) were not related to effect size.
Larger effects were found among men (Δ=1.06, 95CI: .40, 1.71), those with cancer or a fatigue-related disease (Δ=.62, 95CI: .48, .75), and for exercise interventions < 12 weeks (Δ=.97, 95CI: .72, 1.23).
Conclusion: The results suggest that exercise training produces moderate reductions in fatigue and that translational investigations designed to explain the neurobiological mechanisms of exercise can optimize fatigue reduction by employing programs of <12 weeks among those with cancer or fatigue-related diseases. It may be advised to allow individuals to choose exercise mode, intensity, and time in order to promote compliance as these factors did not moderate fatigue reductions. More research in young adults (< 40y) is warranted given the comorbidity of fatigue with other psychosomatic disorders that are rising in the population.

Title: Beta-arrestin2 is required for the behavioral responses to lysergic acid diethylamide

Authors: *W. C. WETSEL[1], R. M. RODRIGUIZ[1], V. M. POGORELOV[1], V. NADKARNI[1], J. D. MCCORVY[2], B. L. ROTH[3]
[1]Dept Psychiat & Behav Sci., Duke Univ. Med. Ctr., Durham, NC; [2]Dept Cell Biology, Neurobio. & Anat., Med. Col. Wisconsin, Milwaukee, WI; [3]Dept Pharmacol., Univ. of North Carolina Chapel Hill Med. Sch., Milwaukee, WI

Abstract: Drugs stabilize specific G protein-coupled receptors (GPCRs) conformations essential for canonical G protein- and β-arrestin- (βArr) mediated signaling. Preferential signaling through G protein-dependent or -independent pathways has been termed functional selectivity, whereby agonists can stabilize distinct signaling complexes referred to as biased agonism (for review see Wacker et al., *Cell* 2017). Recently, we have developed an Arr-biased D2 agonist (UNC9994) that displays potent antipsychotic-like activity *in vivo* (Allen et al., *PNAS* 2011; Park et al., *Neuropsychopharmacology* 2016). Importantly we showed that the behavioral effects of UNC9994 require βArr2 by comparing effects in wild-type (WT) and βArr2 knockout (KO) mice. Lysergic acid diethylamide (LSD) is a potent agonist for most serotonin (5-hydroxytryptamine; 5-HT) receptors (Wacker et al., *Science* 2013) and many other biogenic amine receptors (Kroeze et al., *Nature Struct and Mol Biol* 2015). At 5-HT_2-family receptors, however, LSD is a potent Arr-biased agonist (Wacker et al., *Cell* 2017) and in humans the psychedelic effects of LSD have been ascribed primarily to 5-HT_{2A} receptor agonism. Here, we sought to determine if the behavioral actions of the hallucinogen LSD also require βArr2 in mice. Accordingly, we examined whether mice with global deletion of *Arrb2* respond differently to LSD than WT controls. Adult WT and βArr2-KO mice (N≈10 mice/group) received vehicle or LSD (i.p.) and were evaluated in tests for open field activity, prepulse inhibition (PPI), and ethological behaviors. Baseline motor activities in the open field were similar for WT and βArr2-KO mice. LSD stimulated locomotor activity, rearing, and stereotypical activities in WT mice while these behaviors were blunted in βArr2-KO mutants. The 5-HT_{2A} antagonist MDL-100907 reduced the LSD-stimulated locomotion and rearing in both genotypes; stereotypy was unaffected with the antagonist only in mutants. LSD suppressed PPI in WT, whereas it was unaffected in βArr2-KO mice; MDL-100907 rescued WT responses. LSD increased head-twitch, grooming, and retrograde walking to greater extents in WT than mutant mice, while MDL-100907 decreased these responses. Nose-pokes were enhanced in WT, but not in βArr2-KO mice; MDL-100907 normalized WT responses. Collectively, many LSD-mediated responses are reduced or abrogated when *Arrb2* is disrupted in mice. These findings are consistent with the hypothesis that βArr2-modulated signaling may be critical for LSD's behavioral effects.

Title: Overexpression of dopamine D2 receptors on ventral striatal indirect pathway neurons reduces survival in the activity-based anorexia paradigm

Authors: *A. C. WELCH[1], M. S. MCMURRAY[2], S. C. DULAWA[1]
[1]Psychiatry, Univ. of California San Diego, La Jolla, CA; [2]Psychology, Miami Univ., Oxford, OH

Abstract: Anorexia nervosa (AN) is an eating disorder characterized by severe hypophagia and weight loss, and an intense fear of weight gain. In the activity-based anorexia (ABA) paradigm, rodents exposed to running wheels and restricted food access exhibit extreme weight loss, hypophagia, and hyperactivity compared to rodents exposed to only one of these conditions. Upon reaching 75% of their initial bodyweight, mice are removed from the experiment. Days of survival in the ABA paradigm provide a measure of ABA susceptibility. Thus, the ABA paradigm provides a model for aspects of AN. We previously reported that chronic treatment with dopamine D2 receptor (D2R), D3R, or D2/D3R antagonists reduce weight loss and hypophagia, and increase survival in the ABA paradigm. Furthermore, human imaging studies have reported that recovered female AN patients show increased D2/D3R binding in the ventral striatum. However, whether D2/D3R overexpression in the ventral striatum plays a causal role in AN remains unexplored. We determined the effects of virally overexpressing D2Rs on ventral striatal indirect pathway neurons on ABA in mice. Eight week old transgenic male and female Drd2-cre mice received infusions of an adenoassociated virus (AAV) separately expressing the long form of D2R and mVenus in a Cre-dependent fashion, or a control virus expressing only EGFP in a Cre-dependent fashion. Thus, D2Rs were not ectopically expressed on striatal direct pathway neurons. Four weeks later, mice were 12 weeks old and tested in the open field paradigm, followed 2 days later by the ABA paradigm. Mice were placed in the open field chamber for 30 minutes and movement recorded. Our results showed increased locomotor activity in mice overexpressing D2Rs ($P < .0001$). Mice were then singly housed with a running wheel and received food and water ad lib during baseline. Dependent measures were collected daily for 4 days: bodyweight, food consumption, and wheel running distance. After the baseline period, food was available 7 hours each day starting one hour into the light period (12h:12h). During the restriction phase, the same measures were collected daily, and days of survival were also recorded. The restriction phase lasted up to 14 days. Our results showed that mice

overexpressing D2Rs in ventral striatal indirect pathway neurons showed reduced survival in the ABA paradigm (P <.05) compared to controls. This effect was observed in female (P <.05), but not male mice. Our findings suggest that overexpression of D2Rs on ventral striatal indirect pathway neurons increase ABA behavior and may play a causal role in the development of AN.

Title: Decreased empathy and functional network alteration in a mice model of ostracism

Authors: *S. JUNG[1], J.-H. YOON[2], J. CHUNG[2], Y. JEONG[3]
[1]Korea Advanced Inst. of Sci. and Technol., Taejon-City, Korea, Republic of; [3]Bio and Brain Engin., [2]KAIST, Daejeon, Korea, Republic of

Abstract: Formation and maintenance of social bonding are critical to survival of social animals. Being ignored, rejected and excluded, called ostracism, could break the bonding and threat the quality of life of individuals. Though ostracism is common in any social groups, the effects and the underlying mechanisms are largely unknown. Various paradigms such as social isolation, and social defeat have been developed to understand the effects of being ostracized especially in rodents, however, the existing paradigms are insufficient to explain ostracism because of individualized housing. Here, we developed social exclusion paradigm by make mice carrying butyric acid, smelly liquid making other mice avoid. The social exclusion mouse (SEM) model repeatedly experienced being avoided, staying alone, and being groomed less by cage-mates (allogrooming). SEM showed impaired sociability and empathy-like behaviors chronically. After empathy-like behavior test, *c-fos* driven functional network analysis revealed increased functional connectivity in basolateral amygdala (BLA) connectivity, while in dentate gyrus in control mice. Furthermore, SEM used more segregated network modules than control mice. In conclusion, our repeated social exclusion paradigm could induce the ostracism-like effects and lead to impaired social behaviors and change functional connectivity networks. It may contribute to understand the effects of social exclusion and underlying neural mechanisms.

Title: Role of striatal cholinergic interneurons in the regulation of dopaminergic neurotransmission and implication for striatal-dependent processes

Authors: *M. FAVIER[1,2], H. JANICKOVA[3], M. A. PRADO[3], V. F. PRADO[3], S. EL MESTIKAWY[4]
[1]Psychiatry, Douglas Mental Hlth. Univ. Inst., Montréal, QC, Canada; [2]McGill Univ., Montréal, QC, Canada; [3]Robarts Res. Institute/University of Western Ontario, London, ON, Canada; [4]Psychiatry, Douglas Mental Hlth. Univ. Institute/McGill Univ., Montréal, QC, Canada

Abstract: Cholinergic interneurons (ChIs) from the dorsal striatum are major regulators of striatal function. ChIs express the vesicular acetylcholine transporter (VAChT) but also the atypical vesicular glutamate transporter type 3 (VGLUT3), and consequently signal using both acetylcholine (ACh) and glutamate (Glu). Our study is focused on deciphering the role of Ach/Glu cotransmission by ChIs in the regulation of dopaminergic (DA) neurotransmission and striatal-dependent processes. Using genetic and virus-targeted approaches to delete the expression of VAChT or VGLUT3 in mice, we discovered that ChIs finely modulate DA neurotransmission, by using ACh and Glu which have opposite effects on DA release. Further, we demonstrated that this DA regulation by ChIs was differential across the ventral and dorsal parts of the striatum. We will investigate the functional consequences of this ChIs-driven regulation of DA release using specific behavioural tasks known to assess for striatal-dependent processes.

Title: Cocaine drives schizophrenia-like behaviors via cholinergic neurons within ventral striatum

Authors: *S. HAM, H.-I. IM
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: The function of cocaine as a dopamine reuptake inhibitor plays an important role in establishing and maintaining addiction. However, when used heavily, more than half of cocaine users showed behaviors similar to schizophrenia: it is usually called as cocaine-induced psychosis (CIP) that include hallucinations, delusions, delirium, suicidal thoughts, and loss of touch with reality. Despite seriousness of the disorder, however, very little is known about the neurological mechanisms that mediate CIP. On the other hand, the involvement of various neurotransmitters in psychotic behaviors of schizophrenia had generated considerable interest, which was how cocaine's pharmacological and molecular interactions might affect behavioral changes via neurotransmitter systems. Here, we successfully established CIP mouse model. Subsequently, by examining changes of neurotransmitters in several brain regions, we have found that the level of dopamine and acetylcholine have increased in ventral striatum. Interestingly, the dopaminergic neurons in ventral tegmental area and substantia nigra showed any changes in CIP mice compared to control, whereas the cholinergic neurons in ventral striatum were significantly reduced in CIP mice than in control. Furthermore, schizophrenia-like behaviors of the CIP mice were significantly rescued by nicotine and donepezil (acetylcholinesterase inhibitor). These findings suggest that part of schizophrenia-like behaviors induced by cocaine may be mediated via dysfunction of cholinergic neurons within ventral striatum.

Title: Regulation of amygdalar corticotropin releasing hormone in the peripartum period

Authors: *S. ZOUBOVSKY[1], J. SCHULKIN[2], L. MUGLIA[3]
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Dept. of Neurosci., Georgetown Univ., San Rafael, CA; [3]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Postpartum depression (PPD) affects 10-20% of women and exerts adverse consequences on mother and child. Fluctuations in estrogen (E2) and progesterone (P4) during pregnancy and transition to postpartum period are thought to be important in mediating functional alterations in the maternal brain needed for the emergence of maternal behaviors. However, E2 and P4 changes are also thought to be involved in PPD. Gestational stress and hypothalamic-pituitary-adrenal (HPA) axis abnormalities have also been implicated in the development of PPD. Here, we measure effects of perinatal changes in E2-P4 on corticotropin-releasing hormone (CRH), a principal modulator of the HPA axis and behavioral stress response, and on nuclear steroid hormone receptors/co-chaperones associated with CRH regulation. C57Bl/6 female mice have a significant increase in CRH mRNA in the central nucleus of the amygdala (CeA) and bed nucleus of the stria terminalis (BNST) in the early postpartum period compared to virgin controls. This change is associated with a significant increase in CeA and BNST progesterone receptor (PR) mRNA, although no changes in glucocorticoid receptor (GR) expression are observed. Furthermore, there is a significant upregulation in mRNA of co-chaperones known to orchestrate GR/PR transcriptional activity. Increased CeA PPID and FKBP5 and BNST PPID, FKBP4, and BAG1 expression are observed in the early postpartum period suggesting these molecules as putative regulators of postpartum changes in GR/PR signaling. To further understand if the increase in CeA CRH is mediated by perinatal changes in E2-P4, we measured changes in CRH in an exogeneous E2-P4 model that mimics hormonal levels seen in the peripartum period. There is a significant increase in CeA CRH mRNA following E2-P4 withdrawal when compared to oil withdrawal controls. These changes are associated with behavioral alterations including a significant decrease in latency to first open arm entry in the elevated zero maze and a significant increase in immobility episodes in the forced swim test, suggesting an increased state of alertness. While perhaps beneficial for maternal behavior, this can also create an affective state vulnerable to environmental insults, such as chronic stress. These results provide evidence of postpartum alterations in GR/PR signaling in CeA-BNST neural circuitry following E2-P4 withdrawal. The mechanistic role GR/PR play in mediating CRH changes as well as the effects of gestational stress on GR/PR signaling and their

contribution to postpartum affective dysregulation are currently being investigated by selective spatiotemporal GR/PR modulation using Cre-loxP technology.

Center, Inst. of Living/Hartford Hosp., Hartford, CT; [8]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Psychotic disorders share common phenomenology and genetic risk factors, but specific etiologies and targeted pharmacological treatments remain elusive. Schizophrenia (SZ), schizoaffective disorder (SZA), and bipolar disorder with psychosis (BPP) are all diagnosed based on clinical symptoms, which in their lack of diagnostic specificity, evidence homogeneity between disorders historically considered distinct. Separating probands based on neurobiology instead may yield more meaningful classifications which offer better targets for study of disease mechanisms and treatments. The Bipolar and Schizophrenia Network for Intermediate Phenotypes consortium has collected brain and behavioral data from probands with these three disorders and used k-means clustering and multivariate discriminant analysis to regroup probands into three “Biotypes” based on electrophysiological, oculomotor, and cognitive measures. The present study examines measures of neural white matter (WM), which were not included in the original Biotypes analysis, in order to determine whether Biotypes provide better group separation than diagnostic classification. Diffusion-weighted imaging data were acquired from probands with SZ (n=76), SZA (n=74), and BPP (n=14), as well as healthy comparison (HC) subjects (n=76); fractional anisotropy (FA) values indexing WM structure were calculated and compared between the three diagnostic groups, as well as between the three Biotypes

previously derived. Between diagnoses, mean FA was lower for SZ and SZA probands than HC across several WM tracts connecting frontal, temporal, parietal, and posterior regions, but often not different between BPP probands and HC. Between Biotypes, mean FA was lower for Biotype 1, which includes probands from all three diagnostic categories, than for HC or the other Biotypes across similar tracts. WM differences between Biotypes may reflect true biological alterations, which ultimately provide better classification and possible targets for etiological mechanisms and treatments in psychosis.

Title: Grooming displays robust face validity in the neonatal clomipramine exposure rat model of obsessive compulsive disorder

Authors: *L. PEEBLES[1], K. HILBER[1], J. BICE[1], Z. BUSBY[1], W. FRYLING[1], M. STELZNER[1], D. S. KREISS[1,2]
[1]Macalester Col., Saint Paul, MN; [2]Freshman Res. Immersion Program, Binghamton Univ., Binghamton, NY

Abstract: Obsessive Compulsive Disorder (OCD) is a chronic neuropsychiatric illness that affects 2-3% of the United States population and is characterized by persistent anxiety producing thoughts accompanied by overwhelming urges to perform repetitive ritualistic behaviors. Modern pharmacological treatments for OCD are only effective in 40-60% of patients, have an 8-10 week delayed onset, and are associated with problematic side effects. Animal models of this psychiatric disorder offer an invaluable tool whereby new therapeutic avenues can be explored. Although multiple behavioral assays have been suggested to reflect the repetitive and compulsive symptoms of OCD, no single behavior has been universally accepted as a model of the disorder.

The objective of this study was to explore grooming as an alternative to other types of anxiety-related behaviors in the assessment of the OCD-like phenotype in a novel animal model of OCD induced by neonatal exposure to clomipramine, a serotonin/norepinephrine reuptake inhibitor. Prior studies have demonstrated that the neoclomipramine rodent model has both face and predictive validity in the Hole Board (HB) and Elevated Plus Maze (EPM). In the current study, for the first time, grooming was selected for analysis in this novel model given its frequent over-expression in OCD patients. Grooming, rearing, and HB behaviors were repeated assessed over 3 trials (separated by 1-2 weeks) in adult male Sprague-Dawley rats that had been injected neonatally (Day 9-16) with either 15 mg/kg clomipramine (neoCLOM, n=20) or with saline (neoSAL, n=20). Neo-CLOM "OCD-like" rats consistently exhibited increased grooming versus neo-SALINE control rats across all 3 Trials ($*p_1 = 0.049$, $**p_2 = 0.0071$, $**p_3 = 0.0037$). In contrast, no significant differences between the experimental groups were observed for rearing or head poking measures. Likewise, analysis of the rats' behaviors in the EPM showed no significant differences between these two groups of rats and data from the multiple trials had considerable variability. In conclusion, this study demonstrates that an analysis of grooming offers valuable advantages over other anxiety-related measures as a behavioral assay for animal models of OCD. Grooming behaviors robustly demonstrate phenotypic differences between experimental "OCD-like" and control rats, is consistently expressed across trials, and has high face validity with the human disorder.

Title: Overcoming the one trial tolerance of rat behavior in the elevated plus maze (EPM)

Authors: *K. M. HILBER[1], C. BRANTNER[1], E. CARTER[1], W. FRYLING[1], F. LI[1], S. MOCHIDA[1], H. MUDRICK[1], K. NAZAROVA[1], M. STELZNER[1], D. S. KREISS[1,2]
[1]Macalester Col., Saint Paul, MN; [2]Neurosci. Stream, Freshman Res. Immersion Program, Binghamton Univ., Binghamton, NY

Abstract: Rodent models of anxiety disorders often employ the Elevated Plus Maze (EPM). A higher ratio of time spent in the CLOSED versus OPEN arms of the maze is associated with a higher level of anxiety. A major limitation in using the EPM, however, is the "One Trial

Tolerance" phenomena (File, Mabbutt, & Hitchcott, 1990). This refers to dramatic drop in the animals' exploration of the OPEN arms following the initial exposure to the maze. It has thus been suggested that repeated testing in the EPM for a single rodent is thus experimentally invalid. The aim of this study was to investigate whether manipulation of selected variables of the experimental protocol could increase OPEN arm exploration of male Sprague-Dawley rats (n=20) upon repeated exposure to the arena. For the current study, rats were initially exposed to the arena at an early age (30 days postnatal), observational trials were separated by 10 days, the animals were frequently handled, the housing environments were enriched, and low illumination levels were used when assessing behavior. In accordance with prior studies, OPEN arm exploration was significantly decreased upon the 2nd exposure (Day 40) to the arena. However, by the 4th exposure (Day 60), OPEN arm activity was no longer different from the initial exposure. Moreover, by the 6th exposure (Day 80), OPEN arm activity was actually *increased* above that measured on the 1st Trial. This study thus demonstrates that procedural modifications of the experimental protocol can enable OPEN arm behavior to be fully restored upon successive exposures in the EPM - thereby overcoming the One Trial Tolerance limitation associated with this commonly used apparatus. Adopting these relatively minor experimental modifications enables the anxiety level of an individual rat to be assessed multiple times in the EPM - allowing for a repeated measures design and minimization of the number of animal subjects required for experimentation.

Title: A novel negative allosteric modulator (NAM) of the cannabinoid receptor 1 (CB_1) as a potential therapeutic ligand for the treatment of psychiatric disorders arising from dopamine dysregulation

Authors: *V. LAM[1], G. BAILLIE[2], I. R. GREIG[3], M. H. ABDELRAHMAN[3], L. A. TREMBLEAU[3], R. A. ROSS[1]
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Univ. of Dundee, Nethergate, United Kingdom; [3]Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: The cannabinoid receptor 1 (CB_1) receptor is a G-protein coupled receptor (GPCR) that is ubiquitously expressed in the brain. It has been previously shown that CB_1 receptor antagonists have antipsychotic like effects in animal models of schizophrenia and has therefore been postulated that targeting the CB_1 receptor could provide a novel drug target for the treatment of several psychiatric diseases such as schizophrenia. Unfortunately, the side of effects of an orthosteric antagonist for the CB_1 receptor (rimonabant) in clinical trials led to the withdrawal of the drug from human use. The evidence is clear that the endocannabinoid system is an important and potential therapeutic target in psychiatry. With the discovery of an allosteric binding site on the CB_1 receptor it is possible that allosteric modulators of the CB_1 receptor may offer a unique and novel approach to rebalance the dopaminergic system at multiple points. By targeting the allosteric site of the CB1 receptor, we generated a novel negative allosteric modulator (NAM): ABM300. In cells stably expressing the CB_1 receptor, we assayed ABM300 in several orthogonal assays. These assays included arrestin recruitment, cAMP, and ERK phosphorylation. We tested the ability for ABM300 to allosterically modulate signalling of synthetic cannabinoids CP55940 and WIN55212. In our initial assays using arrestin recruitment, ABM300 was able to show negative allosteric modulation of the agonists CP55940. Further assessment using assays for quantifying cAMP signalling and ERK phosphorylation, also found that ABM300 was acting as a negative allosteric modulator. In addition, in vitro pharmacokinetic and toxicological analysis indicates that ABM300 is stable in our in vitro assays which predicts in vivo drug stability and penetrance into the central nervous system. In conclusion, we show that ABM300 is a novel negative allosteric modulator for the CB1 receptor. Based on its chemical properties, we expect ABM300 to be active in the central nervous system for further in vivo characterization.

Abstract: Background: The prevalence of psychiatric disorders is common, with anxiety, mood disorders, and schizophrenia reporting prevalence rates of 28.3%, 9.5%, and ~1% respectively. However, patient outcomes remain not ideal. Therefore, it is imperative to find novel treatment approaches for these disorders. Dopamine controls cognitive, emotional and motor aspects of goal-directed behaviour, with perturbations in the system playing a role in a number of psychiatric disorders and their underlying symptoms. Relating to the dopamine system, the endocannabinoid systems serves as an important filter of afferent inputs, helping shape how incoming information is conveyed onto dopamine neurons and to output targets. Therefore, we hypothesize that compounds negatively targeting the endocannabinoid system could be candidates in treating positive and affective symptoms in psychiatric illness. We tested the effect of ABM300, a novel negative allosteric modulator (NAM) of the CB_1 receptor (IC_{50} of ~20nM).
Methods: Adult (>P70) GluN1-knockdown (GluN1KD - F1: C57Bl/6J x 129S1/SvlmJ) and DAT-knockout (DATKO - C57Bl/6J), balanced for sex, were treated with either vehicle (1:1:18 – Tween80 : 95% ethanol : saline) or a novel CB_1 negative allosteric modulator (CB_1 NAM), ABM300, at 10mg/kg, tested on behavioural assays, and compared to littermate controls. Locomotor, stereotypic movements and vertical activity were tested, along with anxiety/mania and sensorimotor gating behaviours. All data were analyzed with two- or three-way ANOVA, as appropriate, and corrected for multiple comparisons.
Results: GluN1KD and DATKO mice display hyperactivity, impaired habituation and sensorimotor gating, along with increased stereotypy and vertical activity, in a state of mania-like behaviour. Following acute treatment with ABM300, amelioration of these dysregulated behaviours was observed. GluN1KD mice saw a reduction in locomotor and vertical activity, along with an amelioration of repetitive stereotypic movements and mania-like behaviour. DATKO mice also saw the same amelioration of behaviours as that of the GluN1KD, with additional amelioration of sensorimotor deficits.
Conclusion: The data suggest that CB_1 NAMs represent a novel treatment for psychiatric symptoms as a result of dopamine dysregulation. ABM300 ameliorates dopamine dysregulation in both animal models of psychiatric illness. Furthermore, targeting the endocannabinoid system offers the opportunity to normalize deficits that arise from differing underlying dysfunctions that manifest as similar behavioural changes; both of which are mediated by dopamine dysregulation.

Title: SXC-2023, a potential therapeutic for various CNS disorders, is safe and well-tolerated in phase I clinical studies

Authors: *M. NEARY, C. E. BEYER, D. G. LAWTON, P. P. COTTER, T. BECK
Promentis Pharmaceuticals, INC, Milwaukee, WI

Abstract: A number of disorders of the central nervous system (CNS) are characterized by alterations in glutamatergic neurotransmission and/or oxidative homeostasis. Moreover, a robust impulsive behavioral phenotype and deficits in the brain's inhibitory control circuitry are key features of several of these chronic conditions. The cystine-glutamate antiporter (also known as System x_c^- or Sxc) is expressed within these inhibitory brain pathways (i.e., the cortico-striatal system), where it is capable of modulating glutamatergic signaling and increasing the synthesis of glutathione, an important antioxidant. SXC-2023, a small molecule activator of System x_c^-, is currently being developed for the treatment of trichotillomania, a neuropsychiatric impulse control disorder defined by recurrent hair pulling, which is accompanied by distress and other functional impairments. Here, we present the safety and tolerability profile of SXC-2023 from our first-in-human, Phase 1 studies in healthy volunteers. Following acute administration of a broad pharmacological dose range, SXC-2023 was shown to be safe and well-tolerated with no significant adverse events. Further human studies are underway to assess the safety and pharmacokinetic profile of SXC-2023 following repeated dosing in healthy volunteers. These clinical safety results, together with a compelling preclinical efficacy and toxicology profile (presented separately), suggest that SXC-2023 represents a safe, well-tolerated, and promising approach for the treatment of inhibitory/impulse control disorders such as trichotillomania.

Title: Circuit- and symptom-specific targeted therapy of fragile X syndrome rescues cognitive impairments and normalizes synaptic plasticity in central amygdala

Authors: *E. A. KNAPSKA[1], A. PUSCIAN[2], M. WINIARSKI[1], J. BOROWSKA[1], S. LESKI[3], T. GORKIEWICZ[4], M. CHATURVEDI[1], J. CHMIELEWSKA[6], M. DZIEMBOWSKA[7], L. KACZMAREK[5]

Abstract: Fragile X Syndrome (FXS) resulting from the loss of Fragile X Mental Retardation Protein (FMRP) is the most common monogenetic cause of inherited mental disability and autism. FXS patients display a wide range of cognitive and social impairments, with very high phenotypic variability. However, targeted therapeutic approaches tailored to address particular FXS symptoms have not been developed yet. In both humans and mice lack of FMRP leads to elevated translation of matrix metalloproteinase-9 (MMP-9), an enzyme involved in activity-dependent reorganization of dendritic spines architecture. Notably, abnormal activity of MMP-9-dependent circuits specifically in central amygdala (CeA) disrupts reward learning. Here we show how brain-circuit specific approach aiming at particular molecular mechanism rescue behavioral deficits in symptom-specific manner. We injected Fmr1 knockouts (Fmr1 KO), a mouse model of FXS, with nanoparticles (NPs) releasing TIMP-1, an endogenous inhibitor of MMP-9, into the CeA and tested their cognitive and social abilities in the systems for automated behavioral phenotyping (IntelliCages and Eco-HAB). Further, we combined it with assessment of synaptic plasticity (long term potentiation, LTP) and high-resolution morphology of synapses (electron microscopy). We show that targeted, CeA-limited inhibition of hypertranslated MMP-9: (1) rescues cognitive but not social deficits, (2) normalizes severely impaired CeA LTP, and (3) reverses abnormal CeA synaptic morphology in Fmr1 KOs. NPs used for the delivery of the endogenous MMP-9 inhibitor gradually release the compound assuring stable therapeutic levels over several days. Presented results provide critical insights into molecular and neural correlates of FXS.

Title: Superficial but not basolateral amygdala volume decreases in medication-free patients with obsessive-compulsive disorder

Authors: L. ZHANG[1], X. HU[1], L. LU[2], X. HU[1], X. BU[1], H. LI[1], S. TANG[1], Y. GAO[1], Y. YANG[3], Q. GONG[1], *X.-Q. HUANG[2]

Abstract: Background:Abnormal activities of amygdala were frequently reported in patients with obsessive-compulsive disorder (OCD) but little is known about volumetric alterations in this small structure which consists of several functionally distinct nuclei. The current study aims to investigate the subfields volume in amygdala using a newly developed automatic segmentation technique[1] in a relatively large sample of medication-free OCD patients. **Methods:** High resolution 3D T1 weighted MR Imaging were collected from 81 OCD patients and 95 age- and sex-matched healthy controls(HC). Volume of whole amygdala and 9 subregions (anterior amygdaloid area, cortico-amygdaloid transition area; lateral nucleus, basal nucleus, paralaminar nucleus, accessory basal, medical nucleus, central nucleus and cortical nucleus) were measured using FreeSurfer 6.0. A MANCOVA with age, sex and ICV as covariates was performed to test for amygdala subregion volume differences between groups with Bonferroni correction and post hoc analysis was conducted to explore association between affected subregions and clinical profiles. **Results**: We found that OCD patients had reduced volume of bilateral amygdala (left, $p=0.034$; right, $p=0.002$) and subfields in superficial region including central nucleus(left, $p=0.002$; right, $p<0.001$), cortical nucleus(left, $p=0.001$; right, $p<0.001$) and medial nucleus(left, $p>0.05$; right, $p<0.001$) and in bilateral accessory basal nuclei (left, $p=0.001$; right, $p<0.001$), compared with HC. In addition, negative correlations were observed between illness duration and volume of right central nucleus ($p=0.022$, $r=-0.256$). **Conclusions**: We used a state-of-the-art amygdala segmentation approach and demonstrated that in patients with OCD, volumes reduction in the superficial amygdala regions were more

prominent relative to basal-lateral part and illness course had progressive effect on certain subregion. **Reference:** 1. NeuroImage, 2017,155:370-82

Title: Chronic pain upregulates kappa opioid receptor signaling in the amygdala

Authors: *A. L. SEVERINO[1,2], S. LIU[1,2], S. PICKENS[1,2], R. KARMOUTA[1,2], H. NASEF[1,2], F. M. LESLIE[3], F. I. CARROLL[4], C. J. EVANS[1,2], C. M. CAHILL[1,2]

Abstract: Many patients with chronic pain also present with mood disorders such as anxiety or depression, which negatively impact their quality of life. Given the involvement of kappa opioid receptors (KOR) in eliciting aversive behaviors, including anxiety and depression, we asked whether KORs contribute to the negative affective-like behaviors commonly associated with chronic neuropathic pain. Kappa receptors are distributed widely throughout reward and emotion-processing circuitry including the amygdala, a brain region involved in emotional learning. Our study aimed to characterize KOR signaling-dependent negative affect in the chronic neuropathic (NP) pain state and determine whether KOR signaling is increased in the amygdala in the sciatic cuff model.

We induced NP pain in adult male and female C57/BL6 mice via cuff implantation around the left sciatic nerve or performed sham surgery without sciatic cuff as a control group. Mice developed typical mechanical and thermal allodynia as assessed with von Frey and cold plate tests by behaviorists blinded to surgery and experimental treatments. NP pain was accompanied by affective-like behaviors associated with anxiety, stress and depression using the forced swim stress and light-dark test paradigms, which were blocked by KOR antagonist JDTic. NP mice also exhibit enhanced aversion to KOR agonist, U50488, indicating enhanced KOR signaling in chronic pain.

To characterize components of KOR signaling in the amygdala in the NP pain state, we examined KOR mRNA expression and functional activity of the KOR. Using qRT-PCR, we found that NP pain mice exhibit a significant increase in KOR gene expression in the amygdala and bed nucleus of the stria terminalis (BNST). Using [35S]-GTPγS autoradiography, KOR agonist (U50488)-induced receptor activation was significantly increased in the medial (MeA), central amygdala (CeA) and BLA of NP pain compared to control surgery groups. Furthermore, *in situ* hybridization the KOR encoding gene *oprk1* within the amygdalar subnuclei was performed to determine whether the KOR message was upregulated in glutamatergic or GABAergic neuronal subpopulations.

Our data demonstrate that KOR expression and function are significantly increased in the amygdala of chronic NP pain animals. The upregulation of KOR in these brain regions that mediate emotional leaning may lead to the genesis of negative affect in chronic pain. Furthermore, the emotional component of pain is a significant predictor of quality of life for chronic pain patients, KOR antagonists may be an important therapeutic target for improving treatment of chronic pain.

Title: The atypical antipsychotics amisulpride and clozapine do not share discriminative stimulus properties in C57BL/6 mice

Authors: *F. ZHANG[1], R. RICE[1], T. M. HILLHOUSE[2], H. NANGUNURI[1], K. A. WEBSTER[1], A. N. BALDWIN[1], T. J. DONAHUE[1], J. H. PORTER[1]
[1]Psychology, Virginia Commonwealth Univ., Richmond, VA; [2]Psychology & Neurosci., Weber State Univ., Ogden, UT

Abstract: The benzamide derivative amisulpride (Solian) is an atypical antipsychotic used in Europe and most English speaking countries (except Canada and United States) to treat schizophrenia. Interestingly, at low doses it is also used to treat dysthymia. While its antipsychotic effects are believed to be via blockade of postsynaptic dopamine (DA) D_2 and D_3 receptors in the limbic system, its antidepressant effects are thought to be due to preferential blockade of presynaptic DA D_2 and D_3 receptors (Schoemaker et al 1997; Donahue et al 2014, 2017). Unlike the atypical antipsychotic clozapine, amisulpride has a fairly selective binding profile. In addition to its high binding affinity at DA D_2 and D_3 receptors, it has a high binding affinity at serotonin 5-HT_{7A} and 5-HT_{2B} receptors. We previously reported that in C57BL/6 mice trained to discriminate 10 mg/kg (s.c.) amisulpride from vehicle that clozapine did not generate amisulpride-appropriate lever responding (Donahue et al 2017). In the present study adult male C57BL/6 mice were trained to discriminate 1.25 mg/kg clozapine from vehicle in a two-lever food reinforcement procedure. After the clozapine generalization curve was established, amisulpride was tested for substitution at doses of 20, 40 and 80 mg/kg (s.c.). Amisulpride produced only vehicle-appropriate responding with a maximum of 5.1% clozapine-lever responding at 80 mg/kg with no significant decrease in response rates. These findings confirm our previous results that amisulpride and clozapine do not share discriminative stimulus properties in C57BL/6 mice trained to discriminate amisulpride. These results also confirm findings in rats trained to discriminate 5.0 mg/kg clozapine that amisulpride does not substitute for the clozapine cue (Goudie and Taylor 1998). While the exact mechanisms mediating amisulpride's discriminative stimulus remain to be determined, it is clear from the present and previous studies that amisulpride's discriminative cue properties are not shared by other antipsychotic drugs (either atypical or typical) and that it possesses a unique discriminative cue.

Title: Chemogenetic activation of prefrontal cortex rescues synaptic and behavioral deficits in a mouse model of 16p11.2 deletion syndrome

Authors: *B. A. REIN, W. WANG, F. ZHANG, T. TAN, P. ZHONG, Z. YAN
Physiol. & Biophysics, SUNY Univ. At Buffalo, Buffalo, NY

Abstract: Microdeletion of the human 16p11.2 gene locus has been linked to Autism spectrum disorder (ASD) and intellectual disability, and confers risk for a number of other neurodevelopmental deficits. Transgenic mice carrying 16p11.2 deletion (*16p11*$^{+/-}$) display phenotypes reminiscent of those in human patients with 16p11.2 deletion syndrome, but the molecular mechanisms and treatment strategies for these phenotypes remain unknown. In this study, we have found that bothmale and female *16p11*$^{+/-}$mice exhibit deficient NMDA receptor (NMDAR) function in the medialprefrontal cortex (mPFC), a brain region critical for high level "executive" functions. Elevating the activity of mPFC pyramidal neurons with a CaMKII-driven Gq-coupled Designer Receptor Exclusively Activated by Designer Drugs (Gq-DREADD) led to the restoration of NMDAR function and the amelioration of cognitive and social impairments in *16p11*$^{+/-}$mice. These results suggest that NMDAR hypofunction in PFC may contribute to the pathophysiology of 16p11.2 deletion syndrome, and that restoring PFC activity is sufficient to rescue the behavioral deficits.

Title: The influence of molecular dentate gyrus lesion on behavior and mossy fiber - CA3 synapses in mice

Authors: *F. DYBOWSKI[1], C. A. TAMMINGA[2]
[1]UT Southwestern Med. Ctr., Dallas, TX; [2]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: Psychosis, a predominant symptom domain of schizophrenia, has been characterized in human in vivo imaging and post-mortem studies by decreased hippocampal GluN1 expression in dentate gyrus (DG), CA3 subfield hyperactivity and increased synaptic plasticity markers. Thorny excrescences (TE) constituting the mossy fiber-CA3 synaptic connections have been deemed a tunable gain control of excitatory input and were found increased in post-mortem studies. We hypothesize that drug treatment may reverse the CA3 subfield hyperactivity and abnormal TE morphology, which could lead to reversal of psychosis-like behavioral phenotypes. In order to test that, we administered clozapine to male GluN1 DG-specific knock-out (at least 4 months old) mice. As a measurable output, we looked at the morphology of TEs and performed a battery of behavioral tests split into two cohorts, N=12/group. The behavioral test battery consisted of contextual and cued fear conditioning, open field test, elevated plus maze, pre-pulse inhibition, social recognition memory. Golgi-Cox staining was used to analyze the morphology of TEs and measure total area. These experiments, which are still ongoing, will provide a broad perspective regarding the antipsychotic mechanism underlying current pharmacotherapies and may suggest novel targets for emerging drugs.

Title: Altered cortical development and neural excitability in the medial prefrontal cortex of B-cell CLL/lymphoma 9 mutant mice

Authors: *Y. KUANG
Shanghai Jiaotong Univ., Shanghai City, China

Abstract: B-cell CLL/lymphoma 9 (*BCL9*), located on the human chromosome locus 1q21.1, has been implicated in tumor progression through the Wnt signaling pathway. Human genetic studies have suggested that common *BCL9* variants confer a risk of schizophrenia, bipolar disorder, and autism development. However, the function of BCL9 in central nervous system remains poorly understood. We used in utero electroporation mice and BCL9 mutant mice in our study. Here, we demonstrated BCL9 is highly expressed in mouse brain during the embryonic and early postnatal period. Knockdown BCL9 in E13.5 could severely disturb the migration of cortical neurons and down regulation of Wnt target genes. Knockdown of BCL9 increased ultrasonic vocalization in pups. Interestingly, we identify BCL9 expression level change voltage-dependent sodium channels expression, leading to abnormal neuronal excitability. We also noted that the common BCL9 variants regulate the brain structural volume and psychotic-like symptoms in adolescents. In conclusion, our findings indicate a possible role of BCL9 in the pathogenesis of neurodevelopmental disorders.

Abstract: Several lines of evidence document the association between eating disorders and modern lifestyle, encompassing calorie-rich diets and psychological stress. Binge-eating disorder

(BED) is a eating disorder characterized by excessive consumption of food in a short period of time, along with loss of control and psychological distress. Among the networks that partake in the neurobiological bases of BED a large body of evidence supports the activation of the hypothalamic-pituitary-adrenal stress (HPA) axis. Pharmacological treatments for BED are limited thus highlighting the need to identify novel targets that could lead to the development of more effective therapies. A large body of evidence has accumulated on the role played by the lipid signal oleoylethanolamide (OEA) as a pharmacological target for controlling aberrant eating disorders. As a drug, OEA reduces food intake and body weight gain in laboratory rodents by inducing a state of satiety. Additionaly, OEA dampens the hyperactivity of the HPA axis and ameliorates the effects of stress. On the bases of these premises, in the present study we investigated the effects of OEA on high palatable food (HPF) intake in a rat model of BED. Moreover, we assessed the impact of OEA on the corticotropin-releasing factor (CRF) system which plays a critical role in stress and on the oxytocinergic system which is crucial in mediating the pro-satiety effect of OEA. We used female rats with a history of intermittent food restriction which show binge-like palatable food consumption after the exposure to a “frustration stress”. On the test day, we either exposed or did not expose the rats to the sight of the palatable food (frustration stress) before assessing food consumption. OEA was administered at three different doses (2.5, 5, 10 mg/kg i.p.) and HPF intake was monitored over 2h. After the behavioural experiment brains were collected and *in-situ* hybridization experiment was performed to analyse CRF and oxytocin mRNA expression in selected brain areas. Our results demonstrate that OEA (10 mg/kg) was able to selectively prevent binge eating; the antibinge effect was accompained by a reduction of CRF mRNA within the central-amygdala. Finally, in keeping with our previous observations we found that the antibinge effect of OEA was accompanied by a significant increase of oxytocin mRNA at hypothalamic level. In the current study, we provide for the first time evidence to support that the endogenous fatty-gut lipid OEA exerts a selective inhibitory effects on binge-like eating behavior in female rats, supporting the hypothesis that OEA might represent a novel potential pharmacological target for the treatment of aberrant eating patterns.

Title: Electrophysiological markers of distress in neuropsychiatric illness

Authors: *E. MATTESON[1], N. R. PROVENZA[2], C. LOHMAN[1,3], A. BARRIOS-ANDERSON[4,3], N. MCLAUGHLIN[1,5,3], D. A. BORTON[2,5]
[2]Neuroengineering, [1]Brown Univ., Providence, RI; [3]Butler Hosp., Providence, RI; [4]The Warren Alpert Med. Sch. of Brown Univ., Providence, RI; [5]Carney Inst. for Brain Sci., Providence, RI

Abstract: Adaptive deep brain stimulation (DBS) has the potential to offer improved therapy for neuropsychiatric illnesses by sensing changes in neural activity and adjusting stimulation parameters in response. Such a system should ideally be able to detect the onset of acute distress caused by, for instance, an environmental trigger, so that it can react by increasing stimulation amplitude. In the search for biomarkers that can be used to control adaptive DBS, we record electroencephalography (EEG) while patients perform a novel symptom provocation task that uses physical objects to elicit varying levels of distress, time-locked to EEG signals. We report behavioral and EEG analysis of task performance by patients with specific phobia, patients with obsessive compulsive disorder, and healthy controls.

Title: Genetic effects on mu-opioid receptor ligand biased signaling

Authors: *X. ZHANG[1], S. HUTCHINS[2], R. GILMORE[2], E. VALLENDER[2]
[1]Program in Neurosci., [2]Dept. Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: The opioidergic system has been associated with motivation, reward, emotion, response to stress and pain. Specific genetic mutations in Mu-opioid receptors (OPRM1) have been shown in humans and nonhuman primates to affect pharmaceutical response and the propensity towards substance abuse; however, the specific mechanism by which these polymorphisms exert their effects remain largely unknown. Characterization of the second messenger signaling profile of OPRM1 alleles will further our understanding on molecular basis of associated behaviors and assist in the development of personalized therapeutic OPRM1 ligands. In this study, we explore whether ligand-induced GPCR downstream signaling pathways

are biased across OPRM1 polymorphisms. Two single nucleotide polymorphisms (SNPs) that change protein sequence, C17T and A118G, exist on the OPRM1 N-terminal domain and are common in human populations. Additionally, we are testing a rhesus macaque SNP, C77G, which appears to be functionally and behaviorally parallel. We first transduce transcriptional response element inducible luciferase reporters from four pathways (NFkB, cAMP, MAPK/ERK and MAPK/JNK) into multiple cell lines (SK-N-MC, CHO and HEK 293). We then transfect in a plasmid containing the specific variant of OPRM1 and generate a concentration response curve with DAMGO, beta-endorphin, morphine, and additional ligands. Preliminary data demonstrated that the potency of ligands on each downstream signaling pathways are different and this ligand bias is dependent on genetic polymorphisms, which indicates the existence of an interaction between genetics and ligands on the OPRM1 second massenger signaling pathways. Further, these ligand biased signaling profiles and their genetic influences are paralleled between rhesus macaques and humans, which contributing to the translational utility of these nonhuman primates as preclinical platform for personalized ligand design. Overall, this study has shown the effect of genetic polymorphisms on second messenger signaling recruitment by the OPRM1. These findings have implications not only important for understanding the means by which OPRM1 affects behaviors, but also cruical for how genetic polymorphisms at OPRM1 are likely to differentially affect novel biased ligands.

Title: Systems genetics discovery of genetic, genomic, and gene-by-environment mechanisms driving substance use and sensation seeking

Authors: *P. E. DICKSON[1], T. A. ROY[1], T. D. WILCOX[1], G. MITTLEMAN[2], E. J. CHESLER[1]
[1]The Jackson Lab., Bar Harbor, ME; [2]Psychological Sci., Ball State Univ., Muncie, IN

Abstract: Substance abuse is a critical public health issue with genetic and environmental causes. Sensation seeking is a multifaceted, heritable trait which predicts the development of substance use and abuse in humans, and similar phenomena have been observed in rodents. Genetic correlations among substance use and sensation seeking indicate shared biological

mechanisms. Environmental enrichment attenuates both traits suggesting that effects occur through these shared mechanisms. The molecular and neurobiological mechanisms underlying these relationships remain elusive. We used a systems genetics approach in BXD recombinant inbred (RI) mice to identify (1) genetic mechanisms driving intravenous cocaine self-administration and (2) shared genetic mechanisms underlying operant sensation seeking and alcohol preference. To assess the feasibility of using the BXD RI panel to discover the mechanisms through which environmental factors influence the shared mechanisms underlying substance use and sensation seeking, we quantified the effects of environmental enrichment on operant sensation seeking, preference for a novel environment, and locomotion in a novel environment in the C57BL/6J and DBA/2J inbred strains, the founder strains of the BXD RI panel. We identified strain-dependent effects of housing condition on each of these distinct indexes of sensation seeking. Collectively, these data provide novel and, in some cases, shared biological mechanisms driving substance use and sensation seeking in the BXD RI mouse panel and provide evidence of genotype-dependent effects of environmental enrichment on sensation seeking traits in the BXD founder strains.

Title: Utilizing the BxD genetic reference panel to identify the causal genetic variants of nicotine withdrawal deficits in hippocampal learning

Authors: L. R. GOLDBERG[1], M. G. KUTLU[2], D. ZEID[1], L. SEEMILLER[1], S. GADIWALLA[1], *T. J. GOULD[1]

Abstract: Cognitive deficits, such as disrupted learning, are a major symptom of nicotine withdrawal. These deficits are heritable, yet the genetic basis is unknown. Mice are valuable for identifying novel genes that contribute to variation in traits associated with various stages of addiction, including withdrawal. Our lab has developed a mouse model of nicotine withdrawal deficits in hippocampus-dependent learning, using chronic nicotine exposure via osmotic minipumps and contextual fear conditioning. Previously, we identified differences between

C57BL/6J and DBA2/J mice in cognitive deficits during nicotine withdrawal. Here, we aimed to utilize the recombinant inbred BXD genetic reference panel to identify novel genetic variants underlying nicotine withdrawal deficits in learning. Male and female mice (n=6-11 per sex per strain, 31 strains) received either chronic saline or nicotine (6.3 mg/kg per day for 12 days), and then were tested for hippocampus-dependent learning deficits using contextual fear conditioning. Additionally, using publically available data from GeneNetwork, we identified genetic correlations between nicotine withdrawal deficits in learning and locomotor stimulant response to phencyclidine (PCP) and cocaine, with strains that were less sensitive to stimulant withdrawal-induced cognitive deficits also being shown to be less sensitive to stimulant-induced increases in locomotor activity. Quantitative trait locus (QTL) mapping analyses using GeneNetwork (1000 permutations) identified a significant QTL on chromosome 4 (82.4 Mb, LRS =23.74, $p<0.05$). To prioritize candidate genes, we utilized publicly available hippocampal gene expression data from naive animals to identify potential cis-eQTL. We identified 4 positional candidates (*Ptprd*, *Tyrp1*, *2310067E19Rik*, *Nfib*) that overlapped with our behavioral QTL and correlated with our behavioral data. To expand upon these positional candidates and identify hippocampal transcriptome changes associated with nicotine withdrawal, we will soon complete mRNA-sequencing in the BXD lines exhibiting extreme phenotypic variation.

Title: Sex-dimorphic gene x environment interactions predict tobacco and cannabis lifetime use

Authors: *M. BORTOLATO[1,2,3], S. BROWN[2,4], W. HOSSAIN[2,5], A. M. MANZARDO[2,5], M. G. BUTLER[2,5], P. J. FITE[2,4]

Child Psychology Program, Univ. of Kansas, Lawrence, KS; [5]Departments of Psychiatry, Behavioral Sci. and Pediatrics, Univ. of Kansas Med. Ctr., Lawrence, KS

Abstract: Post-secondary students in Western countries exhibit a high prevalence of cannabis and tobacco use disorders. The etiology of these problems is contributed by several psychosocial factors, including childhood adversity and trauma. The mechanisms whereby these

environmental determinants predispose to the use of these substances, however, remain elusive, due to our poor knowledge of genetic and biological moderators. Recent evidence points to the monoamine oxidase A (*MAOA*) gene as a moderator of the effects of lifetime stress on the initiation of substance use. Building on these premises, in the present study we analyzed whether *MAOA* upstream variable number tandem repeat *(u-VNTR)* alleles interact with child maltreatment history to predict for lifetime cannabis and tobacco consumption. Five hundred college students (age: 18-25 years) from a large Midwestern University were surveyed for their child maltreatment history (encompassing emotional, physical, and sexual abuse, as well as emotional and physical neglect) and lifetime consumption of cannabis and tobacco. Saliva samples were obtained to determine the *MAOA u-VNTR* genotype of each participant. In female students, lifetime tobacco and cannabis use was predicted by the interaction of physical and emotional abuse with high-activity *MAOA* allelic variants; conversely, in males, the interaction of low-activity *MAOA* alleles and physical abuse was associated with lifetime use of tobacco, but not cannabis. These findings collectively suggest that the vulnerability to smoke tobacco and cannabis is predicted by sex-dimorphic interactions of *MAOA* gene with childhood abuse. These biosocial underpinnings of tobacco and cannabis use disorders may prove important in the development of novel personalized interventional strategies for college age students.

Title: Effects of environmental enrichment on behavioral measures of behavioral regulation in heterogeneous stock rats

Authors: *K. ISHIWARI[1], A. M. GEORGE[1], C. D. MARTIN[1], P. J. MEYER[2], O. POLESSKAYA[3], A. A. PALMER[3], J. B. RICHARDS[1]

Abstract: Environmental enrichment has been shown to produce a variety of beneficial neurobehavioral effects in animal models of neuropsychiatric disorders that are associated with maladaptive dysregulation of behavior, such as ADHD, autism, and substance abuse. The present study investigated the effects of environmental enrichment in N/NIH heterogeneous stock (HS)

rats. We examined behavioral measures of psychological traits thought to underlie behavioral regulation and, when dysregulated, predispose individuals to drug abuse. Male HS rats were reared in pairs in standard plastic laboratory cages (n=200) or in groups of 16 in a complex environment consisting of a large multi-level cage filled with pet toys (n=64) starting at approximately postnatal day 30. The two groups were compared for their performance on a battery of behavioral tasks designed to measure various aspects of behavioral regulation (i.e., sensation/novelty seeking, social approach, attentional control, inhibitory control, and impulsive decision making). Specifically, the rats were tested on locomotor response to novelty, light reinforcement, social reinforcement, choice reaction time, and delay discounting tasks. Our results indicated that, compared to the rats reared in standard laboratory cages, the rats housed in the complex environment displayed reduced locomotor response to novelty, reduced operant responding to light and social stimuli, enhanced sustained attention, and enhanced inhibitory control. In addition, their locomotor activity and operant responding habituated more rapidly. However, the results of the delay discounting test, which employed a sequential patch choice procedure, indicated that rats housed in the complex environment discounted delayed water reinforcements more steeply (i.e., "were more impulsive"). Nevertheless, the enriched rats also had higher water consumption rates, suggesting that they were more efficient in their responding and thus better maximized their water intake; this could be viewed as greater behavioral plasticity. Taken together, the present results indicate that, compared to the rats pair-housed in standard laboratory cages, the rats group-housed in the complex environment were able to filter out irrelevant stimuli more effectively (e.g., greater habituation) and thereby regulate their behavior more efficiently (e.g., maximized water intake). Our results suggest that use of standard plastic cages dramatically influences behavior. In future studies, we hope to explore whether these effects compromise the translational validity of animal behavioral studies.

Med., Wake Forest Baptist Med. Ctr., Winston-Salem, NC

Abstract: Introduction: Locomotor behavior is important both because it is of significant biological interest in its own right and because it can sometimes confound other more complicated behavioral measures. We performed a genome-wide association study (**GWAS**) and examined genetic correlations across several cohorts in which locomotor activity was measured. **Methods**: The cohorts differed in many ways, including age, and procedural details like size of arena, lighting conditions and test duration. All subjects were N/NIH heterogeneous stock (**HS**) rats, which were derived from an intercross among 8 inbred rat strains and have been maintained as an outbred population for more than 80 generations. Locomotor traits were measured in three phenotyping centers: Center 1 (University of Michigan): Rats (*N=768, age= 77 days ± sd 5.45*) were placed in the middle of a 45 cm x 15 cm chamber. Noldus Ethovision software was used to track the behavior of the rats for 25 min. Center 2 (University of Tennessee Health Sciences Center): Rats (*N= 665, age= 32 days ± sd 3.35*) were placed in a 100 cm x 100 cm chamber. Noldus Ethovision software was used to track the behavior of the rats for 60 min. Center 3 (University at Buffalo, Research Institute on Addictions): Rats (*N= 891, age= 70 days ± sd 7.24*) were placed in a 24 cm x 45 cm chamber. Beam breaks were used to track the behavior of the rats for 18 min. We used a genotype by sequencing approach to obtain > 6 million SNPs per individual. To detect the genetic basis of these behavioral traits, we estimated the proportion of variance attributable to SNP genotypes (SNP heritability h^2) using GCTA-GREML. We used the GCTA Bivariate GREML analysis to estimate the genetic correlation (*rG*). We performed GWAS using the linear mixed model approach, implemented in the software GEMMA. **Results**: SNP heritability estimates ranged from 0.24 to 0.42. The genetic correlation between centers 1 and 3 were high (0.84 ± se .12), the genetic correlation between centers 2 and 3 was moderate (0.46 ± se .15) and the genetic correlation between centers 1 and 2 was low (0.11 ± se .19).
Discussion: Center 2, which showed the lowest correlations, included younger animals, used a larger open field, and included a longer test than centers 1 and 3; these factors may account for the low correlations between center 2 and centers 1 and 3. Ongoing studies will include a joint GWAS analysis of at least centers 1 and 3; the final sample size of that analysis should be greater than 3,000 and will thus have power to identify loci that account for as little as 1% of total trait variance.

Abstract: Behavioral regulation increases fitness. Adequate regulation of behavior allows animals to respond in an adaptive fashion to environmental changes. Dysregulation of behavior predisposes animals to maladaptive behaviors such as ADHD, autism, drug abuse, and more. Behavioral regulation was measured in a preliminary cohort of 791 N/NIH male and female heterogeneous stock (HS) rats.
Our assessment of behavioral regulation included five behavioral tests; i.) Locomotor response to a novel environment, ii.) Sensory (light) reinforcement, iii.) Social reinforcement, iv.) Reaction time; and v.) Delay-discounting in a patch foraging model. Locomotor response to novelty and light reinforcement are measures of sensation seeking. Social reinforcement plays an important role in facilitating normal social relationships. The reaction time task tested attentional control and preventing distraction by irrelevant stimuli. The delay discounting model of patch foraging tested the rats' ability to make an efficient decision about future rewards and to avoid making maladaptive, impulsive choices. We used a genotyping by sequencing approach to obtain 6 million SNPs per individual rat. To detect the genetic basis of these behavioral traits, we estimated the proportion of variance attributable to SNP genotypes (SNP heritability h2) using GCTA-GREML. A total of 1600 HS rats will be tested by the conclusion of the study. Multiple phenotypes were taken for all of the tasks. Significant heritability was found for the locomotor, light reinforcement, reaction time, and delay discounting tasks. Heritability was highest for locomotor traits (0.31 + 0.05 for total distance).
Other behaviors had moderate heritabilities; 0.27 + 0.06 for mean reaction time; 0.25 + 0.07 for response to social reinforcement; 0.24 + 0.05 for response to light reinforcement; 0.17 + 0.05 for indifference point on delay discounting; 0.34 + 0.06 for series of delays on delay discounting.

Genetic correlations were calculated for pairs of traits to account for pleiotropic effect. Presently, genome-wide association analysis is ongoing, identifying genetic loci implicated in behavioral traits.
Highly genetically correlated traits can be analyzed together, further increasing power to detect loci explaining smaller proportion of total variance.

Title: Deciphering the molecular mechanisms underlying heterogeneous nuclear ribonucleoprotein H1 (hnRNP H1) regulation of methamphetamine-induced dopamine release and addictive behaviors

Authors: *Q. RUAN[1], N. YAZDANI[1], J. BEIERLE[1], K. ZHENG[1], J. J. CHEUNG[1], M. A. COELHO[4], E. A. FULTZ[4], A. F. HEALY[4], F. MORTAZAVI[2], W. LIN[3], P. E. A. ASH[1], D. L. ROSENE[2], A. EMILI[3], B. WOLOZIN[1], K. K. SZUMLINSKI[4], C. D. BRYANT[1]

Abstract: We mapped and validated Hnrnph1 (heterogeneous nuclear ribonucleoprotein H1) as a quantitative trait gene underlying reduced methamphetamine-induced locomotor activity, reward, reinforcement, and dopamine release. Specifically, Hnrnph1 deletion blunted the ability of methamphetamine (MA) to induce and increase extracellular level of dopamine in the nucleus accumbens which was accompanied by a reduction in the level of dopamine metabolite, DOPAC. Importantly, MA-induced glutamate release was not impacted, indicating a dopamine-selective mechanism. To identify the molecular mechanism underlying Hnrnph1 regulation of methamphetamine behavior and dopamine transmission, we hypothesized that a decrease in the number or innervation of dopaminergic neurons could underlie the neurobehavioral results.

However, our results indicated that tyrosine hydroxylase (TH, a precursor for dopamine synthesis and a marker of dopaminergic neurons) immunostaining via immunohistochemistry and Western blot in the striatum and midbrain was increased in Hnrnph1+/- mice in comparison to wildtype. These data suggest an alternate, drug-induced cell biological mechanism by which Hnrnph1 deletion affects the MA neurobehavioral response. MA enters presynaptic dopaminergic neurons via the dopamine transporter (DAT) and dopamine-containing vesicles via the vesicular monoamine transporter (VMAT) to increase synaptic dopamine levels. We tested the hypothesis that MA would induce a translocation of hnRNP H1 from the nucleus to the cytoplasm. We found a marked 2.4-fold increase in the level of synaptic hnRNP H in the striatum of Hnrnp1+/- mice compared to that of the wildtype. Cellular fractionation of striatal tissue indicated a reduction in the level of cytoplasmic hnRNP H in Hnrnph1+/- mice versus the wildtype, which suggested potential mobilization of hnRNP H from the cytoplasm to the synapse. In addition, preliminary findings indicate that MA treatment induces an increase in cytoplasmic but not nuclear hnRNP H in Hnrnph1+/- in comparison to WT mice. Ongoing studies continue to focus on synaptic function of hnRNP H1 in regulating drug-induced dopamine release and behavior using proteomic analysis of synaptic hnRNP H-associated complexes.

Abstract: Opioid use disorder (**OUD**) is a heritable addictive disorder that has reached epidemic proportions in the United States, yet its genetic etiology remains poorly understood. Murine forward genetic studies of addiction traits can identify novel genetic factors and biological pathways relevant to humans, leading to improved therapeutics. We are conducting a large strain survey of a panel of mouse inbred strains for oxycodone (**OXY**)-induced behaviors in our multi-stage addiction assessment protocol (**MSAAP**). Our long-term goal is to conduct high resolution haplotype association mapping of the genetic basis of opioid addiction traits. These traits include acute locomotor response, locomotor sensitization, conditioned place preference, extinction, analgesic tolerance, the emotional-affective component of opioid dependence, and several protracted cognitive and emotional-affective withdrawal phenotypes induced following a period of abstinence from chronic OXY administration. We have thus far tested 12 inbred strains (BALB/cJ, BALB/cByJ, C3H/HeJ, FVB/J, DBA/2J, NOD/ShiLtJ, CBA/J, C57BL/6J, 129s1/SvlmJ, A/J, NU/J, SJL/J). Notably, , we identified robust, male-specific BALB/c substrain differences in protracted withdrawal, including anxiety-like behavior in the light/dark box and head pokes in the hole-board test. We also identified robust differences in OXY hot plate analgesic tolerance between BALB/c substrains. These initial findings indicate that genetic differences in multiple complex behavioral traits are associated with different stages of opioid addiction. The observation of BALB/c substrain differences in protracted withdrawal is particularly promising, as their reduced genetic complexity facilitates rapid identification of novel genetic factors underlying behavioral addiction traits. Complete testing of 30 classical inbred strains will lead to the identification of high resolution genetic loci, candidate genes, and functional variants that will be confirmed via gene editing. Expression QTL mapping, pathway, and gene network analysis will inform the molecular mechanisms that bridge genetic variants with behavior.

Title: Reward threshold as measured via intracranial self-stimulation in Hnrnph1$^{+/-}$ mice showing reduced methamphetamine addictive behaviors

Authors: *K. N. BORRELLI[1], K. R. DUBINSKY[1], J. L. SCOTELLARO[1], E. H. CHARTOFF[2], W. A. CARLEZON, Jr[3], C. D. BRYANT[1]
[1]Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [2]Harvard Med. Sch., Belmont, MA; [3]Dept Psychiat, Harvard Med. Sch./Mclean Hosp., Belmont, MA

Abstract: Substance abuse disorders are heritable, but the genetic basis remains largely unknown. Using quantitative trait locus (QTL) mapping, we identified heterogeneous nuclear ribonucleoprotein H1 (*Hnrnph1*) as a quantitative trait gene (QTG) underlying sensitivity to the locomotor stimulant properties of methamphetamine. Mice heterozygous for a frameshift deletion resulting in a premature stop codon in the first coding exon of Hnrnph1 (*Hnrnph1*$^{+/-}$) show reduced methamphetamine-induced locomotor activity and reduced methamphetamine oral self-administration. We are currently using intracranial self-stimulation (ICSS) to assess reward sensitivity at baseline and following methamphetamine administration in *Hnrnph1*$^{+/-}$ mice. ICSS is used to quantify threshold for self-administration of brain stimulation reward (BSR) delivered through an intracranial stimulating electrode. *Hnrnph1*$^{+/-}$ mice are currently undergoing a unilateral stereotaxic procedure to implant an electrode in the medial forebrain bundle (MFB). Mice will be trained on a fixed-ratio 1 (FR-1) schedule to respond for stimulation, such that a ¼ turn of a wheel manipulandum earns a 500ms train of rewarding stimulation followed by a 500ms timeout. Subjects will then be exposed to a series of descending stimulation frequencies at a set threshold current. Using a frequency-rate curve-shift approach, threshold frequencies required to produce responding will be determined for each animal at baseline and following administration of methamphetamine (0.5, 1.0, or 2.0 mg/kg, delivered intraperitoneally). Histological verification of electrode placement will be performed upon completion of ICSS experiment. Significant changes in ICSS reward threshold related to the *Hnrnph1* disruption would provide further support for its contribution to to the neurobiological mechanisms of stimulation-induced reward sensitivity and the neurobehavioral response to multiple drugs of abuse.

Title: Cyfip1-mediated molecular mechanisms in the regulation of cocaine addiction

Authors: A. KAMALI TAFRESHI[1], K. PRASAD[1], G. BARBAYANNIS[1], A. TASLEEM[1], S. STRATTON[1], I. DENIZ[1], D. L. BENSON[2], *O. BOZDAGI[1]

Abstract: Structural and functional changes in the nucleus accumbens (NAc) are associated with addiction related behaviors such as cocaine seeking. New evidence on genetic risk factors can help elucidate the response to addictive drugs. Cytoplasmic FMR1-interacting protein (*CYFIP)1* has been identified as a risk factor for several neuropsychiatric disorders including schizophrenia, intellectual disability, and autism in humans. Recently *Cyfip2* was identified as a key regulator of locomotor responses to cocaine in mice. Cyfip2 and Cyfip1 are closely related family members, which function to repress protein translation through binding interactions with FMRP, and also to regulate actin cytoskeleton assembly as a component of WAVE regulatory complex. We have previously shown that mice carrying a *Cyfip1* mutation (*Cyfip1*$^{+/-}$) show dysregulated synaptic plasticity and Rac1-dependent enhanced presynaptic function during development in the hippocampus. To test our hypothesis that cocaine related behavioral responses and synaptic function in the NAc are affected when Cyfip1 levels are reduced, we performed open field tests and compared locomotor activity in control conditions and in response to cocaine by using an automated video tracking system. Wild type mice display an increase in locomotor response to the administration of cocaine (15mg/kg) in both genders, as expected. This response is blunted in all *Cyfip1*$^{+/-}$ mice and in male mice more than female. Preliminary data showing GluA1 immunolocalization in the NAc after cocaine injection indicate dysregulated GluA1 levels in *Cyfip1*$^{+/-}$ mice. In order to better simulate the pathophysiology of drug addiction in humans, we also performed a conditioned place preference paradigm, which show increased cocaine seeking in *Cyfip1*$^{+/-}$ mice. Field EPSP recordings in the NAc show comparable post-tetanic potentiation between genotypes. These findings provide a novel cellular mechanism that may contribute to cocaine-induced behavioral alterations. Clarifying Cyfip1's role in cocaine response, locomotor sensitization, and NAc plasticity, which is a previously unexamined target, may be relevant for a variety of disease-related genes with similar functions.

Title: Distinct mRNA profiles for reward devaluation, heroin addiction-like behavior and heroin-induced 'relapse' in the nucleus accumbens of vulnerable and resilient rats

Authors: *J. E. DOUTON[1], C. G. IMPERIO[1], A. J. MCFALLS[2], K. E. VRANA[2], W. M. FREEMAN[3], P. S. GRIGSON[1]
[1]Neural and Behavioral Sci., [2]Dept. of Pharmacol., Pennsylvania State University, Col. of Med., Hershey, PA; [3]Physiol., Oklahoma Univ. Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Understanding the underlying individual differences that lead some, but not others, to develop addiction can provide insight into substance use disorder and into potential treatments for the disease. In our model, rats have 5 min access to 0.15% saccharin followed by 6 h self-administration (SA) of either saline or heroin intravenously (iv). There are 16 such daily pairings followed by tests to assess drug seeking behaviors. In this paradigm, two subpopulations are observed, one that greatly suppresses intake of the heroin-paired saccharin cue (large suppressors) and one that accepts it (small suppressors). Importantly, greater avoidance of the cue is associated with greater addiction-like behaviors (ALBs) such as escalation of drug SA over trials, strong willingness to work for drug, greater seeking during extinction, and greater drug-induced reinstatement (Imperio & Grigson, 2015). Imperio et al. (2016) used next-generation sequencing (RNA-seq) and a subset of these rats to examine the nucleus accumbens (NAc) transcriptome in large suppressor, small suppressor, and saccharin-saline controls (n=5/group). Here, we have revisited this data set to identify genes whose expression is correlated 0.6 or greater (negatively or positively) with saccharin intake and the above described ALBs. In general, the results show that gene expression associated with reward devaluation and ALBs was not only different, but also opposite when overlapping. Specifically, the expression of 78 genes was positively correlated with intake of the saccharin cue, 40 of which were also negatively correlated with one or more of the ALBs and 38 genes unique to saccharin suppression. The expression of 15 genes was negatively correlated with intake of the saccharin cue, 7 of which were positively correlated with one or more of the ALBs and 8 unique to saccharin suppression. A set of only three genes (Orai2, Galc, Higd1b) was positively correlated, and a set of 9 genes (Aurkc, FAM105a, Loc1003637, Nif3l1, Pot1, Rad52, Rexo4, Tmem209, Tmem39b) negatively correlated, with all four ALBs including 1st h SA, 6 h SA, extinction, and PR responding. Finally, regarding heroin-induced reinstatement, the expression of 18 genes was correlated with the behavior and 3/10 of the positively correlated genes (Mir9-2, RDG1306227, and Colec12) also were negatively correlated with saccharin intake. Thus, when examining the mRNA expression of thousands of genes in the NAc of vulnerable and resilient rats, three distinct mRNA profiles were obtained for avoidance of the drug-paired cue, ALBs, and heroin-induced reinstatement, even though these behaviors are, themselves, highly correlated with one another.

Title: Neuroepigenetic remodeling in cocaine addiction associated alternative splicing and behavior

Authors: *S.-J. XU[1], M. CARPENTER[2], Q. HU[3], S. LOMBROSO[2], S. MCCLORY[3], K. LYNCH[3], M. E. WIMMER[4], C. PIERCE[5], E. A. HELLER[6]

Abstract: Histone proteins and their associated DNA function to regulate gene expression in response to environmental changes. To date, numerous studies have implicated epigenetic remodeling of covalent histone posttranslational modifications (hPTMs) in addiction pathologies, yet the precise molecular mechanisms underlying such behavior remains unclear. We tested the hypothesis that trimethylation of histone H3 lysine 36 (H3K36me3) directly mediates alternative splicing in brain, to generate isoforms that facilitate the addiction phenotype. Previous work from our lab found that H3K36me3 enrichment significantly predicts splicing events (Hu et al. 2017) in the nucleus accumbens (NAc), a brain reward region. To further dissect this phenomenon, we injected NAc with HSV-SET2, a histone methyltransferase that catalyzes H3K36me3, or a catalytically-inactive control HSV-R195G, to induce H3K36me3. After confirming H3K36me3 enrichment by western blot and quantitative mass-spectrometry, we processed infected tissue using single sample sequencing (S3EQ) to generate H3K36me3 ChIP- and RNA-seq data from one tissue source to identify H3K36me3 associated alternative splicing events. We identified a subset of neuronal genes that show coincident cocaine-regulated H3K36me3 modification and alternative splicing, which we have validated with qPCR using radiolabeled probes. We are now poised to validate the direct causal relevance of H3K36me3 enrichment to splicing of these target exons, using CRISPR-mediated epigenetic editing (dCas9-SET2). Taken together, our work investigates a novel mechanism for chromatin-mediated

alternative splicing in brain in the context of cocaine addiction, supporting a critical role of epigenetic remodeling in neuronal gene expression, splicing and neuropathological behavior.

Title: Homeostatic mechanisms of alcohol-induced sleep disturbances in *Drosophila*

Authors: *M. E. RAMIREZ ROMAN[1], C. BILLINI[1], G. DE JESUS[1], D. BUFFILL[1], M. PEREZ[1], L. DE JESUS[1], J. L. AGOSTO[1], N. S. ATKINSON[2], A. GHEZZI[1]

Abstract: Exposure to alcohol is known to trigger homeostatic adaptations in the brain that lead to the development of drug tolerance and dependence. These adaptations are also believed to be the root of a collection of sleep disturbances that often manifest during the development of alcoholism. Because both, alcohol dependence and sleep modulation are under homeostatic regulation we hypothesize that these processes share common mechanisms. Here we use a Drosophila model system to test this hypothesis. We find that in Drosophila, acute alcohol exposure causes disturbances in sleep patterns that resemble those described in mammals. These disturbances include an increase in total sleep duration, decrease sleep latency, as well as an increased number of sleep episode per day (fragmented sleep). Furthermore we show that many of the genes implicated in the neural adaptations behind alcohol tolerance, have also been implicated in the regulation of sleep cycles. However, little is known about the direct pathways by which these biological mechanisms interact. In this study, we explore the effect that genes involved in synaptic homeostasis processes have on alcohol-induced sleep disturbances. Our results suggest that sleep and alcohol neuroadaptation share a common regulatory mechanism, and brings us closer to understanding the interaction between these two homeostatic processes.

Title: Analysis of ethanol and ketamine cross-drug interaction reveals potential targets for pharmaco-epigenetic intervention in drug addiction

Authors: *A. M. PADILLA[1], M. RAMÍREZ[3], C. BILLINI[4], M. FRANCIA[2], J. AGOSTO[2], A. GHEZZI[2]
[1]Cell and Mol. Biol., Univ. of Puerto Rico Rio Piedras, Guaynabo, PR; [2]Univ. of Puerto Rico Rio Piedras, San Juan, PR; [3]Univ. of Puerto Rico Río Piedras, San Juan, PR; [4]Univ. of Puerto Rico, San Juan, PR

Abstract: Sustained exposure to drugs leads to homeostatic adaptations in the brain brought on by changes in gene expression at synapses. This genetic plasticity is involved in the persistence of symptoms of drug addiction even after extended periods of abstinence and give rise to the behavioral phenotypes of tolerance and dependence. After exposure to sedatives such as alcohol, epigenetic modifications are known to activate the expression of synaptic proteins. 11 genes acetylated as a consequence of acute ethanol exposure have been previously implicated in this adaptive response. These genes were functionally tested and robustly correlated with the emergence of alcohol tolerance. However, ways in which we can harness the reversibility of this epigenetic landscape pharmacologically to treat alcohol addiction remain unknown. Recent research supports the noncompetitive NMDA antagonist ketamine as a treatment for depression and addiction. It is hypothesized that exposure to ketamine could be modulating the epigenetic regulation of gene expression in favor of changes that oppose the regulatory outcomes observed after alcohol consumption. Here, we use a combination of behavioral analyses of drug exposure in a Drosophila model system and molecular analyses of gene expression to characterize the genetic, physiological and behavioral responses to alcohol and ketamine. After monitoring fly activity patterns, total sleep of female flies increased after exposure to alcohol while males remained near baseline level. After monitoring female and male flies exposed chronically to two ketamine doses, we found 0.1mg/mL dose of ketamine decreases total sleep of female flies. These results suggest that an attenuated dose of ketamine serves to restore the effect of alcohol on fly sleep. Cluster analysis of genes responding to alcohol and ketamine will help us advance the search for a pharmaco-epigenetic treatment that intercepts the development of alcohol tolerance at the initial stages of the cycle of addiction.

Title: Sex differences in intermittent access voluntary alcohol consumption and probabilistic reversal learning tested in protracted withdrawal

Authors: *C. G. AGUIRRE[1], Y. SEGURA[1], S. KOLLI[1], A. STOLYAROVA[1], V. MARTY[2], A. IZQUIERDO[1], I. SPIGELMAN[2]
[1]Psychology, [2]Sch. of Dent., Univ. of California- Los Angeles, Los Angeles, CA

Abstract: Various groups have tested the effect of forced alcohol (ethanol, EtOH) exposure on reversal learning, a widely-used assay of cognitive flexibility. A variety of methods have been implemented for this type of alcohol administration, including intragastric gavage and vapor inhalation, resulting in significant impairments in reversal learning. Although voluntary models of consumption produce lower blood alcohol levels than those induced by forced exposure models (that typically yield tolerance and alcohol dependence), they do allow for individual differences in alcohol consumption and subsequent variability in performance. To our knowledge there has been limited investigation of sex differences in alcohol consumption and their effects on later cognitive flexibility measures. Here, we studied male (n=8) and female (n=8) adult Long Evans rats that underwent 10 weeks of voluntary intermittent EtOH access using a 2-bottle choice (2-BC) procedure. Rats were given access to both water and 10% EtOH for a 24-hour period (3 days/week) and only water on the remaining days. After completing the 2-BC regimen, rats were mildly food restricted to work for food rewards (sugar pellets) in operant conditioning chambers. Rats were then pretrained for probabilistic reversal learning (PRL), which included acclimating to the conditioning chambers, collecting rewards from the magazine, and learning to nosepoke stimuli presented on a touchscreen. The task is designed to assess rats' sensitivity to probabilistic outcomes and their ability to adapt to changes in reward contingencies. In the PRL task, rats chose between two visual stimuli, assigned as the Better (B) or Worse (W) options, rewarded with probability $p_R(B)=0.70$ or $p_R(W)=0.30$, respectively. Thus far, we found a significant within-subject effect of day on EtOH consumption, indicating an escalation of consumption [$F_{(28, 392)}=6.68$, $p<0.0001$], a marginally-significant interaction of sex x day [$F_{(28,392)}= 1.51$, $p=0.05$], and a trend for a significant effect of sex [$F_{(1, 14)}=3.42$, $p=0.09$]. Females reached higher maximum EtOH consumption than males [$t(14)=3.46$, $p=0.004$], and needed

more pretraining sessions to reach criterion to advance to PRL, [t(14)=3.49, p=0.004]. At present, mostly males have advanced to PRL. We plan to correlate EtOH consumption with the number of trials to criterion on PRL. We have also recently found reinforcement uncertainty-induced differential expression of excitatory and inhibitory receptors in basolateral amygdala (BLA), orbitofrontal cortex (OFC), and anterior cingulate cortex (ACC) assessed via immunohistochemistry. These are similar targets of interest for the present study.

Title: Gender-dependent effects of cannabidiol on ethanol binge drinking in mice

Authors: *J. MANZANARES, A. VIUDEZ-MARTÍNEZ, M. GARCÍA-GUTIÉRREZ
Inst. de Neurociencias, Univ. Miguel Hernandez-Csic, San Juan de Alicante, Spain

Abstract: Binge drinking has become a major public health concern due to its high prevalence in modern societies and the scarce and limited pharmacological options available for its clinical management. In this sense, cannabidiol (CBD) has been recently proposed as a potential therapeutic tool in the treatment of alcohol use disorders (AUD) since its administration reduces ethanol consumption, motivation to drink and ethanol-induced relapse in mice. Furthermore, CBD also protects against the neurodegenerative effects induced by ethanol intoxication; however, its effects on heavy alcohol use patterns, such as binge drinking, were unexplored to date. The aim of the present study was to evaluate the effects of CBD on binge drinking and analyze potential gender-related differences. To this purpose, male and female C57BL/6J mice (n=40/sex) were exposed to 4 cycles of the drinking in the dark procedure (DID), a model of binge drinking. Dose-response effects of CBD (15, 30 and 60 mg/kg; i.p.) on the ethanol intake were tested by acute (day-4 of cycle-3) or repeated administration (day-1 to 4 of cycle-4). Changes in the gene expression of tyrosine hydroxylase (TH) and μ-opioid receptor (Oprm1) in the ventral tegmental area (VTA) and in nucleus accumbens (NAc), respectively, were also analyzed by real time PCR. Females exposed to DID exhibited higher values of ethanol intake

compared to their male counterparts (Two-way RM ANOVA; $P<0.001$). Interestingly, TH and Oprm1 gene expression was also significantly higher in females (Student's t-test; $P<0.05$). Repeated but not acute administration of high doses of CBD (30 and 60 mg/kg) significantly reduced ethanol consumption in males (Two-way RM ANOVA; $P<0.05$). Repeated administration of CBD 60 mg/kg also reduced the relative gene expression of TH and Oprm1 in males (One-way ANOVA; $P<0.05$). Nevertheless, CBD failed to induce any of these effects in females. Considering the high rates of ethanol intake by females, it seems feasible to hypothesize that the differential effects produced by CBD could be related with the differential ethanol consumption between both genders. Further studies evaluating the effects of higher doses of CBD and different administration schedules are needed. Taken together, these findings demonstrate for the first time the potential utility of CBD in the treatment of binge drinking by reducing ethanol consumption in a heavy alcohol use pattern and how gender related differences in binge drinking can affect the treatment outcome.

Title: Maternal Separation modifies the circadian rhythm of water intake

Authors: *K. REYES-SANTIAGO[1], L. MOLINA ARCIA[1], M. MENDEZ DIAZ[2], A. E. RUIZ-CONTRERAS[3], O. PROSPERO-GARCIA[4]
[1]Univ. Nacional Autonoma de Mexico, Mexico, Mexico; [2]Univ. Nacional Autonoma de Mexico Facultad de Medicina, Mexico DF, Mexico; [3]Lab. Neurogenomica Cognitiva, Fac. Psicologia, UNAM, D.F., Mexico; [4]UNAM, Mexico, D. F., Mexico

Abstract: Maternal separation (MS) has been implicated in the induction of brain reprogram that negatively impact adult life behaviors. The aim of this work was to determine if MS at early age modifies the endogenous rhythm of water intake and the rhythm of alcohol intake. Male Wistar rats was separated from their mothers during 3h daily from postnatal day (PND) 2 to PND15 (MS), control (NMS) group remained with the mother at all times until the day of weaning, PND21. From PND60, the circadian rhythm of water intake was measured. Two bottles of water were placed in the rats' box during 10 days in light-dark cycle (LDC, 12:12, lights were turned

on at 8:00 a.m.), followed by 2 weeks in continuous darkness. During 2 additional weeks they returned to the LDC. In the following 19 days (LDC) their voluntary consumption of alcohol (1 bottle with 10% v / v of alcohol and the other of water) was evaluated. Results did not show significant differences between MS and NMS subjects in the duration of the endogenous period of water intake. However, differences were found in the endogenous profile of water intake (frequency of activity throughout 24h). In addition, MS spent more days to entrainment than NMS rats. No significant differences were found in the duration of the period during access to alcohol between MS and NMS rats. However, a longer duration of alpha was found during the period of alcohol access both MS and NMS rats. These findings show that MS at early age modifies the circadian rhythm of water intake without affecting the rhythm of alcohol consumption, suggesting that alcohol possesses more strength to synchronize rats' rhythms.

Title: Effects of ethanol pre-exposure and age on the acquisition and extinction of conditioned taste aversion in C57Bl/6J mice

Authors: J. M. CHOQUETTE, I. K. GALIC, E. M. GRAFELMAN, *S. D. DICKINSON
Psychology and Neurosci. Program, St. Olaf Col., Northfield, MN

Abstract: Adolescents, both human and rodent, consume more alcohol than do adults, a finding believed to result from a combination of a propensity for reward seeking and a decreased sensitivity to the aversive effects of alcohol during adolescence. Previous research from our lab shows that alcohol exposure prior to place conditioning in mice produces tolerance to its aversive motivational effects more quickly in adolescents than adults. In addition, findings from one-trial conditioned taste aversion (CTA) studies indicate decreased aversion in adolescent rats, with higher doses sometimes necessary to produce CTA in adolescent mice and rats relative to adult animals. CTA can develop after pairing a tastant (CS) with an injection of alcohol, and is thought to assess the aversive motivational properties of the drug. In the present study, we combined ethanol pre-exposure with a multiple trial CTA procedure to determine the impact of pre-exposure on both the initial level of ethanol-induced CTA as well as its rate of development. We also investigated age-related differences in the extinction of CTA in animals with or without alcohol pre-exposure. Naive adolescent (PND 21) and adult (PND 56) male C57BL/6J mice received a moderate (2 g/kg) dose of ethanol every other day for four days prior to taste

conditioning. On conditioning days, mice received 1h access to a 1.6 mM saccharin solution, then received a moderately high dose of ethanol (3 g/kg) or an equivalent volume saline injection. The conditioning days were followed by extinction trials, whereby the mice were exposed to the saccharin solution with no injection. All mice who received ethanol-paired saccharin exposure show a significant decrease in saccharin consumption over conditioning days, demonstrating the expected development of conditioned taste aversion. Across conditioning days, adolescent mice who received four ethanol pre-exposures learned the CS-US association more slowly than other groups. Retarded acquisition of conditioned taste aversion in the ethanol pre-exposed adolescents suggests that an interaction between age and pre-exposure produces a tolerance to the aversive effects of ethanol. The rate of extinction did not vary significantly on the basis of age or pre-exposure, though a non-significant effect of age showed adolescents tended to consume more saccharin than adults during later extinction trials. More rapid extinction could indicate weaker learning of the taste aversion, or a relative decrease in the magnitude of the aversion. Future research should be aimed at elucidating the mechanisms underlying these age differences.

Title: Adolescent intermittent ethanol impairs behavioral flexibility in rats

Authors: *G. A. GOMEZ ACOSTA, N. Y. A. SEY, Y.-Y. I. SHIH, C. A. BOETTIGER, D. L. ROBINSON
Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Emerging evidence has shown that patterns of teen drinking, which include binge drinking, produce physiological and behavioral effects to the developing brain that can persist into adulthood. Alcohol use disorder (AUD) is associated with behavioral inflexibility and bias toward rewards. We recently reported that adolescent intermittent ethanol (AIE) exposure promoted inflexible sign-tracking (ST) and reduced flexible goal-tracking (GT) in adult rats, which is consistent with enhanced cue conditioning and reduced behavioral flexibility. The present study includes two experiments, both of which tested AIE effects on flexible behavior. Experiment 1 determined whether AIE similarly impaired action selection in a stimulus-response

(S-R) task using a foraging response. Experiment 2 (partial results) sought to replicate AIE effects in promoting STB and the effects obtained in the Experiment. We hypothesized that AIE will promote inflexible behavior independently of the behavior testes, showing that adolescent exposure to ethanol impairs cognitive functioning and increases an individual's vulnerability to develop an AUD during adulthood. Exp. 1: rats were exposed to ethanol during adolescence (5 g/kg/day, 2 days on/2days off, P25 - 55). In adulthood, they were trained to dig for a food reward that was buried in one of two media and cued with one of two odors. Results: AIE and control rats both learned to discriminate olfactory cues, but AIE rats were less likely to learn to reverse that discrimination on the reversal test day. However, AIE rats were faster to return to the original odor discrimination (a second reversal; $p< 0.05$), suggesting perseverative behavior. Exp. 2: after AIE, animals underwent Pavlovian Conditioned Approach where a light was followed for a delivery of 100µL 20% sucrose. Then, after two weeks of food restriction, rats underwent the S-R foraging task. Results: AIE animals decreased flexible GT (reduced elevation score ($p<0.05$), increase receptacle entry (RE) latencies ($p<0.01$) and decrease RE probability ($p<0.01$). For the digging task, AIE rats were less likely to learn to reverse the initial discrimination on the reversal test day ($p<0.05$). No differences were observed in this cohort for the second reversal. Conclusions: While the study is ongoing, the findings are consistent with previous studies reporting that AIE decreases flexible GT behaviors. Also, these results are in concordance with studies of people presenting with substance abuse disorder, who learned new stimulus-response associations similarly to control subjects, but made more perseverative errors when that stimulus-response was replaced (McKim et al., 2016).

Title: Perinatal lead exposure modifies the locomotor effects of ethanol in *Caenorhabditis elegans*: Role of ethanol metabolism

Authors: *P. A. ALBRECHT[1], A. V. CARRANZA[2], R. DEZA-PONZIO[1], L. E. FERNÁNDEZ-HUBEID[1], L. M. CANCELA[1], R. ASÍS[2], M. ASCHNER[3], M. B. VIRGOLINI[1]

Abstract: Previous studies have demonstrated that developmental lead (Pb) exposure induces higher susceptibility to several responses to ethanol in rats. Caenorhabditis elegans has been used to study the neurobehavioral responses to drugs, including ethanol. Within this context, an acute ethanol exposure induces an initial sensitization and afterward tolerance to its sedative effects on motility. Wild-type (N2) nematodes in the L3 stage were exposed to $Pb(NO3)_2$ 5mg/L during 96 h until their progeny reached the L1 stage. Thereafter, they were washed and transferred to a new plate free of Pb with food for 48 h. The ethanol effects on motility were evaluated in L3 controls and perinatally Pb-exposed worms, 2 h after the ethanol concentration in the agar reached 100, 200 or 400 mM. The average speed of ten worms was registered for 2 min period either 10 min or 30 min after the onset of ethanol exposure to evaluate the initial depressor response that was followed by a recuperation effect characteristic of ethanol effects on motility. The results demonstrate that 200 mM of ethanol was the optimal dose to elicit differences between the control and Pb-exposed groups. In effect, the sedative effects of the drug were observed in the controls opposite to the hyperactivity manifested in the Pb-exposed animals. In addition, the use of a mutant strain that lacks the alcohol dehydrogenase (ADH)-like enzyme which metabolizes ethanol to acetaldehyde prevented the manifestation of these differences. Thus, the enduring hypermotility observed in the Pb group after ethanol exposure suggests a potentiation in the development of tolerance to the sedative effects of ethanol. Furthermore, the acetaldehyde seems to play a critical role in ethanol metabolism in the manifestation of these effects in the Pb-exposed worms

Title: Assessing motivational drive to attain ethanol in *Drosophila melanogaster*

Authors: *J. CATALANO[1], N. MEI[2], R. AZANCHI[3], S. SONG[1], T. BLACKWATER[1], F. MAHMUD[1], K. R. KAUN[2]

Abstract: Understanding ethanol's complex effects on reward and motivation circuits in the brain is critical for the development of better biologically informed therapies for ethanol abuse and addiction. Recent advances in neurogenetics have highlighted *Drosophila melanogaster* as an exciting model to study the effects of ethanol at the circuit and single neuron levels. However, methods for assessing motivation for drugs like ethanol are lacking in the *Drosophila* field. To address this methodological gap, we have developed a memory assay for investigating the motivational drive for odors and/or vaporizable stimuli like ethanol. Our results suggest that *Drosophila* demonstrate both seeking and avoidance behaviors for ethanol. Further, high content analysis reveals a number of factors that affect the decisions to seek alcohol. Future studies will assess the necessity and sufficiency of specific neuronal circuits in ethanol mediated seeking and avoidance. This experimental paradigm for estimating motivational drive will allow for circuit, single neuron, molecular, and genetic analyses of ethanol's motivational effects. Our results will also help inform similar conserved circuit motifs in mammalian models.

Title: Day-night variation in ethanol related behaviors in *Drosophila* and mice

Authors: *K. M. CAPRI, M. J. MARONI, M. H. CHASSE, A. V. CUSHMAN, J. A. SEGGIO
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Both acute and chronic ethanol exposure is well known to produce modifications to the biological clock. In turn, mutations to genes that regulate the circadian rhythm also alter ethanol related behaviors and metabolism. Here, we report day-night variation in behavioral outcomes for both *Drosophila* and mice and that acute alcohol exposure may influence those behaviors. For all experiments listed, separate groups of animals were tested for the following behaviors during ZT 6-8 (middle of the day) or ZT 18-20 (middle of the night) while in a 12:12 LD cycle. Male and female flies of wild-type, alcohol dehydrogenase (ADH) nulls, and ADH enhanced mutants were subjected to 500µL of ethanol in a vial to determine their sedation and recovery times for two consecutive days to assess alcohol sensitivity and tolerance respectively. While no differences are found during the first day of ethanol testing, an interaction between time of day and fly strain was found. ADH null strains exhibited longer recovery times during the day compared to at night. ADH null strains during the day had longer recovery times compared to ADH positive strains, but this effect was not observed during the night.

Additionally, ADH positive strains has quicker recovery from acute ethanol during the day than at night. Male Black Swiss mice were either injected with saline or 2 g/kg ethanol and were assayed in the open field, the light-dark (LD) box in bright light and LD box in the dark. Rearing was more prevalent during the day than night for vehicle injected animals, but not ethanol animals. Additionally, ethanol animals during the day had increased distance traveled in the LD box, but there was no difference at night. These results indicate that the time of day may influence behavioral outcomes in commonly used behavioral assays and that ethanol can modulate those behaviors in a circadian manner.

Title: Effects of social environment on alcohol responses

Authors: *C. M. SIERRA, P. R. SABANDAL, K.-A. HAN
The Univ. of Texas at El Paso, El Paso, TX

Abstract: Alcohol consumption is influenced by social environments. Clinical studies indicate that human subjects experience increased euphoria when drinking alcohol in social gatherings compared to drinking alone. Furthermore, animal studies show that housing either in a group (socially-enriched) or isolation (socially-deprived) alters the amount of alcohol intake and sedation latency. There is, however, limited information on the neurobiological mechanism by which social environments affect alcohol intake and responses. To begin to address this knowledge gap, we utilized the *Drosophila melanogaster* model. *Drosophila* has been extensively studied on alcohol-associated behaviors including sedation, tolerance, changes in locomotor activity, behavioral disinhibition and sensitization. In our study, we subjected wild-type flies to either single or group housing and subsequently exposed them to ethanol. We monitored the flies' initial sensitivity to sedation, tolerance development and a locomotor response profile to ethanol. We found that singly housed males or females were less sensitive to the sedative effect of ethanol compared to group-housed flies. This suggests that social isolation reduces ethanol sensitivity, increasing ethanol intake. This may enhance adaptive changes

relevant to alcohol abuse and addiction in socially-isolated animals or individuals. We are currently investigating the underlying neurobiological mechanism. Findings of this study may have novel implications for social environment-dependent alcohol use or addiction. Title: CRF_2receptor regulation of anxiety- and depressive-like behavior following protracted withdrawal from ethanol

Authors: L. MARSHALL, F. SANTOME, *G. R. VALDEZ
Dept Psychol, Grand Valley State Univ., Allendale, MI

Abstract: Alcohol withdrawal is often characterized by symptoms of anxiety and depression. These changes can be long-lasting in nature, which contributes to the challenge of the long-term management of alcoholism. The corticotropin-releasing factor (CRF) system is an important mediator in the behavioral changes following alcohol withdrawal. Two genes encoding distinct G-protein coupled CRF receptors have been identified, the CRF_1receptor and the CRF_2receptor. The strategy of utilizing CRF_1receptor antagonists for treating alcoholism has been aggressively pursued but has thus far been unsuccessful. In contrast, relatively little is known regarding the role of CRF_2receptors in regulating the long-term behavioral changes associated with alcohol dependence. The objective of the present study was to examine the ability of the selective CRF_2receptor agonist urocortin 3 (Ucn 3) to reduce anxiety- and depressive-like behaviors following protracted abstinence from ethanol. In the first experiment, male and female Wistar rats were surgically implanted with intracerebroventricular (icv) cannulas and then fed an ethanol or control liquid diet for 4 weeks. After removal of the diet, they were assessed for physical withdrawal signs, and then left undisturbed for 5 weeks. At the end of this withdrawal period, rats where given icv injections of 10 µg of Ucn 3 or vehicle 10 min prior to testing in the elevated plus maze. Results showed that vehicle-treated rats that were fed the ethanol liquid diet spent less time exploring the open arms of the elevated plus maze, an indication of an increased anxiety-like state, which was reversed by injections of Ucn 3. The second experiment examined

depressive-like behavior using the forced swim test. A second group of male and female Wistar rats were implanted with icv cannulas, fed an ethanol or control liquid diet, and assessed for physical withdrawal signs as described. Following a similar 5-week period of abstinence, rats were exposed to a 5-min session of forced swim stress. The following day, rats were given icv injections of 10 µg of Ucn 3 or vehicle 10 min prior to another 5-min forced swim session that was recorded and examined for time spent immobile. Analysis showed that vehicle treated rats that were fed the ethanol liquid diet spent significantly more time immobile, an indication of an increased depressive-like state, compared to ethanol rats injected with Ucn 3. These results support the hypothesis that CRF_2receptor activation may attenuate long-term changes in stress-related behaviors following protracted abstinence from ethanol, and that CRF_2receptors may provide a novel target for the treatment alcohol-related stress.

Title: Energy drinks and its combination with ethanol, increases anxiety and depression in Wistar rats

Authors: *M. MUNOZ ARENAS[1], D. POBLANO PÁEZ[1], B. B. VÁZQUEZ GONZÁLEZ[1], A. D. DIAZ[2]
[1]Facultad de Ciencias Químicas, BUAP, Puebla, Mexico; [2]Facultad de Ciencias Quimicas, BUAP, Puebla, Mexico

Abstract: The consumption of energy drinks (BE) has increased dramatically in recent years, marketed with the claim that these products provide an energy boost to improve the physical and cognitive performance caused by the ingredients that make them up in the population of adolescents and young adults have become more frequent the consumption of these drinks combined with alcohol to subjectively reduce the effects of alcohol and improve their alertness, however, some researchers and health organizations have expressed concern about the possible health risks associated with the mixture of alcoholic and energy drinks. The objective of this work was to study the behavioral and cellular changes produced by the co-administration of energy drinks and ethanol in Wistar rats. We used 48 male Wistar rats (Rattus norvegicus) of 150 g which were divided into 4 groups: S.S.I. (control), Ethanol, energy drink and energy drink plus ethanol. The administration was carried out daily for a period of 75 days orally. Behavioral tests

were performed before, during and after the administration, which were: tail suspension and open field tests. The co-administration of energy drinks with ethanol causes an anxiogenic state in the study subjects that leads them to increase their motor activity. Finally, rats were gently sacrificed, and we obtained striatum and hippocampus for to meassure the concentration of nitrites (NO2-). We found an increment of nitrites in the subjects administered with the mixture of energy drinks and ethanol. The effects of the consumption of energy drinks combined with ethanol represent a health risk.

Title: Role of perineuronal nets in the IfL during fear extinction and reinstatement after AIE

Authors: *K. L. MARQUARDT[1], L. CHANDLER[2]
[1]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Dept Neurosciences, Med. Univ. S Carolina, Charleston, SC

Abstract: Adolescent alcohol use primes alcohol-cue conditioning systems and reward learning leading individuals who drink during adolescence to be more susceptible to developing a pattern of un-controlled drinking in adulthood. Classically conditioned cue associations can be modeled in rodents with a fear conditioning paradigm, in which a mild foot shock is paired with a tone, the conditioned cue. Extinction learning in which the tone no longer predicts a shock, is mediated by an infralimbic (IfL) cortex and basolateral amygdala circuit. We have previously shown adolescent intermittent ethanol (AIE) exposure slows extinction learning and impairs extinction recall in male rats when tested in adulthood. However, the mechanisms behind this impairment have not been fully explored. Disruption of perineuronal nets (PNN) in the amygdala has been reported to result in a labile fear memory that is susceptible to erasure during extinction learning. In addition, repetitive alcohol consumption in adulthood increases PNN density around parvalbumin positive fast-spiking (FS) interneurons in the frontal cortex. PNNs form preferentially around these FS interneurons and continue to mature well into young adulthood in the prefrontal cortex (PFC), coinciding with maturation of PFC networks. These data lead to our hypothesis that impairment of fear extinction learning and recall in male rats after adolescent alcohol exposure is mediated by aberrant increases in PNN density in the IfL cortex. Beginning

on postnatal day 30, adolescent rats were exposed to five cycles of ethanol vapor chamber exposure. Each two-day cycle consisted of 14-hour vapor chamber exposure, followed by 10-hours out of the chamber, resulting in an average blood ethanol concentration of 250 mg/dl at the end of each cycle. Twenty-four hours, 7 and 26 days following the last cycle of ethanol exposure, PNN intensity in the medial prefrontal cortex (mPFC) was examined utilizing PIPSQUEAK software. Data suggest that AIE increases PNN density in the mPFC, and that this increase persists into adulthood. Furthermore, our data show that fear extinction learning modifies PNN density in the IfL, and that disruption of PNN in the IfL by chondroitinase ABC impacts extinction learning and later extinction retention.

Title: Reward processing alterations for natural reward in alcohol-preferring (P) rats: Incentive contrast, reward discrimination, and alcohol consumption

Authors: *J. J. MCGRAW[1], R. S. GOLDSMITH[2], H. C. CROMWELL[2]
[1]Psychology, Bowling Green State Univ., Lancaster, NY; [2]Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: Relative reward effects highlight the impact of reward value shifts on goal-directed behavior. A popular method used to examine relative reward effects is incentive contrast. Positive contrast is an upshift or increase in behavior toward a particular outcome due to an alternative comparison, while negative contrast is the opposite. The ability to compare rewards and utilize value shifts to make advantageous outcome decisions may be disrupted in substance use disorders such as alcohol use disorder (AUD). We examined the natural reward comparison abilities of Sprague-Dawley (SD) and alcohol-preferring (P) rats in an operant task using 12 sucrose solution pairings to determine 1) the impact of food restriction on contrast; 2) potential line differences in contrast before P rat alcohol exposure; 3) alcohol effects on contrast in P rats; and 4) the impact of reward value shifts on P rat alcohol intake. Animals underwent a repeated-measures design consisting of two single outcome blocks separated by a mixed outcome block. Appetitive and consummatory measures were used to assess positive and negative contrast toward single outcomes relative to alternatives presented during mixed blocks. Restricted naïve P rats show generalization and inverse consummatory contrast as well as impaired relative preference and a lack of reward discrimination. Conversely, they show appetitive contrast and discrimination for sucrose outcomes, suggesting that P rats have enhanced reward seeking but

upon consumption abandon their valuation of initial outcomes due to an impaired memory-based reward process which limits contrast and enables them to be hyposensitive to natural reward unlike alcohol. Alcohol had no effect on the absence of contrast in unrestricted P rats. Alcohol intake and preference were altered after incentive contrast tests but due to a lack of contrast, it was unclear whether sucrose upshift or downshift impacted drinking. We conclude that P rats show inherent deficits in reward processing and altered reward comparison abilities which could highlight genetic predispositions in AUD. Food restriction was found to be a key mediator of contrast in SD rats and P rats and analysis of both phases of motivation (appetitive and consummatory) is crucial in examining contrast and reward comparison abilities.

Title: Modulation of alcohol-seeking behavior by optogenetic induction of corticostriatal LTP in D2-MSNs of transgenic rats

Authors: *A. BINETTE, Y. CHENG, X. WANG, J. WANG
Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Our previous study found that excitation of dopamine D2 receptor-expressing medium spiny neurons (D2-MSNs) in the dorsomedial striatum (DMS) transiently reduced alcohol consumption in mice (Cheng et al., Biological Psychiatry 2017). In this project, we examine whether optogenetic induction of corticostriatal long-term potentiation (LTP) in DMS D2-MSNs alters alcohol-seeking behavior. We used recently developed DRD2-Cre transgenic rats to test this possibility. First, we found that intra-DMS infusion of AAV-DIO-tdTomato led to strong fluorescence expression in DMS neurons that project to the external segment of the globus pallidus, but not in those projecting to the substantia nigra pars reticulata (SNr). In addition, infusion of green beads in the SNr caused green fluorescent labeling of DMS neurons that were not overlapped with tdTomato-positive neurons. These data suggest that Cre is selectively expressed in D2-MSNs. Next, we infused AAV-chronos into the medial prefrontal cortex (mPFC) and AAV-flex-chrimson into the DMS of DRD2-Cre rats and trained the animals to self-administer 20% alcohol in operant chambers. We implanted optical fibers into the DMS, induced corticostriatal LTP by pairing optogenetic mPFC stimulation and optogenetic depolarization of

DMS D2-MSNs, and tested its consequence on operant alcohol-seeking behavior. LTP-induction produced a significant reduction in alcohol consumption which lasted for 10 days. Because depolarization of MSNs can evoke long-term depression (LTD) via endocannabinoid release, we performed a third LTP-induction paired with systemic administration of the endocannabinoid CB1R antagonist AM251. LTP-induction in the presence of AM251 significantly modulated alcohol consumption but not lever presses. Lastly, we performed a devaluation test and found that rats that were sensitive to devaluation showed a greater LTP-induced reduction in lever presses. These data suggest that corticostriatal LTP-induction in D2-MSNs is sufficient to cause a reduction in alcohol consumption.

Abstract: One of the main problems in the treatment of drug addiction is relapse to drug use after extended period of abstinence. In human addicts and rat models, environmental stimuli associated with previous drug use can provoke relapse to drug seeking. Pre-clinical studies have used the ABA renewal procedure to study context-induced reinstatement of drug seeking. Here, we assessed the role of hippocampus in context-induced reinstatement of alcohol self-administration in rats. Male Long-Evans rats were trained to self-administrate alcohol in context A. Alcohol self-administration was extinguished in a distinct context-Context B. On the test day, animals were re-exposed to the alcohol context A or the extinction context B for 30 min. The reexposure to the ethanol-associated Context A reinstated cocaine seeking and increased expression of Fos in the dorsal hippocampus neurons. To assess a causal role for this brain region, after the extinction phase cannulas were bilaterally implanted into the dorsal hippocampus and on the test day animals received either vehicle or Cobalt Chloride 15 min, prior the contexts exposure. The inhibition of dorsal hippocampus attenuated alcohol seeking in

context A. Our results suggest the participation of the dorsal hippocampus in context-induced alcohol seeking behavior

Abstract: Relapse is the major problem in ethanol addiction treatment. After prolonged withdrawal, drug relapse is often precipitated by acute re-exposure to drug-associated environment. Central and basolateral amygdala nuclei play a key role in learned associative behaviors. Thus, molecular and synaptic changes in neurons of the amygdala could be involved in context-induced relapse behavior. Here, we investigated whether context-induced reinstatement of alcohol seeking is correlated to amygdala activation. For this purpose, Long-Evans rats learned to associate a context (context A) with alcohol reward effects. Subsequently, they were exposed to a different non-drug context (context B) to extinct alcohol seeking behavior. Then, context-induced the reinstatement of alcohol seeking was tested by re-exposing the rats to the alcohol-associated context A. The re-exposure to the context A, but not to the context B, caused reinstatement of alcohol seeking. Fos-expressing neurons were increased in basolateral amygdala (BLA) in both contexts. However, in the central amygdala (CeA) the number of Fos-positive cells was increased only in context B. Cholinergic and GABAergic interneurons were the main types of neurons activated in the amygdala nuclei during the reinstatement of alcohol-seeking. Our data suggest that neuronal activation of distinct amygdala nuclei is involved with extinction and/or reinstatement of alcohol self-administration in rats.

Title: Early emotional manifestations of problematic alcohol drinking in rats

Authors: *S. PANDEY, J. R. BARSON
Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Severe alcohol use disorder (AUD), resulting from chronic excessive alcohol drinking, is characterized by dysregulated cognitive, emotional, and motivational states which perpetuate aberrant drinking behavior. While these disruptions and their underlying neuropathology have been investigated in animal models of alcohol addiction, it remains unclear whether alterations in behavior and neurobiology also occur in initial stages of the AUD trajectory. Therefore, we evaluated the emotional state of adult, male Long-Evans rats drinking 20% ethanol for 8 weeks under the intermittent-access paradigm, and compared them with that of animals maintained on water and chow only. Based on their intake level, we further grouped the alcohol drinking animals by tertile split as high drinkers (intake > 6.5 g/kg/24hrs) or low drinkers (intake < 4 g/kg/24hrs). When tested immediately prior to daily ethanol access, and 24 hours since their last access, the high drinkers, compared to the low and water drinkers, showed reduced anxiety and greater exploration in otherwise anxiogenic and risky novel environments (elevated plus maze, light-dark box), but reduced exploration in familiar and relatively safer environments (hole board apparatus, home cage) (n = 5-7/group). These findings with the high drinkers may reflect a sensation-seeking and risk-taking phenotype. Notably, we found that behaviors exhibited in an open field prior to the initiation of alcohol access subsequently changed after several weeks of drinking in the alcohol drinkers, but not in the water drinkers, indicating that these phenotypes likely developed as a consequence of alcohol drinking, rather than reflecting a preexisting difference. We conclude that, even in a non-dependence model, repeated excessive alcohol drinking is linked to robust alterations in emotional states and behavior. These early emotional changes in high alcohol drinkers may strengthen the drive to continue drinking at high levels, pushing them towards dependence. We are currently investigating neurobiological alterations that may mediate these emotional changes. Ultimately, identifying similar emotional changes in humans may be useful in preventing susceptible individuals from progressing into the AUD trajectory.

Abstract: Maternal binge alcohol drinking during prenatal and postnatal periods can be deleterious for the fetus since it occurs during key periods of the brain development. It is known that in utero alcohol exposure may lead to a wide range of long-lasting morphological and behavioral deficiencies known as fetal alcohol spectrum disorders (FASD), associated with a higher risk of later developing neuropsychiatric disorders. However, little is known about the long-term consequences on cocaine use and abuse in individuals with FASD. This study aimed to investigate the effects of maternal binge alcohol consumption cocaine reward-related behaviors in adult offspring. Pregnant C57BL/6 female mice were exposed to an experimental protocol of binge alcohol drinking (drinking-in-the-dark test) throughout gestation up to weaning. Then, male offspring were left undisturbed until they reached adulthood and were tested for cocaine-induced rewarding responses (conditioned place preference, behavioral sensitization and operant self-administration). Results show that prenatal and postnatal alcohol exposure enhances the preference for the lowest dose of cocaine-paired chamber in the conditioned place preference test (5 and 10 mg/kg). Furthermore, early alcohol exposed mice display an attenuated behavioral sensitization to cocaine at both doses tested (7.5 and 10 mg/kg), but greater attenuation was observed with the lowest dose. In addition, cocaine self-administration acquisition was higher in alcohol-exposed mice. Our findings demonstrate that maternal binge-like alcohol consumption during gestation and lactation enhances the sensitivity to the conditioned rewarding effects of cocaine in offspring mice. Together, these data suggest that prenatal and postnatal alcohol exposure may underlie an enhanced susceptibility of alcohol-exposed offspring to develop substance abuse disorder later in adulthood.

Title: Requirement of brain ghrelin signaling in the acquisition of cocaine reward

Authors: D. P. DUNN, J. M. R. BASTACKY, S. ABTAHI, E. HOWELL, *P. J. CURRIE
Dept. Psychology, Reed Col., Portland, OR

Abstract: We have previously shown that microinjection of ghrelin into the ventral tegmental area (VTA) potentiates cocaine-induced conditioned place preference (CPP). Other work now indicates that systemic administration of JMV2959, a ghrelin 1a receptor antagonist, attenuates both cocaine and amphetamine-induced CPP. To further investigate the role of mesolimbic ghrelin in the modulation of cocaine reward, the present study examined the ability of ghrelin administration into either the VTA or nucleus accumbens (NAc) to potentiate the acquisition of cocaine-induced CPP. Additionally, we investigated the impact of JMV2959 pretreatment in order to evaluate the potential attenuation of ghrelin's action on cocaine-induced CPP resulting from the inhibition of ghrelin 1a signaling. Adult male Sprague-Dawley rats were allowed access to either side of the CPP apparatus to establish baseline chamber preferences. The rats were then restricted to either their non-preferred or preferred side over the course of conditioning which lasted for a total of 8 consecutive days. On days in which rats were restricted to their non-preferred side, systemic cocaine (0.5-5.0 mg/kg IP) was injected and followed by either ghrelin (300 pmol), or JMV2959 (10 μg) paired with ghrelin (300 pmol), into either the VTA or NAc immediately prior to the conditioning trial. On alternate days rats were treated with vehicle both IP and centrally and placed into what was initially determined to be their preferred side. CPP was calculated as the difference in the percentage of total time spent in the treatment-paired compartment during the post-conditioning session and the pre-conditioning session. Our results indicated that both VTA and NAc ghrelin potentiated the acquisition of cocaine-induced CPP and that this effect was attenuated by JMV2959. Overall, these findings provide further evidence that central ghrelin 1a signaling is indeed involved in mediating the rewarding effects of psychostimulant compounds.

Title: Continuous social stress: Individual effects on cocaine self-administration in mice

Authors: *D. T. ARENA[1], K. A. MICZEK[2]
[2]Psychology, [1]Tufts Univ., Medford, MA

Abstract: Vulnerability to the effects of social stress can vary greatly across individuals. In C57BL/6J adult male mice, brief episodes of social defeat stress consistently *escalate* cocaine-self administration and heighten reinstatement after periods of abstinence. By contrast, continuous exposure to experiences of social defeat often result in the emergence of depression-like characteristics. Anhedonic behavior as measured by reduced sucrose preference, social interactions and *suppressed* responding for cocaine is hypothesized to be the result of continuous social defeat. The present experiments aimed to delineate the critical parameters of social stress in mice as they engender divergent patterns of intravenous cocaine self-administration. Separate groups of male C57Bl/6J mice were studied after 10 days of either intermittent or continuous social defeat stress, or no social stress. Following a 10-day period, mice were examined for social interaction and sucrose preference. The mice were then implanted with permanently indwelling IV catheters either in the jugular or femoral vein, acquired and maintained cocaine self-administration under a fixed ratio 1 schedule of reinforcement (0.3 mg/kg/inf) and then tested at several doses (0.1, 0.03, 0.01, 0.003, 0.001). Mice that underwent continuous stress reliably interacted less with a social stimulus animal, while intermittent social stress experience had no effect. Intermittent social defeat engendered a consistent increase in cocaine self-administration behavior at the training dose and a significantly sensitized response as measured by increased taking at lower doses. Two divergent phenotypes emerged in subgroups of continuously stressed mice: significantly escalated or significantly suppressed self-administration across all doses tested. These data provide evidence for contrasting effects of, not only intermittent versus continuous social stress, but also continuous social stress alone on subsequent cocaine intake. We seek to characterize the animals that self-administer cocaine either at high or low modes in terms of behavioral and neurochemical profile.

Title: A role for Cdkn1a in mediating the epigenetic inheritance of cocaine resistance in male offspring

Authors: *S. E. SWINFORD-JACKSON[1], B. FANT[1], M. E. WIMMER[2], M. C. KNOUSE[1], A. S. THOMAS[1], R. C. PIERCE[1]
[1]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Psychology, Temple Univ., Philadelphia, PA

Abstract: Preclinical evidence indicates parental exposure to drugs of abuse alters behavior and physiology of offspring. We previously demonstrated that when male rats self-administered cocaine, their male, but not female, progeny displayed reduced cocaine self-administration. The heritable epigenetic marks in sperm, including DNA methylation and histone post-translational modifications, that mediate differences in the reinforcing efficacy of cocaine in offspring are not fully understood. Recent evidence suggests DNA methylation is a stable epigenetic modification which may be involved in transgenerational epigenetic inheritance. Indeed, we identified 272 differentially methylated regions between the sperm of cocaine- and saline-experienced sires using a reduced representation bisulfite sequencing approach. Two hypomethylated promoter regions were upstream of the cyclin-dependent kinase inhibitor 1a (*Cdkn1a*) gene. A potential role for Cdkn1a in modulating cocaine reward is bolstered by a recent report which showed enhanced cocaine conditioned place preference in a global *Cdkn1a* knockout mouse (Scholpa et al., 2016). Here, we tested the hypotheses that Cdkn1a hypomethylation in the sperm of cocaine-experienced sires vs. saline-experienced sires is associated with higher Cdkn1a expression in male offspring, and overexpression of nucleus accumbens Cdkn1a will reduce cocaine self-administration in naïve rats. Expression of *Cdkn1a* mRNA in the nucleus accumbens was upregulated in cocaine- vs. saline-sired male offspring; there was no difference in female offspring. DNA methylation at the *Cdkn1a* promoter in the nucleus accumbens was not altered in cocaine-sired vs. saline-sired male offspring, suggesting that an alternate mechanism, rather than DNA hypomethylation, drives overexpression of Cdkn1a in the accumbens of male offspring. Experiments to functionally validate the impact of Cdkn1a overexpression on cocaine self-administration using a virally-mediated gene delivery in the nucleus accumbens of naïve rats are ongoing. Our results suggest Cdkn1a hypomethylation in sperm is a novel epigenetic mechanism

by which cocaine experience produces transgenerational effects, and Cdkn1a levels in the nucleus accumbens may mediate the reinforcing efficacy of cocaine.

Title: Altered cocaine reward, but not reinforcement, in a neuregulin 1 mouse model of schizophrenia

Authors: *R. CHESWORTH[1], T. KARL[2,3,4]
[1]Sch. of Med., Campbelltown North, Australia; [2]Sch. of Med., Western Sydney Univ., Sydney, Australia; [3]Neurosci. Res. Australia, Sydney, Australia; [4]Sch. of Med. Sci., Univ. of NSW, Sydney, Australia

Abstract: Substance abuse is highly prevalent in schizophrenia patients, worsening symptoms, increasing hospitalisation rates, and reducing the effectiveness of antipsychotic medication. It is unclear why substance abuse is so common in schizophrenia. Limited evidence suggests genetic predisposition for schizophrenia may make patients more susceptible in developing drug addiction. Elevated drug abuse propensity can be examined using mouse models of genetic risk for schizophrenia. The *neuregulin 1* transmembrane domain heterozygous (*Nrg1* TM HET) mouse shows face, construct and predictive validity for schizophrenia, and displays altered behavioural and neural responses to the major psychoactive component of cannabis. However, the rewarding and reinforcing properties of abused drugs have not been assessed in these mice. Thus, we examined the rewarding and reinforcing properties of cocaine in male *Nrg1* TM HET mice, as cocaine is abused in schizophrenia at a rate 10x times higher than in control populations. Cocaine reward (10 and 20mg/kg i.p.) was assessed in conditioned place preference, where the pairing of a drug with a neutral context can produce a preference for the drug-paired context (n=8-10/genotype and dose). At 10mg/kg cocaine, WT mice showed a strong preference whereas *Nrg1* TM HET mice did not develop a preference for the cocaine-paired context. However, at 20mg/kg cocaine, WT mice showed a neutral preference, and *Nrg1* TM HET mice showed a

strong preference for the cocaine-paired context. This suggests higher cocaine doses, at the maximal end of the dose response curve for WT mice, continue to induce reward in *Nrg1* TM HET mice. The reinforcing properties of cocaine were examined using intravenous self-administration (n=8-10/genotype). Reinforced responding for cocaine (0.5mg/kg/infusion) was examined with a fixed ratio 1 schedule of reinforcement (FR1), and motivation for cocaine was tested with a progressive ratio schedule of reinforcement (PR) at the same dose. *Nrg1* TM HET and WT mice made a similar number of cocaine infusions during FR1 training. There were no genotype differences in the motivation to self-administer cocaine. This suggests the reinforcing nature of cocaine at the dose chosen was similar in *Nrg1* TM HET and WT mice. The data presented suggest *Nrg1* TM mutation can increase the rewarding nature of higher dose cocaine. This finding provides first evidence for a potential genetic link between schizophrenia and cocaine abuse, and may help explain elevated abuse rates of this drug in patients. If higher doses are required to induce reward, this can lead to stronger cocaine-induced neural adaptations and a higher propensity for addiction.

Title: Estradiol mediates the development of motivational features of an addicted phenotype in female rats

Authors: *A. BAKHTI-SUROOSH[1], T. NESIL[2], W. J. LYNCH[3]
[1]Psychiatry and Neurobehavioral Sci., [2]Psychiatry & Neurobio. Sci., [3]Psychiatry and Med., Univ. of Virginia, Charlottesville, VA

Abstract: Women develop cocaine addiction faster after initial use compared to men. Animal models reveal a similar vulnerability in females, with estradiol implicated in the development of the features of addiction. However, most of this research has been conducted in ovariectomized females with and without estradiol replacement. In order to focus more directly on the contribution of estradiol, without manipulating all other ovarian hormones, we tested the effects of the estrogen receptor (ER) antagonist tamoxifen in intact females. We hypothesized that tamoxifen would block the development of addiction, as defined by an enhanced motivation for the drug, use despite negative consequences, and relapse vulnerability. Intact female rats were treated chronically (5-days/week) with tamoxifen (1.0 mg/kg; n=12) or vehicle (oil; n=17). A no

treatment group was also included to control for the effects of vehicle (n=9). Motivation for cocaine (0.5 mg/kg/inf) was assessed at baseline (following acquisition) and then following extended access (ExA) self-administration (SA; 24-hr; 4 discrete trials/hr; 1.5 mg/kg/inf; 10 days) and 14-days of abstinence, using a progressive ratio schedule (PR). Use despite negative consequences was then examined on a stable PR baseline by adding histamine, which induces an aversive response (2 and 4 mg/kg), to cocaine solutions. Relapse vulnerability was examined following abstinence in separate groups of rats under an extinction/cue-induced reinstatement procedure (n=8/group). As expected, tamoxifen prevented the development of an enhanced motivation for cocaine. While both the vehicle and no treatment groups showed an enhanced motivation for cocaine, the increase was higher in the no treatment versus the vehicle group (39 versus 18%), indicating that the oil itself reduced vulnerability. In contrast to effects on motivation, tamoxifen did not seem to prevent the development of relapse vulnerability, and actually increased extinction responding, or use despite negative consequences, as all groups showed only moderate decreases in PR SA after histamine was added. These results suggest that while estradiol mediates the development of motivational aspects of addiction, it may not be critical to the development of other key features, including use despite negative consequences and relapse vulnerability. However, given that tamoxifen also tended to decrease intake and inactive responding during ExA SA, and markedly reduced body weight, presumably via an estrogenic mechanism, it is possible some of our findings were mediated independent of tamoxifen's anti-estrogenic effects. Future research is needed to address this possibility.

Title: Intermittent access to cocaine enhances drug-directed motivation without altering response to food stimuli

Authors: *C. P. KING, J. A. TRIPI, H. A. PEARSON, P. MEYER
Psychology, Univ. at Buffalo, Buffalo, NY

Abstract: Patterns of drug-taking behavior are important in determining drug-directed motivation. Specifically, "intermittent-access" schedules of cocaine reinforcement result in "spiking" levels of brain cocaine levels, and lead to enhanced motivation for the drug, compared to "continuous access" schedules in which drug is freely available (Zimmer et al. 2012). In

addition, the tendency to approach food-associated stimuli ("sign-tracking") is associated with sensitivity to the motivational properties of cocaine (Saunders et al. 2010). Thus, to test whether intermittent cocaine access alters the response to food cues, we measured Pavlovian Conditioned Approach (PavCA) behaviors before and after rats had intermittent access to cocaine.
Experiment 1: We measured CS-directed (sign-tracking) and US location-directed ("goal-tracking") behaviors in Sprague-Dawley rats (n = 22) over three days of PavCA. Next, rats were trained to self-administer cocaine continuously for either 2-hours, 6 hours, intermittently in twelve 5 minute bins over 6-hours ("intermittent-access") or saline over 2 hours. Subjects were then assessed for drug-directed motivation using a threshold probe procedure, in which responses needed to maintain preferred level of drug intake are slowly increased. Subjects were then again tested in PavCA for changes in cue-directed approach, followed by a cue-seeking procedure where subjects respond for the cocaine-paired cue. We found that intermittent access rats showed greater motivation to work for cocaine and cocaine cues compared to the continuous access groups and saline controls. However, we found no changes in approach to a food cue following self-administration, suggesting the effects of intermittent access are specific to drug conditioning.
Experiment 2: In a separate cohort, we measured rats' response to an auditory food CS, which elicited goal-tracking in all animals (n = 18). We found that food conditioning was unaffected by drug schedule, again indicating that newly learned approach behaviors to non-drug stimuli are not altered by these different schedules of self-administration.
The results of these two studies indicate that, although intermittent access schedules can potentiate drug-directed behavior, these behavioral effects do not translate to non-drug stimuli. Therefore, it is suggested that neuroadaptations in response to intermittent self-administration are specific to drug domains, and may not produce global changes in stimulus-driven behavior.

Title: Chronic restraint stress and vulnerability to develop cocaine self-administration: Dysregulation of glutamate homeostasis in nucleus accumbens core

Authors: *L. M. CANCELA[1], M. P. AVALOS[1], A. S. GUZMAN[1], D. RIGONI[1], C. GARCIA-KELLER[2], F. A. BOLLATI[1]
[1]IFEC-CONICET. Dept Pharm. Sch. of Chem Sci. Nat Univ. of Cordoba, Cordoba, Argentina; [2]Neurosci., Med. Univ. of South Caroline, Charleston, SC

Abstract: Clinical evidence proved a facilitatory influence of stress on the development of substance use disorders. However, the mechanisms underpinning the comorbidity between stress and drug abuse have not been completely elucidated. Data from our lab demonstrated that chronic exposure to restraint stress engenders long-lasting neuroadaptations in Nucleus Accumbens (NAc), the major limbic-motor integration area, which resulted in sensitized response to cocaine (Esparza et al., 2012). We also showed that an acute exposure to restraint stress revealed that an enduring locomotor sensitization to cocaine is paralleled by an increase in dopamine (DA) within the NAc core, but not the shell. Our lab also found that rats pre-exposed to acute stress showed an increase in basal levels of glutamate (GLU) in the NAc core as measured by the no-net-flux method (Garcia-Keller et al., 2013). A relationship between altered basal GLU and the glutamate transporter GLT-1 levels was proposed to underlie the facilitation of cocaine self-administration (SA) following acute pre-exposure to stress (García-Keller et al., 2016). The present study attempts to determine the long-term effects of chronic pre-exposure to restraint stress on extracellular levels of DA and GLU in NAc, its impact on locomotor activity and drug SA behavior, and the levels of GLT-1 in the neuropathology of cocaine abuse induced by stress. Male Sprague Dawley rats (300-350g) were exposed to chronic restraint stress (2 h x day for 7 days), and 2 weeks later the following experiments were carried out: 1) Determination of DA and GLU extracellular levels in NAc core and shell after saline or cocaine (15 mg/kg i.p.), by microdialysis followed by High-Performance Liquid Chromatography coupled with electrochemical detection, 2) Basal GLU levels in NAc core by the no-net-flux method, 3) GLT-1 protein expression in NAc (preferentially core) by Western blotting, 4) Cocaine SA behavior and locomotor activity following saline or cocaine challenge injection. This study points out that chronic restraint stress induced a dopaminergic sensitization within NAc core, but not shell, after acute cocaine. Also, an increase of basal extracellular levels of GLU in core was observed following chronic stress, which is consistent with the decreased expression of GLT-1 in NAc. We propose that the chronic restraint stress-induced dysregulation of glutamate homeostasis is related to its influence on the development of cross-sensitization to motor stimulant effect of cocaine and the facilitation of the acquisition of cocaine SA behavior.

Title: Large-scale phenotyping of addiction-like behaviors in outbred rats identifies three types of individuals: Resistant, vulnerable, and prone to compulsive-like cocaine use

Authors: *O. GEORGE[1], M. BRENNAN[2], D. CONLISK[2], L. MATURIN[2], L. SOLBERG WOODS[3], A. A. PALMER[4], G. DE GUGLIELMO[2]

Abstract: Identifying the mechanisms that underlie the greater vulnerability to develop compulsive cocaine use represents a major goal for understanding the genetic risk factors for cocaine use disorder and facilitating the identification of novel druggable targets. We performed a large-scale phenotyping study of the escalation of cocaine self-administration in heterogeneous stock (HS) rats, a unique outbred strain of rats that is characterized by high genetic variability that has been developed to mimic genetic variability in humans. Male and female rats were trained to self-administer cocaine (0.5 mg/kg/inf) in 10 daily 2-h sessions (acquisition phase) and 14 daily 6-h sessions (escalation phase). The animals were also screened for compulsive cocaine use using a progressive-ratio schedule of reinforcement and responding despite adverse consequences (contingent footshocks). To minimize cohort-specific effects, we used three large cohorts (n = 46 each) and normalized the level of responding within sex and cohorts using Z-scores. To take advantage of the three behaviors that are related to compulsive intake and further identify individual differences in compulsive cocaine use, we computed an Addiction Index by averaging normalized responding (Z-scores) for the three behavioral tests. The results showed very high individual variability between subjects that allowed us to identify two different populations of rats: vulnerable (80%) and resistant (20%) to compulsive cocaine use. Further screening of the three factors that characterized the Addiction Index allowed us to identify rats with mild *vs*. severe levels of addiction-like behaviors and a subpopulation of rats with compulsive-like responding. The identification of such individual variability will likely facilitate the detection of gene variants that are associated with vulnerable *vs.* resistant individuals. The results of these studies have the potential to have a sustained impact on the field of addiction because they will identify novel druggable targets, provide a comprehensive analysis of compulsive cocaine use in both males and females, and provide a unique data/tissue repository that will facilitate follow-up and replication studies.

Title: FDA-approved 5-$HT_{1B/1D}$ receptor agonist, zolmitriptan, decreases cocaine self-administration in male and female rats

Authors: *R. GARCIA, D. CHARMCHI, A. COTTER, J. BONADONNA, J. L. NEISEWANDER
Arizona State Univ., Tempe, AZ

Abstract: Zolmitriptan is a 5-$HT_{1B/1D}$ receptor agonist that is used clinically to treat migraine headaches. We previously found that zolmitriptan decreases methamphetamine self-administration in male rats. Here we examined if zolmitriptan produces similar effects on cocaine (0.075 & 0.75 mg/kg) and sucrose (45 mg) self-administration in male and female rats. Sprague-Dawley male and free-cycling female rats were tested for the effects of zolmitriptan (0, 3.0, 5.6, & 10 mg/kg, SC) on cocaine and sucrose reinforcement rates on a fixed ratio 5 schedule of reinforcement. In male rats, 5.6 mg/kg of zolmitriptan decreased intake of 0.075 mg/kg cocaine and all doses of zolmitriptan decreased intake of 0.75 mg/kg cocaine. In female rats, 5.6 and 10 mg/kg of zolmitriptan decreased intake of 0.075 mg/kg cocaine and 10 mg/kg of zolmitriptan decreased intake for 0.75 mg/kg cocaine. These same doses of zolmitriptan did not affect sucrose reinforcement rates. The cocaine doses are on the ascending and descending limbs of the dose-effect curve, respectively, suggesting that zolmitriptan decreases cocaine reinforcement in both males and female rats. These findings suggest that zolmitriptan may have clinical efficacy as a treatment for psychostimulant use disorders.

Abstract: Dopamine D3 receptors (D3Rs) are a potential target for developing therapeutic compounds for psychostimulant addiction. Preclinical research has shown that D3R-selective antagonists and partial agonists attenuate measures of motivation for cocaine; however, obstacles for advancing D3R drugs for clinical trials are the bioavailability and/or short half-life of existing compounds. We have synthesized a novel phenylpiperazine, MC250041, that has an elimination half-life > 15 h and is > 1000-fold selective for D3Rs relative to D2Rs. In this study, we tested the effects of MC250041 (MC) on locomotor activity (N=12) and cocaine self-administration (N=10) using male Sprague-Dawley rats. Rats performed an operant lever press response on a multiple variable interval 60-second schedule with altering, 30-min components of cocaine (0.75 mg/kg, i.v.) and sucrose (45 mg) reinforcement. Once rats showed stable reinforcement rates, we tested the rats for MC effects on intake of the reinforcers at doses of 0.0, 3.0, 5.6, and 10.0 mg/kg (i.p.). We also examined the effects of 5.6 mg/kg MC on locomotor activity induced by 15 mg/kg (i.p.) cocaine. The highest dose of MC reduced the number of cocaine reinforcers obtained without altering sucrose reinforcement. MC potentiated cocaine-induced hyperactivity. The results suggest that MC may be useful in treating cocaine dependence. Future studies are planned for testing MC effects in female rats and for testing MC effects under a progressive ratio schedule of reinforcement to study cocaine motivation more robustly.

Abstract: Growing evidence suggests that the ventral pallidum (VP) is critical for drug intake and seeking behavior. Receiving dense projections from the nucleus accumbens as well as dopamine inputs from the midbrain, the VP plays a central role in the control of motivated behaviors. Repeated exposure to cocaine is known to alter VP neuronal firing and neurotransmission. Surprisingly, there is limited information on the molecular adaptations occurring in VP neurons following cocaine intake. To provide insight into cocaine-induced transcriptional alterations we performed RNA-Seq on VP of mice that underwent 10 days of cocaine self-administration (0.5mg/kg/infusion) followed by twenty-four hours of abstinence. We observed differential gene expression in 363 genes between animals that self-administered cocaine and saline controls. Among them, the expression of the transcription factor Nr4a1 showed a robust increase. Further, we observed an increase in the Nr4a1 transcriptional target, Plk2, a molecule important for synaptic and structural plasticity. We are currently using fluorescent *in situ* hybridization to determine which VP projection neuron population displays increased Nr4a1 and Plk2 levels after cocaine self-administration. This includes VP- ventral tegmental area, VP-lateral habenula, VP-mediodorsal thalamus, or VP-nucleus accumbens projection neuron populations. Additionally, we are using adenoassociated virus (AAV) overexpression and CRISPR knockdown manipulation of Nr4a1 and Plk2 to interrogate the role of these molecules in VP neuron subtypes during cocaine self-administration and seeking. Altogether, our work can provide crucial information into the molecular substrates occurring in VP neuron subtypes that underlies cocaine self-administration and relapse-like behavior.

Title: Cocaine-induced histone methylation on Egr3 and Nab2 promoters

Authors: *R. CHANDRA[1], B. B. EVANS[2], M. MCGLINCY[2], A. CHOW[2], K. K. COVER[3], M. ENGELN[1], M. K. LOBO[4]
[1]Anat. and Neurobio., Univ. of Maryland Baltimore, Baltimore, MD; [2]Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [4]Anat. and Neurobio., [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The nucleus accumbens (NAc) is a critical brain region, which mediates motivation for drugs of abuse. The NAc is composed of two types of medium spiny neurons (MSNs), which are differentiated by their enrichment of dopamine D1 vs. D2 receptors. We previously demonstrated that the transcription factor, Egr3, is upregulated in D1-MSNs and down-regulated in D2-MSNs after repeated cocaine exposure. It is postulated that Egr3 regulates its co-repressor, Nab2, and they both act together as a feedback mechanism to repress Egr3 transcription. Consistent with this, we observe a reduction of Nab2 in D1-MSNs and an increase of Nab2 in D2-MSNs after repeated cocaine exposure. Interestingly Egr3 also targets many histone methyltransferase and demethylase enzymes. Our previous work demonstrates that Egr3 transcriptionally regulates a histone lysine methylation enzyme in NAc after repeated cocaine exposure and we are currently investigating Egr3 binding on promoters of histone demethylase enzymes including lysine specific histone demethylase 1A, KDM1A, under these same conditions. In parallel we have examined mRNA levels of KDM1A in NAc D1-MSNs and D2-MSNs after repeated cocaine. Similar to Egr3, we observe an enrichment of KDM1A mRNA in D1-MSNs and a reduction in D2-MSNs in the cocaine group compared to the saline control group. We are also examining KDM1A binding and associated histone methylation marks at Egr3 and Nab2 promoters after repeated cocaine exposure. Using chromatin immunoprecipitation (ChIP) we observe altered KDM1A binding, as well as altered H3K4me3 and H3K9me2 on Egr3 and Nab2 promoters in NAc in the cocaine group compared to saline controls. Overall our studies are providing new information into the effects of cocaine on histone demethylation and its potential regulation of Egr3 and Nab2 transcription in MSN subtypes.

Title: Chemogenetic inhibition of prelimbic cortical output to paraventricular nucleus of the thalamus prevents anxiety-related behaviors and attenuates cocaine seeking

Authors: *G. GIANNOTTI, S. M. BARRY, B. M. SIEMSEN, J. PETERS, R. A. REICHARD, T. C. JHOU, J. F. MCGINTY
Med. Univ. of South Carolina, Charleston, SC

Abstract: A major clinical issue in addiction is the high rate of relapse even after prolonged abstinence. Our lab has shown that a single infusion of brain-derived neurotrophic factor (BDNF) into the prelimbic (PL) cortex immediately after the last cocaine self-administration session attenuates reinstatement of cocaine-seeking. To dissect the contribution of different cortical efferents to BDNF-mediated attenuation of relapse, we used a combinatorial viral approach to selectively express hM4Di DREADD or mCherry in PL cortical neurons projecting to nucleus accumbens (NAc) core or posterior paraventricular nucleus of the thalamus (pPVT). Male rats were trained to self-administer cocaine for 14 consecutive days. Immediately after the last cocaine self-administration, all rats received an injection CNO (10 mg/kg, I.P.) followed by an infusion into PL cortex of PBS or BDNF 30 min later. Rats then underwent 6 days of abstinence followed by a post-abstinence test under extinction conditions, extinction training to criterion and a cue-induced reinstatement test. As expected, Infusion of BDNF in the mCherry-expressing rats attenuates cocaine seeking. However, activation of hM4Di DREADD in PL->NAc core pathway blocked the BDNF-mediated attenuation of relapse but had no effect on subsequent drug-seeking. Interestingly, inhibition of PL->pPVT, a brain region linked to stress and anxiety, blocked subsequent cocaine-seeking. Moreover, 2h after the last cocaine self-administration session we found that Fos-IR was increased in anxiety-related brain regions, suggesting that early withdrawal may engage anxiety-related structures that support subsequent relapse. To test whether the pPVT is mediating anxiety-related behaviors, rats were tested in the elevated zero maze 2h after the last cocaine self-administration session. We found that activation of hM4Di DREADD in PL->PVT pathway attenuates anxiety-related behaviors compared to mCherry expressing animals. To strengthen the hypothesis that pPVT contributes to the aversive effect of cocaine after its acute rewarding effects disappear, we investigated whether inhibition of pPVT with GABA receptor agonists, baclofen/muscimol, would block avoidance conditioning in a classic operant runway task. As expected, over the sessions PBS-infused rats showed a progressive increase in the run time and number of reversals. However, infusion of bac/mus into pPVT 5 min after the rats reached the goal box after each session blocked the development of conditioned avoidance. These data demonstrate that inhibition of PL->pPVT pathway or pPVT itself prevents anxiety-like behaviors that ultimately contribute to cocaine-seeking.

Title: Biphasic effect of abstinence from cocaine self administration on structural plasticity and AMPA receptor expression in prelimbic cortical neurons projecting to the nucleus accumbens core

Authors: *B. M. SIEMSEN, G. GIANNOTTI, J. A. MCFADDIN, M. D. SCOFIELD, J. F. MCGINTY
Med. Univ. of South Carolina, Charleston, SC

Abstract: Cocaine-induced alterations in dendritic spine morphology in the prelimbic (PrL) cortex and nucleus accumbens (NAc) core are implicated in relapse after abstinence. During early withdrawal from cocaine self-administration (SA) in rats, there is profound dephosphorylation of several markers of glutamatergic transmission including ERK2, GluN2A/B-containing NMDA receptors, as well as CREB in PrL cortex. A single intra-PrL infusion of BDNF normalizes the phospho-protein disturbances during early withdrawal, as well as glutamate release in the NAc core, suppressing relapse. However, one week of abstinence from cocaine SA augments PKA activity, elevating GluA1 and CREB phosphorylation in the PrL cortex. Intra-PrL infusion of the PKA inhibitor, Rp-cAMPs, normalizes the hyper-phosphorylation of CREB and GluA1, suppressing relapse. Because these adaptations have been shown to be associated with altered dendritic spine morphology, we hypothesized that PrL-NAc core neurons would show reduced dendritic spine head diameter and density during early withdrawal, with the opposite occurring after one week of abstinence. Male Sprague-Dawley rats (*N*=32) received an intra-NAc core CAV2-Cre microinjection followed by intra-PrL AAV5-hSyn-DIO-mCherry to label PrL-NAc core neurons, followed by intravenous catheters. Rats underwent 12-14 days of cocaine SA or yoked saline and were perfused either 1) two hours or 2) one week after the final SA session. Coronal sections containing the PrL cortex were immunoprocessed for mCherry and the AMPA receptor subunits GluA1/2, as well as the activity markers pCREB and Fos. High-resolution confocal microscopy was used to image distal apical tuft spine segments of layer V PrL-NAc core neurons. Z-stacks were deconvolved (Huygens) and were 3D reconstructed in Imaris. Experiments were performed individually for GluA1 and GluA2 at both timepoints, and spine data were pooled between experiments. Results showed that cocaine SA decreased Fos immunoreactivity in PrL-NAc neuronal nuclei as well as spine head

diameter, and GluA2 immunoreactivity in putative mushroom-type spines, during early withdrawal, indicating suppressed PrL-NAc core activity at this timepoint. However, after one week of abstinence, dendritic spine density was decreased but spine head diameter and GluA1/2 immunoreactivity in putative mushroom spines were increased in PrL-NAc core neurons, suggesting augmented PrL-NAc core glutamate transmission. Experiments are ongoing to examine pCREB immunoreactivity in PrL-NAc core neurons during early withdrawal and after one week of abstinence.

Title: Parallel but independent hierarchies of temporal and reward integration across cortex

Authors: *M. MORADI SPITMAAN[1], H. SEO[3], D. LEE[4], A. SOLTANI[2]
[1]Psychological and Brain Sci., [2]Psychological & Brain Sci., Dartmouth Col., Hanover, NH; [3]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [4]Neurosci., Yale Sch. of Med., New Haven, CT

Abstract: To uncover principles of cortical computations, previous studies have independently estimated time constants related to intrinsic fluctuations of neural activity and reward feedback in multiple cortical areas. One study reported a hierarchy of intrinsic timescales across cortex (Murray et al., 2014), whereas another identified a power-law distribution of timescales for reward-related neural activity (Bernacchia et al., 2011). These studies, however, used two very different methods for estimating timescales without apparent connections between the results. Importantly, the relationship between the timescales and the task selectivity of individual neurons has not been examined. Here, we developed a general method to simultaneously estimate intrinsic and reward-memory timescales of neural activity observed during a virtual competitive game in the prefrontal (ACC, dlPFC, and dmPFC) and posterial parietal cortex (LIP) of rhesus monkeys, along with the selectivity for task-relevant information. First, we found that our method can replicate previous findings on the hierarchy of intrinsic timescales and a power-law distribution of reward-memory timescales. We also observed a hierarchy for reward-memory timescales that mirrors the hierarchy of intrinsic timescales across the same cortical areas. Second, we examined both intrinsic and reward-memory timescales for neurons with different types of selectivity (choice, reward, and their interaction) and found that the hierarchy of intrinsic timescales was preserved for neurons with different types of selectivity. In contrast,

reward-memory hierarchy was not consistent for different types of neurons and was not present in purely choice-selective neurons. Finally, we did not find any systematic relationship between intrinsic and reward-memory timescales of individual neurons in any cortical areas. Overall, our results reveal a hierarchy for integration of reward signals similar to that for intrinsic timescales when they are estimated simultaneously along with neural selectivity for task-relevant information. Nevertheless, the observed hierarchies of intrinsic and reward-memory timescales were independent, and thus must be generated through different mechanisms.

Title: A novel paradigm for studying causal inference and temporal credit assignment in nonhuman primates

Authors: *S. K. MURRAY[1], D. LEE[2], H. SEO[3]
[1]Interdepartmental Neurosci. Program, [2]Neurosci., [3]Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: Previous research has demonstrated that humans and other animals can continually update expected outcomes, or values, of alternative actions based on reward prediction errors. However, in natural environments, causally linked events are often separated in time and by other intervening, but unrelated, events. Furthermore, actions and their outcomes often occur in variable and complex sequences. In such cases, causal inference based on an accurate model of the environment is necessary to update the value of the causative action with the corresponding outcomes appropriately. This problem of linking a particular outcome to its causative action is often referred to as the temporal credit assignment problem. Despite the importance of causal inference and its necessity for solving the temporal credit assignment problem, little is known about the underlying brain mechanisms. As a first step towards understanding how different regions of the primate prefrontal cortex contribute to achieving this complex function, we developed a novel behavioral paradigm. We trained a rhesus monkey to learn the values of multiple actions by iteratively making choices among three alternative peripheral targets. Feedback for the choice on each trial was temporally delayed and delivered after another choice in the subsequent trial. Therefore, the feedback at the end of a given trial was not causally related to the choice in that trial, but rather to the choice made in the previous trial. In order to properly associate action and outcome to inform subsequent choices, the animal must rely on a causal model in which feedback is delayed by one trial. Using a logistic regression model, we found

that animal's choice was determined conjointly by the past choice and its delayed feedback (t-test for regression coefficient, $p<0.001$). By contrast, the conjoint influence of the past choice and causally unrelated immediate feedback was not significant (t-test, $p=0.29$), suggesting that the animal updated the values of different actions based the correct causal model of the task. This result shows that our experimental paradigm provides a new tool necessary to study the neural mechanisms underlying causal inference and resolution of the temporal credit assignment problem.

Title: Resetting the integrator in perceptual decision-making is reflected in FEF activity

Authors: *M. SHINN[1], H. SEO[2], D. EHRLICH[1], D. LEE[3], J. D. MURRAY[2]
[1]Yale Univ., New Haven, CT; [2]Psychiatry, [3]Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Multiple studies have observed a pause or dip in the neuronal activity recorded from the primate frontal eye field (FEF) and lateral intraparietal area (LIP) immediately after the onset of a saccade target. This has been hypothesized to reflect the resetting of information accumulation. Here, we sought to determine whether such a dip in neural activity can be induced by quantitative and more subtle changes in an ongoing sensory stimulus that requires a resetting of evidence accumulation. Two rhesus monkeys were trained to perform a two-alternative forced-choice color-discrimination task, while their saccade reaction times (RT) and single-neuron activity in the FEF were measured. In each trial, the animal was required to determine the majority color in a square consisting of blue and green pixels which were rearranged at 20Hz. The ratio of between green and blue pixels (coherence) for this discriminative stimulus (DS) varied randomly across trials. In addition, DS was preceded by a prestimulus (PS) consisting of equal numbers of green and blue pixels that lasted for 0, 400 or 800ms. Animals were allowed to shift their gaze any time after the onset of the DS and were rewarded only when they chose the target with the same color as the majority of the pixels in the DS. The maximum coherence was set so that the transition from PS to DS was easily noticeable. We found that during the trials with long PS, the frequency of saccades decreased with coherence during an interval between

100 and 200ms after DS onset. This could be accounted for by a drift-diffusion model modified to include the resetting of the evidence integration that was more likely to occur with increasing DS coherence. Consistent with this behavioral model, we found that the FEF activity was reduced approximately 100 ms after the onset of DS, and the size of this dip in FEF activity increased with DS coherence. Although a similar dip in the FEF activity was seen immediately after PS onset, its size was not substantially related to the coherence of DS presented without PS (0ms PS). These results support the idea that the dip in FEF activity is associated with resetting of the integrator during perceptual decision-making, and suggest that the resetting of the integrator reflects the detection of a change in the sensory input.

Title: Behavioral mechanisms of reward signaling in the medial and orbital prefrontal cortices

Authors: *L. M. AMARANTE[1], M. S. CAETANO[2], M. LAUBACH[1]
[1]American Univ., Washington, DC; [2]Univ. Federal Do ABC, Santo Andre, Brazil

Abstract: Neuronal activity in the medial prefrontal cortex [mPFC] is synchronized to reward consumption and encodes reward value (Horst and Laubach, 2013; Amarante et al., 2017). Here, we examined several behavioral mechanisms underlying mPFC reward signaling, and also made parallel recordings in the orbital prefrontal cortex [OFC] to assess mPFC-OFC interactions during reward consumption. Rats were trained to perform the Shifting Values Licking Task [SVLT] (Parent et al., 2015) and were subsequently implanted with multi-electrode arrays in the mPFC (prelimbic and adjacent medial agranular areas) and the OFC (lateral orbital and agranular insular areas). Recordings were made in three modified versions of the SVLT: (1) contextual coding was assessed in sessions with reward values (16% and 4% concentration liquid sucrose) held constant over blocks of trials or randomly interleaved across trials; (2) relative value coding was assessed in sessions with three levels of reward, presented in alternating pairs (4% vs 2% sucrose or 4% vs 8% sucrose) over the blocks of trials; and (3) shifts in fluid volume (25 vs 10 ul reward per pump activation), as opposed to shifts in sucrose concentration, were presented in alternating blocks across the session. Spectral analysis of LFPs revealed that lick-entrained activity was coherent across areas, with strong directional influences of the rostral mPFC over

the caudal mPFC and OFC. LFPs in both cortical areas encoded contextual information: e.g. the strength of entrainment to the lick cycle was enhanced when reward values were blocked as compared to when values were randomly interleaved (encoding context, not content). LFPs in both areas also encoded relative value: e.g. stronger entrainment to licking for 4% sucrose when it was presented in alternation with 2% sucrose compared to alternation with 8% sucrose. Finally, LFPs in both mPFC and OFC encoded shifts in fluid volume in a similar way to shifts in sucrose concentration, suggesting that differences in the palatability and magnitude of liquid rewards are similarly encoded in these cortical areas. Together, our studies suggest that neuronal activity in the mPFC exerts top-down influences over the OFC to mediate value-guided control over consummatory actions.

Title: Divergence across the rostral-to-caudal axis of the mPFC in the motivational control of behavior

Authors: *H. C. GOLDBACH, T. K. SWANSON, M. LAUBACH
American Univ., Washington, DC

Abstract: Recent studies from our laboratory have established that the medial prefrontal cortex [mPFC] is crucial for the expression of incentive value when rats consume liquid sucrose rewards (Parent et al. 2015). Neuronal recordings in the mPFC further reveal modulations of spike activity and field potential when rats initiate reward consumption that encode differences in reward magnitude (Amarante et al. 2017). These findings were obtained using an operant task based on classic incentive contrast procedures (Flaherty 1982). Here, we used two other types of behavioral tasks to determine if the mPFC is involved in the motivational control of reward consumption. First, rats were tested in a Progressive Ratio Licking Task [PRLT] (Sclafani & Ackroff 2003), in which they had to persistently lick to receive liquid sucrose rewards. The number of required licks increased by 1 after each reward. This design can be used to assess whether reinforcer efficacy depends on a given brain region. Rats were trained to perform the task until they had stable breakpoints before being implanted with guide cannula for delivering muscimol (1μg/μL in 0.5μL) to the mPFC. Cannula were implanted across the rostral-to-caudal axis of the mPFC, targeting the rostral medial orbital and caudal prelimbic areas. Rats with rostral mPFC inactivations (4.2-4.7mm AP) showed reduced rates of performance, and showed changes in microstructural measures of licking, engaging in very brief licking bouts. Rats with

caudal mPFC inactivations (3.2-3.7mm AP) performed the task at a faster pace (reminiscent of Horst and Laubach 2009; 2012) and prolonged their licking bouts. Breakpoints were not affected by inactivations of the mPFC, with the exception of two rats that had cannula implanted in the rostral pole. Second, a different cohort of rats was tested in an operant task in which they nosepoked to produce access to sucrose from an opposing reward port. Similar to results from the PRLT, rostral inactivations led to slower pace and increased collection latencies and caudal inactivations led to faster pace and reduced collection latencies. Together, these studies suggest that while the mPFC is necessary for the expression of incentive value (Parent et al. 2015), there is heterogeneity across the rostral-caudal axis of the mPFC for other measures of motivation, such as response latencies and breakpoints.

Title: Strategic factors in the two-armed bandit task: Computational model, validation in rodents, and role of mPFC

Authors: *T. K. SWANSON[1], H. C. GOLDBACH[2], F. Z. FERNANDEZ[2], B. B. AVERBECK[3], M. LAUBACH[2]
[1]Biol., [2]American Univ., Washington, DC; [3]NIMH/NIH, Bethesda, MD

Abstract: Two-armed bandit tasks (TAB; aka probabilistic reversal learning) are used to assess the neural basis of cognitive flexibility. In these tasks, reversals in reward probabilities over options follow either a performance-based criterion or are blocked over trials, independent of performance. The consequences of this difference in task design are not clear. To address this issue, we developed a normative model of the TAB task, based on win-stay/lose-shift strategies. The model revealed a dominant role of lose-shift behavior (negative feedback) in determining the number of reversals in the performance-based design and of win-stay behavior (positive feedback) in determining choice accuracy in both designs. A reinforcement learning algorithm found evidence for learning around the first reversal in each session, and stable values for alpha and beta thereafter. We validated the model by training rats to perform a spatial TAB task, using training procedures based on recent primate studies (Costa et al. 2015). We found that rats can rapidly be trained to perform the TAB task, even with reward probabilities of 70% and 30% across choice options. Crucially, and in contrast to published studies, rats were trained with deterministic outcomes before experiencing probabilistic outcomes. Using this method, our animals performed well above the choice accuracies and reversals per session that have been

reported in the literature (e.g. Bari et al. 2010; Dalton et al. 2016). When presented with probabilistic (80%-vs-20%) outcomes in a one-hour session (>200 trials), our animals performed with choice accuracies of >70% and made >20 reversals when tested with a performance-based criterion (8 consecutive "correct" choices) and with choice accuracies of >70% when tested with blocked reversals (30 trials per block). Reversible inactivations of the medial prefrontal cortex (mPFC) impaired TAB performance. Infusions of muscimol (5 ng/ul) led to reduced task engagement, reduced choice accuracy, and, in some cases, spontaneous alternation. Together, our studies establish a rodent spatial TAB task that has a clear computational basis, behavioral performance on par with studies in primates, and depends on the mPFC.

Title: Prelimbic-accumbal pathway encoding during learning predicts and is causally linked to behavioral flexibility

Authors: *E. A. WEST, M. NIEDRINGHAUS, R. M. CARELLI
Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Animals depend on the ability to modify their behavior to achieve specific outcomes, i.e., behavioral flexibility. The prelimbic cortex (PrL) and nucleus accumbens (NAc) core are necessary for reinforcer devaluation, a test of behavioral flexibility. Previously, we have shown that the degree of encoding in the core predicts the ability of rats to shift behavior later (West and Carelli 2016). Here, we aimed to determine if PrL input is linked to both NAc core cue-encoding and behavioral flexibility. Specifically, male Long-Evans rats (n=21) rats were presented with two distinct cues as conditioned stimuli (CS+; one predicting a sugar pellet and one predicting a food pellet) and two cues that did not predict a reward (CS-); 10 trials each. We recorded neural activity in the PrL and NAc core while rats underwent pavlovian conditioning (10 daily sessions). After 10 sessions, rats were given a devaluation procedure to induce a conditioned taste aversion (LiCl, i.p., 0.3 M; 10 ml/kg) to the sugar pellets. Rats were then tested on the same pavlovian conditioning task (under extinction) to evaluate their ability to avoid CS+ associated with the devalued outcome. Rats spent significantly less time in the food cup during the CS+

associated with the devalued outcome (10.7% +/- 1.4%) compared to the CS+ that predicted the nondevalued outcome (15.2% +/- 1.5%). Recordings of PrL neurons during pavlovian conditioning revealed distinct populations that were excited or inhibited during cue presentations (classified as "phasic"). The change in the number of neurons that were classified as "excited" to the cue from day 1 to day 10 of learning predicted how well rats flexibly changed behavior during testing (R^2= 0.47, p <0.05; measured as a Devaluation Index; DI, West and Carelli 2016). There was no correlation in the change in neurons that were classified as "inhibited" to the cue (R^2= 0.15, p >0.1). In addition, the change in PrL-NAc coherence from Day 1 to Day 10 of learning at the Gamma50 and Gamma80 frequency band predicted how flexible the rats performed during testing (R^2= 0.59, p <0.05 and R^2= 0.82, p <0.05, respectively). This suggests that synchronized high gamma activity between PrL and NAc core during learning is linked to behavioral flexibility in this task. In support, we found that optically inhibiting the PrL-NAc pathway during pavlovian conditioning (during the cue presentations) impaired behavioral flexibility (control, n=6, DI= 0.27 +/- 0.04); halo, n=6, DI=-0.08 +/- 0.13), p<.05), indicating that this pathway is required during cue-outcome acquisition to allow for flexible behavior.

Title: Effects of prior cocaine exposure on delay-based decision making and prelimbic cortical activity

Authors: *M. L. NGBOKOLI, T. M. MOSCHAK, R. M. CARELLI
Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Individuals suffering from a substance use disorder often show higher rates of impulsive behavior (Coffey et al., Exp Clin Psychopharm, 2003), including an inability to delay gratification (known as delay discounting). Delay discounting relies upon the ability to discriminate both different reward magnitudes as well as different delays to reward, and work has begun to independently investigate the effects of drugs of abuse on magnitude and delay sensitivity. Our lab recently found that abstinence from cocaine self-administration impairs magnitude discrimination and abolishes dopamine encoding of food reward in the nucleus accumbens (NAc) shell (Saddoris et al., Neuropsychopharm, 2017). However, little work has

investigated the neurocircuitry underlying cocaine's effects on delay-based decision making. While the NAc shell appears important in magnitude processing, the NAc core seems to play a stronger role in the processing of delay. Further, the prelimbic cortex (PrL), which projects to the NAc core, exhibits neuroadaptations following cocaine abstinence (West et al., Eur J Neurosci, 2014) and is implicated in delay discounting (Churchwell et al., Behav Neurosci, 2009). Here, we investigated the effects of cocaine self-administration history and abstinence on delay-based decision making and PrL activity using electrophysiological methods. Adult, male Sprague Dawley rats were trained to self-administer cocaine (n=7; 0.33 mg/inf, 2 h per session) or water (to a receptacle) with yoked intravenous saline (n=6) during 14 daily sessions, followed by 30 days of experimenter-imposed abstinence. Rats were then trained to press levers associated with discrete cue lights in a delay task consisting of three trial types. On forced delay trials, a cue light predicted the opportunity (5 s later) to press a lever for a delayed reward (4 s delay). On forced immediate trials, another cue light predicted the opportunity to press a different lever for an immediate reward. During free choice trials, both cue lights and levers were presented, and rats could freely choose either option. Preliminary data indicate that animals with a history of cocaine were faster to press the lever regardless of trial type compared to their saline counterparts, but there was no effect of prior cocaine on free choice behavior. Preliminary results also suggest a correlation trend between PrL firing rate and reaction time ($r = 0.7296$, $p = 0.064$); additional analyses are ongoing. For comparative purposes, we are also examining the effects of prior cocaine experience on uncued delay-based decision making and PrL firing following cocaine history and abstinence.

Title: Integration of value across dimensions in ventromedial prefrontal cortex

Authors: G. LOCONTE[1], H. AZAB[3], M. WANG[4], *B. Y. HAYDEN[2]
[1]Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Minnesota, Saint Paul, MN; [4]Brain and Cognitive Sci., [3]Univ. of Rochester, Rochester, NY

Abstract: In the natural world, the value of a course of action can depend on multiple parameters that can vary independently. In these multi-attribute decisions, value computation requires the on-line integration of the values of each attribute. At the neural level, value

integration can be distinguished from multiplexed responding by a positive correlation between the firing rate tuning functions of variables that influence value in the same way. Here we examine the integration properties of three important value-related brain regions, ventromedial prefrontal cortex (vmPFC, Area 14), pregenual cingulate cortex (pgACC, Area 32), and ventral striatum (VS) in rhesus macaques. We used a two-alternative forced-choice task with staggered option representation while recording from each area. Options differed along the dimension of stakes (two possible juice sizes for winning) and probability (100 values), and all rewards were juice aliquots. Stakes and probability were chosen randomly and independently for each offer on each trial. We found that both vmPFC and VS integrated the two dimensions but that pgACC multiplexed them (i.e. did not integrate to compute value). Moreover, we found that although values were integrated in vmPFC and VS, they were not fully integrated. That is, responses in these regions reflect a partially completed integration process, suggesting that later regions likely complete the process. These results challenge the idea that either vmPFC or VS serves as the endpoint of a value computation process. Moreover, given the integrated value signals observed in human vmPFC, they endorse the hypothesis that Area 14, not area 32, is the macaque homologue of human vmPFC.

Title: Cocaine exposure sharpens ventral striatum's encoding of variables in a gambling task

Authors: *P. MEHTA[1], B. J. SLEEZER[2], B. Y. HAYDEN[3]
[1]St Paul, MN; [2]Neurobio. and Behavior, Cornell Univ., Ithaca, NY; [3]Univ. of Minnesota, Saint Paul, MN

Abstract: The ventral striatum (VS) has been implicated as an important component of reward circuits in the brain, active during activities such as substance abuse and gambling. The interaction between substance abuse and encoding of neuroeconomic factors such as risk and reward is relevant both to learning about how substance use can impact human decision making, as well as to understanding how altering VS neurotransmitter levels alters its spike activity patterns. Here, we examine the neural encoding of task variables in rhesus macaque (*Macaca mulatta)* ventral striatum as they perform a gambling task, with and without daily cocaine exposure. Monkeys were presented two successive gamble offers represented as colored bars that

indicated both the size of the reward and the probability of receiving it if that option were selected. The monkeys were then allowed to make a choice between the two offers, which resulted in either reward delivery or lack thereof contingent upon the reward probability. We compared monkeys' behavioral performance and VS neural activity while they performed the task clean, to while they performed the task during a period of days where they received daily self-administered doses of cocaine. Behaviorally, we found that monkeys demonstrated a modest increase in accuracy during cocaine exposure, (selecting the option with the higher expected value of the two). We hypothesize that this increase in accuracy may be due to sharper encoding of the task variables in VS. During offer presentation, more neurons encode the size of the reward during cocaine exposure. Furthermore, the difference in firing rates between different reward sizes is greater in the cocaine condition. Cocaine exposure also brings about an overall increase in signal-to-noise ratio of firing rates: the standard deviation of normalized firing rates over the 2 second period during which offers are being viewed is increased during cocaine exposure. Finally, during cocaine exposure, there is an increased correlation between reward encoding and probability encoding, indicating that cells are encoding these two variables more similarly. These results suggest cocaine exposure heightens the sensitivity of VS in terms of encoding variables relevant to reward-motivated task performance.

Title: Economic decision-making in freely moving monkeys performing a delay-based foraging task

Authors: *T. CASH-PADGETT, B. Y. HAYDEN
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Decision-making behavior, especially in foraging-based paradigms, may differ with the degree of overlap between an experiment and behaviors that were selected for in an animal's natural environment. Studies of decision-making in nonhuman primates have largely relied on saccade-based tasks, however, and there is still relatively sparse data on value-based decisions in freely moving animals. We examine economic choice behavior in a room-sized environment as rhesus macaques make wait/skip decisions on the basis of wait time required to receive reward.

The length of time is signaled on an LED screen, and is only visible when the subjects are in proximity to the feeder. This behavioral paradigm is known as the 'Restaurant Row', and has been previously used to study economic decision-making and regret in rodents. When a subject approaches a feeder and views the delay, it enters the 'offer zone', and when a subject holds down a lever in order to count down the delay, it enters the 'wait' zone', thereby yielding two distinct economic decisions that must be made. While delays vary pseudorandomly during a session, rewards are consistent within a session for each feeder, and session times are a set duration. We find that subjects consistently accept offered rewards from a full range of delays, but are more willing to wait when a shorter delay is signaled. Thresholds for deciding to wait vary on the basis of the subjective value of rewards obtained from a given feeder. The behavioral results from this experimental paradigm are consistent with foraging-based models of choice behavior, but also suggest differences in attitudes towards risk from those previously observed in saccade-based decision-making tasks.

Title: Independent coding of reward and perceptual salience in the lateral intraparietal area in value-based decisions

Authors: *Z. WU[1], X. CAI[2], A. CHEN[1]
[1]East China Normal Univ., Shanghai City, China; [2]NYU Shanghai, Shanghai, China

Abstract: It is generally believed that when making economic choices, we first assign values to available options then compare them to generate a decision. The lateral intraparietal area (LIP) has been considered a candiate neural substrate where action values associated with saccade are represented and compared. This proposal is largely based on the finding that in monkeys making value-based decisions, activity of an LIP neuron correlates with the reward expected from saccade into the neuron's response field. In the mean time, LIP neurons receives projection from many visual areas and they respond with higher firing rate to visual stimuli of higher luminance, suggesting that their activity reflect not only reward but also perceptual salience. To understand

the detailed representation of these two streams of information and its implication for value-based decisions, we trained monkeys to perform a two-alternative choice task in which we independently manipulated reward and perceptual salience by varying the volume of juice and the relative luminance associated with each target. We discovered that the animal's choice was driven by reward but not perceptual salience. We thus recorded from LIP to investigate how its activity may contribute to such choice behavior.
We have recorded 177 neurons in LIP of which 48% (86/177) showed significant spatial tuning. Preliminary results show that the early activity of 39.5% (34/86) neurons was significantly modulated by the amount of reward presented on the neuorns' preferred hemifield. We also discovered that luminance level of the visual stimuli significantly affected the activity of 29.1% (25/86) LIP neurons indicating that the visual responses in LIP are modulated by perceptual salience as well. However, the same neurons tend to be modulated by either reward or salience but not both (only 8 out of 86 neurons responded to both reward and salience). Furthermore, we divided the neurons into anterior (36/86) and posterior (50/86) groups according to the recording coordinates along the anterior-posterior axis relative to the interaural line. Compared to the posterior group, anterior LIP neurons are more sensitive to reward ($p<0.05$, non-paired t test) but less sensitive to luminance ($p<0.01$, non-paired t test) and the reverse is also true.
In summary, both reward and perceptual salience are represented by LIP but are encoded by separate population of neurons. Furthermore, there seems to be a gradient in response to reward and perceptual salience along the anterior-posterior axis of LIP.

Title: Transient tuning of dACC neurons with mixed selectivity in a naturalistic pursuit task

Authors: *J. TU, S. M. YOO, B. Y. HAYDEN
Ctr. for Magnetic Resonance Res., Univ. of Minnesota, Minneapolis, MN

Abstract: The real-world foraging decision-making is a dynamic process, which extends the time and the space. In order to reproduce this kind of naturalistic decision-making process, we devised a joystick-controlled dynamic interactive pursuit task that resembles naturalistic hunting behaviors. To capture real-time changes in neural activity and task conditions, we simultaneously recorded neural activities in the dorsal anterior cingulate (dACC) with 96 channel-floating

microarray and the position of the avatar of the animal and computer-controlled prey. With the rich and complex task conditions we questioned: 1. Is the tuning for task variables in the dACC neurons sustained throughout the trial, or is there a temporal progression? 2. Is there an overlap between the population of neurons coding task variables and whether the tuning for different task variables evolves together? 3. Is the dimensionality of neural representations in such a naturalistic task comparable to other simpler choice tasks (e.g. 2AFC gambling tasks)? Here, we found most neurons in the dACC are tuned to the task variables only transiently in the naturalistic pursuit task. In addition, we found multiplexed neurons that are tuned for different task variables, but the tunings evolved at different times through the trial progression. Despite the high complexity of the task, the dimensionality of neural representations retrieved from dACC activities in the naturalistic pursuit task was only slightly higher than simple economic choice tasks.

Title: Foraging behavior and risk preference in freely moving Rhesus macaques

Authors: *B. R. EISENREICH[1], B. Y. HAYDEN[2]
[1]Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Minnesota, Saint Paul, MN

Abstract: Within the natural environment animals face a critical challenge in balancing the costs and benefits of searching for and consuming different food sources, or more generally rewards. Across taxa, risk appears to be a key variable that influences how these judgments are made. One puzzling finding is the tendency of primates to be risk seeking within economic tasks, as a large body of research in other species has found the opposite trend. A possible explanation for this apparent discrepancy is the tendency of using highly controlled tasks that mimic the statistics of the natural environment, while limiting the animal's ability to engage in unrestrained behavior. Here we examined foraging behavior under conditions of risk while allowing primates to move freely about a large cage. Importantly, we demonstrate an approach that allows for the performance of unrestrained behaviors and is compatible with wireless electrophysiology, without having to sacrifice control of the environmental statistics. Our preliminary results are suggestive of risk aversion in primates and highlight the importance of unrestrained behavior on decision-making.

Title: An attentionally-aligned model of value-comparison

Authors: *H. AZAB[1], R. MORENO BOTE[2], B. Y. HAYDEN[3]
[1]Univ. of Rochester, Rochester, NY; [2]Pompeu Fabra Univ., Barcelona, Spain; [3]Univ. of Minnesota, Saint Paul, MN

Abstract: Existing models of value-based choice posit a competition between separate neuronal populations, each dedicated to the stable representation of the value of a particular available option. In maintaining the values of options simultaneously, these models do not account for the role attention plays in making such decisions. Recent studies have shown that single neurons in several prefrontal reward areas as well as the ventral striatum switch between representations of the values of different options depending on which of these is currently the focus of attention. We propose a neuron-level model where a single population of neurons represents the value of the currently attended option, and its value modulates the value representation of subsequent options. In this framework, values are represented relatively rather than in absolute terms, in the context of other options in the environment. This setup allows options to be evaluated in a serial, attention-guided manner. Activity simulated from this model aligns with several findings observed in prefrontal cortex neuronal populations; including mutual inhibition between offer values, as well as representation of sequentially-attended offers in similar formats. We also explore the dynamics of this model when presented with more than two options.

Title: The role of the orbitofrontal cortex in expectation and motivation

Authors: *Z. S. GILLIS, E. L. RICH
Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Expectations color our perceptions and guide our decision-making. Maladaptive expectations are features of a variety of psychiatric disorders such as major depressive disorder, and can bias behavior towards unfavorable outcomes, making them a prime target for treating mental illness. Currently, the neural mechanisms that give rise to expectations, and how these expectations alter networks involved in perception and decision-making, remain unclear. The OFC is known to encode the value of reward-predictive stimuli, and distinct regions of OFC may serve different functions in updating stimulus values. To better understand the mechanisms through which expectations are formed and updated, we trained two monkeys on a reward expectation task in which pictures served as stimuli predicting rewards with varying levels of sweetness and bitterness. During forced choice trials, only one reward-predictive stimulus was offered. During free choice trials, the subject was presented with two options, which he could choose between. In order to receive an initial reward in either trial type, the subject fixated on a stimulus and simultaneously released a touch sensor bar. The initial reward delivery was followed by a period of 4 seconds, during which the subject could freely tap the bar for small amounts of additional reward. Both subjects formed clear and stable reward preferences, selecting sweeter or less bitter rewards on free-choice trials, and tapping the bar more frequently for more preferred rewards. Therefore, bar tapping provided a time-varying behavioral measure of motivation to earn each reward. To determine whether bar tapping was motivated by expectations or actual rewards received, mismatch trials were included in which the reward delivered was not the expected reward. We found that subjects were initially motivated by expectations, but after a few seconds subjects adjusted their bar tapping, so behavior was better predicted by the actual rewards. Preliminary data from chronic electrophysiological recordings in this task suggest that the OFC is preferentially activated on mismatch trials. Using multi-probe arrays we will record simultaneously from OFC and gustatory cortex to determine how expected values and taste perception dynamically motivate behavior.

Title: Representations and dynamics in OFC and ACC in a value based decision making task

Authors: *P. ENEL[1], J. D. WALLIS[2], E. RICH[1]
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: A long line of research has shown that the orbito-frontal cortex (OFC) and the anterior cingulate cortex (ACC) are heavily involved in value based decision making. However, representations and dynamics of each of these prefrontal areas in this context are still not clear. To better characterize these aspects of neural population activity, we trained two monkeys to perform a decision making task and recorded the activity of OFC and ACC neurons. In this task, visual cues predicting an amount and type of reward were presented to monkeys. Cues represented four different amount of reward, and either a primary reward in the form of juice or a secondary reward represented by the increase of a bar presented on screen at the time of reward. Every 4 trials, monkeys cashed in the secondary reward as an amount of juice equivalent to the size of the bar. In a quarter of the trials, the monkeys were allowed to choose from two reward predicting cues while in the rest of the trials, only one cue was presented. The presentation of the cues and their associated reward were interleaved with a joystick response task introduced to keep monkeys focused. We conducted population analyses of recorded neurons to characterize the representation structures and dynamics associated with different aspects of the task, and contrasted them between OFC and ACC. Preliminary results show a sustained encoding of value and reward type throughout the trial, from cue presentation to reward delivery, including during the unrelated joystick response task.

Title: An analysis of the activity in frontal cortex ensembles during a 3-lever decision making task

Authors: *J. K. SEAMANS[1], E. EMBERLY[2], B. CARACHEO[3]
[1]Psychiatry, UBC, Vancouver, BC, Canada; [2]Simon Fraser Univ., Cancouver, BC, Canada; [3]UBC Brain Res. Ctr., Vancouver, BC, Canada

Abstract: It is often said that the rodent medial prefrontal cortex (mPFC) plays a role in decision making but it is unclear what is involved in this process from a mechanistic point of view. To gain insight into how frontal cortex neurons encode value-based decisions, tetrode recordings were performed while rats tried to determine which one of 3 randomly chosen levers was baited each day. Although the baited lever yielded a pellet every time it was pressed, there was considerable variation across rats with 6/10 exploiting the baited lever within 50-100 trials while the remainder distributed presses across the 3 levers throughout the session. We initially focused on those sessions where rats learned to exploit the baited lever. The decision process was evaluated using a multi-category logistic model where each lever was represented by an energy state as defined by the weighted linear combination of the top 15 principle components of ensemble activity. Based on a subset of trials, the model attempted to maximize the probability that a given energy state was associated with one of the 3 lever choices. The model was then used to predict lever choices based on the ensemble activity during the remaining set of test trials. The time bin where the energy level of a given lever achieved a local minimum was taken as the decision point. We found that the model achieved >95% accuracy in predicting the chosen lever on test trials if it was trained on the 5s window preceding the lever press. This was true regardless of whether the chosen lever was the one that was baited or not. However, when the training window was shifted to the time of the lever press or the time of reward delivery, performance of the model declined significantly. This implied that the ensemble states associated with the decision were different from the ensemble states associated with the lever presses or the outcomes, calling into question the assumption that the neurons 'weighed' each option during the decision process. Ongoing analyses will compare how the decision process varied across sessions with different distributions of lever press choices.

Title: How over interpretation of simple behavioral models can lead to unexpected results: In search of the optimal sampling distributions for delay values on the Restaurant Row task

Authors: *N. J. POWELL[1], S. GUPTA[2], A. R. MALHOTRA[2], J. K. SEAMANS[3]
[1]Psychiatry, [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Psychiatry, UBC, Vancouver, BC, Canada

Abstract: We attempted to utilize an optimal sampling distribution on the restaurant row task (Steiner and Redish 2014) to sample animal's decision behavior as efficiently as possible, but because the sampling distribution lead to changes in the overall economic structure of the task and a more difficult state recognition process, the "optimal" distribution ended up providing less accurate measurements of the animal's underlying preferences. In the Restaurant Row task (Steiner and Redish 2014) animals make sequential wait/skip decisions at 4 feeder locations offering different flavors of food with a randomly chosen delay on each visit. The probability of waiting out a particular delay length vs skipping it is used to determine animal's preference for each food flavor. Specifically, the animal's preferences on this task are modeled by fitting a logistic function to their probability of waiting for a reward as a function of delay length. The threshold values of these logistic functions represent the relative value of each reward option. The longer animals are willing to wait, the more valuable the reward. Previously delay values were sampled randomly from a uniform distribution, which results in a large number of easy decisions (delays well below or above threshold will be accepted or rejected at nearly 100% rates). In order to maximize the information gained from each feeder visit, it would be optimal to sample most heavily near the threshold of the sigmoid function where the information density of each decision is the highest. We therefore used delays chosen from a normal distribution with an adjusting mean matched to the animal's indifference threshold. We compared this to a uniform delay distribution and to a bimodal delay distribution where delays were primarily either below or above the indifference threshold (which was helpful for training purposes). Although overall flavor preferences seemed to be similar no matter which sampling distribution was used, we found the "optimal" sampling pattern to be the least accurate at revealing underlying flavor preferences because the distinctions between delay values for the "optimal" distribution were the least clear, and the absence of extreme decisions changed the economic framework of the task in unanticipated ways. This example is a useful reminder that although behavior may be summarized by a simplified mathematical model, full behavioral effects are only realized by considering the interactions of multiple different systems working together as a complex whole.

Title: A circuit mechanism for pro-variance bias in decision-making: Behavior, computational modeling, and pharmacology

Authors: *N. H. LAM[1], S. E. CAVANAGH[3], L. T. HUNT[4], S. KENNERLEY[3], J. D. MURRAY[2]
[1]Physics, [2]Dept. of Psychiatry, Yale Univ., New Haven, CT; [3]Sobell Dept. of Motor Neurosci., Univ. Col. London, London, United Kingdom; [4]Wellcome Ctr. for Integrative Neuroimaging, Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: In perceptual or value-based decision-making tasks, noisy stimuli can lead subjects to accumulate evidence across time as a decision strategy. In such paradigms, choice behavior can exhibit pronounced biases departing from optimal integration. In this study, we combined computational modeling of neural circuits with psychophysical choice behavior, and its alteration by pharmacology, to investigate the mechanisms of evidence accumulation in decision-making. Two monkeys (Macaca mulatta) were trained to perform a two-alternative forced-choice task. In each trial, the animal was required to discriminate the mean heights of two vertical bars whose heights varied every 250ms, with 4 or 8 samples. Critically, the sample variance for one option's stream of evidence was twice as large as the other. We found that the animals exhibited a bias in their choices toward the option with larger variance, i.e. a pro-variance bias (PVB) effect. Decision-making performance was also studied under pharmacological manipulation by subanesthetic administration of the NMDA receptor antagonist ketamine.
To investigate a potential circuit mechanism underlying the PVB, we analyzed a biophysically-based computational model of a spiking cortical circuit which was previously applied to temporal integration of evidence in perceptual decision-making (Wang, 2002). The model also exhibited a PVB, with similar magnitude to the monkeys, demonstrating a potential circuit mechanism of the PVB which is intrinsic in recurrent decision-making dynamics. Nonlinear dynamical systems analysis of a mean-field approximation provides a mechanistic explanation of the PVB in the model: strong stimuli have an asymmetrically larger effect than weak stimuli.
To relate the circuit model to the empirical ketamine behavior, we characterized the effects of NMDA receptor antagonism at two key synaptic sites: inhibitory interneurons, elevating excitation-inhibition (E/I) ratio; versus excitatory pyramidal neurons, lowering E/I ratio. We found these distinct E/I perturbations induced dissociable effects in the psychophysical kernel and PVB. In the empirical data, ketamine administration degraded performance through overall reduced sensitivity to the stimulus, but increased the weighting of stimulus variance on choice relative to the mean stimulus value. In the circuit model, we found that this pattern of behavior is consistent with lowered E/I ratio weakening accumulation of evidence. These results suggest a neural circuit mechanism for PVB in decision-making, with implications for cognitive deficits in neuropsychiatric disorders associated with cortical E/I dysfunction.

Title: Behavioural and neural evidence for irrational biases during evidence accumulation decisions

Authors: *S. KENNERLEY[1], L. T. HUNT[2], S. E. CAVANAGH[1]
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: The gradual accumulation of noisy evidence is a fundamental component of decision-making. Recent work has used tasks where subjects must count the number of evidence pulses (e.g. auditory clicks) corresponding to two choice options during a stimulus period and choose which had the most cumulative evidence supporting it when cued to respond. Humans and rats use an optimal strategy to solve these decisions, assigning equivalent weighting to evidence received throughout the stimulus period (Brunton et al. 2013). However, when combining multiple pieces of information in real-world decisions, the number of different pieces of evidence favouring each option cannot merely be counted. Instead, evidence of different sizes and valences must be accumulated to form an overall integrated value associated with each choice option. Using a more complicated task where subjects must average across multiple pieces of evidence with distinct magnitudes, systematic irrationalities in human decision-making have been characterised (Tsetsos et al. 2016). We employed a similar task design in macaque monkeys to allow us to study the neural basis of these irrationalities. Two monkeys (Macaca mulatta) were trained on a two-alternative value-based evidence integration task. A series of bars, each with different heights, were presented on the left and right-side of a computer monitor (200ms presentation; 50ms interval).The number of sample presentations was either four or eight in different trial blocks. Following a post-stimulus delay (500±250ms), subjects were cued to choose one of the two options. Before the bars were presented, a cue instructed the subjects whether choosing the option with either the highest (High Context) or lowest (Low Context) average bar-height would be rewarded. Subjects displayed a high level of performance on this challenging task; where both the number of samples to integrate and the contingency (High v Low Context) was changing across blocks of trials. Regression analysis showed subjects were

using the average bar height in the stream to guide their choices; rather than counting the number of individual frames favouring either option. However, they also displayed two key irrational behavioural biases. Firstly, subjects overweighted stimuli early in the trial - resulting in a *primacy bias*. Secondly, subjects preferred to choose options with a greater variance in evidence strength across the sample stream: *pro-variance bias*. We will investigate the neural basis of these biases, as well as contrasting the roles of different brain areas in evidence accumulation, by simultaneously recording single-neurons across Prefrontal and Parietal Cortex.

Title: An investigation of predictive coding and behavioural flexibility in the primate prefrontal cortex using multi-area, multi-electrode electrophysiological methods

Authors: *E. BOSCHIN, J. M. GALEAZZI GONZALEZ, M. O'NEILL, Z. WU, M. J. BUCKLEY
Univ. of Oxford, Oxford, United Kingdom

Abstract: Individual neurons are capable of encoding expectations about events, for example the probability of receiving a reward following an action; furthermore, they encode prediction errors when these expectations are not met, for example when a reward is not received after an action that was previously rewarded. These prediction errors are then used to compute a new, updated prediction, about the likelihood of that event. The continuous loop of predictions, prediction errors and updates, is a type of computation crucial for learning and flexible, adaptable behaviour. Single-cell neurophysiological recordings in monkeys have demonstrated that several prefrontal areas are involved in coding predictions and prediction error information. However, the study of each area in isolation has so far not allowed for elucidating how interactions between brain regions give rise to predictive mechanisms that support learning and flexible behaviour.
Here, we introduce the first study that seeks to address these questions by applying multi-electrode techniques to different frontal regions in the macaque monkey. We present exploratory results from two 64-electrode micro-arrays (‘Utah arrays’) implanted in the anterior cingulate gyrus (ACC) and dorsolateral prefrontal cortex (dlPFC), which allowed us to record both single-

and multi-unit activity, as well as local field potentials, simultaneously from both areas, while the monkey is engaged in a novel two-step navigation task within a virtual dynamic maze involving probabilistic decision-making and flexible updating of behavioural plans.
For each array, we obtained a substantial yield of about 70-80 clusters comprising single-unit and multi-unit activity. Within these clusters, we identified units that respond to task-relevant aspects of the task - such as, for example, reward and reward expectation (in both ACC and dlPFC) and state transitions (in dlPFC) - and oscillatory activity in the beta and gamma bands that appear consistent with current predictive coding theories of how predictions versus prediction errors might be transmitted across networks of neuronal populations. We discuss these findings in the context of our current understanding of predictive coding models, as well as with regards to future applications of the task to further investigate these mechanisms in other brain regions and in combination with more advanced analytical tools to address network-level dynamics.

Title: Multi-neuronal, multi-area, neurophysiological interactions underlying dynamic stimulus- and action-value coding in the macaque prefrontal cortex during learning and decision making

Authors: *M. O'NEILL, E. A. BOSCHIN, J. M. GALEAZZI GONZALEZ, Z. WU, ESQ, M. J. BUCKLEY
Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Individual neurons are capable of encoding integrated value signals that are essential to inform learning and guide decisions. For example, the expected value of receiving a reward following a stimulus or an action encoded as the product of the probability and magnitude of the expected outcomes. These values signals can be used to compute a behavioural choice, and combined coding of stimulus and action values is a type of computation crucial for learning and flexible, adaptive behaviour.
Single-cell neurophysiological recording studies have demonstrated that several prefrontal areas are involved in coding stimulus and action values. However, the study of each area in isolation

does not address how interactions between brain regions give rise to integrated value signals that support learning.
We present the first study that applies multi-electrode techniques simultaneously to four different regions in prefrontal cortex to show how interactions within and between these regions facilitates information processing and transfer about different types of value signals across the network to drive learning and decisions.
We developed a Stimulus To Action Response Task (START) that facilitates dissociation of stimulus- and action-values while macaques learn to associate stimuli and actions with probabilistic rewards. Moreover, START reveals dissociable effects on behaviour: preferences for actions based on stimuli are learnt rapidly within sessions, whereas differences in reaction times develop over days (between sessions) as habit behavior begins to form. This behavioural dissociation provides us with a means to compare goal-directed and habit-based neuronal correlates of behavior.
Four multi-electrode micro-arrays were implanted in ventrolateral prefrontal cortex (x96), dorsolateral prefrontal cortex (x32), orbitofrontal cortex (x96), and frontopolar cortex (x32) of the macaque, allowing us to record both single- and multi-unit activity, as well as local field potentials, simultaneously from all four areas, while the monkey performs START. We obtained a substantial yield of 130-140 clusters from each of the 96 electrodes in OFC and vlPFC, and 30-40 clusters from each of the 32 electrodes in FPC and dlPFC. Within these clusters, we identified units that respond to event-related aspects of the task such as visual cues (predicting rewards) and juice rewards, and oscillatory activity in the beta-gamma bands evoked by cues and rewards in OFC, and rewards in vlPFC, dlPFC and FPC. These observations are consistent with the suggestion that OFC is predominantly involved in learning cue-reward associations relevant for goal-based decision-making processes.

Title: Exploring the underlying computations and functional interactions of macaque prefrontal areas in rule-based decision making: Recording simultaneously from multiple chronically implanted multi-electrode arrays

Authors: *J. M. GALEAZZI, *J. M. GALEAZZI GONZALEZ, E. A. BOSCHIN, M. O'NEILL, Z. WU, M. J. BUCKLEY
Univ. of Oxford, Oxford, United Kingdom

Abstract: Previous studies have identified several prefrontal areas that contribute to separable cognitive processes in rule-guided behavior. Using a Wisconsin Card Sorting Test (WCST) analog, it has been suggested that the dorsolateral prefrontal cortex (dlPFC) plays an important role in maintaining the representation of an abstract rule in working memory while the ventrolateral prefrontal cortex (vlPFC) supports rule implementation. The orbitofrontal frontal cortex (OFC) plays a prominent role in rapid updating representations of rule value based on reward, while the anterior cingulate cortex (ACC) plays a key role in executive task control, integrating information for correct and incorrect trials. Moreover, recent studies exploring the role of the frontopolar cortex (FPC) suggest a key role in representing the relative value of unchosen alternative rules or stimuli. As neuronal activity from these different areas was not previously recorded simultaneously we do not yet understand the underlying computations and functional interactions operating within and between these regions. We present here the first study that applies multi-area multi-electrode recording techniques to five different frontal regions implicated in rule-guided behaviour. Multi-electrode micro-arrays ('Utah arrays') were chronically implanted in dlPFC, vlPFC, OFC, ACC and FPC of the macaque, allowing us to simultaneously record single and multiunit activity and local field potential (LFP) from all five regions while the monkey performs a WCST analog. Here we present preliminary results showing the neural activities underlying the representation of abstract rules. We obtained a typical daily yield of 90-110 separable clusters from all arrays combined, with single and multiunit activity responsive to different task-relevant components. For example, we found pre-reward and post-reward unit responses in dlPFC and vlPFC, in some cases signaling expected reward delivery and maintaining this firing activity. In OFC, we predominantly observed units with more delayed post-reward response. These responses are consistent with a role of dlPFC and vlPFC in maintaining abstract rule representations; wheras OFC responses update after the reward has been delivered to determine rule value. We found similar patterns in FPC, including units with pre-reward firing followed by an immediate decay. We also found a modulation of LFPs within beta and gamma bands in FPC, whereas power increases in delta and theta were observed in dlPFC, vlPFC and OFC. We discuss these findings and provide a theoretical framework of how these regions interact.

Title: The effects of frontopolar cortex lesions on resting state functional connectivity networks in non-human primates

Authors: *M. J. BUCKLEY, M. AINSWORTH, A. BELL, Z. WU
Oxford Univ., Oxford, United Kingdom

Abstract: Recent lesion studies demonstrate that macaque frontopolar cortex (FPC) plays essential roles in mediating exploration and rapid learning about the relative value of alternatives of a broad kind (Boschin et al., 2015; Mansouri et al., 2015; 2017). However, little is known about the influence of FPC upon whole brain networks. Resting state functional connectivity (rsfc) analyses examine the correlations in spontaneous brain activities in the absence of external stimuli or task demands and so offer a tool for understanding functional organization across whole brain networks. In our study, we performed rsfc scans on thirteen monkeys (control group) once, and seven other monkeys (FPC lesion group) post-operatively (eight weeks after lesions). By applying a fine-scale atlas to parcellate macaque brain regions (Van Essen et al., 2011), we acquired rsfc data from 260 regions in both lesion and control groups. We first applied a brain-wide search for the difference between the two groups using a non-parametric permutation test, which revealed that there were 59 regions wherein significant changes in rsfc with other areas were identified. Most of the functional connections among the 59 regions were enhanced in the lesion group compared with the control group. To aid visualization, we applied K-means clustering to further divide the 59 regions into 8 clusters, roughly corresponding to frontal, somatosensory, parietal, cingulate and temporal regions. By applying multidimensional scaling analysis, most of the clusters fall closer together in scaled space in the lesion group compared with the control group. Specifically, connectivities between frontal and other regions (e.g. somatosensory, temporal, parietal) were typically enhanced, while decreased connections were typically observed between cingulate, somatosensory and temporal regions. We interpret these results in the context of FPC-mediated influence on brain networks extending both within and beyond prefrontal cortex.

Title: ACC LFP-aided decoding of EEG signals during sequential foraging decisions

Authors: *A. RAMAKRISHNAN, D. BERKAY, M. L. PLATT
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Food, water and other essential resources are often distributed in spatially localized patches in the environment and foraging animals must choose whether to continue staying in a depleting patch or to leave for a richer one. The marginal value theorem (MVT) provides a normative approach to maximize energy intake by determining the optimal time to depart a patch based on the overall richness of the environment. Although animals, including humans, obey the MVT on average, they display systematic individual differences in foraging behavior. Stress, anxiety or subclinical psychiatric conditions like depression may underlie these behavioural biases. Understanding the neural basis of foraging decisions may help to determine biomarkers to identify these biases and develop possible interventions to mitigate them. Previously, in our lab, we measured neuronal spiking activity in primate dorsal anterior cingulate (dACC) - a brain region involved in monitoring reward and exercising cognitive control. We found that dACC neurons encoded a decision variable that signalled the relative value of leaving a depleting resource for a new one, and Kolling et al 2012 identified a similar signal in foraging humans using fMRI. Here we build on and extend these findings by examining ACC local field potentials (LFPs) - that reflect the input signals to the ACC and contribute to the scalp EEGs - for information guiding foraging decisions. To do this, we obtained LFPs from 2 NHPs using linear multichannel arrays and identified the relevant temporal and spectral components of the LFP-based decision signal. We also obtained EEG from 45 human participants using a modified Emotiv wireless EEG device performing the same foraging task and assessed the feasibility of identifying the relevant LFP components in the EEG signal. Preliminary results suggest that LFPs indicate when and whether NHPs will choose to abandon a patch. Strong modulations in the theta, beta and gamma bands were observed around the time of leave decisions. A supervised machine learning algorithm trained on LFPs could predict decision time significantly better than chance. Next we will identify and extract the relevant signal components from the above-mentioned algorithm to inform EEG data analysis to predict biases in foraging decisions.

Title: Using EEG and pupillometry in a foraging task to establish biomarkers for anxiety

Authors: *D. BERKAY, A. RAMAKRISHNAN, J. A. STYLLI, M. L. PLATT
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Reward maximization while foraging is a crucial problem all animals, including humans, need to solve. Although both human and non-human animals adopt optimal foraging strategies on average, individuals vary considerably in their foraging behavior. Variation in the fundamental computations underlying foraging may provide a powerful opportunity to identify biomarkers of neural circuit dysfunctions associated with mental disorders, thereby obviating the need to obtain self-report and potentially providing deeper insights into the neural mechanisms that cause neuropsychiatric disorders. A neural circuit connecting posterior and anterior cingulate cortices with norepinephrinergic neurons in the locus coeruleus has been implicated in variation in foraging behavior. This circuitry is also associated with anxiety disorders, suggesting a possible biological connection between the two. To test this idea, we measured the behavior of human participants performing a patchy foraging task where they made stay/leave decisions in environments varying in richness, while we monitored pupil size, which indexes norepinephrine tone, and EEG-based frontal theta band signals associated with anxiety. Anxiety was assessed by self-report using the State-Trait Anxiety Inventory. We found that a supervised machine learning algorithm could predict anxiety scores using patch leaving time, pupil diameter, and EEG theta band power. To test the functional links between these potential biomarkers and anxiety levels, we conducted a second study in which we exposed participants to physical and social stress and then measured changes in behavior. Preliminary results reveal that increasing anxiety through stress induction provokes earlier patch leaving times. Together, our results show that both momentary and long-term anxiety can be decoded from EEG and pupil dynamics during foraging, reflecting computations that are fundamental to the behavior, and ultimately, biological success of all animals. These findings may provide new approaches for early detection of neuropsychiatric disorder onset, monitoring response to treatment, and relapse prevention, particularly in individuals, such as children, for whom self-report is less reliable.

Title: Decoding spatial position reveals prospection and working memory in rodent rat cingulate cortex

Authors: *A. J. GRUBER[1], A. MASHHOORI[2], D. R. EUSTON[3]
[1]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Univ. of Lethbridge, Lthbridge, AB, Canada; [3]Univ. Lethbridge, Lethbridge, AB, Canada

Abstract: The anterior cingulate cortex (ACC) encodes information supporting mnemonic and cognitive processes. Moreover, individual ACC cells in rodents have very broad representation of space. We show here that ensemble ACC activity in a behaving rat can be decoded via machine learning to accurately predict an animal's position on a track with high spatiotemporal resolution. A deep neural network was over 30% more accurate than a Bayesian decoder. ACC neurons encoded the current state of the animal and task, except for brief excursions that sometimes occurred at target feeders. During excursions, the decoded position became more similar to a remote target feeder than the rat's physical position. Excursions recruited activation of neurons encoding choice and reward, and the likelihood of excursions at a feeder was inversely correlated with feeder preference. These data suggest that the excursion phenomenon was related to evaluating real or fictive choice outcomes, particularly after disfavoured reinforcements, similar to proposals derived from experiments in primates. We propose that the multiplexing of position with choice-related information forms a mental model isomorphic with the task space (e.g. a cognitive map), which can be mentally navigated via excursions to recall multimodal information about the utility of remote locations. We suggest this dynamical phenomenon may be a form of prospection. We further found that controlling for position-related variance of neural firing revealed evidence of a memory trace that could disambiguate the sequential context of a common running trajectory in a multi-trajectory sequence task. We suggest that this is a working memory. In sum, we propose that encoding of spatial aspects of a task in ACC serves as a framework for the encoding of memories over short and long time scales.

Title: Early network dynamics underlying the maturation of the medial entorhinal cortex

Authors: *F. DONATO, S. G. COGNO, H. A. OBENHAUS, R. I. JACOBSEN, M.-B. MOSER, E. I. MOSER
Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) contains the basic elements of the brain's representation of space. The most abundant cell type contributing to this representation is the grid cell, which is active at multiple spatial locations (fields) that are arranged in a hexagonal pattern tiling the entire available environment. Since no external stimuli occur with a grid-like pattern, this periodic firing is likely generated by intrinsic network computations supported by local microcircuit connectivity. Grid cells exhibiting correlated firing in one context (i.e., grids of the same module and with the same fields location) are still correlated when the animal explores a different enclosure, or when activity is driven by self-organized dynamics during sleep. This suggests that synaptic connectivity in the network is hard-wired into a topology that supports the regular firing of grid cells. However, the regular firing of grid cells emerges at the end of a protracted period during postnatal life that coincides with the structural and functional maturation of the network. The mechanisms underlying the developmental refinement of the grid map are still unknown: cells with correlated firing could be pre-configured to connect preferentially based on their developmental origin; alternatively, synchronous firing might emerge during maturation to shape functional connectivity. Here, we want to investigate how correlated activity among ensembles of neurons evolves in the developing MEC network (P14-P35). To this end, we induce the expression of a genetically encoded calcium indicator through an ultrasound-guided viral injection on postnatal day 1, and image the activity of large populations of neurons in layer two of the MEC while mice perform a spontaneous locomotor task under a 2-photon microscope. Our results indicate the presence of subsets of neurons that repeatedly fire together from P14 on. The number of subsets, the number of neurons that each subset contains and how robust those subsets are changes with maturation. This suggests that early network dynamics shape the connectivity, and thus the correlation structure, of the entorhinal network. Nevertheless, preconfigured ensembles might account for the subsets of correlated neurons observed early during development.

Title: Episodic time coding in lateral entorhinal cortex

Authors: *A. TSAO[1], J. SUGAR[1], L. LU[1], C. WANG[2], J. J. KNIERIM[2], M.-B. MOSER[1], E. I. MOSER[1]
[1]Kavli Inst. for Systems Neurosci., Trondheim, Norway; [2]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: The encoding of time and the binding of time to events are critical components for episodic memory, but how these processes are carried out within the hippocampal-entorhinal circuit is still unclear. Here, we investigated temporal coding in lateral entorhinal cortex (LEC). We focused on LEC because (i) this area is a major source of cortical input to the hippocampus, (ii) previous work has shown that responses in LEC to physical stimuli could be unstable across time, and (iii) a clear underlying function has not yet been defined for LEC. We recorded neural activity for more than an hour while rats ran in a box whose walls alternated between black and white over 12 trials (461 cells from 3 male rats). An extended number of trials was used to increase the likelihood that animals defined multiple temporal contexts across the experiment, and to allow the effects of wall color to be separated from the effects of any temporal coding. We previously found that temporal information was robustly encoded within the overall population state in LEC during free behavior, and widely distributed across the entire LEC population through cells exhibiting classical linear selectivity for time as well as cells exhibiting mixed selectivity for time and other external features (Tsao et al., SfN 2017). We have now examined LEC activity at both the single-cell and population level in more detail. At the single-cell level, for cells exhibiting selectivity for time in the form of ramping activity, we measured their time constants, and found that they spanned a wide range, suggesting that this subpopulation of cells is capable of carrying temporal information across a wide range of timescales. At the population level, we characterized the evolution of population activity in LEC using various distance measures on population activity states and found that population activity changed in a manner reflecting the animal's experience, as opposed to trivial noise. We previously also reported on changes in LEC activity at the single-cell level when animals' experiences were constrained by structured behavioral tasks to be similar across repeated trials. We have now looked at population-level encoding of time during these tasks, and find that the encoding of temporal flow across trials was reduced while the encoding of relative passage of time within single trials was improved (334 cells from 5 male rats), suggesting that temporal information arises inherently from the representation of experience being generated in LEC. Overall, the temporal information we observe in LEC may be integrated with spatial inputs from MEC in the hippocampus, allowing the hippocampus to store a unified representation of what/where/when.

Title: Object-vector coding in medial entorhinal cortex: Object shape and object dimensions

Authors: E. R. SKYTØEN[1], Ø. A. HØYDAL[2], S. O. ANDERSSON[1], *E. I. MOSER[3,1], M.-B. MOSER[1]
[2]Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, Norw, [1]NTNU, Trondheim, Norway; [3]Kavli Inst. Systems Neurosci, Trondheim, Norway

Abstract: Mammals use distances and directions from local objects to guide navigation, but how such vector-based navigation strategies are implemented in neural representations of space has not been resolved. Recently, we reported that a class of cells in the medial entorhinal cortex (MEC) encodes allocentric vectors to discrete objects in the environment (Høydal et al., SfN 2017). Recordings from more than 500 MEC cells in more than 8 adult male C57B6 mice show that such 'object-vector cells' (more than 100) fire whenever the animal is at a certain direction and distance relative to an object, independently of the direction of movement through the location and independently of whether objects are novel or familiar. When the object is displaced, the firing fields of object-vector cells move accordingly, so that tuning to object distance and direction remains constant. Object-vector encoding occurs irrespective of object identity, but exactly how object shapes and dimensions influence the firing properties of the cells has not been determined. To address this question, we recorded object-vector cells in the MEC of freely moving male mice while systematically varying the size of objects in the animal's proximal environment. Our data show that object-vector cells respond strongly to objects that vary more than an order of magnitude in diameter (for cylinders), length (for prisms with a rectangular base), or height (for prisms with a square base). We found no strong tendency for object-vector cells to encode specifically vectors from objects of any particular shape or dimension, except that tall objects elicited more firing than flat objects of similar width. A small subset of object-vector cells also responded to peripheral walls of the recording box (border cells) but for such cells there was often no correlation between distance and direction from object and wall, respectively, suggesting that object-vector cells respond to a wider class of objects, with other properties, than border cells and boundary-vector cells. Collectively, our observations show that object locations are integrated into metric representations of self-location, with

specific subsets of MEC neurons encoding vector relationships to individual objects of a wide range of shapes and dimensions.

Title: The relationship between the relative firing rates of individual grid fields and hippocampal remapping

Authors: *C. LYKKEN[1], B. R. KANTER[1], J. DICKINSON[2], K. ASUMBISA[1], C. G. KENTROS[1]
[1]Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway; [2]Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Place cells in the hippocampus fire action potentials in specific locations in the environment. They are stable across repeated exposures to the same environment, but they remap in distinct environments, exhibiting unpredictable changes in their firing rate and/or location. Under the same conditions that elicit remapping, the hexagonal pattern of grid cells in medial entorhinal cortex (MEC) layer II (a main input to the hippocampus) shifts and/or rotates (Fyhn et al., 2007). However, all evidence thus far indicates that grid cells shift coherently, which is therefore incapable of producing the orthogonal spatial representation observed during hippocampal remapping. We recently uncovered an additional mechanism whereby changes in the firing rates of individual grid fields drive remapping of place cells, even when grid field locations remain stable (Kanter et al., 2017). We did this by manipulating the activity of a subset of MEC layer II neurons using transgenic expression of an hM3Dq DREADD (Designer Receptor Exclusively Activated by Designer Drugs). Injection of the designer ligand clozapine-N-oxide (CNO) depolarizes MEC neurons and causes remapping of CA1 place cells in a familiar environment. Here, we further explore the relationship between grid field firing rate changes and place cell remapping. First, we show that changing the firing rates of individual grid fields is

sufficient to cause remapping in a winner-take-all model of grid-to-place cell formation (de Almeida et al., 2012). Furthermore, in both experimental and simulated data, we can successfully predict where a place cell will remap to based on its activity pattern before CNO administration. We then demonstrate that the dynamics of the CNO-induced remapping tightly correlate with the CNO-induced changes in grid field firing rates. More specifically, we observed that the changes in grid field firing rates and the remapping in CA1 both exhibited high short-term stability. Over several hours, however, there were subtle changes in the rankings of individual grid fields that were concomitant with a partial reduction in the stability of the CNO-induced remapping. Critically, when the rankings of individual grid fields reset following an extended break in the recording, place cells also resumed their baseline firing patterns. Finally, we demonstrate that repeating our manipulation (by injecting CNO again the following day) elicited similar changes in grid field firing rates and place field locations, which is also recapitulated by our model. Taken together, we provide strong evidence that the firing rates of individual grid fields play an important role in determining place field location.

Title: Functional characterization of neurons in layer V of the medial entorhinal cortex

Authors: *D. C. ROWLAND[1], H. A. OBENHAUS[1], R. R. NAIR[1], C. G. KENTROS[2], E. I. MOSER[3], M.-B. MOSER[3]

Abstract: Layer V of the medial entorhinal cortex (MEC) consists of two sublayers: a superficial layer Va and a deep layer Vb (Sürmeli et al., 2015). The principal cells in these two sublayers differ dramatically in their morphology, gene expression and connectivity. Most notably, Layer Va is the nearly exclusive output from the MEC to areas outside the hippocampal and parahippocampal region, including the prefrontal and retrosplenial (RSC) cortices. In contrast, layer Vb cells appear to project mainly within the entorhinal cortex. Although layer Vb cells project mostly locally, they receive input from both hippocampal and non-hippocampal sources, positioning them as key integrators in the circuit. Therefore, knowing the functional properties of cells in these two sublayers is critically important for understanding local computations within the MEC and the contribution of the MEC to the global network. To address the functional properties of layer Va cells, we used AAV-retro viruses (Tervo et al., 2016) carrying ChR2/H134R into the RSC of wild-type mice and targeted optrodes to layer Va of the MEC (Rowland et al., SfN, 2017). The retrograde spread of the modified virus from the RSC to the MEC labelled layer Va cells nearly exclusively and allowed us to identify the cells in vivo using an optogenetic tagging approach. The identified Va cells displayed high levels of mixed selectivity. The tagged Va cells were most often informative of some combination of position, direction and running speed, but were rarely canonical grid cells or head direction cells. Thus, the output from the MEC appears to be a multiplexed representation of position, direction and speed. To target layer Vb cells, we turned to a new transgenic mouse line that expresses tTA nearly exclusively in layer Vb of the entorhinal cortex (Blankvoort et al., 2018) and injected these mice with a tTA-dependent virus carrying the channelrhodopsin-2 variant oChief for optogenetic tagging. Functional characterization of this line is in progress.

Abstract: The medial entorhinal cortex (MEC) is thought to create a map of local space using a set of functionally specific and largely distinct cell types: grid cells, head direction cells, border cells, speed cells, and object-vector cells. If and how the functional characteristics of those various cell types are reflected in the anatomical organization of the MEC network is still under debate, however. A non-random anatomical organization would be consistent with the patchy organization of entorhinal layer 2 (Burgalossi et al., 2011) as well as reports of anatomical clustering among grid cells (Heys et al., 2014). Yet a clear understanding of the broader organization of the multi-cell-type network, at both micro and macroscales, has been held back by the absence of suitable neurophysiological methods. While single-unit electrophysiological recordings in freely moving animals enable the precise characterization of cellular firing properties, anatomical relationships can only be indirectly inferred. In vivo two-photon calcium imaging allows for the quantification of firing behaviors of large numbers of simultaneously recorded neurons as well as their precise anatomical organization. However, current two-photon microscopy systems require the animal to be head-fixed and spatial tuning is then inferred from navigation in virtual environments, which have been shown by a number of groups to be problematic for the analysis of spatially selective neurons. Here we show results from imaging large areas of MEC in more than five C57Bl6 mice using a miniaturized two-photon microscope (Zong et al., 2017). The newly developed microscope weighs 2.4 grams and allows recordings of GCaMP6-labelled cells in layer 2/3 of MEC via a compound implant consisting of a gradient refractive index (GRIN) lens and a micro prism implanted in between MEC and the cerebellum. With a 410x410 µm field of view, it allowed us to record simultaneously from several hundred cells in MEC labelled with genetically encoded calcium indicators in animals moving around in a 80x80 cm large open field. The resolution of the two-photon system allowed us to obtain recordings from cellular compartments as well as whole populations of neurons comparable to state-of-the-art benchtop microscopes. Miniaturized two-photon microscopy therefore enables unprecedented insights into the anatomical and functional network architecture of spatially modulated cell types in MEC and other brain regions.

Title: Positive acceleration selectively controls theta frequency in the hippocampus and entorhinal cortex

Authors: *E. KROPFF CAUSA[1,2], J. E. CARMICHAEL[3], M.-B. MOSER[2], E. I. MOSER[2]
[1]Leloir Inst. - IIBBA - CONICET, Buenos Aires, Argentina; [2]Kavli Inst. Systems Neurosci, Trondheim, Norway; [3]Psychology and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Local field potential oscillations provide clues to understand the dynamics of large populations of neurons. In rats, the theta rhythm organizes neural activity across brain structures including the hippocampus and entorhinal cortex. Recent evidence points to a role of the theta cycle in packing together related information to produce an epoch of local computation. An additional role in spatial navigation is supported by decades of research reporting that theta frequency encodes running speed linearly, so that displacement can be obtained through theta frequency integration. Here we show, however, that this relationship is an artifact caused by the fact that, until the recent introduction of the bottomless car paradigm, the speed and acceleration of rats could not be systematically disentangled. Our results indicate that theta frequency is linearly related to positive acceleration alone, and not modulated by negative acceleration or speed (Kropff et al., SfN 2017). The rhythmic spiking of neurons follows a similar pattern, implying that both theta frequency and rhythmic spiking are nonholonomic and thus non-univocally related to displacement or any other kinematic variable. This control of theta frequency by acceleration does not require visual or motor cues, and is independent of phase precession-related variations of intrinsic firing frequency. Our results suggest that variations in theta frequency reflect a temporally precise mechanism for speeding up computations in the entorhinal-hippocampal circuits. We extend previous reports by speculating on the purpose of frequency increase. The entorhinal path integrator presumably uses information about speed but not about acceleration, as suggested by failed attempts to find acceleration-coding cells. During acceleration episodes, it should make errors in the estimation of the rat's trajectory, causing an alteration in grid spacing, as suggested by preliminary evidence that we here provide and discuss for the first time. Performing a greater number of shorter computational steps during these

acceleration episodes might help the system to improve statistics on one hand and to reduce the magnitude of these errors by reducing the temporal integration window on the other.

Title: Grid cell formation and early postnatal experience

Authors: *I. U. KRUGE, T. WAAGA, T. WERNLE, E. I. MOSER, M.-B. MOSER
Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) contains functionally specific cell classes that dynamically represent an animal´s location. A key cell type is the grid cell, whose receptive fields tile the environment in a strikingly hexagonal fashion. A central question is whether the emergence of this pattern reflects maturational processes, or whether it is shaped also by early postnatal experience. Whereas place, head direction and border cells have adult-like features when rat pups leave the nest for the first time, grid cells continue to develop for another two weeks (Langston et al. and Wills et al., Science 2011). To determine whether the extended maturation of grid cells makes them more sensitive to spatial experience, we raised 7 male or female rats for the first months of life in opaque spherical homes (Kruge et al., SfN 2016). These environments deprived the rats of opportunities to anchor representations to borders. Control animals were raised in opaque cubical boxes (n=4), or in transparent enriched environments (n=4). At mean age 13-16 weeks, animals were implanted with tetrodes in MEC. After recovery in the home environment, each animal was briefly taken out and tested for the first time in an open square food-foraging box. Testing was repeated on 2-7 consecutive days. In sphere-raised animals, the final analyses show that the symmetric, hexagonal firing pattern of grid cells was nearly absent during the first trial in the open square (only 6% grid cells). Rats raised in cubical cages displayed strong periodic firing from the onset (15% grid cells), indistinguishable from that of rats raised in enriched environments (15% grid cells). However, after repeated exploration of the open square, periodic grid patterns appeared also in sphere-raised animals (25% grid cells), suggesting that the initial deficit can be overcome. In the present report, we examine the

effect of timing of the geometric deprivation. The effect of rearing environment was age-specific. Adult rats (n=4) moved from enriched to spherical environments for minimum eight weeks showed no subsequent disruption in grid patterns (17% grid cells). Altogether, our results suggest (i) that a minimum of experience with geometric boundaries, at young age, is required for stable grid patterns to be formed rapidly in new environments, (ii) that the effect of restricted spatial experience can be overcome with relatively short training, pointing to a strong role for maturational processes, and (iii) that there is a sensitive period for experience-related effects on grid cell formation, where exposure to environmental boundaries is required for the ability to rapidly form grid patterns only at a young age.

Title: Correlation structure of grid cells is preserved during sleep

Authors: *R. GARDNER[1], L. LU[2], T. WERNLE[3], M.-B. MOSER[4], E. I. MOSER[4]
[1]Kavli Inst. for Systems Neurosci., Trondheim, Norway; [2]Baylor Col. of Med., Houston, TX; [3]Kavli Inst. for Systems Neuroscience/Cnc, Trondheim, Norway; [4]Kavli Inst. Systems Neurosci, Trondheim, Norway

Abstract: The periodic spatial receptive fields of grid cells in the medial entorhinal cortex (MEC) are hypothesized to provide a universal coordinate system for physical space. The mechanisms that generate grid patterns are unknown, but the continuous attractor family of models is noteworthy since it predicts several essential features of grid cells - particularly, modular organization and invariant spatial relationships between grid cells within a module. Crucially, continuous attractor models rely on patterned recurrent connectivity in which cells with similar receptive fields are preferentially connected. We predicted that such a connectivity scheme would give rise to population activity patterns which persisted beyond navigational periods. We identified sleep as an ideal state in which to probe for signatures of continuous-

attractor-like connectivity, due to the absence of environmental influences on MEC network activity.
We recorded from MEC grid (n = 138), head-direction (HD, n = 95) and conjunctive grid-HD (n = 39) cells in adult male rats (n = 7), during open-field foraging (RUN), slow-wave sleep (SWS) and REM. We calculated functional connectivity (FC) between co-recorded cell pairs by fitting a generalized linear model (GLM) to the cells' spike rates, including the global population rate as a covariate. This allowed us to estimate FC between cell pairs, independently of global rate fluctuations.
The spatial phase offset of grid-cell pairs within a module was negatively correlated with the cell pairs' FC during SWS and REM sleep: cell pairs with small phase offsets showed positive FC, while cells with large phase offsets showed negative FC. Strong FC was not seen between grid cells from different modules. Additionally, HD phase offset in pairs of grid-HD and pure HD cells was negatively correlated with FC during sleep. We hypothesized, based on the preservation of MEC spiking correlations, that a latent grid signal persists within grid-cell population states. By modelling the latent grid signal as a random-walk process, we estimated the grid drift rate that best explained the FC temporal dynamics. We observed a 4-5-fold acceleration of the estimated grid drift rate in SWS relative to RUN. Furthermore, the relationship between grid scale and drift rate during RUN was lost during SWS.
In summary, we find a fixed, modular correlation structure in MEC that spans arousal states, as would be expected in a continuous-attractor-type network. Further investigations may elucidate the brain areas and cell types participating in grid module networks - particularly CA1 place cells, which provide an essential input to grid cells in some continuous attractor models.

Title: Theta-phase dynamics of retrospective and prospective positions signals in medial entorhinal cortex

Authors: *A. Z. VOLLAN, R. J. GARDNER, M. B. MOSER, E. I. MOSER
Fac. Of Med. and Hlth. Sciences, NTNU, Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: Cells in the rodent hippocampus (HC) and medial entorhinal cortex (MEC) are characterized by their sharp spatial receptive fields during navigational tasks. However, there is evidence that HC and MEC cells do not merely signal the animal's current location, but also inform about locations in the near past and future. Theta phase precession (seen in HC place cells and MEC layer II grid cells) demonstrates that individual units' spatial receptive fields change position as a function of spike theta phase (O'Keefe & Recce, 1993; Hafting et al., 2008). Furthermore, HC place-cell ensemble recordings have suggested that place field position shifts are coherent, representing trajectories that move forward from the animal's present position each theta cycle (Foster & Wilson, 2007; Feng et al., 2014; Sanders et al., 2015). This phenomenon, typically called "theta sequences", "look-ahead" or "mind-travel" has been hypothesized to support alternating encoding and retrieval epochs (Hasselmo, 2014) and goal-directed route planning (Wikenheiser & Redish, 2015), and has been hypothesized to be driven by the MEC grid-cell network (Sanders et al., 2015). However, the prevalence and ensemble-level coherence of retrospective/prospective signalling in MEC is poorly understood.
To investigate the representation of past and future position in MEC, we analysed recordings of grid cells (n = 813) from adult male rats (n = 16) while the animals foraged in an open field arena. We systematically shifted the locations of spikes retrospectively and prospectively in space, using the rat's head direction to determine the shift direction. We measured each cell's prospective/retrospective (P/R) bias by finding the position shift that maximized its spatial information. We observed a continuum of P/R biases among the population of grid cells, which was strongly linked to the cells' theta phase preference: trough-locked cells were more prospective in their signalling, while peak-locked cells were more retrospective. This relationship supports the hypothesis that individual cells' P/R representations are dictated by an underlying P/R network state. Furthermore, we observed more burst-firing in prospective cells than in retrospective cells, suggesting that anatomical cell types are differentially involved in P/R signalling. We are presently employing large-scale ensemble recordings in MEC to investigate how P/R signals are coordinated within/between grid modules and anatomical layers.

Title: The effect of recent experience on hippocampal remapping and spatial memory impairment

Authors: *V. A. KVEIM, B. R. KANTER, C. LYKKEN, C. G. KENTROS
Kavli Inst., Trondheim, Norway

Abstract: Hippocampal place cells are thought to support the spatial component of episodic memory. Each cell is active within a particular place in an environment (place field), and this representation can be stable for many days. When an animal enters a distinct environment, however, place cells remap (change their firing rate and/or location) to form an orthogonal spatial representation. Although previous work has established a link between remapping and memory impairment, task performance can be preserved following extensive remapping under some conditions (Jeffery et al., 2003). Remapping is typically caused by switching contexts or altering sensory cues, but we recently reported a novel technique to induce remapping without any changes to the environment (Kanter et al., 2017). To do this, we used transgenic mice expressing the hM3 DREADD (Designer Receptor Exclusively Activated by Designer Drugs) in a subset of stellate cells in medial entorhinal cortex (MEC) layer II, the main spatial input to the hippocampus. Injection of the designer ligand clozapine-N-oxide (CNO) depolarized MECII neurons and elicited remapping of CA1 place cells in a stable open field environment. In a separate group of animals, the same manipulation impaired performance in the Morris water maze. Since animals were not recorded while performing a spatial task, it is still unknown whether remapping is the primary cause of this memory impairment. To directly address this question, we recorded place cells while well-trained animals performed a hippocampal-dependent Y-maze task following depolarization of MECII neurons. Spatial memory was impaired in this task as well if there was a 24-hour delay between the test session and the previous training session, but not if the delay was only 30 minutes. Surprisingly, we observed extensive remapping of CA1 place cells regardless of the timing, which raises the question of why performance differed between the two protocols. One possibility is that the hippocampal map exhibits hysteresis after a training session, thereby enabling a smooth transition between place cell representations. Interestingly, the hippocampal representation was biased toward task-relevant locations of the maze (decision and reward) in both training and test sessions, and task performance increased both within a test session and between consecutive test sessions. Taken together, these findings suggest that animals can rapidly learn to use a new hippocampal map to guide a previously learned behavior.

Title: Optical stimulation of the pathway from the basolateral amygdala to the medial entorhinal cortex in rats enhances retention of spatial learning

Authors: *K. L. WAHLSTROM[1], R. T. LALUMIERE[2]
[2]Dept. of Psychological and Brain Sci., [1]Univ. of Iowa, Iowa City, IA

Abstract: Previous work on multiple memory systems suggests that spatial learning is mediated by hippocampus-based systems and that the basolateral amygdala (BLA) modulates the consolidation for this type of learning. The medial entorhinal cortex (mEC) is a critical region in the hippocampus-based system for processing spatial information and, as an efferent target of the BLA, is the likely mechanism by which the BLA influences spatial learning. Therefore, the present study examined whether optically stimulating activity in the BLA-mEC pathway alters the consolidation of spatial learning. Previous studies also suggest that hippocampus-based and caudate-based systems compete in the consolidation of spatial and cued-response memory, respectively. Therefore, this study also examined whether optically stimulating the BLA-mEC pathway alters the consolidation of cued-response learning. To address these questions, the BLA of male Sprague-Dawley rats were transduced to express ChR2(E123A), and fiber optic probes were implanted in the mEC to provide illumination of BLA axons. A Barnes maze was used to assess learning. During the training trials, the escape port of the maze was either located in the same position for each trial (spatial) or was marked with a distinct cue immediately above it, and the port and cue were moved in unison to a different cardinal direction for each trial (cued-response). Rats were given consecutive training trials on either task, followed immediately by 15 min of optical stimulation (8 or 40 Hz) of the BLA-mEC pathway. Rats were returned to the Barnes maze 2 d later for a single retention test. Rats that received 8 Hz but not 40 Hz optical stimulation of the BLA-mEC pathway following spatial and cued-response training had enhanced and impaired retention, respectively. These findings are consistent with the hypothesis that the neural systems mediating these two types of learning compete with one another. A follow-up study was conducted to examine ARC (activity-regulated cytoskeleton-associated protein), a plasticity-associated protein implicated in hippocampal-dependent learning and memory. Male and female Sprague-Dawley rats were trained on the spatial or cued-response version of the Barnes maze, and were sacrificed 1 h after the start of training. Brains were removed and flash-frozen and tissue punches were collected for ARC protein analysis. Western

blot was used to determine the density of ARC protein in the dorsal hippocampus. Results revealed that there were significantly higher levels of ARC in the dorsal hippocampus of male and female rats that were trained on the spatial task compared to both the cued task and a no-training control group.

Abstract: A key tenet of hierarchical reinforcement learning (HRL) is the relevance of different levels of temporal abstraction at different stages of learning and planning. When planning hierarchically, the brain should be able to flexibly specify the resolution of its state representation. Given that the hippocampus and entorhinal cortex are thought to be important brain areas for representing state, we developed a model of the hippocampal-entorhinal circuit and investigated whether the temporal resolution of state can be modulated and adapted for diverse cognitive functions.
Building on work describing grid cells as encoding eigenvectors of the environment transition matrix (Stachenfeld et al, 2017), we show how such entorhinal representations can be flexibly adapted to timescales of interest. This type of grid code “factors” the representation of time and position within a task such that a linear readout of a position-sensitive grid population and a distinct neural population encoding time predicts position at the encoded timepoint. This mechanism can be applied forward in time for prospective planning or backwards in time in order to flexibly modulate the temporal window of credit assignment during learning. In the context of HRL, if the time-coding cells encode a timepoint far into the future then a single circuit iteration outputs an estimate of the stationary state distribution which reflects the hierarchical structure of the environment. This representation can then be utilized as a pseudo-

reward “map”. According to this mechanism, higher pseudo-rewards are attributed to, for example, topological junctions which have previously been proposed as natural subgoals for HRL.
Furthermore, the recurrent nature of the entorhinal-hippocampal circuit has a natural correspondence in our model which supports the “roll-out” of place cell activation sequences. With simulations, we show how the time-coding population can dynamically scale the temporal coarseness of sequential position sampling, leading to non-local “jumps”. These jumps can interleave global position shifts with local searches and selectively visit natural subgoals in accordance with the multi-scale structure of the environment. Thus, this dynamical mode of our model can support the retrieval of states in an order distinct from that in which they were experienced but which is optimized for planning. In addition, our model replicates several empirical phenomena influenced by environment topology, such as the rapid sweeping of sequential place cell activity to and from maze junctions, a behavioral bias toward traversing environment boundaries, and the Levy walk statistics of large-scale foraging.

Title: A topographical map of space: Micro-organization of grid cells in the medial entorhinal cortex

Authors: *Y. GU[1], S. LEWALLEN[1,2], A. A. KINKHABWALA[1,3], C. DOMNISORU[1,2], K. YOON[4,5], J. L. GAUTHIER[1], I. R. FIETE[5], D. W. TANK[1]

Abstract: Topographical maps are intriguing features of brain structure, in which the anatomical organization of neurons corresponds to specific properties of encoded variables. Although it is still unclear how these maps relate to functional mechanisms, they have been observed in many sensory and motor systems, such as the retinotopic map in primary visual cortex and the somatotopic map in somatosensory cortex. In contrast, topographical maps for cognitive variables are rarely reported.

Here we report a fine-scale topographical map in a high-level cognitive cortical circuit in the rodent brain. Using cellular-resolution two-photon calcium imaging during virtual navigation, we investigated the relationship between the anatomical organization and functional properties of grid cells, which represent a cognitive code for location during spatial navigation. We found a substantial degree of grid cell micro-organization in layer 2 of mouse medial entorhinal cortex. First, grid cells and modules all clustered anatomically. In addition, grid cells within the same module are topographically arranged. In the local neighborhood, grid cells are spatially organized according to the relative offsets of their spatial tuning phases, and exhibit a pattern in which anatomically nearby grid cells have more similar phases than distal grid cells. On a larger spatial scale, grid cell phases repeat their local pattern to form a noisy two-dimensional lattice structure that tiles the anatomical surface of the cortex. This map of grid cells contributes to a foundation for evaluating circuit models of the grid cell network, and is consistent with continuous attractor models as the mechanism of grid formation. The relationship between the anatomical distribution of grid cells and their function in mouse MEC demonstrates how topography and function can be intimately related in neural circuits underlying cognitive variables.

Title: Relatively specific inhibition of grid cells by somatostatin positive interneurons in medial entorhinal cortex

Authors: *R. M. HAYMAN[1], N. BURGESS[2]
[1]Inst. of Neurol., London, United Kingdom; [2]UCL, London, United Kingdom

Abstract: The role, if any, of GABAergic interneurons in generation of the periodic grid code found in medial entorhinal cortex (mEC) is currently unknown, although continuous attractor models predict a specific pattern of recurrent inhibition (1). Exciting parvalbumin positive interneurons has been shown to inhibit all major cell types in the mEC (2), but we wondered whether exciting the next most common, (somatostatin positive, SST+) interneurons would have a more specific effect.
To assess this we used a combination of optogenetics and tetrode recordings in SST+-Cre mice.

We found that increasing the activity of SST+ cells strongly inhibited grid cells, had a mild effect on speed cells and theta-modulated cells and little to no effect on either border or head-direction cells. The latency of the effect on grid cells following SST+ cell activation strongly suggests a mono-synaptic connection between SST+ interneurons and grid cells and a longer, possibly multi-synaptic, latency to speed and theta-modulated cells. During the period of optogenetic stimulation the properties of grid cells were not noticeably affected; spatial phase, wavelength and orientation remained the same as during baseline but with a reduced firing rate. Similarly the depth of theta modulation was not significantly affected and neither was a measure of a cells speed tuning. The few identified SST+ cells (those with a short enough latency following light onset) had patchy spatial receptive fields and were weakly modulated by the animals speed. Our findings indicate a relatively specific role of SST+ interneurons in the inhibition of grid cell firing.

Title: A computational model of visual recognition memory via grid cells

Authors: *A. BICANSKI, N. BURGESS
Inst. of Cognitive Neurosci., UCL, London, United Kingdom

Abstract: Grid cells represent environmental location and likely underlie path integration, imagined movement, and the computation of movement vectors during spatial navigation. However, recent results suggest that some entorhinal cells can also exhibit grid-like firing patterns in response to saccades, i.e. in visual space. Here we propose a mechanistic model of object, face, and scene recognition that makes use of grid cell representations to encode the translation vectors between salient features. Drawing parallels to active exploration in spatial tasks, we propose that visually driven grid cells calculate saccade vectors moving from one salient feature of an image to the expected location of the next. A sequence of saccade vectors which visits salient features of an image is identified with recognition of the layout of the image (i.e., going beyond recognition of the individual features). The proposed model provides an

explicit neural mechanism underlying the long-held view that directed saccade vectors support hypothesis-driven, constructive perception and recognition, and the first quantitative explanation of a possible role for grid cells in visual processing. The variance of activity across grid cells sampled along saccade trajectories varies with saccade direction with 6-fold symmetry, which may explain recently reported fMRI findings. The model also suggests a functional explanation for why some kinds of visual memory involve the medial temporal lobe. The mechanism is robust with regards to visual occlusions, is invariant with respect to the apparent size and position of the stimulus in the visual field, and suggests a large number of experimental predictions.

Title: Entorhinal neurons exhibit cue locking in rodent VR

Authors: *G. CASALI, C. DOWELL, S. SHIPLEY, R. HAYMAN, C. BARRY
Cell and developmental biology, UCL, London, United Kingdom

Abstract: The spatially regular firing pattern of rodent medial entorhinal (mEC) grid cells is hypothesized to function as a spatial metric relevant for navigation. The exact computations that generate grid-patterns are unknown but experimental evidence suggests that both self-motion integration and environmental cues contribute to the formation and stability of grid cell firing. The development of the virtual reality (VR) for head-fixed mice confers a number of experimental advantages and has becoming increasingly popular as a method for investigating spatially-selective cells. Recent work conducted in 1D virtual linear tracks showed that cells in MEC fire at regular intervals in virtual space analogous to grid cells in real linear tracks. We recorded from mEC as mice traversed virtual tracks, identifying a population of neurons with firing fields modulated by regularly repeating visual cues - thus resembling regular grid cell firing patterns. However, in the open field these cells lacked the six-fold periodicity typical of grid cells, exhibiting weakly spatial firing. In the virtual environments the frequency of their firing-pattern precisely corresponded to visual features in the VR, indicating that their apparently grid-like activity was likely an artefact induced by composite responses to visual cues. In light of these results we highlight the importance of controlling the periodicity of the visual cues in VR and the necessity of open field recordings for the accurate characterisation of mEC cells.

Title: Relationship between place cell recruitment and the spatial scale of open-field environments revealed using a novel scalable recording apparatus

Authors: *S. TANNI, C. BARRY
Cell and Developmental Biol. Dept., Univ. Col. London, London, United Kingdom

Abstract: The representation of space in hippocampal circuits and how it supports navigation has been studied extensively in minimalistic experimental environments. However, our understanding of how hippocampal networks encode large and complex spaces is limited. The spatial scale of experiments in freely moving rodents is in part limited by lack of technological solutions for this purpose. We developed an open-source, modular, scalable system to control interactive spatial tasks in large-scale environments. Thus, allowing us to perform extremely long duration electrophysiological recordings in which animals explore large spaces. Prior work, conducted on linear tracks, indicated that place cell recruitment followed a logarithmic relationship over scale [1]. To determine if a similar pattern was evident in the open-field, we performed recordings in environments of variable sizes up to 9 m^2, using our novel control system.
Open Ephys recording system was used for electrophysiological recordings, while online position tracking and reward mechanisms utilized multiple Raspberry Pi units that were controlled wirelessly by a Linux based PC. Two types of reward mechanisms, scattered pellets and localized milk drops, ensure sufficient coverage of open-field for studying spatial cells as well as goal orientated navigational behaviour.
Place cells were recorded in male Lister Hooded rats during foraging in distinct environments of different sizes. We found a non-linear relationship between the size of the open-field environment and the properties of place fields. Specifically, the distribution of place fields relative to the environmental boundaries depended on the size of the environment. These results show the importance of large scale open-field recordings for understanding the properties of

hippocampal circuits during real world navigation.

Title: Absence of visual input affects place and grid cell activity

Authors: *Y. LU, G. CHEN, N. BURGESS, T. WILLS, F. CACUCCI
Univ. Col. London, London, United Kingdom

Abstract: It is known that visual cues can exert control over the spatial firing fields of place and grid cells. However, it is still an open question whether vision affects grid and place fields independently or not and whether that influence is uniform across the whole environment. Previous studies have shown that, in mice, grid cells lose their hexagonal firing regularity in familiar environments when the lights are turned off (see 1). To further explore the relationship between grid cell and place cell firing, it is interesting to know how place cell firing in mice responds to absence of visual input. We recorded place and grid cells concurrently while mice performed random foraging in the dark followed by a control trial in the light. Our results demonstrated that the spatial selectivity of place cell firing was largely preserved while their spatial tuning stability was decreased. Specifically, some place cells fired at a lower rate and some had firing fields that shifted in location. The spatial regularity of grid cell firing patterns was also disrupted. Moreover, place and grid fields closer to the walls showed better stability compared to fields away from the environmental boundaries. 1) Chen, Manson, Cacucci, Wills. Abstract: We present a mouse virtual reality (VR) system which restrains head-movements to horizontal rotations and is compatible with multi-photon imaging. We show that this system allows expression of the spatial navigational behaviour (returning to an unmarked goal location) and the spatial neuronal firing patterns characteristic of real open arenas, including place, grid and head-direction cells. Using genetically encoded GCaMP6f mice we demonstrate stable 2-photon fluorescence imaging of neuronal activity of large populations in hippocampal area CA1. Imaging during active spatial navigation in open environments demonstrates the spatial activity patterns of place cells, enabled by software developed to un-rotate the images acquired.1) Chen, King, Lu, Cacucci, Burgess, bioRxiv 2018 doi: https://doi.org/10.1101/246744

Title: Grid cell phase coding does not require constant rhythmicity

Authors: *D. BUSH, N. BURGESS
UCL Inst. of Cognitive Neurosci., London, United Kingdom

Abstract: Phase coding - the encoding of information in spike phase relative to an ongoing oscillation in the local field potential (LFP) - offers numerous theoretical advantages over an equivalent firing rate code. Empirical studies have provided evidence for phase coding across multiple species and cortical regions. For example, grid cells in rodent medial entorhinal cortex, which are characterised by a regular triangular array of spatial firing fields, exhibit 'theta phase precession' - spiking at progressively earlier phases of the 5-11Hz theta oscillation as each firing field is traversed. It has often been assumed that such phase coding relies on a high amplitude baseline oscillation with relatively constant (theta) frequency. However, recent data demonstrate that grid cells in both bats and humans exist in the absence of a constant frequency oscillation in either the spike train or LFP, calling into question the existence of phase coding in these species. We show that, if the intrinsic firing frequency of grid cells varies relative to a dynamically changing baseline frequency according to movement velocity, then grid cell firing patterns can efficiently multiplex information about location, running speed, movement direction and a fourth variable such as anxiety. We simulate a population of grid cells that exhibit phase precession against a baseline oscillation with highly variable frequency recorded from depth electrodes in human hippocampus. We then show that it is possible to accurately decode location from population firing rates, consistent with previous studies; movement direction from firing phase, analogous to experimentally observed 'theta sweeps' of activity along the animal's current trajectory; running speed from mean firing rates; and anxiety from the baseline oscillation frequency. In addition, we investigate how firing phase might be used to reduce errors in decoded location that arise from stable differences in in-field firing rates. Finally, we describe analytical methods that can identify phase coding in the absence of a constant frequency oscillation, as in single unit recordings from the bat or human brain.

Title: Predictive coding in the bat hippocampus

Authors: *D. OMER, N. ULANOVSKY
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Hippocampal place cells represent the current position of the animal - and recent studies in bats and rats found that the position of other animals is represented by hippocampal 'social place-cells'. Previous studies in rodents showed that CA1 neurons also exhibit prospective coding, anticipating the animal's choice behavior. In bats, little is known about how the hippocampus represents future spatial trajectories. To examine this question we used a delayed match-to-place task which was used previously to demonstrate social place-cells: In each trial, one bat ('observer') had to observe and remember the flight-trajectory of the other bat ('demonstrator'). After a short delay, the observer had to imitate the demonstrator's flight to receive a reward. We recorded hippocampal dorsal-CA1 neurons in the observer. In this study we focused on the delay period between the return of the demonstrator and the takeoff of the observer. Our preliminary results suggest that firing patterns of CA1 neurons in the observer bat are anticipating his flight trajectory a long time before his takeoff - while the two bats are stationary on the same start-ball.

Title: Representation of 3D space in the entorhinal cortex of flying bats

Authors: *G. GINOSAR, A. FINKELSTEIN, L. LAS, N. ULANOVSKY
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Grid cells recorded from animals exploring 2D planes, fire in an hexagonal pattern across the environment. However, many animals navigate through 3D space, but no studies have characterized the 3D volumetric firing of grid cells. Here, we trained Egyptian fruit bats (*Rousettus aegyptiacus*) to fly in a large room, while we wirelessly recorded single-neuron activity in medial entorhinal cortex (MEC). Our results revealed structured firing in the 3D firing-rate maps, with multiple firing-fields. The spacing between firing-fields was more variable than in perfect synthetic 3D lattices, but was less variable than shuffled data: about 20% of the multi-field neurons were 3D grid cells, exhibiting a significantly fixed distance scale. This result supports a distance-coding function for grid cells. The 3D grid cells seemed to form a functional continuum - in terms of spatial structure - with the less structured multi-field neurons. The population of multi-field cells in bat MEC exhibited an anatomical gradient of spatial scales along the dorso-ventral axis of MEC, with inter-field spacing increasing more ventrally - similar to what is seen in rodents in 2D. We also found a number of other 3D spatial cell types in bat MEC, including (i) 3D border cells, (ii) 3D head-direction cells, and (iii) a new class of MEC neurons that fired selectively near specific landing-balls - but not near other balls. Taken together, these data suggest a rich 3D spatial representation in the MEC of flying bats - including coding of 3D space by grid cells, coding of 3D geometry by border cells, as well as object-related coding in the bat MEC.

Title: Representation of large-scale spaces in the hippocampus of flying bats

Authors: *T. ELIAV, L. LAS, N. ULANOVSKY
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Most animals navigate daily over distances spanning from hundreds of meters to many kilometers. However, over the last forty years, hippocampal research focused on spatial representations in small laboratory environments. Nothing is known about hippocampal neural codes for large spatial scales - the scales of natural navigation of rodents, bats and other mammals. Here we addressed this question for the first time, by developing a unique setup - including a very large environment with an ethologically-relevant spatial scale. We studied Egyptian fruit bats - flying mammals that are excellent navigators over large scales, and which have rodent-like hippocampal spatial representations in small laboratory environments. We developed an on-board wireless neural-logging system, which allows recording single-units over

unlimited distances. We built a 200-m long tunnel where bats can fly freely; bat's position was tracked using an RF localization device that measures distances to a ground-based antenna array - yielding high accuracy of ~10-cm, much better than GPS. Bats flew back-and-forth along the tunnel, more than 100 laps per-session (>20-km total distance). Preliminary recordings from hippocampal area CA1 showed some firing properties that were similar to findings in small-scale laboratory environments, such as directionality and field-asymmetry. However, most properties were very different: (i) Individual cells exhibited multiple fields per neuron. (ii) We found very large fields in dorsal CA1 - up to 20-30 meters. (iii) A given neuron could exhibit multiscale spatial coding - with different place-fields of the same neuron having very different sizes, ranging from sub-meter to 20-30 m. These large variations in scale were unrelated to local landmarks, and could not be explained by the animal's flight speed, which was extremely stable along the tunnel - suggesting that CA1 neurons have a genuine multi-scale representation. Taken together, the firing properties of CA1 neurons in this large-scale environment suggest a representation that is very different from findings reported in the laboratory.

Title: The beneficial role of noisy inhibitory signaling in collective behavior

Authors: *H. C. BELL[1], F. D. BROCCARD[2], Y. ZHU[3], J. C. NIEH[4]
[2]Inst. for Neural Computation, [3]Computer Sci. and Engin., [4]Div. of Biol. Sciences; Section of Ecology, Behavior, and Evolution, [1]Univ. of California San Diego, La Jolla, CA

Abstract: Noise, defined as anything that interferes with the transmission, reception, or interpretation of a signal from sender to receiver during communication, is a ubiquitous feature of biological systems. Although traditionally viewed as an inevitability that systems learn to cope with, some recent findings suggest that noise can be beneficial under certain conditions - for instance, by fostering behavioral and phenotypic variability and via mechanisms such as stochastic resonance. Our work focuses on understanding the role of spontaneous (noisy) signaling in collective decision-making. Using honey bees as our model system, in conjunction with computational modeling approaches, we demonstrate that noisy inhibitory signaling in complex systems can confer an adaptive advantage under dynamic conditions. In particular, collectives implementing such noisy signals are more robust to perturbation and less likely to make Type I errors.

Title: Effect of anterior cingulate cortex lesions on social vicarious reinforcement in monkeys

Authors: *B. M. BASILE[1], J. SCHAFROTH[1], C. KARASKIEWICZ[1], S. W. CHANG[2], E. A. MURRAY[1]
[1]Lab. of Neuropsychology, Natl. Inst. of Mental Health, NIH, Bethesda, MD; [2]Yale Univ., New Haven, CT

Abstract: Humans and monkeys will sometimes work to see a conspecific get rewarded, a phenomenon called vicarious reinforcement. Behavior in vicarious reinforcement tasks and similar social decisions correlate with the activity of neurons in the anterior cingulate cortex (ACC) in monkeys and with blood oxygen-level dependent changes in the ACC in humans. These correlations suggest a critical role for the ACC in social decisions. However, some human patients with accidental damage that includes the ACC are unimpaired on a number of tasks that assess social cognition. We addressed this discrepancy by testing rhesus monkeys (*Macaca mulatta*) on a social vicarious reinforcement task before and after selective, bilateral ibotenic acid lesions of the ACC. An actor monkey sat facing a computer screen while a recipient monkey sat next to the screen facing the actor. On each trial, actors were required to fixate on a visual cue that rotated to predict one of three reward offers: juice to oneself, juice to the other monkey, or juice to neither monkey. Actors could accept the offer by making a saccade to a peripheral target or reject the offer by not making a saccade. Before surgery, all monkeys showed a moderate but reliable preference for giving juice to the other monkey over giving it to neither monkey. Unexpectedly, pupil size was wider in anticipation of the less-preferred *neither* trials than the more-preferred *other* trials, suggesting that eye movements tracked outcome valence whereas pupil size, a measure of autonomic arousal, tracked outcome salience. After surgery, both lesion and control groups maintained their social preferences to the pre-operatively learned cues. We will also discuss results from post-operative learning of novel cues. These data speak to the causal role of the primate ACC in vicarious reinforcement.

Title: Effect of primate amygdala and anterior cingulate cortex lesions in viewing biologically relevant stimuli

Authors: *J. SCHAFROTH[1], B. M. BASILE[2], D. R. LUCAS, III[3], E. A. MURRAY[4]
[1]Lab. of Neuropsychology, Natl. Inst. of Hlth., Bethesda, MD; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Health, NIH, Bethesda, MD; [3]NIH, Bethesda, MD; [4]Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD

Abstract: Human and nonhuman primates live in complex social structures. Recent research has posited a distributed neural network, sometimes called the "social brain", that preferentially processes social information. Two brain regions implicated in social processing are the amygdala and anterior cingulate cortex (ACC). In primates, amygdala neuronal activity correlates with important aspects of hierarchical ranks, faces, and social decisions, and ACC activity correlates with aspects of observational learning and vicarious reinforcement. However, there is still a paucity of evidence about the causal roles these structures have in processing social information. In addition, the extent to which the neural correlates are due to the information being specifically social or generally biologically relevant remains unknown. Here, we evaluated if rhesus macaques (*Macaca mulatta)* with bilateral, excitotoxic, lesions of the amygdala or ACC viewed biologically relevant stimuli abnormally compared to unoperated controls. Controls (n=10) and monkeys with amygdala (n=8) or ACC (n=3) lesions viewed 15-second videos from three categories of biologically relevant stimuli: conspecifics, food, and predators. Monkeys also viewed control movies that displayed similar backgrounds without active entities and scrambled versions of all videos. We hypothesized that if the amygdala and ACC are involved in processing biologically relevant stimuli, damage to these areas would result in abnormal viewing patterns for all three classes of stimuli. Surprisingly, our preliminary analysis showed no robust effect of either lesion on viewing social videos. However, monkeys with amygdala damage spent more time viewing food videos compared to the other groups. In addition, relative to controls, both the amygdala and ACC lesion groups spent more time viewing predator videos. Both findings were driven by long fixations (>0.5 sec), suggesting attentional rather than exploratory viewing. Group differences in the spatial distribution of attention to various scene elements will also be discussed. Overall, these data provide causal evidence that the primate amygdala and ACC

contribute generally to the processing of biologically relevant stimuli as opposed to narrowly to the processing of social information.

Title: Single-neuronal correlates of group behavior and reciprocity in three interacting macaques

Authors: *R. BÁEZ-MENDOZA, E. P. MASTROBATTISTA, A. J. WANG, K. HU, Z. M. WILLIAMS
Dept. of Neurosurg., Massachusetts Gen. Hospital-Harvard Med. Sch., Boston, MA

Abstract: Reciprocity is a central feature of social interaction in both humans and animals. It allows individuals to forge alliances and function within groups and is instrumental in augmenting both individual and mutual fitness. Its dysfunction is also a prominent feature of many psychiatric conditions and prominently contributes to social behavioral disorders. Yet, the precise neuronal computations that underlie reciprocity and group behavior remain poorly understood. Here, we obtained multiple-neuronal recordings in the anterior cingulate cortex (ACC) of small groups of rhesus macaques as they performed a structured reciprocity-based social task. We devised a three-agent social task in which three macaques interacted with each other over multiple rounds. The task required the monkeys to sit around a rotary table apparatus; in each trial, one individual would offer a food reward to one of the other two. Throughout sessions, individuals within groups of three could reciprocate past rewards that had been delivered to them by other group members. Based on this design, we could dissociate basic computations associated with interactive behavior, social preference, and group dynamics. Within experimental sessions, we also controlled for animal position and gaze contact between actor and potential recipients. Behaviorally, we find that the monkeys demonstrated a strategic preference for other individuals and that they favored rewarding those who reciprocated. At the neuronal-level, a distinct subpopulation of neurons tracked the reward received by other group members. However, they also maintained a representation of distinct individuals and their association with reciprocated reward. These findings reveal neurons in the primate ACC that

encode information about particular individuals, their behavior within social groups and their reciprocity. Together, they also lay the future groundwork for studying social behavior in humans and for testing neurobiology-guided clinical treatments.

Title: Dorsal premotor neurons distinguish between self and other's future choices

Authors: *L. FERRUCCI[1], R. CIRILLO[2], E. MARCOS[2], S. FERRAINA[3], A. GENOVESIO[4]
[1]Univ. of Rome Sapienza, Roma, Italy; [2]Sapienza Univ. of Rome, Rome, Italy; [3]Sapienza Univ. Rome, Rome, Italy; [4]Sapienza Univ., Roma, Italy

Abstract: Social interaction plays a fundamental role in primate life. The premotor cortex is assumed to be involved in representing self and others' behavior since the discovery of mirror neurons in its ventral part. The dorsal premotor cortex (PMd) is tought to play a similar role, with a neural network responsible for planning and executing actions that overlaps with the network for observation of other's actions. We used a social interaction task in which two male rhesus monkeys were required to interact with a human partner, alternating their roles as actor or observer. The monkeys were trained to perform two versions of a non-match-to-goal (NMTG) task: a spatial version (S-NMTG) and an object version (O-NMTG). The rule in the two versions of the task was identical: in each trial, the monkeys were required to select the object (in O-NMTG) or the position (in S-NMTG) that did not match the one chosen in the previous trial. In both versions, the new object/location had to be chosen in order to receive a reward. During the recording sessions, monkeys interacted with a human partner in a subset of trials; in these trials, the monkey had to monitor the human partner performing the task and to observe the target chosen, in order to discard it and chose the new one in the successive trial. We recorded in the PMd the activity of 210 single cells in Monkey 1 and 118 single cells in Monkey 2, for a total of 328 neurons. We analyzed the neural activity in human and monkey trials during the delay period, since in this period there was no movement. In contrast to previous studies, we found that only a minority of the task-selective neurons (19%) exhibited congruent directional activities (mirror-like) for both one's own and other's future actions. Moreover, some neurons predicted the future response (left versus right) only during the human's performance without coding the

response during the monkey's own turn. Our results suggest that PMd could play a crucial role in social cognition. It appears that PMd is not mainly involved in mirror-like processes but that this area can contribute to distinguish between one's own and other's actions. Overall, PMd could very well play an important role during social interaction given its connectivity with other frontal areas involved in the "social network", such as lateral prefrontal cortex and supplementary motor areas.

Title: A method to analyze sociability in the common marmoset based on 3D tracking

Authors: *D. BUITRAGO-PIZA[1], G. M. PARFITT[2], B. W. CORRIGAN[3], J. C. MARTINEZ-TRUJILLO[4]
[2]Dept. of Neurosci., [1]Western Univ., London, ON, Canada; [3]Neurosci., [4]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

Abstract: Common marmosets create complex social networks within family groups, their social interactions rely greatly on visual and auditory cues, making them an ideal model of human social aspects. In this work, we sought to identify general social interest in freely moving marmosets using 3D body position and orientation in a semi naturalistic environment in the presence of social novelty. In the study, two adult marmosets were habituated for two weeks to freely move inside a plexiglass recording chamber with four vertical levels while wearing a detachable vest with affixed infrared reflective markers that allowed 6 degrees of freedom positional camera tracking (Optitrack, Natural Point Inc, USA). After two weeks, the animals became used to roam on all the 4 different levels of the chamber developing a natural preference to stay on higher levels from the ground. After the habituation period, 15 minutes sessions were recorded with a clean transparent box attached to the bottom level of the chamber. The marmosets had visual access to it at all times, 4 conditions were presented inside the box on different days: monkey dummy, same sex novel juvenile, same sex novel mature marmoset, and an empty box control. Distance from the tracked marmoset body (D) and orientation (O) relative to the box were computed and normalized to the maximal possible distance and angle respectively. An index (1-[D x O]) was used as a score of sociability. The results showed that in

both animals scores were higher when a novel mature marmoset was inside the box (n1 = 0.55, n2 = 0.52), following by juvenile inside the box (n1 = 0.46, n2 = 0.47), dummy (n1 = 0.4, n2 = 0.43) and empty box (n1 = 0.35, n2 = 0.27) respectively. Direct interactions (Di) were considered as events in which the marmoset approached the box within 5 cm distance. Di were higher for the mature marmoset than in all other conditions (n1 = 38, n2 = 14), following by juvenile (n1 = 0, n2 = 2), dummy (n1 = 0, n2 = 0) and empty box (n1 = 6, n2 = 0). Our results describe a reliable and relative unexpensive method to measure sociability in marmosets.

Title: Evaluation of the 3-chamber sociability test in the olfactory bulbectomized (OB) rat model of depression

Authors: *K. L. MCHUGH[1,2], H. DOHERTY[1,2], P. CALCAGNO[1,2,3], M. CLARKE[1,2,3], D. EYERMAN[4], C. SANCHEZ[4], M. ROCHE[3,2], D. P. FINN[1,2], J. KELLY[1,2]
[1]Pharmacol. and Therapeut., Natl. Univ. of Ireland Galway, Galway, Ireland; [2]Galway Neurosci. Ctr. NCBES, Galway, Ireland; [3]Physiol., Natl. Univ. of Ireland, Galway, Galway, Ireland; [4]Alkermes, Inc., Waltham, Massachusetts, MA

Abstract: Introduction:
The olfactory bulbectomy (OB) rat model is a well-established model with a number of behavioural changes, some of which are attenuated by chronic antidepressant treatment. The 3-chamber sociability test evaluates rodents' ability to discriminate between an unfamiliar and a familiar rat, and has value in the context of assessing cognitive function. The objective of this study was to evaluate the 3-chamber sociability test in the OB model by examining differential housing (single versus paired), and the effect of chronic administration of the antidepressants desipramine and fluoxetine.
Methods:
Male Sprague Dawley rats (200-250g) underwent surgery (sham or OB) under isoflurane anaesthesia, or did not undergo surgery (naïve). In the single – *vs*. group-housing study, rats were singly housed or pair housed (either paired shams, paired OB, or a sham paired with an OB)

following surgery (n=8). In the antidepressant study, rats were singly housed and two weeks post-surgery rats received daily subcutaneous injections of vehicle (saline), desipramine or fluoxetine (both 10mg/kg) for two weeks (n=8). Four weeks post-surgery, rats were tested in the 3-chamber sociability test, consisting of three consecutive ten-minute time-trials; the *habituation trial* (empty arena), the *sociability trial* (novel rat vs. empty cage) and the *social preference trial* (now familiar rat vs. novel rat). Total distance moved was recorded using Ethovision® technology. The degree of habituation was calculated as the 3rd trial as a percentage of the 1st trial. Duration exploring was manually scored. Data are expressed as mean ± SEM and analysed using two-way ANOVA, followed where appropriate by *post-hoc* Student Newman-Keuls test; $p<0.05$ was deemed statistically significant.

Results: In the sociability trial, OB rats paired together, spent less time exploring the novel rat than their sham counterparts. In the social preference trial, all OB rats, regardless of housing, spent less time exploring the novel rat as well as displaying a significant habituation to the apparatus when compared to sham counterparts. Sham-operated and naïve rats behaved similarly to each other, irrespective of housing. Treatment with antidepressants did not attenuate the OB-related changes.

Conclusion: Olfactory bulbectomy causes altered social cognition with pronounced reduction in social preference and habituation to the test arena. These results add an additional behavioural alteration to the model, but one that is not altered by chronic antidepressant treatment.

Title: The medial prefrontal cortex is involved in social odor recognition memory in rats

Authors: *S. ROBINSON[1], S. J. ALDRICH[1], L. GRANATA[2], R. D. HEINZ[2], C. M. DAVIS[2]
[1]Psychology Dept. and Neurosci. Program, Hamilton Col., Clinton, NY; [2]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The medial prefrontal cortex (mPFC) is critical for several cognitive processes including olfactory discrimination and social cognition, but its specific role in memory processing when social cues are involved is unclear. Using a chemogenetic approach in rats, we assessed the role of the mPFC in encoding and expression of recognition memory during a social odor task. In the same animals, we also assessed the role of the mPFC in sustained attention using the rodent psychomotor vigilance test (rPVT). The social odor recognition task involves three phases (familiarization, habituation, and recognition) and requires olfactory-based discrimination between familiar odors and novel odors from conspecifics; failure to show preference for novel odors on the test phase indicates a memory deficit. The rPVT is a sustained attention test that measures accuracy, premature responding, and responses times to the presence of a stimulus light that appears after a random waiting period, between 3-10 seconds. pAAV-hSyn-hM4D(Gi)-mCherry was injected bilaterally into the mPFC and then prior to specific phases of behavioral testing, clozapine-N-oxide (CNO), was systemically injected to temporarily and remotely silence mPFC neurons. The results of the social recognition task revealed that CNO (1 mg/kg, i.p.) 30 min prior to the habituation phase was without effect on performance during habituation, but did impair memory for a novel odor the following day during the recognition test. These effects were not likely a function of CNO drug state because the impairment was observed during the drug-free test, which occurred 24-hrs after the CNO injection. In a second experiment designed to measure mPFC-mediated attention and performance, rPVT sessions were conducted after CNO administration (0 - 5 mg/kg, i.p., depending on session) and revealed that a dose of 1 mg/kg of CNO resulted in premature responding, but not impaired response times. These data show that silencing the mPFC impaired performance of recognition memory, without

inducing a motor impairment in the psychomotor vigilance test, indicating that the mPFC could be involved in the encoding and consolidation of information about social odors.

Title: Alteration in the brain induced by memory retrieval

Authors: *M. MARUI[1], K. ADACHI[1], S. TOMONAGA[2], T. HAYASHI[1], M. NAGASAWA[1]
[1]Meijo Univ., Nagoya city/ Aichi prefecture, Japan; [2]Kyoto Univ., Kyoto city/ Kyoto prefecture, Japan

Abstract: Background: Dementia is a social issue to be solved. World Health Organization reported that 50 million people are suffering from dementia around the world, and the number of subjects will grow year by year. Memory impairment is one of characteristic symptoms of dementia and lead the reduction of ‘‘Quality Of Life’’. Therefore, the therapeutic treatment and prophylaxis of memory impairment needs to be established. Memory function is consisted of three processes, ‘’encoding’’, ‘’storage’’ and ‘’ retrieval’’, and many dementia patients impaired their retrieval processes. However, the retrieval mechanism in memory function remains unclear. Thus, the aim of the present study was to establish an animal model which is effective to elucidate the mechanism for retrieval process. In addition, the alterations that retrieval process induced in the brain were evaluated.
Material and Method: Object recognition test (ORT) with some modifications was performed to enhance a memory retrieval. Male 8-week-old ICR mice were allowed to explore in the black square arena with two identical objects for 5 min. This trial was performed once a day for 3 days. On 4th day, control (CON) mice explored the familiar objects for 3 min, while ‘‘memory retrieval’’ (MR) mice explored an identical object and a novel object. Mice tend to show an interest in a novel object. Accordingly, a ratio of latency to explore a novel object on 4th day, an index of retrieval-based behavior of MR mice was calculated form the following formula; 100 × latency exploring a novel object /latency exploring both objects. In CON mice, an expediential ratio of latency to explore a novel object was estimated by a similar method. After these trials, mice were sacrificed under anesthesia and their brains were immediately dissected several regions. Protein expression analysis in the hippocampus and cerebral cortex was verified by two-dimensional electrophoresis, and metabolites in the hippocampus were determined by GC-MS
Result: A ratio of latency to explore a novel object of MR mice was significantly higher than

those of CON mice (MR mice: 73.7±3.5%, CON mice: 52.5±2.6%). This result shows that MR mice recognized a familiar object. Consequently, it was suggested that an animal model established in the present study was useful for enhancing a memory retrieval. The protein expressions in the hippocampus and cerebral cortex were changed due to the retrieval process. Several novel protein spots expressed in MR mice comparing CON mice. Additionally, the concentrations of a metabolite and an amino acid in MR mice were significantly lower than those in CON mice. These metabolites may be possible to utilize as biomarkers for dementia.

Title: The role of Igsf9b in prefrontal cortical function

Authors: *C. ALEXANDROPOULOS, S. YANG, N. MACK, Y.-C. LI, W.-J. GAO
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The medial prefrontal cortex (mPFC) plays an important role in psychiatric illnesses. GWAS studies suggest that mutations in gene *IGSF9B* correlate with negative symptoms of schizophrenia and depression in humans. It is reported that Igsf9b, coded by *IGSF9B,* is widely distributed in neocortex and localized at inhibitory synapses. However, little is known about the function of Igsf9b in mPFC-dependent behaviors. To investigate this, we knocked down Igsf9b in the mPFC by bilaterally injecting AAV5-GFP-U6-mIGSF9b-shRNA into mPFC of male and female C57BL/6 mice. To assess behavioral phenotypes mimicking psychiatric illnesses, the following behavioral tasks were employed: locomotion, T-maze forced alternation, three chamber sociability, and forced swim tasks. Preliminary data indicated that Igsf9b knockdown in male mice took longer to reach criterion in the T-maze task, suggesting potential learning deficits. However, their performance in the working memory task did not differ from the scramble control male mice. Additionally, Ifsf9b knockdown males displayed a reduced social interaction in the three-chamber task compared to control males. Conversely, Igsf9b knockdown in female mice did not show distinct differences from control female mice in both T-maze and three-chamber tasks. However, female, but not male, Igsf9b knockdown mice exhibited increased hyperactivity in the locomotion task compared to control female mice. Both male and

female Igsf9b knockdown mice did not differ from control mice in the forced swim task, suggesting no sign of depressive behavior These results suggest that Igsf9b mutations may impact negative symptoms in schizophrenia, with sex differences, but it may not contribute to depressive symptomatology.

Title: Social dominance in a rat model of fragile-X syndrome

Authors: *K. SAXENA[1], J. WEBSTER[1], A. HALLAS-POTTS[1], R. MACKENZEI[2], G. TAYLOR[1], P. SPOONER[1], D. THOMSON[1], P. KIND[1,3,4,5], S. CHATTARJI[6,3], R. MORRIS[1,3,4,5]
[1]Univ. Of Edinburgh, Edinburgh, United Kingdom; [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Ctr. for Brain Develop. and Repair, Bangalore, India; [4]The Patrick Wild Ctr., Edinburgh, United Kingdom; [5]Ctr. for Discovery Brain Sci., The Univ. of Edinburgh, Edinburgh, United Kingdom; [6]Natl. Ctr. for Biol. Sci., Bangalore, India

Abstract: The neurodevelopmental disorder, Fragile-X, is the most common inherited, monogenetic cause of intellectual disability. It is caused by the mutation in the Fmr1 gene resulting in a decrease in the production of fragile- x mental retardation protein (FMRP). One of the primary symptoms of a child suffering with Fragile-X is difficulty in social interaction. Modeling the syndrome in rodents has revealed cns abnormalities (anatomical and physiological) that could lead to better understanding, but there has so far been little study of social interactions in relation to this condition (c.f. de Esch et-al.*Neurobiolol.Dis.*2014). Subjects: We have used a Fmr1 Knock-out rat model and examined the impact on social dominance and hierarchy using tube-test (Wang et-al.*Science.*2011). The study was performed on 56 rats, housed 4 animals/cage, with cages of KOs (Fmr1 Knock-outs, n=4) or WTs (Wild types, n=3) or Mixed lines (2 KO and 2 WT, n=7). Results: *Phase 1:* The hierarchy was measured 10 sessions of pairwise interactions between all animals of a cage using the tube-test. A social hierarchy was shown by both KOs and WTs, with the hierarchy in WT cages being significantly less variable ($t=2.99$, $df=26$, $p=0.006$) relative to KO cages. In this variability, it appeared that KOs displayed a bimodal distribution whereby some animals were "hyper stable" and others "hyper-unstable".

In mixed cages, WT animals were relatively more dominant over the KOs (Chi-square=14.63, df 1, p=0.0001). *Phase 2*: Animals in different cages were then also tested in a pairwise manner. The WT dominance phenotype was lost in stranger encounters, with prior experience having a larger effect, i.e animals that were high ranking in the phase 1 tended in phase 2 also (Chi-square=102, df=1, p<0.0001). However, paradoxically, KO won more contests than WTs when higher rankers competed, but the pattern was reversed for low-ranking contests. This intriguing finding could possibly be explained by the cognitive inflexibility or repetitive behaviour phenotype that is observed in Fragile-x animals, arguably analogous to what is seen in humans. Detailed behaviour profiling (pushing, resistance, withdraw etc.) revealed that high-ranked animals showed significantly more pushes (F (5,84)=12.5, p<0.001) and less 'retreats' (F (5,84)=12.5, p<0.05) relative low ranked rats. Conclusion: Even though the fragile-x is a monogenic condition, experience has an impact on the stability of rank and upon interactions with other animals, possibly mediated by synaptic alterations on thalamic prefrontal pathways (Zhou et-al.*Science*.2017). Nature and nurture are important and should be considered in the development of therapeutics.

Title: Analysis of the role of 5-HT2aR as a target for enhanced social cognition and episodic memory

Authors: *N. V. WEISSTAUB[1], A. SACSON[2], J. F. MORICI[2], P. BEKINSCHTEIN[3]
[1]Inst. de Neurociencia Cognitiva Y Traslacional, Buenos Aires, Argentina; [2]Inst. de Neurociencia Cognitiva y Traslacional, Ciudad Autonoma de Buenos Aires, Argentina; [3]Inst. de Neurociencia Cognitiva y Traslacional, Ciudad Autonoma Buenos Aires, Argentina

Abstract: Social Cognition encloses a large variety of behaviors and it is a domain commonly affected in psychiatric disorders. Serotonin has been linked to social behavior in humans due to its association with the regulation of mood and anxiety behaviors and also due to the use of selective serotonin reuptake inhibitors as the first line of treatment for a large number of these disorders. Recently it has become clearer that episodic memory systems can interact with social

cognitive processes and that appropriate memory processing is important to navigate the social world. Interestingly, somebrain areas involved in social cognition overlap with the ones involved in episodic memory. In this work we analyzed if chronic administration of the antidepressant fluoxetine (FLX) affects social interaction and memory processes and a putative role of 5-HT2aR in this effect. For this purpose, we administrated a chronic oral dose of FLX (10 mg/kg) to wild type (WT) and 5-HT2aR knockout mice (KO). After 4 weeks of FLX administration, the animals performed a series of behavioral tasks that include novelty suppressed feeding (NSF), social interaction (SI) and novel object recognition (NOR). We used a NOR task with a 3 min training session that was not enough to generate a long-term NOR memory at 24 h in WT or KO mice. Interestingly, after FLX treatment WT but not KO mice remembered having seen the familiar object during a test performed 24 h after training. We observed no interaction between genotype and treatment when mice were trained to generate a long.term memory. In the social interaction task, chronic FLX increased the exploration time of the social stimuli in WT but not in KO mice. These results suggest that chronic fluoxetine can influence social interaction and episodic like memory and that these effects are at least partially mediated by 5-HT2aR.

Abstract: There is growing evidence that environmental factors, such as immune activation, contribute to the severity and range of cognitive phenotypes in neuropsychiatric disorders. However, the cell types and the molecular mechanism(s) responsible for these cognitive phenotypes remain unclear. We have multiple lines of evidence that in male mice with a tuberous sclerosis mutation ($Tsc2^{+/-}$), immune activation during a critical phase of post-natal development, triggers an mTOR-dependent, self-perpetuating cycle of IFN production in microglia. This disrupts hippocampal plasticity and causes behavioral phenotypes, including social memory deficits as well as alterations in ultrasonic vocalization patterns (USV), under conditions that do not affect either wild type or female mice. Importantly, our human epidemiological studies show a strong correlation between the prevalence of infections during childhood, and a future diagnose of neuropsychiatric disorders, suggesting that our results in mice are mirrored by human findings. These results open new therapeutical opportunities for neuropsychiatric disorders, and demonstrate the critical importance of microglia during early post-natal development in cognitive function, including social memory.

Title: Contribution of nucleus accumbens to impulsive choice behavior based on the last reward experience

Authors: *J. YUZA[1], M. OKUBO[2], Y. KOMURA[3], R. KAJIWARA[4]
[1]Meiji Univ., Kanagawa, Japan; [2]Meiji Univ., Kawasaki, Japan; [3]AIST, Tsukuba, Japan; [4]Meiji Univ. / Dept. of Electro. & Bioinfo., Kawasaki, Japan

Abstract: The nucleus accumbens (NAc) is proposed to be critical in integrating various kinds of information to control impulsive behavior (Basar et al. 2010). Actually, previous anatomical studies suggest that the NAc is a part of larger neural network including the limbic structures as well as motor structures, by which the NAc could integrate the value of expected rewards with the impulsive-motor planning. In the present study, we designed the two-choice task using modified M-shaped-maze for investigating the waiting behavior for delayed reward in rats, and

investigated the involvement of the NAc. In the center lane of M-shaped-maze, we mounted an infrared sensor, which cue-triggered the start of reinforcement tone stimulus (8kHz, 70dB) from the right or left lane. The stimulus was presented at the correct lane where rat obtained the sucrose reward. There is a "waiting-zone" at the exit of center lane, just in the middle of a path connecting the right and left lanes. At the waiting-zone, a light emitting diode (LED) was mounted to signify the end of waiting period to rats. And the rat has to wait at waiting-zone before going into the correct lane until the LED switched on, subsequently the solenoid valve connected to the drinking port was opened. The experimental system was controlled by original software developed on the LabVIEW platform, and the waiting period, i.e. "*delay* for the reward" was presented randomly (0, 5, 10, 15 20, 25 seconds). In the test sessions of the behavioral task, the probability for rats to obtain the rewards is more than 50% when the delay was shorter than 15 sec. Concerning to the numbers of unrewarded trials, both "waiting-error" and "choice-error" were observed. As the delay increased, the waiting-error increased, but the choice-error was not increased. In addition, waiting error seemed to be correlated with the delay period presented in the previous trial. This observation indicates that our behavioral paradigm might measure the mnemonic function as well as the control of impulsion. Inactivation of the NAc by injecting the fluorescent muscimol which is an agonist of gamma-aminobutyric acid-A receptor revealed that the NAc would be critical for waiting behavior but not for the mnemonic trace produced in a previous trial.

Title: Striatal electrophysiological fingerprint during social interaction in freely moving rats

Authors: *R. L. REDONDO[1], R. LUETOLF[1], J. TAMPE[1], O. FAJARDO[2], M. BAINIER[1], P. SCHOENENBERGER[1]
[1]pRED, NORD, [2]pREDi, F. Hoffmann-La Roche Ltd, Basel, Switzerland

Abstract: The ventral striatum (VS) is a key node in the brain circuitry controlling motivation, decision making, sociability, and reward processing. Excitatory input from cortical and limbic structures, as well as prominent dopaminergic signals, converge in the VS. While in humans, diminished fMRI BOLD striatal responses to social reward have been reported in Autism (Scott-Van Zeeland et al. 2010), in rodents, gamma oscillations (GO) in the striatum have been linked to reward expectation and delivery (van der Meer et al. 2010). In relation to sociability, increases in GO in the prefrontal cortex have been linked to social cues in mice (Cho et al. 2015).

The goal of this study was to investigate striatal electrophysiological responses to social cues in freely moving rats. Sprague-Dawley rats with single wire electrodes in the VS explored an open field arena with two Plexiglas boxes inserted in opposite corners. The boxes had rows of small holes in order to facilitate visual, audible and olfactory exploration. The main sociability experiment consisted of two blocks with three contiguous sessions each: The first session being 10 min with empty Plexiglas boxes; the second session being 15 min with an unfamiliar conspecific in one insert and an object in the other; and the third session being 5 min with empty boxes again. After this first block, pharmacological compounds could be administered; Vehicle was used for the assay development described here. 30 min after compound administration the second block was repeated with the same specifications. Video-tracking allowed us to segment brain activity, according to the position of the nose of the experimental animal (object (OZ), animal (AZ) and neutral zone (NZ)).
Our data show an increase in the power of GO specific to i) within a session, when in the AZ versus NZ and OZ; ii) between sessions, when the AZ contains a conspecific compared to the same zone when empty.
In summary, the VS shows higher 80 Hz GO power in proximity to social cues compared to inanimate objects or empty environments. There was a dissociation between behavior and electrophysiology in that the degree of increase in GO did not correlate with the behavioral prosocial response. We are searching for manipulations that specifically affect the VS responses to social cues.

Abstract: Social processes are pervasive to daily human culture and critical for mental wellbeing. Social cues, such as the presence of a familiar social partner, can serve as signals to help discriminate environmental stimuli as safe or fearful. This "Social-Enhanced Safety Learning" is critical for preventing chronic fear and anxiety. Social-Enhanced Safety Learning is modeled in rats, which learn to reduce anxiety-like response to an anxiogenic stimulus via recurring presence of a social partner during the anxiogenic exposure; this paradigm is termed Social Familiarity-induced Anxiolysis (SoFiA). Rats exposed to traumatic brain injury (TBI) fail to acquire SoFiA. TBI rats demonstrate accumulated neurotoxin and altered excitatory/inhibitory signaling in orbitofrontal cortex (OFC), a region that may contribute to TBI-induced SoFiA deficit due to its known regulation of social, emotional, and cognitive behaviors. To investigate this, gene expression of GABA and Glutamate-related genes were compared between TBI and sham rat OFC. OFC of TBI rats had higher expression of metabotropic glutamate receptor types 1 and 5 (mGluR1/5) compared to OFC of sham rats. Non-injured rats injected with selective mGluR1/5 agonist, but not saline vehicle, into OFC failed to acquire SoFiA behavior, suggesting OFC may play a key role in acquiring SoFiA. To investigate this, rat OFC was temporarily inhibited with $GABA_A$ agonist, Muscimol, daily prior to SoFiA behavior training sessions. Rats receiving Muscimol injections failed to acquire SoFiA unlike their saline-vehicle injected counterparts. SoFiA is a complex behavior requiring social, emotional, and cognitive processes. To begin delineating which component(s) of SoFiA the OFC may be regulating, rats with either intact or inhibited (via Muscimol) OFC were assessed for social preference and social recognition behaviors. While social preference was unaffected by OFC inhibition, social recognition was impaired. In addition, injection of mGluR1/5 agonist into OFC impaired social recognition. These converging lines of evidence suggest that OFC plays a key role in social recognition and disruption of OFC-mediated social recognition processes may impair more complex behaviors such as Social-Enhanced Safety Learning.

Title: Social enrichment enhances, while social isolation impairs, social recognition memory in male rats

Authors: *M. TOYOSHIMA, M. SUGITA, Y. ICHITANI, K. YAMADA
Univ. of Tsukuba, Tsukuba-Shi, Japan

Abstract: Memory span, which means the maximum number of items to be memorized at once, is an index for evaluating the animals' memory ability as well as the length of retention period of memory. We previously reported that the housing environment during the developmental period affected social, but not object, memory span in adult rats. The rats housed with many cage mates (social enrichment) were able to memorize more conspecifics at once compared to the rats housed singly (social isolation). In the present study, we compared social memory span between social isolated and social enriched rats in terms of a longer retention period. Wistar-Imamichi male rats were assigned to one of two groups at 21days age: social isolation or enrichment. In the social isolation group, the subjects were housed singly in standard cages, while socially enriched rats were housed in groups of ten in a large cage. Social memory test was started at 10 weeks old. In the sample phases, the subject rats were allowed to freely explore an open-field arena in which 2 or 5 different juveniles were presented for 5 min. The sample phases were repeated 3 times with 5 min ITI. Fifty min after the third sample phase, subjects were again placed in the field in which one of the sample juveniles was replaced with a novel juvenile, and their exploration behavior to each juvenile was analyzed. Socially enriched rats were able to discriminate a novel conspecific from the other familiar ones in both of 2- and 5-item conditions, while socially isolated rats failed to discriminate between novel and familiar conspecifics even under the 2-item condition. These results suggest that social enrichment enhances rats' social memory ability including memory span and retention period, whereas social isolation impairs the ability.

Title: Activation of oxytocin receptor-expressing neurons in anterior cingulate cortex during helping behaivor in rats

Authors: *A. YAMAGISHI, N. SATO
Dept. of Psychological Sci., Kwansei Gakuin Univ., Nishinomiya, Japan

Abstract: The neuropeptide oxytocin may affect social behavior, and it is known that the oxytocin receptors are expressed in anterior cingulate cortex, insular, and amygdala. In this study, we examined c-fos expression of the oxytocin receptor-expressing neurons in these regions when rats show helping behavior. An experimental box consisted of pool and ground areas, and the pool area had water with the depth of 40 mm. The two areas were partitioned by a clear plate with a hole which connects the two areas. A clear circular door closed the hole. The rats were housed in pairs for 14 days. After the housing period, one of the pair was assigned to a helper. The helper was placed in the ground area, and his cagemate was locked in the pool area. When the helper opens the circular door, the cagemate can escape from the pool area. We behaviorally tested whether the helper opens the door to help the cagemate for 10 days. The helper rats were divided into Early, Late and Control groups. The Early group was tested until the helper shows the door-opening behavior 2 times. The Late group was tested until the helper shows that consecutive 3 times in 90 sec. The Control group were never tested. We compared the number of c-fos positive cells of oxytocin receptor-expressing and not expressing neurons in anterior cingulate cortex, insula, and amygdala of the 3 groups using triple immunofluorescent labeling. As a result, in the anterior cingulate cortex, there were more c-fos positive neurons in the Late group than that of the Control group regardless of the oxytocin receptor expression. This result suggests that neural activity of anterior cingulate cortex may play a role in helping behavior.

Title: Rousseau's rats. Cooperation, communication and constructing social contracts in an iterated Stag Hunt task

Authors: *S. M. RENNIE, E. J. DEWITT, A. SILVA, J. FRAZAO, M. MOITA
Fundação Champalimaud, Lisboa, Portugal

Abstract: Coordinating cooperative behaviors, the basis of social contracts, is fundamental for animals to form complex societies. To model coordinated behavior in rodents, we developed a task that tests rats in a risky Stag Hunt (SH) game. In the SH players choose either to risk cooperating for a high reward, which is risky, as it requires a coordinated cooperative choice or

to defect and receive a moderate safe reward regardless of the other's choice. The SH has two pure equilibrium strategies, mutual cooperation, which maximizes reward, and mutual defection, which minimizes risk. A third equilibrium is a mixed strategy (MS) where both rats independently cooperate with a probability that renders the utility of cooperating the same as that of defecting, minimizing risk. However, if rats coordinate their cooperative choices they can also increase their gains.In our task each rat could observe the other during decision making. Social information and reward contingencies could be precisely controlled whilst body and head position were tracked. This allowed us to ask whether, and under what conditions, freely behaving rat dyads were capable of coordinated cooperation and which, if any, equilibria behavior would be adopted. We tested 10 rat dyads and found that they overcame an initial preference for defection establishing high levels of stable cooperation close to the MS equilibria. Dyads rapidly re-established this behavior following a reversal of the assignment of cooperate and defect arms, demonstrating that rats made choices flexibly and had a strong preference for the MS strategy. Manipulating social information revealed that rats use social cues for generating and stabilizing strategic coordinated cooperation that relied on learning the contingencies between the behavior of others and outcomes. Using GLMs we show that rats built a model of the other's choices based on recent trial history. However, the rats' trajectories reflected changes-of-mind that occurred more often on trials were behavior contradicted model predictions, indicating rats revised their choice based on the other rats' behavior. Including the other's choice in the current trial improved the model's predictive accuracy. Over sessions rats were less variable and showed fewer changes-of-mind. More direct trajectories constitute clearer cues that could be used to improve coordination. Rats can solve the cooperation problem selecting a MS equilibrium, in a risky SH task to establish a rudimentary social contract. They do this by refining and interpreting social cues and building models of their opponents' choices, showing a level of socio-eonomic sophistication rarely seen outside of primate lineages.

Title: Searching for neural substrate underlying rule-observance behavior of competing mice in social conflict

Authors: *J. BYUN, A. ALKAHWAJI, H.-S. SHIN
Ctr. for Cognition and Sociality, Inst. For Basic Sci., Daejeon, Korea, Republic of

Abstract: Violating social rules might bring immediate individualistic profit, whereas orderly resolution by consent rules requires patience, but enhances long-term mutual benefit. However, the neural circuits mediating these socio-economical strategies are remained unclear. Here, we developed modified two-armed maze that uses wireless electrical brain stimulation as reward. First, the mice were individually operant-trained to initiate and then receive the reward at the signaled arm. Then, two mice were coupled and had to cooperate to initiate reward but then to compete over reward allocation. Mice develop and observe a rule of reward zone allocation that increases the total amount of reward and reward equity between the pair. Now we are investigating on the role of medial prefrontal cortex (mPFC) in reward zone allocation by using chemogenetic DREADD system and in vivo unit recordings. These results will provide a framework for understanding the circuit basis of interactive social behavior.

Title: Age affects social interaction and social novelty seeking in mice

Authors: *A. C. BARCELOS[1,2,3], F. MOURO[1,2], A. SEBASTIÃO[1,2]
[1]Faculdade de Medicina da Univ. de Lisboa, Inst. De Medicina Mol., Lisbon, Portugal; [2]Inst. de Farmacologia e Neurociências, Faculdade de Medicina, Univ. de Lisboa, Portugal, Lisbon, Portugal; [3]Serviço de Psiquiatria, Hosp. Garcia de Orta, Almada, Portugal

Abstract: Sociability in later life and its importance for heathy ageing has been gathering interest in recent years. The positive emotions that are related and experienced during social interactions represent the central reason behind the benefits of social interaction on cognitive processes. In fact, elder people less satisfied with their social networks show greater reductions in cognitive functioning over time. Furthermore, neurodegenerative diseases can be associated with social withdrawal and modifications in social behavior in elder people. How age itself affects social behavior without major interference with other life style confounding variables is difficult to disentangle in human studies. In this work we used the mouse as mice as animal model, to assess how sociability is affected by age. Sociability and reaction to social novelty was evaluated through the Three-Chamber Sociability and Social Novelty Test. On a first stage, to

test sociability, animals had the opportunity of interacting with an unknown conspecific of the same age and gender or with an inanimate object. On a second stage, to study social novelty seeking behaviour, animals were presented with a social novelty, by replacing the object with a new unknown conspecific. Anxiety and locomotion scores were assessed on the Open-Field Test (OFT). Control adult animals (15 weeks old), showed a preference for interacting with an unknown conspecific and also a marked preference towards social novelty, spending more time interacting with a novel partner than with a familiar one. Interestingly, old mice (60 weeks old) did not display the tendency for interacting with the conspecific observed in adult animals. Besides sociability, the social novelty preference of these animals was also affected. Importantly, there were no significant differences on the Open Field Test (OFT), when evaluating motor abilities and anxiety for adult and old animals. Also, by comparing the percentage of time spent interacting with the different stimuli (conspecific, object or social novelty), there were no marked reductions on the exploratory drive of old animals when comparing with adult ones. This data allow excluding deficits in locomotion, reduction in the motivation to explore, and also, anxiety increases, as contributors for the observed results. Being so, our data strongly suggests that age can play an important role in sociability since old animals displayed decreases in sociability and social novelty seeking. These results highlight the impact of age on important social behaviors, thus pointing towards the need of active strategies designed minimize this naturally occurring tendency.

Title: Muscarinic acetylcholine receptors play a role in social learning in female mice

Authors: *K. S. ERVIN[1], S. HOWARD[1], P. SANKAR[1], E. CHOLERIS[2]
[2]Psychology, [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Social learning is a unique form of cognition in which an animal acquires information from a conspecific, rather than individually through trial and error. Social learning is common and important in many animals and in humans, but we know little about the underlying neurobiological mechanisms. Social learning can be studied using the social transmission of food

preferences (STFP), a natural learning phenomenon in rodents. In the STFP, an observer prefers a food it smelled on the breath of a conspecific demonstrator over other novel food choices. From studies using the general muscarinic acetylcholine receptors (mAChR) antagonist scopolamine, we know that mAChRs are involved in acquisition of a socially learned food preference (Boix-Trelis et al, 2007, Neurobiol Learn Mem, 87:659; Carballo-Márquez et al, 2009, Hippocampus, 19:446; Carballo-Márquez et al, 2009, Neurobiol Learn Mem, 91:98). However, we still do not know which specific mAChR subtypes drive these effects on social learning. The M1 and M2 receptor subtypes are involved in other types of learning and therefore could also play a role in the STFP (Van Der Zee and Luiten (1999). Prog Neurobiol, 58:409). Our aim was to determine whether M1 or M2 blockade with dicyclomine or AFDX-116, respectively, would disrupt social learning in the STFP. Female CD1 observer mice were treated intraperitoneally with dicyclomine (1, 4, 8, 16, or 32mg/kg) or AFDX-116 (1, 3, 6, or 12mg/kg) 30min prior to a social interaction with a demonstrator. Observers were then individually housed and tested for food preference 48h later. Social learning was blocked by the highest dose of dicyclomine (32mg/kg), suggesting that M1 mAChRs may play a role in social learning. Since the effect occurred only at the highest dose, there may have been a loss of selectivity and other subtypes may be involved. Results of the STFP with the M2 antagonist AFDX-116 will futher elucidate the respective roles of the M1 and M2 receptors. Our findings help to clarify how the cholinergic system mediates social learning, an important yet understudied form of learning in humans and animals.

Title: Memory and integration of faces and vocalizations in neuronal populations in the primate prefrontal cortex

Authors: *S. SHAH[1], T. LINCOLN[2], K. KEVELSON[2], L. M. ROMANSKI[2]
[1]Neurosci., Univ. of Rochester Sch. of Med. and Den, Rochester, NY; [2]Dept Neurosci., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY

Abstract: The ventrolateral prefrontal cortex (VLPFC) plays an important role in language and communication. Previous studies have shown that VLPFC neurons respond to and integrate face

and vocalization stimuli and hold information about these stimuli online during working memory. Prefrontal neurons are highly selective in their responses to specific auditory and visual stimuli. Moreover, the magnitude and direction of multisensory responses is dependent upon particular combinations of faces and vocalizations, as well as their temporal synchrony and semantic congruence. Furthermore, neighbouring cells show responses to similar modalities and categories of stimuli. This suggests that there may be a topographic organization of the features encoded and integrated by single prefrontal neurons. However, real-world approximations of brain function require that we investigate memory and perception at the level of cell ensembles. Thus, in the current study, we used multiple single electrodes and linear electrode arrays to record simultaneously from multiple neurons while nonhuman primates performed an audiovisual working memory task using dynamic face and vocalization stimuli as the memoranda. Responsive neurons were further tested with additional exemplars of faces, vocalizations and their combination. We manipulated the stimuli along relevant feature axes including identity, vocalization category, semantic congruence, and temporal synchrony to investigate the salience of these features. We recorded from pairs and clusters of prefrontal neurons and assessed stimulus selectivity, task parameter selectivity and functional interactions between neurons within and across ensembles. By investigating the multisensory response structure at the level of neuronal ensembles in this manner, we will be able to determine what aspects of communication stimuli are being encoded and integrated by prefrontal neurons.

Title: Contrasting characteristic behaviors in common laboratory mouse strain

Authors: R. SULTANA[1], *O. M. OGUNDELE[2], C. C. LEE[3]
[1]Comparative Biomed. Sci., [2]Louisiana State Univ., Baton Rouge, LA; [3]Comparative Biomed. Sci., Louisiana State Univ. Sch. of Vet. Med., Baton Rouge, LA

Abstract: Mice models are widely used to study various neurological disorders. From development to degenerative pathophysiology, the use of mice models has allowed for the study of disease mechanism and identification of therapeutic targets. Although the behavioral characteristics of these mice models are commonly used as assays for presumed neural alterations, the genetic background of these animals can strongly influence their baseline

behavior. Among the many mouse lines, the C57BL/6J, BALB/c, CBA and 129S inbred lines along with CD1 (an outbred line) are among the most commonly used to study neurological disorders, and associated pathology in the brain. However, comparing across studies that utilize different strains is complicated owing to an incomplete knowledge of between strain variability on commonly used behavioral metrics. Thus, in the present study we aimed to classify these strains behaviorally through several of the most commonly used behavioral tests: social interaction test, forced swim test, boli count, tail suspension test, stress calls, Y-maze, spontaneous alternation, pre-pulse inhibition. In our study we found that the animals behaved differently in terms of sociability/novelty, learning-memory, cognition, negative behaviors such as despair, stress calls etc. These results further bolster the effect of background genetics on behavioral phenotype as well as predisposition to neurological diseases. The latter also provides insight in to how genetics as a component must play a role in the susceptibility of some to the development of particular neurological diseases.

Title: Functional assessment of the neuronal circuits underlying social hierarchy through whole-brain IEG screening and targeted DREADD manipulation

Authors: *H. K. OYIBO, G. B. KELLER
Neurosci., Friedrich Miescher Inst. for Biomed. Resear, Basel, Switzerland

Abstract: Rank in a social hierarchy can determine access to shelter, food, mates and/or reproductive success; with dominant individuals receiving superior access to each at the detriment of subordinates. Social stratification offers benefits to subordinates as well, although they have restricted access to resources, a predefined pecking order minimizes risky conflicts with stronger dominate individuals reducing resources expended on clashes and unnecessary injuries. Perhaps for these reasons, in many animals, including humans, social hierarchy is determined early in a given social context and is fairly stable. However, it is still unclear what neural circuits underlie the formation, maintenance and flexibility of this interactive behavior. In order to interrogate the neural circuit mechanism of social hierarchy we have used fluorophore-linked immediate early gene (IEG) transgenic mice in social hierarchy ranking assays and screened brain-wide for regions differentially activated in low vs. high raking mice. We identified several such regions including orbital frontal cortex (OFC), and medial prefrontal cortex (mPFC). To determine the functional role of these regions in social behavior, we used

targeted DREADD (designer receptors exclusively activated by designer drugs) expression and manipulation. This provided us with evidence for the direct involvement of OFC in hierarchy behavior. Further experimentation will include the interrogation of the role of various cell types within in OFC in hierarchy behavior.

Title: Causal manipulations of live social gaze by microstimulating the primate prefrontal cortex

Authors: *S. FAN, O. DAL MONTE, N. A. FAGAN, C. C. J. CHU, S. W. CHANG
Psychology, Yale Univ., New Haven, CT

Abstract: A typical gaze interaction among two or more individuals is made up of a series of contingent behaviors that unfold over time. Correlative evidence from electrophysiological recording studies in non-human primates as well as neuroimaging studies in humans have shown that several regions in the prefrontal cortex, the superior temporal sulcus, as well as the basolateral amygdala (BLA) are implicated in social gaze processing. Our recent data support that different prefrontal areas as well as BLA encode various aspects of social gaze, and that prefrontal areas and BLA are synchronized during specific social gaze events (see Dal Monte et al., 2018 SfN abstract). However, the causal contributions of these brain regions in social gaze remain unknown. Here, we therefore tested whether and how causally manipulating specific populations of neurons impacts social gaze using a live gaze interaction paradigm, in which we can accurately record spontaneous social gaze behaviors between pairs of rhesus macaques. We investigated this question in three prefrontal areas—the anterior cingulate gyrus (ACCg), dorsomedial prefrontal cortex (dmPFC), and orbitofrontal cortex (OFC)—as well as BLA. We applied closed-loop microstimulations that are contingent upon specific social gaze events. Specifically, we triggered the onset of microstimulations by three distinct types of social gaze events—1) looking at the partner's face, 2) looking at the partner's eyes, and 3) mutual eye contact. We also explored some aspects of the microstimulation parameter space to characterize a set of parameters that can effectively and reliably modulate social gaze behaviors. Depending on the stimulated brain region and the type of gaze events triggering the microstimulation, we observed distinctive changes in social gaze behaviors. Our findings inform some of the causal workings underlying dynamic and contingent social gaze in the primate brain.

Title: Social action monitoring in the mirror and the mentalizing systems of the macaque brain

Authors: *T. NINOMIYA, A. NORITAKE, M. ISODA
Div. of Behavioral Develop., Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Understanding others' actions and their consequences is of crucial importance for social life. Recent studies have revealed that the primate brain is equipped with two systems for processing such social information; the mirror system and the mentalizing system. However, it is still under debate as to how, if any, the two systems interact during social information processing. To address this issue, we trained monkeys to perform a role-reversal choice task. This is a turn-taking task involving two monkeys and required them to utilize each other's action for optimizing their own behavior. In each trial, one monkey was assigned as the actor and the other monkey as the observer. The roles of the actor and the observer alternated every three trials. The actor chose one of three targets while the observer holding his start button throughout the trial. Only one button was associated with a reward in each trial, whose position remained the same for a block of 11-17 trials. The position-reward contingency was changed in an unpredictable manner. Both monkeys were rewarded with a drop of water when the actor made a correct choice, whereas neither monkey was rewarded if the actor made a wrong choice. Neural activities were recorded simultaneously in the ventral premotor cortex (PMv) of the mirror system and the medial frontal cortex (MFC) of the mentalizing system using linear-array multicontact electrodes while the monkeys were performing the task. We found a set of neurons that were excited by the actions of its own, those of the partner, or both in each area. Some of these neurons differentiated the correct and error choices. The number of neurons selective for the partner's action in MFC was larger than that in PMv. The direction of information flow was investigated between PMv and MFC by applying a multivariate Granger causality analysis to local field potentials measured in each area. We found that Granger information flow was significantly larger from PMv to MFC than in the opposite direction during both action execution and action observation. These results indicate that PMv may provide MFC with information

related to others' ongoing action. We suggest that the mirror and mentalizing systems cooperate to predict others' action and its consequence.

Title: Social curiosity in rhesus monkeys

Authors: *J. A. JOINER[1,2], N. A. FAGAN[1], S. W. C. CHANG[1]
[1]Psychology, [2]Yale Univ., New Haven, CT

Abstract: Learning about the world is a critical feature of cognition that allows animals to manipulate their environment. Animals derive value from many different sources, and these rewards can modify behavior. Primary reinforcers like food are rewarding, but animals also experience reward from other stimuli. Some of these sources of reward are intangible, like information. Like humans, monkeys find information inherently rewarding, displaying a preference to reveal information about upcoming primary reinforcers (Bromberg-Martin & Hikosaka, 2009).

Information has utility to an organism that can use it, such as knowing where food is. However, for animals living in social groups, acquiring information from or about others is necessary. This is especially true for nonhuman primates, which live in large and hierarchically organized societies, where processing social information can be just as critical to survival as information about food.

Here, we extend an information seeking paradigm designed by Bromberg-Martin and Hikosaka into the realm of abstract, social information. We first trained monkeys on an advance information seeking task, in which monkeys can choose to see a cue that tells them in advance how much juice they are about to receive in an environment with variable reward magnitude. The choice to receive that information does not alter the amount of juice received. We replicate their finding that monkeys prefer advance information about reward magnitude. Specifically, 75-95% of the time, monkeys chose advance information, with some individual differences.

We then trained monkeys on a social variant of this task. In the social information seeking, the animal can choose a cue that tells them in advance the facial expression of a picture of a monkey face that they will be viewing for 500ms, followed by a fixed reward amount that is always delivered upon the completion of each trial. Even though this cue does not impact which face the

monkeys will see, the monkeys prefer to know the valence of the face in advance 65-80% of the time. While preference is somewhat dampened in the social information seeking task, it is critical to note that this is an abstract level of information toward which animals can express curiosity. These results indicate that advance information seeking is not just an effect of curiosity toward a primary reinforcer, but also extends to curiosity about social information. Our results suggest that curiosity in nonhuman primates can be translated into increasingly abstract levels of information.

Title: Neural coding of live social gaze interactions

Authors: *O. DAL MONTE[1], S. FAN[2], N. A. FAGAN[2], C. C. J. CHU[2], S. W. CHANG[2]
[1]Dept. of Psychology, [2]Yale Univ., New Haven, CT

Abstract: Gaze interaction, particularly eye contact, is central to social behavior. It allows individuals to communicate with one another and infer attention, emotion, and intentions from others. Single-neuron recording studies in non-human primates and neuroimaging studies in humans have indicated that several prefrontal cortical regions and the basolateral amygdala (BLA), among others, are implicated in the processing of social gaze. However, the precise mechanisms underlying how prefrontal and amygdala neurons encode social gaze events remain elusive. To address this gap, we investigated neuronal correlates of social gaze using a live gaze interaction paradigm, in which we can study spontaneously occurring gaze interactions between pairs of rhesus macaques. We recorded single-neuron and local field potential activity from three prefrontal structures - the anterior cingulate gyrus (ACCg), the orbitofrontal cortex (OFC), and the dorsomedial prefrontal cortex (dmPFC) - and BLA, in order to investigate the contribution of each brain region, as well as the coordination between each of the prefrontal regions and the BLA, in guiding social gaze. We aligned the neuronal data to two types of spontaneous social gaze events - 1) looking at the partner's eyes, and 2) mutual gaze to the eyes by both monkeys (mutual eye contact). We observed notable heterogeneities in the temporal dynamics of spiking activity. Moreover, proportions of significantly modulated cells that differentiated looking at the

eyes from looking at the other parts of the face changed around the time of the gaze event. Similarly, the proportion of a sub-group of these cells that significantly differentiated mutual eye contact from non-mutually looking at the eyes also changed around the time of the gaze event. Furthermore, when the monkey looked at the partner's eyes, compared to the other parts of the face, the coordination between prefrontal areas and BLA exhibited a robust increase in the field-field coherence in the gamma band (50-70 Hz). In contrast, upon mutual eye contact, compared to non-mutually looking at the eyes, we found changes in the coherence not only in the gamma band but also markedly in the low frequency ranges (0-15 Hz). Our findings suggest that various social gaze events are computed across multiple brain regions and their synchrony patterns reflect particular social gaze functions.

Title: Tensor component analysis (TCA) of spiking activity related to social gaze dynamics in prefrontal cortex and the amygdala

Authors: *C. C. CHU[1], O. DAL MONTE[1], S. FAN[2], N. FAGAN[2], S. W. CHANG[2]
[1]Dept. of Psychology, [2]Yale Univ., New Haven, CT

Abstract: Human and non-human primates gain critical information about their conspecifics using gaze. However, little is known about how social gaze is computed in the brain. Toward answering this question, we recorded single-neuron and local field potential activity from four different brain regions during spontaneously occurring social gaze interactions (Dal Monte et al., 2016): dorsomedial prefrontal cortex (dmPFC), anterior cingulate cortex gyrus (ACCg), orbitofrontal cortex (OFC), and basolateral amygdala (BLA). We examined how these regions encode social gaze variables by focusing on spiking activity related to looking at the eyes of the partner monkey. Based on the single neurons recorded, we found that each region exhibited heterogeneous temporal dynamics relative to the time of looking at the eyes of the conspecific partner (see Dal Monte et al., 2018 SfN abstract). To better characterize population spiking dynamics, we applied the tensor component analysis (TCA) - a dimension reduction method based on canonical polyadic decomposition, which unfolds neural responses to neuron, time, and trial dimensions (Williams, AH et al., 2017). Whereas TCA indicated that dmPFC modulates its

firing rates in a manner that is time-locked to when monkeys looked at the partner's eyes, BLA exhibits both excitatory and suppressive rate modulation patterns mostly after the onset of this social gaze event. Furthermore, TCA revealed that OFC modulates firing rates on a longer time scale around the same social gaze event. Notably, ACCg exhibits oscillations and rate modulations after looking at the partner's eyes. These TCA results mirrored the neural features observed using Principal Component Analysis (PCA) of the same data. Overall, TCA and PCA analyses suggest that amongst the four brain regions we sampled, each exhibits different time-locked modulations of neural features (rate and oscillation) during social gaze. Overall, TCA provides a useful tool to characterize complex neuronal dynamics. **Reference** Williams, Alex H., Tony Hyun Kim, Forea Wang, Saurabh Vyas, Stephen I. Ryu, Krishna V. Title: Observation learning in rats: Effect of strain and hormonal status

Authors: *R. TROHA, J. WANG, T. SHAO, E. MARKUS
Univ. of Connecticut, Storrs, CT

Abstract: Observational, or imitative, learning is a vital skill for survival. This type of social learning plays an important role in human development. Albert Bandura's seminal research showed that children which observe an adult interact with a doll in a certain manner will behave in a similar manner with the doll later on. However, observational learning is also important for other species. For example, consider a rat in a new environment and does not know where to find food. A rat that can learn a food location by observing a conspecific finding food is more likely to survive in its environment than a rat which does not learn through observation.
We have developed an observational learning paradigm in which rats must learn the location of

food in a T-shaped maze through observation. This is a working memory task with the correct goal changing on a daily basis. Therefore, the observer must attend to the demonstrator rat's performance on a daily or continuous basis.
Female F344 rats can be trained to use observational learning on this task. However they exhibit observational learning only when the demonstrator rat is near them but not they are observing from a distance. Furthermore there was no effect of the how familiar they were with the demonstrator rat.
Previous research suggests that during the proestrous stage of the rat estrous cycle, there is an increase in both estrogen and oxytocin in the brain. Oxytocin is known to play a role in mediating social and bonding behaviors in rodents.
To explore these issues further we trained female Long Evans Hooded rats on this task. These animals have a better visual acuity than F344. In addition we tracked their estrous cycle to determine hormonal effects on the degree of observational learning.

Title: Observational learning in rats: Effects of number and quality of observations

Authors: *E. J. MARKUS[1], R. TROHA[2], D. DONG[3], N. HERNANDEZ[2], T. SHAO[2]
[1]Univ. of Connecticut, Storrs Manfld, CT; [2]Univ. of Connecticut, Storrs, CT; [3]Univ. of Connecticut, South Windsor, CT

Abstract: Observational learning is an important skill for survival. This type of social learning plays a central role in human development (e.g. Bandura) and observational learning deficits have been linked to disease states such as autism and schizophrenia. Observational learning is also relevant for other species. Learning from the trial and error of others is more efficient than searching yourself when foraging the environment for food. It is also "safer" to acquire information regarding locations of danger in the environment by watching where conspecifics are threatened and how they may/may-not escape the danger.
Previous studies of observational learning have focused on multiple observations of a fixed solution to a problem (e.g. tool use, goal location). The current paradigm differs in that the solution changes across days, requiring the rat to attend daily to the "current solution".

Specifically F344 rats observe a demonstrator rat find the goal arm in a T-shaped maze, with the rewarded arm changing in a pseudorandom fashion.
The observer rats showed better than chance choices on their first trial on the maze. Factors such as the proximity to the demonstrator rat, number of observed trials, quality of the observed trials, and previous experience all determined the performance of the observing animal. The identity of the demonstrator and quality and number of observations from a distance has less of an impact on performance.

Title: Dual gating by vasopressin of hippocampal CA2 soma and presynaptic terminals in lateral septum

Authors: *F. LEROY[1], L. M. BOYLE[1], J. PARK[1], A. ASOK[2], D. H. BRANN[1], T. MEIRA[1], E. W. BUSS[1], E. R. KANDEL[2], S. A. SIEGELBAUM[1]
[1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]Dept. of Neurosci., Columbia Univ. / HHMI, New York, NY

Abstract: Although the hippocampus is well known to play a central role in declarative memory, its importance for motivated behaviors, including social aggression, remains relatively unexplored. We find that hippocampal CA2 pyramidal neurons, previously implicated in social memory storage, promote social aggression through output to a lateral septal circuit that disinhibits neurons in the ventral medial hypothalamus, which triggers attack on a conspecific. *In vivo* fiber-photometry revealed enhanced CA2 activity during social encounters, with a selective increase in CA2 output to LS preceding attacks. Here we address how a single hippocampal subregion can control both social memory and social aggression. Are there dual populations of CA2 neurons, one projecting to CA1 to mediate social memory and one to LS to promote aggression? Or might a single CA2 population differentially elicit aggression versus social exploration as a result of the internal state of the animal? In dual tracer analysis we now find that most, if not all, CA2 pyramidal neurons bifurcate to project to both CA1 and LS. This suggests that CA2 output may be gated by a neuromodulator whose release depends on internal state. We

focused on the social neuropeptide arginine vasopressin (AVP) as it is known to promote aggression and social memory, and CA2 PNs are highly enriched in the vasopressin 1b receptor (AVPR1b). We hypothesized that the source of vasopressin input to the LS (bed nucleus of the stria terminalis and/or medial amygdala) might differ from the AVP input to dorsal hippocampus (hypothalamic paraventricular nucleus), suggesting the presence of parallel bottom-up and top-down modulatory circuits regulating social aggression and social memory. Our initial results confirm these dual sources of vasopressin input and we are examining their differential control over social memory or social aggression. Furthermore, we show that AVP enhances social aggression by acting on AVPR1b on CA2 presynaptic terminals in lateral septum to enhance excitatory synaptic transmission. In this manner, vasopressin release in lateral septum may serves as a gate driven by an animal's internal state that enables a single brain region to either store declarative memory of a social encounter or promote motivated social aggression.

Title: Social memory encoding by Vasopressin 1b receptor-expressing Pyramidal neurons in CA2 hippocampal subfield of mice

Authors: *A. CYMERBLIT-SABBA[1], M. STACKMANN[1], S. K. WILLIAMS AVRAM[1], M. C. GRANOVETTER[1], A. SMITH[2], H.-J. LEE[3], J. SONG[1], W. YOUNG III[1]
[1]NIMH, Bethesda, MD; [2]Dept. of Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS; [3]Microbiology & Immunol., Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Recognitions of others may occur at different levels: social hierarchical status, health (e.g., parasitic load), emotions (e.g., stress-empathy), genetic relatedness (kin recognition) familiarity (have I met you before?) and individual identity (yes, you are Alma) (Colgan, 1983). To maintain successful complex social behaviors, the neural network must allow dynamic acquisition, representation and retrieval of the social cues. The involvement of the CA2 subfield of the hippocampus in social memory have been well established. Still, the way these memories are encoded by it remains, for the most part, unknown. We imaged the calcium transients in selective pyramidal neurons within the CA2 subfield - those that express cre from the Avpr1b

promoter in a mouse knockin line to activate virally delivered GCaMP - of socially behaving mice to map the neural response to the stimuli presented. Our results show increased response upon presentation of a novel stimulus with a subsequent decrease when the stimulus is removed from the cage. Moreover, upon familiarization, neural representation becomes sparser and activity is attenuated in a stimulus-specific manner. Although the cells response to both social and non-social stimuli, the population response is significantly greater when the social stimulus is presented. Our preliminary results suggest a preferred social encoding by these vasopressin 1b receptor-expressing pyramidal neurons, with a possible mechanism of repetition suppression.

Title: Oxytocin receptor-positive dentate neurons mediate the effects of state-dependent memory on social behavior

Authors: *M. MEYER[1], K. NISHIMORI[2], J. RADULOVIC[3]
[1]Northwestern Univ. - Chicago, Chicago, IL; [2]Grad Sch. of Agric Sci, Tohoku Univ., Sendai-Shi, Japan; [3]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Stress-related memories are typically encoded so that they can be retrieved robustly. However, under certain conditions, memories cannot be retrieved by natural recall cues, unless the brain is in the same state as during encoding. Such ‘state-dependent’ memories, have been implicated in several psychopathologies, including traumatic amnesia. For instance, patients suffering from stress-related disorders commonly have dissociative symptoms related to their inability to recall the traumatic event unless they are in a similar psychological or physiological state as when the trauma occurred. Despite inaccessibility to retrieval under normal conditions, state-dependent memories may subsequently affect other behaviors, as dissociative amnesia is highly correlated with deficits in social functioning. We therefore investigated phenotypic effects of state-dependent memory on social behavior in mice. In a pharmacological model of state-dependent memory, we demonstrated that state-dependent contextual fear conditioning impairs sociability and social recognition. Based upon accumulating evidence that hippocampal oxytocin

receptors are required for social recognition, but not sociability behavior, we used chemogenetic approaches to test the role of oxytocin receptor-positive neurons in the effects of state-dependent memory on social behaviors. Our experiments demonstrated that oxytocin receptor-positive dentate neurons mediate the observed sociability deficit, such that chemogenetic inactivation successfully rescues behavior. These studies begin to elucidate cellular mechanisms by which state-dependent memories affect social behaviors.

Title: Ventral hippocampal inputs to the mPFC regulate social memory

Authors: *M. PHILLIPS[1], L. POZZO-MILLER[2]
[1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Neurobio., Univ. Alabama-Birmingham, Birmingham, AL

Abstract: Altered ventral hippocampal (vHIP) input to the medial prefrontal cortex (mPFC) has been implicated in many disorders including autism, schizophrenia, and PTSD. Here we use *Mecp2* knockout (KO) mice as a model of the autism-associated disorder Rett syndrome to define the behavioral consequences of altered vHIP-mPFC projections. We first identified an increased influence of vHIP afferents on mPFC network activity in *Mecp2* KO mice when compared to wildtype (WT) littermates, as determined by larger and wider spreading voltage sensitive dye (VSD) signals during subthreshold synaptic potentials evoked by stimulation of vHIP fibers in mPFC slices. To identify active neurons during specific behavioral tasks, we performed retrobead tracing to label pyramidal neurons in the vHIP that project to the mPFC, followed by c-Fos immunohistochemistry as a surrogate of neuronal activity. This approach revealed that mPFC-projecting vHIP neurons are selectively activated in WT and *Mecp2* KO mice during social tasks, compared to non-social tasks and to other vHIP projection neurons. Using unbiased machine-learning classifiers to score behaviors in freely moving mice, we

identified social memory deficits in *Mecp2* KO mice. To test if stronger vHIP inputs to the mPFC are causal to social memory deficits in *Mecp2* KO mice, we altered the activity of mPFC-projecting vHIP neurons by intersectional chemogenetics. Increasing the activity of mPFC-projecting vHIP neurons between P34-P45 with an excitatory DREADD impaired social memory in WT mice. In addition, this manipulation resulted in larger vHIP-evoked VSD signals in mPFC slices, resembling those in *Mecp2* KO mice. On the other hand, reducing the activity of mPFC-projecting vHIP with an inhibitory DREADD was sufficient to restore social memory in *Mecp2* KO mice, while reducing vHIP-evoked VSD signals in mPFC slices, resembling responses in WT mice. Further analyses revealed that the amplitude of vHIP fiber-evoked VSD signals in mPFC slices of inhibitory DREADD-expressing *Mecp2* KO mice correlate with their performance in social memory tasks. These data demonstrate that the vHIP-mPFC projection is necessary for social memory.

Title: Socially learned food preferences are associated with sex-specific changes in dorsal hippocampal dopamine release in mice

Authors: *R. MATTA, M. J. RUSSELL, C. L. LIMEBEER, L. A. PARKER, E. CHOLERIS
Dept. of Psychology and Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: Social learning allows animals the ability to exploit the ‘expertise of others’ to possibly avoid some of the risks that are often associated with trial-and-error individual learning. One form of social learning, often studied in the lab, is the social transmission of food preferences (STFP). Our previous work using systemic treatments of dopamine (DA) receptor antagonists has shown an involvement of DA D1-type receptors in social learning (but not food intake), and DA D2-type receptors in food intake (but not social learning) in the STFP in female mice (Choleris et al., 2011). We are now examining the potential brain region(s) underlying these effects. Dopaminergic projections ascend from the ventral tegmental area (VTA) to many limbic brain structures, including the hippocampus, which has been established as necessary for the initial encoding/acquisition of the STFP in rodents. Our previous work using DA receptor antagonists infused directly into the dorsal hippocampus has shown that female mice rely on both DA D1- and D2-type receptors, while male mice only rely on DA D1-type receptors (Matta et

al., 2016, 2017). In this study we examined whether social learning in the STFP was associated with changes in dorsal hippocampal DA release in male and female mice. This study involved the use of *in vivo* microdialysis sampling (flow rate of 0.6 μL/min, samples collected every 20 min), and high-performance liquid chromatography (HPLC) detection of dopamine. We found that both females and males acquired a socially learned food preference and there were no sex differences in total food intakes. Females and males also spent more time investigating a socially demonstrated/learned (DEM) diet odor than a NON-DEM diet odor. Direct comparisons between males versus females showed that hippocampal DA release during the NON-DEM diet odor (novel food), NON-DEM social (no social learning), and STFP was greater for males than females. Comparisons directly to baseline samples further showed that male hippocampal DA release increased during the NON-DEM diet odor, NON-DEM social, STFP exposure, and choice test. On the other hand, female hippocampal DA release decreased during the NON-DEM diet odor, NON-DEM social, and STFP exposure. Notably, there was no difference between female vs. male oronasal investigation durations during the STFP, suggesting that the sex differences in dorsal hippocampal DA release during STFP could not be explained by differences in exposure to the socially carried food odor found on the breath of the DEM. Together, the current and our previous findings suggest sex-specific mechanisms in dorsal hippocampal DA mediation of social learning.

Title: Delineating the hippocampal circuitry underlying pair bonding in prairie voles

Authors: *J. A. TEMPLE[1], M. A. BEST[1], H. R. DOUGHERTY[1], Z. R. DONALDSON[2]
[1]Univ. of Colorado Boulder, Boulder, CO; [2]MCBD/Psychology & Neurosci., Univ. of Colorado, Boulder, Boulder, CO

Abstract: Pair bonds are long-lasting social attachments that form between mating partners. While pair bonding is common among humans, the majority of mammals, including laboratory

rats and mice, do not exhibit this trait. Instead, socially monogamous prairie voles, which form life-long pair bonds, provide an excellent model for studying attachment in adults. To date, the study of pair bonding in prairie voles has focused on neuromodulatory systems, including oxytocin, vasopressin, dopamine and endogenous opiates, while the specific neural circuits that modulate attachment remain largely unexplored. The ventral hippocampus has been implicated in regulation of emotions and social memory across a variety of rodent species. Thus, we asked whether the ventral hippocampus is required for a selective partner preference, a behavioral indicator of pair bonding. We used ibotinic acid to bilaterally lesion the ventral CA1 region in female prairie voles. After two weeks of recovery, estrogen-primed females were paired and mated with a male. Twenty-four hours later, we performed a partner preference test, which revealed that lesion animals failed to form a preference, while sham animals exhibited a strong preference for their mate. Our ongoing work is examining the specific role of different hippocampal projections in different phases of pair bonding. This research will provide a novel dissection of the role of hippocampal systems in pair bonding behavior, potentially providing valuable insights into how disruption of these circuits contributes to social deficits.

Title: Exploring the role of hippocampal area CA2 in the pilocarpine mouse model of mesial temporal lobe epilepsy

Authors: *A. WHITEBIRCH[1], K. S. VADDURI[2], B. SANTORO[2], S. A. SIEGELBAUM[2]
[1]Neurosci., Columbia Univ., New York, NY; [2]Dept of Neurosci., Columbia Univ. Coll P & S, New York, NY

Abstract: Mesial temporal lobe epilepsy (MTLE) is a drug-resistant form of epilepsy associated with a pattern of pathology termed mesial temporal sclerosis, in which there is extensive cell loss in hippocampal areas CA1 and CA3 while the dentate gyrus and CA2 regions remain relatively intact. The fact that the hippocampus is a major site of seizure activity in MTLE, despite the degeneration in CA1 and CA3, suggests that epileptiform activity may be generated in or

conveyed through surviving CA2 circuitry. Accumulating evidence suggests that CA2 may have a key role controlling hippocampal network excitability in the healthy brain, but CA2 circuits have not been well-characterized at a physiological level. CA2 pyramidal neuron (PN) axons form local collaterals and project throughout the hippocampus, contributing to a recurrent excitatory network that generates both normal and pathological forms of synchronous activity. Despite anatomical evidence, recurrent connectivity among CA2 PNs has not been investigated electrophysiologically. Back-projecting axons from CA2 are known to evoke direct excitatory and feedfoward inhibitory responses in CA3, but the role of this circuit in MTLE has not been investigated. Importantly, changes to CA2 excitability or functional synaptic connectivity in epileptic mice and the contribution of CA2 to hippocampal hyperexcitability remain unexplored. To address these gaps in knowledge, I use optogenetic and chemogenetic approaches in the *Amigo2-Cre* mouse line to selectively target CA2 PNs. This targeted approach enables characterization both of CA2 circuits in normal tissue and of alterations to CA2 intrinsic and extrinsic electrophysiological properties in the pilocarpine mouse model of MTLE. I hypothesize that in MTLE area CA2 acts as a hub supporting the generation and propagation of epileptiform activity in the hippocampal network. My preliminary data from normal mice suggest that CA2, like CA3, is part of an auto-associative network. Thus, CA2 PNs send longitudinal connections that excite other CA2 neurons. As reported by others, CA3 excitation by CA2 is normally limited by strong feed-forward inhibition. Data from pilocarpine-treated mice reveal increased intrinsic excitability of CA2 PNs and suggest enhanced excitatory synaptic input to CA2 as a result of decreased feedforward inhibition. Furthermore, in an *in vitro* model of pharmacologically-induced epileptiform activity, acute silencing of CA2 PNs reduced population bursting in CA1. Moving forward, this research will advance our understanding of the role of CA2 in the generation of seizures in MTLE, one of the most common and difficult to treat forms of focal epilepsy.

Title: Modified firing in hippocampal area CA2 in a mouse model of schizophrenia during social tasks

Authors: *M. L. DONEGAN[1], F. STEFANINI[1], S. FUSI[1], J. A. GORDON[2], S. A. SIEGELBAUM[3]
[1]Neurosci., Columbia Univ., New York, NY; [2]Office of the Director, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Dept of Neurosci., Columbia Univ. Coll P & S, New York, NY

Abstract: Social interaction and bonding are crucial for mammalian survival, providing a support system for offspring rearing, increased security, and reduced expenditure of resources. Recent work on area CA2 of the hippocampus has shown it is necessary for the formation of social memory, and that optogenetic stimulation of neuromodulatory inputs to CA2 improves social memory. CA2 has also been implicated in neuropsychiatric diseases associated with altered social behavior. Thus, patients with schizophrenia and bipolar disorder show specific losses of parvalbumin-positive (PV+) interneurons in CA2 but not neighboring CA1 and CA3. Of particular interest, these alterations in CA2 are recapitulated in the Df(16)A+/- mouse model of the 22q11.2 deletion syndrome, which confers a 30-fold increased likelihood of developing schizophrenia in humans. Thus, these mice show an age-dependent loss of PV+ interneurons specific to CA2, as well as a deficit in social memory. CA2 pyramidal neurons also become hyperpolarized in these mice via an upregulation of the TREK-1 outward rectifying potassium channel. Although CA2 has been implicated in social memory and its disorders, little is known about the normal in vivo firing properties of CA2, and how these may be altered in disease. To characterize CA2 firing during social behavior we recorded extracellularly from CA2 of both wild-type and Df(16)A+/- mice during a modified 3 chamber social interaction task during which the mice interact with: 1) an empty chamber, 2) novel objects, 3) littermates, and 4) novel mice. In wild-type animals, CA2 firing is highly heterogeneous during this task, and CA2 spatial firing is diffuse and unstable from session to session. CA2 pyramidal cells from Df(16)A+/- mice show no change in average or peak firing rates during these tasks, suggesting that the hyperpolarization and reduced inhibition may be compensatory. However, CA2 firing patterns of Df(16)A+/- mice are significantly more stable across the different sessions, with greater spatial information content. CA2 population activity in wild-type mice is better able to decode the context in a session—for example, whether a mouse is in a social versus non-social session—compared to neurons from Df(16)A+/- mice. These results indicate that changes in firing patterns of hippocampal area CA2 are necessary for social memory, and the increased stability of CA2 firing patterns may contribute to social deficits associated with neuropsychiatric diseases such as schizophrenia.

Title: Correlations of autism-like behaviors and altered hippocampal circuit following febrile seizures

Authors: *Y. YU, J. KANG, K. LEE, D.-Y. YOO, D.-K. PARK, K.-H. PARK, D.-S. KIM
Col. of Med., Soonchunhyang Univ., Cheonan-Si, Chungcheongnam-Do, Korea, Republic of

Abstract: Febrile seizure (FS) is the most common seizure type in the infant and young child. FS induce functional changes in the hippocampal circuitries and then contributed toward the development of temporal lobe epilepsy (TLE). Moreover, the hippocampus is critical for encoding declarative memory and especially, dysfunction of CA2 pyramidal neurons caused a pronounced loss of social memory in genetic and autism models. On the other hand, autism is a neurodevelopmental disorder characterized by deficits in social interaction, restricted and repetitive behaviors. Therefore, in this study, we are identifying the interrelation that autism-like behavior and dysfunction hippocampal circuits in FS animal model. In the results of this study, to characterize of behavioral disturbance by emotional, social and cognitive dysfunction, we were experimented behavior test. In addition, we were investigated field excitatory postsynaptic potential (fEPSP) in the hippocampus for identifying impairs synaptic transmission, observed that resultant slope of fEPSP were markedly reduced more than control level. Additionally, immunoreactivity of interleukin-6 (IL-6) was enhancing those CA2 regions of hippocampus and cerebellum compared with control. Therefore, our findings in present study revealed that autistic neuroanatomical structures and neuronal plasticity in development periods after FS, thus it might seem to be involved to potential onset of autism by genetic alterations following FS.

Title: Maturation of excitatory synapses studied in parallel with spatial navigation ability in the juvenile rat

Authors: *N. VALIBEIGI[1], C. KIMBALL[2], D. CHEN[4], R. H. OGOE[5], D. G. MCHAIL[2], T. C. DUMAS[3]

Abstract: Spatial navigation in rodents depends on neural networks in the hippocampus, a forebrain structure known for its role in human episodic memory. This critical ability emerges at about three weeks of age [postnatal day, (P)21] in rodents, in parallel with functional changes at hippocampal excitatory synapses. In particular, hippocampal AMPA receptors shift in composition from predominantly GluA1-containing to GluA3-containing, and this prolongs the synaptic response and lowers the threshold to induce long-lasting changes in synaptic strength. In prior research, we demonstrated that treatment of juvenile rats with AMPAKINE drugs, which prolong excitatory synaptic responses, elicited more mature spontaneous alternation in a Y-maze. Since free exploration in the Y-maze does not have distinct learning and memory phases, we adapted the Barnes maze task for juvenile animals. We explored relationships between AMPAR subunit expression and spatial learning and memory abilities in juvenile Long Evans rats just under (P17-20) and just over three weeks (P22-25). Half of the animals at each age were treated with AMPAKINE drug before Barnes maze testing and double immunofluorescent labeling (GluA1, GluA3) was performed on thin brain sections from maze trained animals and naïve controls. It was found that while AMPAKINE delivery did not affect learning at either age, older animals treated with AMPAKINE showed a more direct approach to the goal location in memory probes than older control animals. Ongoing analyses will assess whether developmental differences in AMPAR subunit expression are related to maze performance. Together, the results will help clarify what aspects of spatial learning and/or memory are impacted by maturation of hippocampal AMPARs

Title: NYX-458, a novel small molecule NMDA receptor modulator, enhances novel object recognition in rats

Authors: *E. M. COLECHIO[1], T. K. BHATTACHARYA[2], J. AGUADO[2], J. GAJDA[2], A. BARTH[2], E. RODRIGUEZ[2], P. KANSARA[2], E. POLLARD[2], M. A. KHAN[3], P. K. STANTON[4], X. L. ZHANG[4], M. S. BOWERS[2], J. R. MOSKAL[2], C. N. CEARLEY[2]

[1]Behavioral Pharmacol., Aptinyx, Inc., Evanston, IL; [2]Aptinyx Inc, Evanston, IL; [3]Aptinyx, Inc, Evanston, IL; [4]Cell Biol. & Anat., New York Med. Col., Valhalla, NY

Abstract: Aptinyx has developed a novel class of small molecule N-Methyl-D-aspartic acid receptor (NMDAR) modulators with broad applicability across neurologic and psychiatric disorders. Aptinyx compounds display differential binding to NMDARs containing the A, B, C, or D NMDAR2 subtypes. Using the [3]MK-801 potentiation assay with HEK cell membrane extracts containing specific NMDAR2 subtypes, we found that NYX-458 binds the B and D, but not A or C subtypes. Given the central role of NMDARs in synaptic plasticity, NYX-458 effect on long-term potentiation (LTP) was evaluated. NYX-458 was found to enhance the magnitude of LTP at Schaffer collateral/CA1 hippocampal synapses when applied to slices at 100 nM. Given this, we tested the hypothesis that NYX-458 would facilitate cognition using the NOR assay. This assay is based on rats' instinctive preference for exploring novel objects, stimuli, and environments and is considered a measure of recognition memory. Administration of NYX-458 (0.01, 0.1, 1, or 10 mg/kg, PO) 1 h before the sample trial (T1) increased exploration of the novel object relative to the familiar object in the test trial (T2) conducted 24 h later. Further studies demonstrated that the effect was only seen when compound was administered prior to T1 and not when administered either immediately following T1, or 1 h before T2, suggesting that NYX-458 selectively facilitates encoding of object recognition versus consolidation or retrieval. Studies were also performed to better understand the duration of effect and a single dose of NYX-458 (0.1 mg/kg, PO) improved object recognition memory when administered up to 48 h before T1 and continued to be effective when the T1-T2 intertrial interval was extended to 48 h. Additional pharmacokinetic and safety pharmacology studies showed that NYX-458 exhibited high oral bioavailability and brain penetrance, with no psychotomimetic or locomotor effects seen in either open field or Rota-rod assays. Together, these data indicate that NYX-458 is a novel, well-tolerated, orally bioavailable NMDAR modulator that exhibits pro-cognitive effects.

Title: NYX-458, a NMDA receptor modulator, when tested in aged F344 rats, facilitates LTP and reverses age-related cognitive deficits as measured by the Morris water maze

Authors: *A. L. BARTH[1], J. D. AGUADO[2], A. MOGHADAM[4], P. K. STANTON[5], M. A. KHAN[1], J. R. MOSKAL[6,3], C. CEARLEY[2]
[1]Aptinyx Inc, Evanston, IL; [2]Res., [3]Aptinyx Inc., Evanston, IL; [5]Cell Biol. & Anat., [4]New York Med. Col., Valhalla, NY; [6]Northwestern Univ., Evanston, IL

Abstract: Aptinyx has developed a novel class of small molecule orally bioavailable N-methyl-D-aspartate receptor (NMDAR) modulators with broad applicability across CNS disorders. NYX-458 has a preference for NMDAR2B and NMDAR2D receptor subtypes and shows cognitive enhancement in rodent learning models with no toxicity or safety pharmacology concerns at all doses tested. In the present study, NYX-458 was initially evaluated for effect on aged F344 (26-27 months-old) rat hippocampal long-term potentiation (LTP) and long-term depression (LTD). NYX-458 was then evaluated in aged F344 rats tested in the Morris water maze (MWM) for efficacy in treating age-related cognitive decline.The magnitude of stimulus-evoked LTP in aged F344 rat was markedly reduced relative to young adult (3 month old F344)

rats. Bath application of NYX-458 (50 and 100 nM) to hippocampal slices in vitro from aged rats was shown to enhance the magnitude of long-term potentiation (LTP) at Schaffer-collateral-CA1 synapses to levels seen in young adult rats. LTD at hippocampal Schaffer-collateral-CA1 synapses and was not significantly different in aged rats from young adult rats. NYX-458 (50, 100 and 500 nM) had no effect on LTD in either young adult or aged rats. Lastly, we assessed NYX-458 (0.1, 1, and 10 mg/kg, PO) for effect on aged rat performance in the fixed platform version of the MWM. In these assays, young rats, when released twice per day from four equally spaced starting positions around the perimeter of the pool (in a pseudorandom order to prevent a procedural learning strategy), were able to use extra-maze cues to locate a hidden circular platform that remained in the same location across all 4 training days. Unlike young rats, aged rats did not show improvements in performance (as measured by reductions in path length, latency to the platform, and Gallagher's measure) across all 4 training days. Importantly, administering NYX-458 (1 mg/kg) at 1 hour prior to the start of testing on each day, brought aged rat performance to young rat performance levels by day 4. Taken together, these data suggest that NYX-458 enhances synaptic plasticity mechanisms associated with learning and memory and has therapeutic potential for treating age-related cognitive decline.

Title: Neuroprotective effects of chronic memantine treatment on okadaic acid (ICV) induced neurotoxicity at behavioral, structural and molecular level in rats

Authors: *G. BESELIA[1,2], M. DASHNIANI[1], M. BURJANADZE[1], N. CHKHIKVISHVILI[1], L. KRUASHVILI[1], M. CHIGLADZE[1]
[1]Lab. of Behavior and Cognitive Functions, I. Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia; [2]Dept. of Behavioral Sci., Petre Shotadze Tbilisi Med. Acad., Tbilisi, Georgia

Abstract: In the present study, intracerebroventricular (ICV) injection of okadaic acid **(**OA) in rats was used as a memory impairment and hippocampal neurodegeneration animal model. The possible beneficial effect of memantine - NMDA (N-methyl-D-aspartate) receptor antagonist on the OA-induced spatial memory impairment was examined in Morris water maze (MWM). The neuroprotective potential of memantine on OA-induced structural and molecular changes in the hippocampus and medial septum (MS) was evaluated by immuno and Nissl staining. The OA induced neurotoxicity and neuroprotective effects of chronic memantine treatment at behavioral, structural and molecular level was evaluated in 4 groups of animals: control rats injected i.p. with saline or memantine and **OA injected rats** treated i.p. with saline or memantine. OA was dissolved in artificial cerebrospinal fluid (aCSF) and injected ICV 200 ng in avolume of 10 µl bilaterally. Vehicle control received 10 µl of aCSF ICV bilaterally. Memantine (5 mg/kg, i.p) or saline were given daily for 13 days starting from the day of OA injection. Experimental protocol was approved by Animal Studies Committee of I. Beritashvili Center of Experimental Biomedicine. The results described in this chapter showed that bilateral injection of OA causes a deficiency of spatial memory and loss of hippocampal cells in this model and demonstrated for the first time, to our knowledge, reduces the number of cholinergic and GABAergic medial septal neurons. These changes are observed in patients with Alzheimer's disease and, therefore, reinforce the importance of this model for the investigation targets of new therapeutic strategies. The results have shown that the chronic exposure of memantine can prevent a deficiency of spatial memory and that an improvement in memory function correlates with the prevention of OA-induced neuropathological changes in the hippocampus and MS. This fact, on the one hand, points to the involvement of neuropathological processes developed in the hippocampus and MS in memory impairment caused by OA, and, on the other hand, the involvement of NMDA receptors in the neurotoxicity of OA.

Title: Dopamine and norepinephrine transporter inhibitors act synergistically to enhance long-term memory

Authors: *M. M. PANTONI, C. DOAN, T. QIU, L. HAMMAM, S. G. ANAGNOSTARAS
Psychology, UC San Diego, La Jolla, CA

Abstract: Psychostimulants (e.g., amphetamine and methylphenidate) are highly effective cognitive enhancers, yet have a high potential for addiction. It is widely believed that norepinephrine transporter (NET) inhibition is exclusively responsible for the procognitive effects of psychostimulants. However, increasing evidence suggests that dopamine transporter (DAT) inhibition is also required for psychostimulant-induced long-term memory (LTM) enhancement. Although DAT inhibition is responsible for the addictive potential of psychostimulants, drugs with weak affinity for DAT may not produce addiction. In the present study, we examined the combined effects of strong NET inhibition (e.g., atomoxetine, nisoxetine) and weak DAT inhibition (e.g., bupropion) on LTM in mice (adult, male and female, n = 8 to 24 per dose group) using Pavlovian fear conditioning. While individually these NET and DAT inhibitors had no effect on LTM across a range of doses, the combination of certain doses significantly enhanced LTM relative to saline controls. Additionally, combined NET and DAT inhibition did not produce reinforcement on a conditioned place preference test. We propose that a pharmaceutical combination of strong NET and weak DAT inhibition could lead to the development of a highly effective cognitive-enhancing medication that lacks the potential for addiction.

Title: Iso-alpha-acids, bitter components in beer, improve memory function via dopaminergic activation in hippocampus

Authors: *Y. ANO[1], A. HOSHI[2], S. UCHIDA[3], K. YAMADA[3], K. KONDO[1]
[1]Res. Labs. for Hlth. Sci. & Food Technologies, [2]Central Labs. for Key Technologies, Kirin Company, Limited, Yokohama, Japan; [3]Kyowa Hakko Kirin Co., Ltd., Shizuoka, Japan

Abstract: Background Our group previously demonstrated that iso-α-acids, bitter components in beer, prevent Alzheimer's disease pathology in the transgenic model mice (Ano et al., 2017), but the effects of iso-α-acids on neuronal activity and memory function have not been elucidated. In the present study, the effect of iso-α-acids on memory function was investigated.Materials and Methods To investigate the effects of iso-α-acids on memory impairment induced by Aβ, the spatial and episodic memories were evaluated by spontaneous alteration test of Y-maze and by novel object recognition test (NORT) at 1 hour after oral administration of donepezil or iso-α-acids in 6-week-old male ICR mice treated intracerebroventricularly with oligomer Aβ1-42. Next, to evaluate in amnesia or normal condition, mice orally given iso-α-acids were subjected to the Y-maze trial after the intraperitoneal injection with scopolamine or to NORT. Besides the behavioral evaluations, for measuring the effects of iso-α-acids on monoamine productions in the brain, the monoamine levels in the hippocampus of SD rats orally administered with iso-α-acids was measured using a microdialysis system. Finally, to determine the involvement of dopamine receptor, mice given iso-α-acids were treated with scopolamine and SCH23390 which is dopamine D1 receptor antagonist before the Y-maze test. Results Intakes of iso-α-acids significantly improved memory impairment of spontaneous alterations in Y-maze and novel object approaching time in Aβ-inoculated mice, which was equivalent to donepezil. A single intake of iso-α-acids also improved the scopolamine-induced amnesia and enhanced episodic memory in normal mice. These results suggest that intakes of iso-α-acids enhance the hippocampus dependent memory function. Microdialysis analysis revealed that an intake of iso-α-acids significantly increased dopamine release in the hippocampus of SD rats compared with control treatment. Treatment with dopamine D1 receptor antagonist attenuated the improvement of spontaneous alteration by iso-α-acids. These results suggest that an intake of iso-α-acids improves memory function via dopaminergic neuronal activation. Conclusion The present study revealed that intakes of iso-α-acids, hop derived bitter components in beer, enhance dopaminergic systems in the hippocampus and spatial and episodic memories. Some reports described that dopamine is involved in the hippocampus dependent memories. Intakes of iso-α-acids might contribute to the improvement of cognitive decline through the activation of memory functions.

Title: The effects of serotonergic hallucinogens on temporal processing

Authors: *B. AKDOGAN[1], S. DEWIL[1], B. COTTEN[2], A. WANAR[2], J. GINGRICH[1,3], P. D. BALSAM[2,3]
[1]Columbia Univ., New York, NY; [2]Barnard Col., New York, NY; [3]New York State Psychiatric Inst., New York, NY

Abstract: Impairments in temporal processing occur in many psychiatric disorders including schizophrenia. However, despite the fundamental role of timing in adaptive behavior and goal-directed action, the neural substrates of timing deficits observed in schizophrenia are not well-characterized. To begin addressing this question, we targeted the 5-HT_2 receptors which are implicated in timing behavior and in hallucinations, a symptom of schizophrenia. Specifically, we first trained mice in a temporal bisection task in which they learned to categorize durations as short or long. We then administered the hallucinogen 2,5-dimethoxy-4-iodoamphetamine (DOI) at one of three doses (0.3, 1.0, 3.0 mg/kg) prior to test sessions. Systemic DOI injections led to dose-dependent disruptions in mice's duration discrimination performance. Specifically, higher doses of DOI administration flattened and shifted the response functions to the right, indicating that mice were more variable in their temporal choices and had a higher tendency to categorize experienced durations as short. These results corroborate the importance of serotonergic signaling in timing ability and suggest that disruptions in serotonergic signaling in schizophrenia patients may contribute to hallucinations and more generally to an altered sense of reality including changes in temporal information-processing.

Title: Effects of 5-HT6 receptor blockade on repetitive behaviors in the BTBR mouse model of autism spectrum disorder

Authors: *S. PETERSON[1], R. POSADAS[2], A. HERNANDEZ[2], J. DURO[2], D. LOPEZ-SANCHEZ[2], D. A. AMODEO[2]
[1]Psychology, California State Univ. San Bernardino, Upland, CA; [2]Psychology, California State Univ. San Bernardino, San Bernardino, CA

Abstract: Repetitive behaviors are a prevailing symptom across several neuropsychiatric and neurodevelopmental disorders. To date, there is a lack of effective treatments for the attenuation of repetitive behaviors with restricted interests (RRB) in autism spectrum disorder (ASD). The 5-hydroxytryptamine 6 (5-HT6) receptor is of particular interest as a therapeutic target because blockade has been shown to have pro-cognitive affects and is a promising novel target for attenuating behavioral rigidity. The current experiments aim to better determine how the 5-HT6 receptor antagonist BGC 20-761 attenuates repetitive grooming and behavioral inflexibility in the BTBR mouse model of ASD and control C57BL/6J strain. Mice were tested on three separate behavioral measures including the 8-arm spatial strategy task (behavioral flexibility), repetitive grooming (sensorimotor stereotypy) and locomotor activity. Mice received an injection of vehicle, 0.1, or 1 mg/kg BGC 20-761 before each of six consecutive days of testing. Initial experiments demonstrate that vehicle treated BTBR mice show an impairment in the 8-arm spatial strategy task. We predicted that 5-HT6 receptor antagonist treatment would attenuate the behavioral inflexibility expressed by BTBR mice in this particular task. Contrary to our predictions, BGC 20-761 did not attenuate behavioral flexibility in BTBR mice compared to C57BL/6J controls. Current studies are examining the effects of 5-HT6 receptor agonist EMD386088. BGC 20-761 at both 0.1 and 1 mg/kg BGC 20-761 reduced repetitive grooming in the BTBR mouse. Vehicle and BGC 20-761 treated BTBR mice showed comparable locomotor activity. Together these findings suggest that 5-HT6 receptor blockade with BGC 20-761 may be effective at reducing the sensorimotor repetitive behaviors in ASD but may not be effective for the more cognitively-based repetitive choice behavior.

Title: Neurobehavioral effects of chronic risperidone administration on juvenile male rats

Authors: *M. F. DE BUTTE, L. BOMAN
Psychology, Sociology, and social work, West Texas A&M Univ., Canyon, TX

Abstract: Despite substantial increases in the use of antipsychotics to treat various psychiatric conditions in children, there is a lack of literature regarding long-term effects of early treatment. Some studies have indicated that early administration results in differential alterations to neurotransmission systems, but few studies have investigated whether there are long-term behavioral modifications. Therefore, the aim of the current study was to investigate the neurobehavioral effects of low dose risperidone (a commonly prescribed antipsychotic) treatment using juvenile rats. Twenty-four male Sprague-Dawley rats were either subcutaneously implanted with a continuous release risperidone pellet (.04 mg/day) or a placebo pellet. To encompass the peri-adolescent to adolescent timeframe (postnatal day 40-60) thought to be important for brain development, male rats began risperidone treatment at post-natal day 35. Six weeks following commencement of risperidone treatment, all rats were tested on a battery of behavioral assessments including open field, object recognition, Morris Water Maze, and Y-Maze spontaneous alternation tasks. Risperidone treatment did not affect open field, object recognition, or Morris Water maze tasks. A significant effect was found on the Y-maze. Although all rats exhibited normal spontaneous alternation, risperidone treated rats demonstrated significantly higher same arm returns, indicative of a working memory deficit. Continued research is needed to determine whether early exposure to risperidone may lead to differences in spatial working memory at longer time-points. These results seem to indicate that early low dose risperidone treatment does not severely impair behavior during the peri-adolescent and adolescent period in rats.

Title: Fenfluramine is a sigma-1 receptor positive modulator in mice

Authors: *T. MAURICE[1], A. GAMMAITONI[2], B. S. GALER[2], P. MARTIN[2]
[1]INSERM UMR-S1198, Montpellier, France; [2]Zogenix Inc., Emeryville, CA

Abstract: Fenfluramine (*N*-ethyl-α-methyl-3-(trifluoromethyl)-benzeneethanamine, FFA) is a potent serotonin releaser activating multiple 5-HT receptor subtypes. In Dravet syndrome, a

severe epilepsy syndrome starting within the first year of life and due to a de novo mutation ineSCN1A sodium channel in up to 80% of the cases, the drug was recently shown in a Phase 3 trial to have profound (63.9%) greater reduction in mean monthly convulsive seizures compared to placebo ($p<0.001$). Beyond serotonin, FFA also binds to other receptors, particularly showing high nanomolar affinity for the sigma-1 chaperone protein (S1R). In a functional assay, FFA slightly increased the S1R agonist (+)-SKF-10,047-induced increase in the twitch contraction amplitude, suggesting a complex mode of action at S1R. We therefore examined the FFA action at S1R in a functional assay (the S1R/BiP dissociation) and in behavioral responses (forced swimming and two memory tests). Although not explicitly linked to FFA activity in DS, the behavioral responses can provide important insight into FFA mechanism of action. FFA failed to dissociate S1R from BiP in a cell-based assay, but potentiated the S1R agonist PRE-084 effect. FFA, dose dependently but in a bell-shaped manner, attenuated MK-801-induced learning impairments in the spontaneous alternation and passive avoidance tests in mice. In co-administration studies with PRE-084, FFA potentiated the S1R agonist effect and precise calculations of combination indices showed synergy at the lowest doses combination. In addition, the (+)-isomers of both FFA and its metabolite norfenfluramine (NF), showed antidepressant activity in the FST test. Serotonergic receptor antagonists prevented the effect of both (+)-FFA and (+)- NF. The S1R antagonist NE-100 fully prevented only the (+)-FFA effect. These results confirmed a S1R pharmacological component in FFA behavioral effects and both the cell-based assay and the memory tests suggest that the drug behaves as a potent S1R positive modulator, an effect that likely reinforces its known serotoninergic pharmacological actions.

Title: Cognitive enhancement and metabolic effects of Vyvanse in rats

Authors: *H. M. MURPHY[1], C. H. WIDEMAN[2]
[1]Dept Psychol, [2]Dept Biol., John Carroll Univ., University Heights, OH

Abstract: Cognitive enhancers are drugs that improve higher-order mental processes including memory, creativity, focus, and motivation in healthy individuals and psychomotor stimulants are a major class of drugs utilized as cognitive enhancers. Vyvanse (lisdexamfetamine) is classified

as a psychostimulant. It is a prodrug of dextroamphetamine involving a lysine group which is cleaved off through an enzymatic reaction in the blood that liberates the active component. Prodrugs have been shown to be a more therapeutic alternative to traditional drugs. Vyvanse is approved by the United States Food and Drug Administration (FDA) to treat Attention-Deficit/Hyperactivity Disorder (ADHD), and Binge Eating Disorder. Dextroamphetamine is a serotonin, dopamine, and norepinephrine agonist. The present study investigated the effects of Vyvanse on spatial working memory, body weight, adiposity, activity, and anxiety in rats. Six control and six experimental male rats were placed in individual cages equipped with a running wheel attached to a device that recorded activity. Food and water were provided ad-libitum. The study was divided into three periods: 1) habituation, 2) experimental - in which Vyvanse was given orally to experimental rats, and 3) withdrawal. Control rats received a placebo in periods 2 and 3. Spatial working memory was examined utilizing the methodology of the Morris Water Maze. Animals were evaluated by performance in the maze each day during the experimental and withdrawal periods. Each assessment consisted of two trials. The first was a sample trial in which an escape platform was discovered by trial and error. The second was a test trial in which the platform location was recalled using working memory. Platform placement and start location of the rats were changed every session. It was hypothesized that Vyvanse would effectively enhance spatial working memory in rats and would have a significant influence on body weight and adiposity without side effects on activity level or anxiety. Results supported the hypothesis. Compared to control rats, Vyvanse treated rats had significant improvement in working memory and significantly lowered body weight, as well as significantly decreased mesenteric, renal, and epididymal adiposity. No significant effects on activity level or anxiety were noted in experimental animals. These results support other studies demonstrating that prodrugs can reduce unwanted side effects of the respective active component. Future studies with prodrugs could explore the promising effects of such compounds for treatment of cognitive diseases involving the nervous system.

Title: Exploration of polyfunctional flavonoids based compounds in Alzheimer’s disease: Design, synthesis and biological evaluations

Authors: *M. SINGH[1], O. SILAKARI[2]
[1]Chitkara Col. Of Pharm., Chitkara Univ., Rajpura, India; [2]Dept. of Pharmaceut. Sci. & Drug Res., Punjabi Univ., Patiala, India

Abstract: Polyfunctional compounds comprise a novel class of therapeutic agents for the treatment of multi-factorial diseases like Alzheimer's disease (AD). Following this approach, a new series of flavonoids were designed, synthesized and biologically evaluated against acetylcholinesterase (AChE), advanced glycation end products formation (AGEs) with additional free radical scavenging activity. The *in vitro* studies showed that the majority of synthesized derivatives inhibited acetylcholinesterase (AChE) with IC_{50} values in the nanomolar range. Among them, inhibitors FLV-16 and FLV-32, strongly inhibited AChE, and were more potent than the reference compound donepezil. Moreover, the molecular docking study displayed that most potent compounds simultaneously bind to catalytic active site (CAS) and peripheral anionic site (PAS) of AChE. Besides, these compounds also exhibited greater ability to inhibit advanced glycation end products formation with additional radical scavenging property. Thus, flavonoids might be the promising lead compound as potential poly-functional anti-Alzheimer's agents.

Title: Exercise mediates anesthetic recovery in diabetic and control rats

Authors: *C. SINON[1], A. OTTENSMEYER[2], A. SLONE[3], M. PARDUE[4], P. S. GARCIA[5]
[1]Neurosci., [2]Med., Emory Univ., Atlanta, GA; [3]Medicine, Health, and Society and Child Develop., Vanderbilt Univ., Nashville, TN; [4]Georgia Inst. of Technol., Atlanta, GA; [5]Anesthesiol., Atlanta VA Med. Ctr. / Emory Univ., Decatur, GA

Abstract: Type 2 diabetes mellitus is the most prevalent metabolic disease worldwide. Diabetes is associated with decreases in cortical volume and an increased risk for experiencing cognitive impairments. It has been previously reported that diabetic patients experience impaired cognitive function following cardiac surgery, especially on speed-related tasks. In an animal model of type 1 diabetes, exposure to isoflurane anesthesia without surgery is sufficient to cause memory problems. Exercise is often prescribed for diabetic patients and regular physical activity is

hypothesized to decrease the risk of postoperative cognitive impairments. This study presents the first results of our investigation into the effects of diabetes and of exercise on recovery from isoflurane anesthesia in a type 2 diabetes rat model. Wistar (n = 32) and Goto-Kakizaki (GK) type 2 diabetes (n = 32) rats between 3-4 months old underwent forced treadmill exercise or remained idle on a stationary treadmill for 10 days. Rats then received either a 2-hour exposure to 1.5-2% isoflurane in oxygen at 1L/min or oxygen. At two hours, rats were removed and placed into a recovery chamber. Time to appearance of post-anesthetic milestones were recorded for 30 minutes, after which the rat was moved to a video-monitored rodent cage environment for 1 hour to record post-anesthesia behavior. Pre- and Post-anesthesia Y-maze spatial alternation was recorded to determine cognitive performance on a spatial memory task. At baseline, diabetic rats show a decrease in spontaneous alternation behavior ($p = 0.0291$) and in maze exploration ($p < 0.0001$). Rats receiving ten days of forced treadmill exercise displayed no difference from idle rats in their emergence times from isoflurane general anesthesia (Return of Righting Reflex, $p = 0.9259$), but exercise hastened the appearance of our general recovery marker (Sticky Dot) post anesthesia for both Wistar and GK rats ($p = 0.0079$,). Rats that underwent exercise and isoflurane treatment display a decrease in spatial working memory compared with other experimental groups, as revealed by a significant main effect for anesthetic treatment & activity on a post-anesthesia Y-maze test. At baseline, we found the diabetic rats were less active and showed decreased spatial working memory compared to Wistar rats in the Y-maze. Forced exercise training prior to general anesthesia resulted in hastened recovery from isoflurane regardless of the presence of metabolic syndrome. Despite the lack of an effect of diabetic status on post-anesthesia behavioral outcomes, these results suggest a need for further study of the general interaction between exercise and recovery from anesthesia.

Title: Effects of the chronic administration of caffeine and pramipexole on recognition memory and nerve growth factor expression in the hippocampus of mice

Authors: *L. MARTINEZ MENDIETA[1], P. HORTA LÓPEZ[2], F. LUNA MORALES[2], V. ALATRISTE BUENO[2], D. I. LIMÓN[2], I. MARTÍNEZ GARCÍA[2]
[2]Pharm., [1]Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Caffeine is an adenosinergic antagonist, a psychoactive drug widely used around the world. Experiments in animals have been shown that caffeine improves memory, an effect related to modulation of neurotransmitters involved in plasticity at CNS. On the other hand, pramipexole (PPX), a dopaminergic D2/D3 agonist, has described as a drug that enhances the expression of neurotrophins and improves memory in animal models. The aim of the present work was to evaluate the effect of chronic administration of caffeine or PPX on the recognition memory test and its effects on the expression of the nerve growth factor (NGF) and its receptor tyrosine kinase A (TrkA) in the hippocampus. Female, adult, CD1 mice (28-30 g) were housed in groups and different groups were formed with caffeine (0.2 and 0.2 mg/kg i.p.) and saline solution (SSI) as vehicle group daily for 10 days; PPX (0.5 mg/kg i.p.) and SSI as vehicle group daily for 14 days and its vehicle. At the end of pharmacological treatment, the test of recognition of objects was used to evaluate the memory of mice. After animals were sacrificed by an anesthetic administration and each brain was perfused by intracardial administration of paraformaldehyde (4% in PBS, pH=7.4). The immunohistochemistry to NGF and TrkA and Nissel-staining were performed in the hippocampus and expression analysis was done for CA1, CA2, CA3 and dentate gyrus of the hippocampus. Our results showed that caffeine in low doses of 0.1 and 0.2 mg/kg or PPX doesn´t modify the learning and memory tests. In contrast, both treatments of caffeine or PPX caused an increase in the expression of NGF and its receptor TrkA in different areas of the hippocampus in mice. It's highly probably that neurotrophic effects of caffeine and PPX are related to NGF and TrkA expression and its survival pathways, so future studies are needed to understand its beneficial effects.

Title: Standardized extract of ginkgo biloba modulates expression of the brain derived neurotrophic factor (bdnf) in the dorsal hippocampal formation of the rats subjected to the novel object recognition memory

Authors: *B. G. MURATORI[1], C. ZAMBERLAM[2], T. BIUDE[2], B. NOZIMA[2], J. CERUTTI[2], S. CERUTTI[3]

[1]Biol. Sci., Univ. Federal of São Paulo, Sao Paulo, Brazil; [2]Morphology and Genet. Dept., Univ. Federal of São Paulo, São Paulo, Brazil; [3]Morphology and Genetics; Biol. Sci. Dept., Univ. Federal of São Paulo, Sao Paulo, Brazil

Abstract: Data from our group showed that standardized extract of *Ginkgo biloba* (EGb) modulates acquisition and extinction of the conditioned suppression by inducing differential CREB-1, GAP-43 and GFAP gene and protein expression in the dorsal hippocampal formation (DHF). However, it is unclear whether the procognitive effects my be observed in anothers memoris., additional approaches are needed to better understand the effect of EGb on memory, particularly in non-aversive tasks. We investigated the effects of treatment with EGb on acquisition of novel object recognition (NOR) memory in rats. In addition, we investigated the NOR-induced protein expression of the Brain Derived Neurotrophic Factor (BDNF) in the dorsal hippocampal formation (dHF) of control groups (vehicle and Diazepam® (4 $mg.kg^{-1}$) and EGb-treated groups of rats. Adult male Wistar rats from 10-12 weeks old were subjected to handling for five days. A single dose of EGb (0.25, 0.5 and 1.0 $g.kg^{-1}$), Diazepam or vehicle (0,9% salina) was administered prior to the acquisition session (familiarization 1) (day 6), which the animals were exposed to two distinct objects in order to become familiar for 15 min in a wood box (40 x 40 x 40 cm) with a floor demarcated into squares (n = 10/group). Twenty-four hours after (day 7), the animals were subjected to the second familiarization session (familiarization 2), in the same condition described for training 1. On the 8th day, the subjects are allowed to explore two objects (one familiar and one new) to evaluated the NOR memory (T1). Exploration ratio (ER) was calculated to to evaluated differential time spent to explore novel and familiar object. In order to exclude the potential effect of confounding variables, as locomotor and exploratory activity of animals, we also evaluated the number of contact frequency, rearing, ambulation, grooming. The animals were euthanized after completion the test 1 session and the dorsal hippocampal formation (dHF) was extracted to analyze the expression of the BDNF, an important molecules involved on mechanisms underlying **memory** formation by the Western Blot technique. Two-way RM ANOVA revealed a significant interaction between groups and trials ($F_{28,315}$= 2.605; P<0.0001).The mean ER showed that EGb-treated groups (250 $mg.Kg^{-1}$; ER=0.70; P=0.0011; 500 $mg.Kg^{-1}$, ER=0.66; P=0.0084; and 1000 $mg.Kg^{-1}$, ER=0.86; P<0.0001) take more time explore new object when compared with vehicle group (TE=0.42). Furthermore, EGb increased, in a dose-dependent manner, the BDNF levels in the dHF. Our data show that EGb modulates non-aversive memory acquisition, which was associated with increased BDNF expression in DHF.

Title: Subchronic treatment with Morin improves memory in healthy mice

Authors: *H. MARTINEZ-CORIA[1,2], N. SERRANO GARCIA[2], G. S. LOPEZ-CHAVEZ[2], A. Y. GONZALEZ-MUÑIZ[2], H. E. LOPEZ-VALDES[1], M. OROZCO-IBARRA[2], M. A. TORRES-RAMOS[2]
[1]Univ. Nacional Autonoma de Mexico, Mexico City, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico City, Mexico

Abstract: Introduction: Cognitive improvement has been linked to the consumption of various polyphenols of natural origin. Morin is a polyphenol present in various fruits such as figs and blackberries, has antioxidant, neuroprotective and anti-inflammatory activity, among others. The brain regions involved in memory are the hippocampus and the entorhinal cortex, responsible for memory consolidation and one of the first brain regions to be affected in Alzheimer's disease.
Objective: To characterize the effect of morin on recognition memory in healthy adult mice and their possible molecular mechanism.
Material and Methods: 60 healthy adult mice (25-30 g, C57BL / 6) were divided into groups of 10 animals: control (saline solution), vehicle (DMSO) and those treated with morin. Morin was administered i.p. In different doses (1, 2.5, 5 and 10 mg / kg / 24 h for 10 days). The new object recognition memory test was performed at 10 days of treatment. The brains of the mice were processed for histological characterization and protein expression by immunohistochemistry analysis.
Results: The IR index obtained in the different groups was (% ± SEM): Control = 60 ± 1.8, Vehicle = 64 ± 3.0, 1 mg / kg = 79 ± 4.15, 2.5 mg / kg = 72.31 ± 4.58, 5 mg / kg = 69.95 ± 4.05, 10 mg / kg = 64.39 ± 5.61. Significant IR was observed in mice treated with 1 mg / kg of morin relative to control and vehicle ($p < 0.001$ and $p < 0.01$ respectively, ANOVA followed by Tukey's post hoc test). The behavioral effect correlates with increased expression of the IL-4, GFAP and pro-BDNF proteins.
Discussion and Conclusions: Morin, in low concentrations, improves memory recognition of new object in healthy adult mice. We suggest that the molecular mechanism involved is due to the production of BDNF via the activation of astrocytes produced by the increase of IL-4. Activation of astrocytes by IL-4 and IL-13 has been reported to favor the production of BDNF involved in improved memory and increased expression of proteins involved in the synapse.

Title: Cognitive consequences of opioid analgesics on nonhuman primate memory

Authors: *C. JOHNSON[1], B. M. ROEDER[2], J. B. DAUNAIS[5], J. R. STAPLETON-KOTLOSKI[6], J. A. ROWLAND[7], E. E. ROGERS[7], C. T. WHITLOW[7], L. J. PORRINO[3], S. A. DEADWYLER[4], R. E. HAMPSON[4]
[1]Wake Forest Sch. of Med., Winston-Salem, NC; [2]Neurosci., [3]Physiol. & Pharmacol., [4]Wake Forest Sch. of Med., Winston Salem, NC; [5]Dept Physiol & Pharmacol, [6]Neurol., [7]Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: The use and abuse of opioid analgesics has become a major problem for public health. In addition to the abuse potential, there is growing concern for both acute and long-term cognitive consequences for use of opioid pain relievers. Prior findings from this Program have demonstrated that cognitive processing by nonhuman primates (NHPs) in a delayed match to sample (DMS) memory task is altered via hippocampal and prefrontal cortical disruption by drugs of abuse (Hampson et al., Psychopharmacology, 2011; 213:105-118), sleep deprivation (Porrino et al., PLoS Biology, 2005; 3:e299) and whole-brain irradiation (Robbins et al., Radiat Res., 2011; 175:519–525). We therefore initiated a pilot study to determine cognitive effects of acute does of opioid agonists and antagonists in support of efforts to develop effective addiction therapies and alternatives to opioid analgesics.
Four nonhuman primates (NHPs) were tested for acute effects of full and partial opioid agonists and antagonists to compare effects on performance of a complex memory task. NHPs (macaca mulatta) were trained in a rule based spatial vs. object delayed match-to-sample (DMS; Hampson et al., 2013) task with 2-7 images placed on eight symmetric locations on the screen with variable delay epochs of 1-60s. The following opioids were tested: Naltrexone (antagonist) 0.1 and 0.3 mg/kg i.m., Oxycodone (agonist) 0.3 mg/kg i.m., Buprenorphine (partial agonist) 0.06 mg/kg i.m., Methadone (agonist) 0.5 mg/kg i.m. Naltrexone 0.01 mg/kg IV was kept on hand as a rescue dose in case of respiratory depression, anesthesia or distress. NHPs received drug 30 minutes before DMS testing twice per week, with a minimum of two days between drug administration.

Results showed that low dose naltrexone (0.1 mg/kg i.m.) had no effect on performance of the DMS task (and was actually facilitatory in one NHP); however the high dose (0.3 mg/kg i.m.) as well as oxycodone and buprenorphine suppressed DMS performance by as much as 15%. Methodone was still in testing at the time of submission. Thus the use of alternate opioid agonists/antagonists in the course of addiction treatment still risks cognitive impairment. Results will be further discussed in terms of magnetoenchephalographic (MEG) and functional magnetic resonance (fMRI) imaging or resting state brain activity in the same NHPs to determine neural substrates affected by opiates, as well as analysis of proposed countermeasures for opiate analgesic addiction and their consequences on cognition and memory.

Abstract: Epidemiological and clinical studies suggest that a neurodevelopmental dysfunction could be one of the main exploratory hypotheses of schizophrenia (SCZ), which symptoms lead to severe personal and social dysfunctions. A variety of animal and human studies found a dysregulation of the endocannabinoid system (both in term of cannabinoid receptors CB1 or CB2 and endocannabinoid ligands anandamide or 2-arachidonoylglycerol) in psychosis; thus, the pharmacological exploitation of the endocannabinoid system could be a novel approach for treating SCZ. In the present study, we aimed to investigate 1) the potential effects of perinatal administration of delta-9-tetrahydrocannabinol (Δ^9-THC), the main psychotropic compound of *Cannabis sativa* on neurophenotypic presentations using a set of behavioral test battery, and 2) if

the pharmacological modulation of the endocannabinoid signaling could reverse the schizophrenia-like phenotype. At adulthood, Δ^9-THC -exposed rats engaged in less social interaction as well as they shown cognitive impairment, which were reversed by the chronic treatment with the non-psychotropic phytocannabinoid cannabidiol (CBD). At molecular level the altered cannabinoid CB1 expression in the prefrontal cortex was also reversed by CBD treatment. These results suggest that pharmacological modulation of the endocannabinoid tone could be a novel potential therapeutic target for the treatment of schizo-affective disorders.

Title: Two rounds of transcriptional regulation in the insular cortex are necessary for conditioned taste aversión storage

Authors: *L. A. RODRÍGUEZ-BLANCO[1], A. RIVERA-OLVERA[1], M. L. ESCOBAR[2]
[1]Facultad de Psicologia, UNAM, Mexico City, Mexico; [2]UNAM, Fac Psicologia, Mexico City, Mexico

Abstract: Nowadays it is widely accepted that long-term memory (LTM) establishment requires synthesis of new proteins, even many hours after memory acquisition. Some studies have shown the existence of at least two different time windows for the amnesic effect of protein synthesis inhibitors. In this regard, we have previously reported that protein synthesis inhibition 7 hours after acquisition in the insular cortex (IC) prevents the consolidation of conditioned taste aversion (CTA), a well-established learning and memory paradigm in which an animal associates a novel taste with nausea. In spite of this, little is known about the requirement of new mRNA during storage of CTA-LTM. Behavioral studies have emphasized the importance of a single time window sensitive to inhibitors of mRNA synthesis at or around the time of training. On the other hand, regulation of transcription through epigenetic mechanisms has been shown to occur in response to new experiences which result in gene expression changes that are necessary for LTM storage. Accordingly, it has been demonstrated that transcription regulation via histone acetylation is essential for memory establishment. The aim of the present study was to evaluate

the effect of the inhibition of transcription as well as deacetylation of histones in the IC at two temporal windows on the consolidation of CTA, through an intracortical microinfusion of 5,6-dichloro-1-beta-D ribofuranosyl-benzimidazole (DRB) or MS-275, respectively. Thus, animals received a microinfusion of DRB or MS-275 in the IC either immediately or 7 hours after CTA acquisition. Our results show that transcription inhibition impairs CTA memory consolidation, whereas histone deacetylation inhibition strengths this memory immediately and 7 hours after the acquisition session. These findings reveal that CTA memory requires at least two rounds of transcriptional modulation events in the IC in order to consolidate this memory trace.

Title: Effect of the inhibition of palmitoylation on the formation and maintenance of spatial memory

Authors: *O. G. URREGO MORALES[1], I. DELINT-RAMÍREZ[2], F. BERMUDEZ-RATTONI[3]
[1]Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico; [2]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Austin, TX; [3]UNAM, Mexico City DF 04510, Mexico

Abstract: Protein palmitoylation (addition of lipid palmitate) is a post-translational modification that modifies the hydrophobicity of proteins. This process allows the interaction of proteins with the lipids of the cell membrane and the subcellular membranes, regulating the location and function of these proteins. In the nervous system, palmitoylation regulates vesicular trafficking and the localization of neurotransmitter receptor proteins in processes of synaptic plasticity. The genetic and pharmacological approaches in murine models have reported the participation of palmitoylation in spatial memory processes. However, these approaches have not evaluated the effects of palmitoylation during the different phases of spatial memory; that is, acquisition, consolidation and retrieval. Therefore, in this work, we studied the participation of palmitoylation during the three phases of memory to understand a possible regulatory mechanism of the proteins involved in memory processes. For this, we evaluated the effect of the inhibition of the palmitoyl acyltransferase enzymes in the dorsal hippocampus with the

irreversible 2-bromopalmitate inhibitor. The drug was administered to different groups of animals during the three phases of memory in two different behavioral models of spatial memory that depend on hippocampal activity. The results showed that the inhibition of palmitoylation affected the acquisition and consolidation, but not spatial memory retrieval. In addition, it was observed that the expression of glutamatergic receptors NMDA and AMPA in the hippocampus increases after learning. The expression of the AMPA receptor was modified when the palmitoyl acyltransferase enzymes were inhibited, but the NMDA receptor remained unchanged. In conclusion, palmitoylation of proteins mediated by palmitoyl acyltransferase enzymes participates in the formation and maintenance of spatial memory throughout AMPA receptor trafficking.

Title: Prenatal alcohol-induced deficits in trace fear conditioning and Morris water maze place learning are ameliorated by the histamine H_3 receptor inverse agonist SAR152954

Authors: *J. L. WAGNER[1,2], S. D. DAVIES, 87131[2], A. H. MOEZZI[2], K. S. LUJAN[2], E. J. RAPPAPORT[2], D. A. HAMILTON, 87131[2,3], D. SAVAGE, II[2]

Abstract: Hippocampal-sensitive behaviors, such as contextual fear conditioning and spatial navigation, are among the learning tasks most affected by prenatal alcohol exposure (PAE). These tasks could serve as behavioral screening tools for novel agents with efficacy in treating learning disabilities associated with Fetal Alcohol Spectrum Disorder (FASD). We have reported that a single treatment with the histamine H3 receptor inverse agonist ABT-239, administered at the onset of training in either one trial of delay contextual fear conditioning or water maze place training, reverses PAE-induced deficits in the retention of learning. Here, we investigated the ability of a second H3 receptor inverse agonist namely, SAR152954, to affect PAE-induced deficits in fear-conditioned learning and on spatial learning and memory. Moderate PAE offspring were generated as described by Savage et al., (2010). Offspring from 38 separate Long

Evans rat dams were weaned at PD24 and group-housed until six months of age. On the first day of training, offspring from each prenatal treatment group were given a single injection of either 0.1 mg/kg SAR152954 or vehicle 30 minutes prior to the first training trial. Female offspring were then subjected to fear conditioning, in which they are given two trials separated by a 90-second inter-trial interval. Each trial consisted of a 5-second 90 dB tone conditioned stimulus (CS), followed by a 60-second trace interval that co-terminated with a 2-second 1 mA foot-shock unconditioned stimulus (US). One day later, the rats were exposed to a single CS exposure to test for retention of the CS-US association. After a single injection of SAR1521954, male offspring were given 12 Morris water maze place-training trials in series with an inter-trial interval of 5-10 minutes. One week later, the rats were tested for retention of the place location. There were no main or interactive effects of prenatal group or drug treatment on acquisition during training in either trace fear conditioning or Morris Water Maze place acquisition. However, in both behavioral tasks, a two-way repeated measures ANOVA revealed a prenatal group by drug interaction. Saline-treated PAE rats performed significantly worse than either control group during test trials. Performance by SAR152954-treated PAE rats was significantly better than vehicle-treated PAE rats and not different than control groups. These results indicate that SAR152954, another H3 receptor inverse agonist, reverses PAE-induced deficits in hippocampal-sensitive learning tasks and that agents with this mechanism of action warrant consideration as novel agents in treating learning deficits associated with FASD.

Title: Pharmacological blockade of adenosine A_{2A}but not A_1 receptors enhances goal-directed valuation in satiety-based instrumental behavior

Authors: *J.-F. CHEN[1,2], Y. LI[3], Y. HE[2], X. PAN[2], Y. RUAN[2], L. HUANG[2], C. HE[2], Z. WANG[3], X. ZHANG[3]

Abstract: The balance and smooth shift between flexible, goal-directed behaviors and repetitive, habitual actions are critical to optimal performance of behavioral tasks. The striatum plays an essential role in control of goal-directed versus habitual behaviors through a rich interplay of the numerous neurotransmitters and neuromodulators to modify the input, processing and output functions of the striatum. The adenosine receptors (namely A_{2A}R and A_1R), with their high expression pattern in the striatum and abilities to interact and integrate dopamine, glutamate and cannabinoid signals in the striatum, may represent novel therapeutic targets for modulating instrumental behavior. In this study, we examined the effects of pharmacological blockade of the A_{2A}Rs and A_1Rs on goal-directed versus habitual behaviors in different information processing phases of instrumental learning using a satiety-based instrumental behavior procedure. We found that A_{2A}R antagonist acts at the coding, consolidation and expression phases of instrumental learning to modulate animals' sensitivity to goal-directed valuation without modifying action-outcome contingency. However, Pharmacological blockade and genetic knockout of A_1Rs did not affect acquisition or sensitivity to goal-valuation of instrumental behavior. These findings provide pharmacological evidence for a potential therapeutic strategy to control abnormal instrumental behaviors associated with drug addiction and obsessive-compulsive disorder by targeting the A_{2A}R.

Title: Antagonism of muscarinic, but not estrogen receptors, impairs divided attention in male rats

Authors: *N. PISTORY, P. R. NICKLAS, M. L. GROFT, K. ZIMMER, D. E. MOSURA, W. R. HAWLEY, P. J. MCLAUGHLIN
Dept. of Psychology, Edinboro Univ. of Pennsylvania, Edinboro, PA

Abstract: GPR30 is a central, membrane-bound estrogen receptor that is expressed in basal forebrain cholinergic cells, and which regulates cholinergic outflow in hippocampus. The receptor plays a role in spatial working memory that may be mediated by muscarinic receptors. Regulation of other cognitive processes has been speculated, but not demonstrated. Divided attention (DA) is an understudied cognitive domain that may be increasing in health relevance with added distractors in daily experience, and may also be vulnerable in dementia. We developed an operant, crossmodal model of DA in male rats which featured an auditory sustained attention (SA) component, with an unpredictable, low reinforcement-rate visual distractor task using preferred reinforcers. Experiment 1 compared effects of the muscarinic antagonist scopolamine on both SA and DA (i.e., SA with a distractor) tasks. The DA task was found to be more challenging, as evidenced by lower stimulus sensitivity (d'). Scopolamine impaired performance similarly on both tasks, contrary to expectation. However, a floor effect may have been present, due to low baseline performance of the DA task. After the first experiment, auditory signal durations were increased in order to reduce attentional load. Doing so produced higher baseline performance, similar to the SA task. In Experiment 2, the GPR30 antagonist G15 (0.5 and 1.0 mg/kg) was given subcutaneously, both alone and prior to administration of a dose of scopolamine (0.05 mg/kg) that was subeffective in Experiment 1. It was hypothesized that G15 would impair DA alone, or potentiate the effect of low-dose scopolamine. In Experiment 2, only DA was assessed, using the version with longer stimulus durations. G15 was ineffective, either alone or prior to scopolamine. However, scopolamine impaired DA, in line with the proposed floor effect in Experiment 1. The inability of G15 to alter effects of scopolamine on DA may indicate a dissociation of the role of GPR30 in DA, compared with spatial working memory, although longer-term administration may also be required. There may also be a lack of endogenous tone of estrogen in cholinergic regulation. In any event, these results suggest a limited role of GPR30 blockade in attention in the presence of increased distraction.

Title: Potentiation of muscarinic acetylcholine receptor 4 (m_4) as compensation for transcription factor 4(tcf4) deficiency

Authors: *A. MOORE[1], A. J. WU[2], J. D. WEISS[1], L. CHEN[2], R. G. GOGLIOTTI[1], C. M. NISWENDER[1], J. D. SWEATT[1]
[1]Pharmacol., [2]Col. of Arts and Sci., Vanderbilt Univ., Nashville, TN

Abstract: Transcription Factor 4 (TCF4) regulates several important neuronal processes such as DNA methylation, long-term potentiation and memory formation. Mutations in the gene encoding TCF4 cause the neurodevelopmental disorder, Pitt Hopkins Syndrome (PTHS) and single nucleotide polymorphisms (SNPs) of TCF4 have been associated with schizophrenia. PTHS is characterized by severe intellectual disability, autism-associated behaviors, motor incoordination, breathing abnormalities and impaired gastrointestinal motility. There are currently no available treatments for PTHS patients. The Sweatt laboratory has characterized a genetically engineered mouse model of PTHS that shows deficiencies in learning and memory. Further characterization of this line revealed a significantly increased rate of breathing that may be comparable to tachypnea observed in PTHS patients. RNA sequencing studies of wild type (WT) and *Tcf4*$^{+/-}$ mouse hippocampal tissue have shown a significant increase in *Chrm4* transcript levels in *Tcf4*$^{+/-}$ mice, the gene that encodes the M_4 muscarinic acetylcholine receptor which suggests TCF4 may regulate *Chrm4* transcription. Recent work from the Vanderbilt Center for Neuroscience Drug Discovery (VCNDD) has shown that potentiation of M_4 receptor signaling yields cognitive-enhancing effects in a mouse model of psychosis, positioning this receptor as a novel therapeutic target for schizophrenia. We report here that a positive allosteric modulator of the M_4 receptor exhibits cognition-enhancing effects in Tcf4-haploinsufficient mice. Excitingly, in addition to our results in a rodent model of Tcf4 deficiency, M_4 receptor potentiation has also shown efficacy in models of other neurodevelopmental disorders, such as Rett syndrome and Fragile X syndrome, where it has recently been shown that enhancement of M_4 receptor signaling can normalize cognitive phenotypes. These data suggest that regulation of M_4 signaling plays a role in compensating for cognitive dysfunction in multiple neurodevelopmental disorders and the current study aims to validate the M_4 receptor as a novel target for PTHS.
We thank the Pitt Hopkins Research Foundation for funding through the Sarah Huffman Young Investigator Award.

Abstract: Insulin delivery to the brain has recently been identified as a potential therapeutic target for cognitive disorders associated with abnormal brain energy metabolism. Although insulin is transported across the blood-brain barrier, peripheral routes of administration are problematic due to systemic effects of insulin on blood glucose. Intranasal (IN) administration is being investigated as an alternative route. We conducted a direct comparison of subcutaneous (SC) and IN insulin, assessing plasma and brain pharmacokinetics and blood glucose levels in the mouse. SC insulin (2.4 IU) achieved therapeutically relevant concentrations in the brain but dramatically increased plasma insulin, resulting in severe hypoglycemia and in some cases death. IN administration of the same dose resulted in similar insulin levels in the brain but substantially lower plasma concentrations. IN dosing had no significant effect on blood glucose. When administered daily for 9 days, IN insulin increased brain glucose and energy metabolite concentrations without causing overt adverse effects. We next assessed whether insulin delivered via the IN route could achieve dose linearity in the brain, and conducted a preliminary assessment of its therapeutic index by neurohistopathology. Together, these findings suggest that IN insulin may be a safe therapeutic option for cognitively impaired patients.

Title: A central nervous system-penetrant soluble guanylate cyclase stimulator reduced spine density loss in aged rats and mice

Authors: *S. CORREIA[1], J. E. JONES[1], C. REX[2], G. LIU[1], A. CARVALHO[1], P. GERMANO[1], R. R. IYENGAR[1], C. J. WINROW[1], M. G. CURRIE[1], J. R. HADCOCK[1]
[1]Ironwood Pharmaceuticals, Cambridge, MA; [2]Dept of Neurobio., Afraxis Inc., San Diego, CA

Abstract: Soluble guanylate cyclase (sGC) is a signaling enzyme expressed in many cell types in the body including the central nervous system (CNS), and its activity results in the production of cyclic guanosine-3′,5′-monophosphate (cGMP) from guanosine-5′-triphosphate (GTP). We evaluated the effects of IWP-247, a CNS-penetrant sGC stimulator, on spine density in pyramidal neurons of the CA1 hippocampal area and layer 3 medial prefrontal cortex (L3 mPFC) of aged rats and mice. During normal aging, the number of spines is reduced in many brain areas, and spine loss correlates with decreased synaptic function. Spine loss is exacerbated in neurodegenerative disorders such as Alzheimer's Disease and is thought to contribute to dementia symptoms. In the first study, 16-month-old male C57BL6 mice were treated for 4 months with either 1 mg/kg IWP-247 or vehicle in rodent chow. Three-month old mice were also treated with vehicle rodent chow for 4 months. Brains were collected, labeled with DiI, and hippocampal CA1 and L3 mPFC pyramidal neurons were imaged using Airyscan super-resolution microscopy. 3D images were analyzed for spine density and morphology by analysts blinded to experimental conditions. The density of mushroom-type spines in CA1 hippocampal neurons of aged mice treated with vehicle chow was lower than in young mice. The density of mushroom spines in CA1 neurons of aged mice treated with IWP-247 was greater than in aged vehicle-treated mice and similar as in young mice. There was no difference in spine density of L3 mPFC pyramidal neurons between any groups. In the second study, 22- to 24-month-old rats were treated with 0.3 or 1 mg/kg IWP-247, or vehicle in chow for 1 month. Two- to three-month old rats were also treated with vehicle rodent chow for 1 month. Brains from the rats in the 4 groups were collected and processed as described above. The density of total spines in L3 mPFC neurons in aged rats treated with 1 mg/kg IWP-247 was comparable to the young rats, and greater than in aged vehicle rats. Overall these results suggest that sGC stimulation may provide neuroprotective effects and improve synaptic function by reducing spine density loss in neurodegenerative diseases.

Title: The brain penetrant soluble guanylate cyclase stimulator IWP-247 improved thigmotaxis and increased hippocampal N-acetylaspartate (NAA) concentrations in aged rats

Authors: *J. E. JONES[1], C. J. WINROW[1], S. S. CORREIA[1], S. JACOBSON[1], R. HODGSON[2], J. PUOLIVALI[2], K. LEHTIMÄKI[2], A. CARVALHOA[1], P. GERMANO[1], J. V. TOBIN[1], K. TANG[1], R. R. IYENGARA[1], M. G. CURRIE[1], J. R. HADCOCK[1]

Abstract: The number of Americans 65 or older is projected to more than double in the next 40 years to 88.5 million by 2050. Even in individuals without dementia, many will experience age-associated memory impairment as part of the normal aging process which is associated with reduced brain metabolites such as N-acetylaspartate (NAA) and N-acetyl aspartyl glutamate (NAAG). Soluble guanylate cyclase (sGC) stimulators are small molecules that potentiate the nitric oxide (NO)-sGC-3',5'-cyclic Guanosine Monophosphate (cGMP) signaling pathway, causing increased cGMP production, which modulates physiological mechanisms such as vasodilation, fibrosis, and inflammation. This study investigated the effects of IWP-247, a CNS-penetrant sGC stimulator, on cognitive deficits and hippocampal brain metabolites caused by the normal progression of aging in healthy 21-month-old male Wistar rats.
Rats received daily oral doses of IWP-247 or vehicle and were tested in the Morris water maze (MWM). Aged rats received vehicle (n=17) or IWP-247 (1 mg/kg, n=18, or 10 mg/kg, n=20); and young rats (2-3 months old) received vehicle (n=20). Daily dosing occurred 30 min before MWM training or testing. MWM began following the first dose on day 1 with visible platform training, followed by hidden platform training on days 2-9, and a probe trial on day 10. There

were no significant differences in visible platform training between groups including swimming speed. During hidden platform training, all groups of aged rats had significantly higher thigmotaxis (measure of strategy) values than young rats. Both groups of aged IWP-247-treated rats had significant improvements in thigmotaxis compared to aged vehicle-treated rats and thigmotaxis values equivalent to young rats by day 4. By day 9, all aged rats performed like the young rats, suggesting that aged healthy rats have a minor impairment in learning and when given enough training can perform equally to young rats. IWP-247 appeared to accelerate the learning process in the MWM paradigm. Following the MWM study, rats continued on their prior dosing regimens for 20 more days. On day 30, one hr after oral administration of vehicle or IWP-247, hippocampal magnetic resonance spectroscopy (MRS) was performed and brain metabolites analyzed. Aged vehicle-treated rats had significantly lower levels of NAA+NAAG compared to young vehicle-treated rats. Levels of NAA+NAAG were similar in aged rats treated with either dose of IWP-247 and young vehicle-treated rats. In conclusion, treatment with IWP-247 had a beneficial effect on cognitive performance and restored important hippocampal brain metabolites in 21-month-old male Wistar rats.

Title: Synaptic consolidation as a temporally variable process: Uncovering theparameters modulating its time-course

Authors: *M. A. CASAGRANDE[1], J. HAUBRICH[2], L. K. PEDRAZA[1], B. POPIK[1], J. A. QUILLFELDT[1], L. D. ALVARES[1]

Abstract: Memories are not instantly created in the brain, requiring a gradual stabilization process called consolidation to be stored and persist in a long-lasting manner. However, little is known whether this time-dependent process is dynamic or static, and the factors that might modulate it. Here, we hypothesized that the time-course of consolidation could be affected by specific learning parameters, changing the time window where memory is susceptible to retroactive interference. In the rodent contextual fear conditioning paradigm, we compared weak and strong training protocols and found that in the latter memory is susceptible to post-training hippocampal inactivation for a shorter period of time. The accelerated consolidation process triggered by the strong training was mediated by glucocorticoids, since this effect was blocked by pre-training administration of metyrapone. In addition, we found that pre-exposure to the training context also accelerates fear memory consolidation. Hence, our results demonstrate that the time window in which memory is susceptible to post-training interferences varies depending on fear conditioning intensity and contextual familiarity. We propose that the time-course of memory consolidation is dynamic, being directly affected by attributes of the learning experiences.

Title: A central nervous system-penetrant soluble guanylate cyclase stimulator increases cerebral blood flow and modulates fMRI-BOLD responses in rodents

Authors: *C. J. WINROW[1], J. E. JONES[1], P. GERMANO[1], S. JACOBSON[1], S. S. CORREIA[1], K. W. TANG[2], J. TOBIN[1], R. R. IYENGAR[1], P. P. KULKARNI[3], C. F. FERRIS[4], M. CURRIE[1], J. R. HADCOCK[1]

Abstract: Disrupted cerebral blood flow (CBF), diminished endothelial function, and dysregulation of the neurovascular unit are key components of several neurological diseases, and are commonly observed in many dementias. Nitric oxide (NO) signals through soluble guanylate cyclase (sGC) to produce 3',5'-cyclic guanosine monophosphate (cGMP) from guanosine-5'-triphosphate (GTP), resulting in the modulation of a variety of physiological processes including blood flow, inflammation, and endothelial and neuronal function. NO-sGC-cGMP signaling is also impaired across a variety of neurological diseases including Alzheimer's disease and vascular dementia. Given its critical role in modulating NO signaling, sGC has emerged as a therapeutic target for diseases in which NO-sGC-cGMP signaling is impaired. IWP-247 is an orally bioavailable, central nervous system (CNS)-penetrant, small-molecule sGC stimulator that increases cGMP levels throughout the brain in animal models. We evaluated the effects of IWP-247 on CBF using cranial laser doppler and fMRI-BOLD in rodent studies. Regional CBF was measured in anesthetized male rats. Following baseline recording, intravenous administration of the nitric oxide synthetase inhibitor N(ω)-nitro-L-arginine methyl ester (L-NAME) was delivered to induce a 25% reduction in CBF. Following the reduction in CBF, subcutaneous administration of IWP-247 reversed L-NAME-induced deficits in rats. In awake adult male rats, intravenous dosing of IWP-247 increased fMRI-BOLD signals above baseline in discrete brain areas including amygdala, hippocampus, thalamus, and reticular activating regions, compared to vehicle treated animals. By contrast, the peripherally restricted sGC stimulator (IWP-040) showed minimal effects on fMRI-BOLD signals with modest activation of regions including the amygdala, entorhinal cortex and ventral subiculum. Taken together, IWP-247, a CNS-penetrant sGC stimulator, increased regional CBF and activated brain regions involved in attention, learning and memory in nonclinical studies. These results support further evaluation of sGC as a therapeutic target for the treatment of neurological disorders.

Title: Distinct patterns of activity are associated with spatial memory encoding in the anterior but not posterior hippocampus

Authors: H. A. FRITCH, S. P. MACEVOY, B. M. JEYE, *S. D. SLOTNICK
Boston Col., Chestnut Hill, MA

Abstract: There are many hypotheses regarding specialization of the anterior versus posterior hippocampus including memory encoding versus retrieval, other cognitive processes versus spatial memory, and global spatial representations versus local spatial representations (Poppenk, Evensmoen, Moscovitch, & Nadel, 2013). In the present fMRI study, we aimed to evaluate whether the pattern of activity in the anterior hippocampus or the posterior hippocampus was associated with spatial memory encoding. During encoding, participants viewed abstract shapes in the center of each visual field quadrant while maintaining central fixation. During retrieval, old shapes were presented at fixation and participants identified the previous quadrant of each shape. A general linear model analysis revealed that accurate *retrieval* of shapes in each quadrant, exclusively masked by accurate memory for shapes in the other quadrants, produced a distinct activation in the hippocampus (Jeye, MacEvoy, Karanian, & Slotnick, 2018). A multi-voxel pattern analysis was conducted to assess whether there were distinct patterns of activity associated with *encoding* shapes in each quadrant within the anterior hippocampus (Talairach y-coordinates –20 to –9) or the posterior hippocampus (y-coordinates –33 to –22). On an individual participant basis, for each encoding quadrant, response patterns were split into halves by run (e.g., odd runs versus even runs) and then the patterns in one data half were classified based on patterns in the opposite half. A classifier was able to distinguish patterns evoked by items in each quadrant at significantly above chance accuracy in the anterior but not posterior hippocampus, and accuracy in the anterior hippocampus was significantly greater than accuracy in the posterior hippocampus. These findings indicate that spatial memory encoding of items presented in each visual field quadrant is associated with patterns of activity in the anterior but not posterior hippocampus, which supports the hypothesis that the anterior hippocampus is preferentially associated with encoding. Moreover, if the global-representation hypothesis of the anterior hippocampus is correct, the present results suggest participants did not encode the precise spatial location of each item during our task.

Title: Human medial temporal lobe contributions to learned approach-avoidance conflict detection and resolution

Authors: *S. CHU, M. MARGERISON, S. THAVABALASINGAM, E. B. O'NEIL, R. ITO, A. C. H. LEE
Univ. of Toronto, Toronto, ON, Canada

Abstract: Human and rodent studies have highlighted a critical role for the anterior portion of the hippocampus (ventral in rodents) in the processing of learned approach-avoidance conflict, a scenario that arises when a stimulus is associated simultaneously with both positive and negative valences. It remains unclear, however, if this region contributes to the detection and/or resolution of approach-avoidance conflict. Moreover, relatively little work has examined the potential involvement of other medial temporal lobe structures. To address these issues, 20 neurologically healthy participants first learned to approach or avoid a series of single novel visual objects in a computerised game, with the goal of maximising their score. Approaching a positive object led to the gain of points, whereas approaching a negative object resulted in point loss. Conversely, avoiding a positive or negative object had no impact on a participant's score. Following successful learning, subjects were presented with pairs of these objects during fMRI scanning. Crucially, the objects within each pair possessed either the same valence (positive-positive or negative-negative, i.e. no approach-avoidance conflict) or different valences (positive-negative, i.e. high approach-avoidance conflict). On each trial, participants were required to respond to each pair by either (1) making an approach-avoid decision in order to score points (decision trials); (2) indicating whether the presented objects had the same or different valences (detection trials); or (3) following a visual instruction to approach or avoid (action trials). Comparing brain activity across these conditions allowed for the identification of regions involved in conflict resolution and detection. Within the medial temporal lobe, significant activity was observed in the anterior hippocampus and perirhinal cortex, with activity in these regions fluctuating according to the level of approach-avoidance conflict, and whether participants made an approach-avoidance decision as opposed to solely detecting the presence of conflict. Our findings provide further insight into learned approach-avoidance conflict processing and reveal differential contributions of the hippocampus and surrounding medial temporal lobe structures.

Title: Crossmodal integration performance is specifically related to medial perirhinal cortex thickness in very early Alzheimer's disease

Authors: *S. KRUMM[1], A. U. MONSCH[1,2], J. REINHARDT[4,5], R. W. KRESSIG[1,3], K. I. TAYLOR[1,2,6]
[1]Memory Clinic, Basel Univ. Ctr. for Med. of Aging, Felix Platter Hosp., Basel, Switzerland; [2]Fac. of Psychology, [3]Fac. of Med., Univ. of Basel, Basel, Switzerland; [4]Div. of Diagnos. and Interventional Neuroradiology, Univ. Hosp. Basel, Basel, Switzerland; [5]Dept. of Neuroradiology, Univ. Hosp. Zurich, Univ. of Zurich, Zurich, Switzerland; [6]Ctr. for Speech, Language and the Brain, Dept. of Exptl. Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Neuropsychological dysfunction in Alzheimer's disease (AD) is hypothesized to occur when neuropathology disrupts the functioning of the corresponding brain systems and compensation strategies fail. Although the clinical setting routinely applies well-established neurocognitive tests to track and diagnose AD, tasks that specifically measure the integrity of the cortical region first affected by neurofibrillary tau pathology (i.e. medial perirhinal cortex [mPRC]) are not yet readily available. In view of AD neuro-pathogenesis, measures of mPRC functioning may represent earlier cognitive markers of incipient AD than e.g. common episodic memory tests. We therefore identified a cognitive assessment of purported mPRC function, i.e. crossmodal integration of visual object representations and environmental auditory stimuli (Taylor et al., 2006). To test whether this task specifically reflects mPRC-related dysfunction in AD, we administered it to very early AD patients (n = 12; 10 male; mean MMSE score = 26.33 ± 1.56; mean age = 74.50 years ± 6.45; mean education = 15.25 years ± 2.42) and cognitively healthy normal controls (n = 21; 12 male; mean MMSE score = 29.05 ± 1.07; mean age = 68.81 years ± 11.49; mean education = 14.48 years ± 4.22). All participants were simultaneously presented with a color object photograph and an environmental sound (n= 40 trials in total). Participants had to decide as quickly as possible whether these two stimuli belong together or not (e.g., a picture of a cat and the sound 'miau'). High-resolution 3T magnetic resonance images were acquired from all participants. Regions first affected by neurofibrillary tau pathology (i.e. mPRC, lateral perirhinal cortex, and entorhinal cortex) were manually drawn on coronal slices of

the native space cortical surface reconstruction generated by FreeSurfer, according to anatomical landmarks described in Kivisaari et al. (2013). A linear regression with total intracranial volume as covariate revealed that only average cortical thickness in the left mPRC, but not cortical thickness of the lateral perirhinal cortex or entorhinal cortex, predicted performance on the crossmodal integration task: $F(2, 30) = 5.570$; $p = .009$; $R^2 = .271$; $\beta = 2.669$. These findings confirm that crossmodal integration is specifically associated with mPRC integrity, and suggest that this task may provide a very early marker of incipient AD.

Title: Factors, other than amnesia, that predict performance on tests of news event memory

Authors: A. T. J. CAWLEY-BENNETT[1], I. E. ASP[1,2,3], S. GOLSHAN[3,1], *C. N. SMITH[1,3]
[1]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [2]Psychology, [3]Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: Damage to the medial temporal lobe (MTL) is associated with retrograde amnesia, that is, difficulty remembering information acquired prior to the onset of amnesia. Tests of notable public events (news events) are useful tools for measuring retrograde memory and assessing the severity of retrograde amnesia. Yet, memory for news events is likely to be influenced by factors other than amnesia. For example, how often one follows news events or the number of different sources one uses to learn about news events could affect performance. These types of factors may be problematic when interpreting retrograde amnesia in patients because one does not know if poor performance on the test results from brain injury or depends on factors unrelated to neuroanatomy, such as minimal exposure to news events. We tested recall and recognition memory for 60 notable news events that occurred in the recent past (from 2009 to 2017) in 150 healthy participants aged 25 to 82 using Amazon's Mechanical Turk. In addition to traditional participant characteristics (sex, age, education), we obtained subjective reports of the amount of exposure to news events (frequency of exposure to news events and the number of news sources used). We found that the amount of education, the frequency of exposure to news events, and the number of news event sources significantly predicted both recall and recognition

accuracy. Specifically, participants performed better if they had more education, frequent news exposure, and learned about news from many sources. Next, we compared the size of the effects on accuracy due to these participant characteristics to the size of the effect on accuracy due to amnesia in three memory-impaired patient groups: patients with bilateral hippocampal lesions (N=9), patients with large MTL lesions (N=2), patients with mild cognitive impairment (MCI; N=15, thought to be a transitional stage between healthy aging and Alzheimer's disease). We found that sizes of the effects of education (more educated vs. less educated), exposure frequency (frequent vs. not frequent), and number of sources (many sources vs. few sources) were similar to the size of the effect between control participants versus memory-impaired patients with hippocampal lesions or MCI. These results suggest that a number of factors can influence performance on tests of news events. Thus, poor performance in this type of test can result from having limited education or limited exposure to news events and not brain injury. Therefore, it is important to account for these factors when using tests of news event memory to determine the severity of retrograde amnesia in neurologic or psychiatric patients.

Title: Eye movements support the link between conscious memory and medial temporal lobe function

Authors: *Z. J. URGOLITES[1,4], C. N. SMITH[4,1], L. R. SQUIRE[4,1,2,3]
[1]Dept. of Psychiatry, [2]Dept. of Neurosciences, [3]Dept. of Psychology, UCSD, La Jolla, CA; [4]Veterans Affairs San Diego Healthcare Syst., San Diego, CA

Abstract: When individuals select the recently studied (and familiar) item in a multiple-choice memory test, they direct a greater proportion of viewing time towards the to-be-selected item when their choice will be correct than when their choice will be incorrect. Thus, for both correct and incorrect choices, individuals indicate that the chosen item is old, but viewing time

nevertheless distinguishes between old and new items. What kind of memory supports this preferential viewing effect? One possibility is that hippocampus-independent (unconscious) memory supports this effect because eye movements appear to reveal information beyond what is reflected in overt behavioral choice. Alternatively, conscious, hippocampus-dependent memory might support this effect. If so, the preferential viewing effect should be related to established measures of declarative memory (i.e., accuracy scores, confidence ratings, and response times). In Experiment 1, 30 young adults made three-alternative forced-choice recognition memory judgments for targets (200 photographs of scenes studied 30 min earlier) and foils (each target was presented together with two thematically-related novel scenes). They exhibited the preferential viewing effect: individuals looked longer at the selected item when it was correct than when it was incorrect. In addition, they were more confident and responded faster when their choice was correct than when their choice was incorrect. Moreover, the size of the preferential viewing effect was strongly correlated with recognition accuracy as well as with the differences in confidence ratings and in response times for correct and incorrect choices. Importantly, in four analyses that minimized the contribution of declarative memory in order to detect a possible contribution from other processes, preferential viewing of the old scene did not occur. Thus, the preferential viewing effect reflects conscious memory for which items are old and which items are new. In Experiment 2, five memory-impaired patients with medial temporal lobe lesions made recognition memory judgments for targets (100 photographs of scenes studied 1 min earlier) and foils. The patients exhibited poor recognition accuracy and reduced differences in confidence ratings and response times for correct and incorrect choices in comparison to controls. We conclude that the preferential viewing effect is a phenomenon of conscious, declarative memory and dependent on the medial temporal lobe. The findings support the link between medial temporal lobe function and declarative memory. When the effects of experience depend on the medial temporal lobe, the effects reflect conscious memory.

Title: How does the hippocampus simultaneously learn episodes and regularities?

Authors: *B. SHERMAN, N. B. TURK-BROWNE
Psychology, Yale Univ., New Haven, CT

Abstract: Any given experience allows us to extract idiosyncratic details about that particular episode, as well as regularities that hold across related experiences. These mnemonic functions require fundamentally different computations: episodic memory employs sparse representations to keep similar experiences distinct, whereas statistical learning requires more overlapping representations to strengthen common elements. The tension between these competing functions was thought to be solved by mapping them onto distinct brain systems — the hippocampus for episodic memory and neocortex for statistical learning. However, this view has recently been challenged by empirical evidence of statistical learning in the hippocampus and by a computational model of the hippocampus that exhibits both episodic memory and statistical learning using different pathways. Although this latter model has been supported by studies that assessed episodic memory and statistical learning in isolation, both forms of learning likely occur in parallel. This raises the question of whether and how the hippocampus can simultaneously acquire information about episodes and regularities. One possibility is that episodic encoding may interfere with statistical learning (or vice versa), given their shared use of the CA1 subfield and of common input/output structures. Another possibility is that statistical learning improves predictability and provides richer temporal context, allowing for better encoding of idiosyncratic details. In two initial behavioral studies, participants viewed a stream of trial-unique scenes drawn from sequential category-level pairs (e.g., beach->mountain) and then were administered a surprise memory test. In Experiment 1, we found that recognition memory was significantly better for second, relative to first, items of a category pair. Importantly, this effect was specific to high-confident responses and emerged over the course of statistical learning. In Experiment 2, we collected temporal source judgments at test to ensure that we were probing hippocampal memory. Consistent with the previous experiment, the precision of source memory declined for first items encountered late vs. early during learning, whereas source memory for second items resisted such interference. Together, these data provide converging evidence of a synergistic relationship between episodic memory and statistical learning. Given these behavioral interactions, we are now using high-resolution fMRI to investigate the neural mechanisms of episodic memory and statistical learning within the hippocampus, including their interactions across subfields.

Title: Distinct hippocampal representations of predicted features and objects

Authors: *L. RAIT, P. KOK, N. TURK-BROWNE
Yale Univ., New Haven, CT

Abstract: Sensory processing is strongly influenced by prior expectations. Expectations about both simple features (e.g., orientation) and more complex objects (e.g., shape) modulate processing in visual cortex. However, it is unclear whether these two kinds of expectations arise from the same top-down sources and operate via the same underlying mechanisms. To investigate this, we exposed human participants to complex auditory cues predicting either the orientation of a subsequent grating stimulus (Experiment 1, N=24), or the shape of an abstract Fourier descriptor object (Experiment 2, N=24). We measured brain activity using high-resolution functional magnetic resonance imaging (fMRI). We compared the influence of predictions about the orientation vs. shape. Using inverted encoding models, we found that expectations about both orientation and shape modulated visual cortex, facilitating processing of expected stimuli relative to unexpected stimuli. However, expectations about orientation and shape were represented differently from each other in the hippocampus. In Experiment 2, we found that the pattern of activity in the hippocampus contained a representation of the shape that was predicted by the auditory cue. However, this was not true for orientation in Experiment 1, where the pattern of activity in the hippocampus did not contain a representation of the orientation that was predicted by the cue. To interrogate the circuitry of these expectation signals further, we applied an automated segmentation method to distinguish subfields of the hippocampus. Where shape expectations were represented in CA3 (combined with CA2 and dentate gyrus), grating expectations were *negatively* represented in this subfield. These findings are especially striking given that the design of both experiments was identical, differing only in whether the visual stimuli were abstract shapes or oriented gratings. Finally, when oriented gratings were expected but omitted, the pattern of activity in V1 reflected the expected orientation, suggesting that such expectations can evoke a template of the predicted feature in sensory cortex. In contrast, this did not occur for shapes that were expected but omitted. Altogether, our findings suggest that expectations about low-level features and higher-level objects may involve distinct neural mechanisms.

Title: Volume of posterior hippocampus is positively related to object-location associative memory in healthy adults

Authors: J. SNYTTE[1], A. ELSHIEKH[1], R. K. OLSEN[3], L. MANNING[1], *M. N. RAJAH[2]
[1]Grad. Program in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Psychiatry, McGill Univ., Verdun, QC, Canada; [3]Rotman Res. Inst., North York, ON, Canada

Abstract: The medial temporal lobes (MTL) are important for episodic memory. Yet, it remains unclear if specific regions of the MTL support memory for distinct features of an episodic event. In the current study we examined if individual differences in grey matter volumes of MTL regions were related to remembering object-location vs. object only information about past events in healthy individuals (N = 18; mean age = 21.41, mean years of education = 14.82). High resolution T2-weighted structural MRI images (TR 2500ms, TE 198 ms, 320 slices of 0.60 mm thickness, 0.64 x 0.64 x 0.64 mm voxels, FOV = 206) were obtained from each participant. We used a hybrid approach of manual segmentation using the OAP protocol (Olsen et al., 2013; Palombo et al., 2013) and the Multiple Automatically Generated Templates (MAGeT; Chakravarty et al., 2013) brain algorithm to measure the grey matter volume of the perirhinal, entorhinal and parahippocampal cortices, and anterior and posterior hippocampus. Participants also performed an object-location associative episodic memory task. Behavioral accuracy measures for associative (object-location) memory, recognition (object only) memory, misses, correct rejections and false alarms were calculated. Bivariate correlation analyses were conducted to determine if regional volumes correlated with specific mnemonic responses. We found that bilateral posterior hippocampal volumes were positively correlated to object-location memory (right, $r = +0.55$, $p = 0.02$; left, $r = +0.54$, $p = 0.02$) and negatively correlated with misses (right, $r = -0.48$, $p = 0.04$; left, $r = -0.47$, $p = 0.05$). No other significant correlations were observed, but data collection is ongoing. This study provides evidence for the role of posterior hippocampus in supporting object-location associations, and depicts a relationship between volume and cognition mediated by individual differences in healthy young adults.

Title: Neural basis of episodic memory intermediate-term after medial temporal lobe resection

Authors: *W. JEONG[1,2], H. LEE[3], J. KIM[4], C. CHUNG[4,2]
[1]Dept. of Neurosurg., Seoul Natl. Univ. Hosiptal, Seoul, Korea, Republic of; [2]Neurosci. Res. Inst., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Dept. of Mental Hlth. Res., Natl. Ctr. for Mental Hlth., Seoul, Korea, Republic of; [4]Dept. of Brain and Cognitive Sci., Seoul Natl. Univ. Col. of Natural Sci., Seoul, Korea, Republic of

Abstract: Purpose: How the brain supports intermediate-term preservation of memory in patients who underwent unilateral medial temporal lobe resection (MTLR) have not been demonstrated yet. To understand the neural basis of episodic memory intermediate-term after surgery for temporal lobe epilepsy (TLE), the relationship between the activation of hippocampus (HIP) during successful memory encoding and individual memory capacity was investigated in patients with MTLR.
Methods: Thirty-five adult patients who underwent unilateral MTLR at least 1 year before recruiting and who had a favorable seizure outcome were enrolled (17 left MTLR, 18 right MTLR; mean follow-up = 6.31±2.72 years). All patients underwent a standardized neuropsychological examination of memory function and functional MRI scanning with a memory encoding paradigm of words and figures. Activations of HIP during successful memory encoding were calculated and compared with standard neuropsychological memory scores, HIP volumes, and other clinical variables.
Results: Greater activation in HIP contralateral to resection was related to higher postoperative memory scores and greater postoperative memory improvement than the preoperative baseline in both patient groups. Specifically, postoperative verbal memory performance was positively correlated with contralateral right hippocampal activation during word encoding in the left surgery group. In contrast, postoperative visual memory performance was positively correlated with contralateral left hippocampal activation during figure encoding in the right surgery group. Activation of the ipsilateral remnant HIP was not correlated with any memory scores nor volumes of HIP; however, it had a negative correlation with the seizure onset age and positive correlation with the duration of illness in both patient groups.

Conclusions: For the first time, neural basis that support effective episodic memory intermediate-term after unilateral MTLR were characterized. The results provide evidence that the engagement of HIP contralateral rather than ipsilateral to resection is responsible for effective memory function intermediate-term (> 1 year) after surgery. Engagement of material-specific contralesional HIP, verbal memory for the left surgery group and visual memory for the right surgery group, was observed. Engagement of material-specific contralesional HIP, verbal memory for the left surgery group and visual memory for the right surgery group, was observed.

Title: Human episodic memory system is composed of several components served by specific temporal sub-regions: Insights from temporal lobe resection

Authors: *D. KIM[1], J. KIM[1], C. CHUNG[1,2,3]
[1]Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Neurosurg., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [3]Neurosci. Res. Inst., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Introduction: Medial temporal lobe structures are pivotal for episodic memory. However, it is still remained controversial whether certain temporal sub-regions are more crucial for specific aspect of episodic memory. Observation of post-operative changes in comprehensive neuropsychological tests in patients who underwent temporal lobe epilepsy surgery provides excellent chance to investigating organization of human memory system. Here, we analyze the relationship between the resection extent of each temporal sub-regions and the postsurgical memory changes in patients who underwent mesial temporal lobe epilepsy surgery. **Methods:** Included are 75 patients (left, n=43; right, n=32) with mesial temporal lobe epilepsy who underwent unilateral anteromedial temporal resection. Resection areas were manually delineated on each of patient's normalized MRI space. Then, we performed two forms of analysis. In the first one of region of interest analysis, we segmented resection areas into sub-regions using modified AAL atlas and investigated the correlation between resection volume of each temporal sub-region and memory test score changes. In the second one, we performed voxel based

statistical analysis that depends only on the resection maps regardless of segmentation into sub-regions to define the detail structures critical for specific memory sub-function. **Results:** In the verbal subtest that requires 30 minutes delayed recall of serial word list (15 word), the left lateral temporal region was related to post-operative memory decline. For the recognition of the same task, resection of left mesial and lateral temporal regions excluding hippocampus were associated with postoperative functional decline. For the verbal subtest in which patients learn 7 pairs of unrelated words, post-operative memory decline was correlated with resection of left hippocampus. **Conclusions:** We revealed that specific temporal sub-regions play specific role in verbal memory. These results can be explained by the two component left temporal model of verbal memory, a mesial protosemantic component operationalized as arbitrary paired associate learning that is 'context-rich' memory and a lateral semantic component operationalized as performance on which semantic structure can readily be imposed 'context-free' memory.

Title: Scaled environmental representations in the medial temporal lobe

Authors: *H. R. EVENSMOEN, H. RISE, L. RIMOL, A. K. HABERG
NTNU, Trondheim, Norway

Abstract: We do not store accurate representations of our environments, but scaled environmental representations that results in local clustering of environmental landmarks. The aim of this study was to investigate how these scaled environmental representations are encoded in the medial temporal lobe.
In this study, the participants (31 males) had to learn 35 small virtual environments, during functional magnetic resonance imaging (fMRI) at 3T (voxel size = 1.9x1.9x1.9mm, 32 channel head coil). The environments consisted of five objects that formed a unique positional pattern within the environments. Each environment was enclosed by one of 10 differently shaped outer walls. The participants were given 30 seconds with free exploration, followed by 15 seconds of poststimulus encoding, to learn each environment. This was followed by 15 seconds with odd-even judgements. The participants had to complete seven runs. Each run involved five environments. After each run, the participants' ability to associate the objects together, associate the objects with the outer wall, recreate the objects positional pattern, place the objects positional pattern relative to the outer wall, place the objects in their position within the positional pattern,

were tested for each environment.
Preliminary results showed that the activation in the posterior PHC, part of the parahippocampal place area, increased as the object landmarks scaled positional pattern became more accurate.

Title: Auditory and visual mnemonic discrimination are correlated in healthy young adults

Authors: L. GIRAUD-CARRIER[1], D. K. BJORNN[1], C. TOWNE[2], *B. KIRWAN[1]
[1]Psychology, [2]Neurosci., Brigham Young Univ., Provo, UT

Abstract: Memory specificity is the ability to discriminate between similar memories. To date, research looking at memory specificity in humans has focused on visual stimuli and a direct comparison of performance on visual and auditory memory specificity is lacking. We conducted a behavioral experiment to determine if memory accuracy varies between auditory and visual sensory modalities. We also collected confidence rates to examine how subjective confidence in recognition memory judgments varied according to sensory modality. We hypothesized that memory specificity would be better with visual stimuli than auditory stimuli and that participants would be more confident of their answers to the visual stimuli.Data were collected from 154 healthy young adult participants, (79 male, 94 female). The task consisted of 8 blocks, alternating between 4 blocks of visual stimuli and 4 blocks of auditory stimuli, and each of the participants randomly receiving either visual or auditory stimuli first. Each block contained a study and a test portion. In the study portion participants were presented with novel stimuli and asked whether the stimulus is generally found “indoors” or “outdoors” to ensure attention to the stimulus during encoding. In the test portion, participants were presented with stimuli that were either the same or similar to those from the study portion. Participants gave combined recognition memory and confidence judgments as “definitely old,” “maybe old,” “maybe similar,” and “definitely similar.” Stimuli were presented for 2.5 seconds, the response period was 1.5 seconds, and an intertrial interval was 0.5 seconds.Performance on auditory and visual blocks were significantly correlated, but participants were able to discriminate visual stimuli significantly better than auditory stimuli. Confidence ratings were significantly higher for visual than for auditory stimuli as well. The findings of the present study give direct evidence that humans are better at discriminating visual memory than auditory memory over similar delays and similar levels of interference. The present study also develops the foundation for a task that

can be later used to examine hippocampal subfield activity using functional magnetic resonance imaging.

Title: Preferential viewing of changes in familiar scenes is impaired in patients with medial temporal lobe lesions but spared when they are (occasionally) aware of what has changed

Authors: C. N. SMITH[1,2], *L. R. SQUIRE[1,2,3,4]
[1]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [2]Psychiatry, [3]Neurosciences, [4]Psychology, UCSD, San Diego, CA

Abstract: There is disagreement about what kind of memory is impaired after damage to the medial temporal lobe (MTL). One idea is that the ability to acquire conscious memory is impaired. Another idea is that memory for relations or associations between items is impaired (i.e., regardless of conscious awareness for what has been learned). These ideas have been examined in studies of experience-dependent eye movements. For example, healthy individuals preferentially view the changed region of a familiar scene (i.e., the manipulation effect), and this effect is observed only when they are aware of what has changed. We examined the relationship between the manipulation effect and awareness in patients with MTL lesions. If the impairment reflects a loss of conscious memory, then patients should be impaired at explicitly identifying the manipulations, but they should exhibit the manipulation effect on the few occasions when they can identify what has changed. Alternatively, if the impairment reflects a loss of relational memory, then the manipulation effect should be absent regardless whether patients can identify what has changed. We tested eye movements and memory of scenes in controls and 5 memory-impaired patients with damage limited to the hippocampus or MTL. Participants viewed 12 familiar, repeated scenes and 12 familiar scenes where a change (manipulation) had been introduced. After viewing each scene, participants indicated if the scene was repeated or manipulated and then were asked to identify what had changed in each manipulated scene. The

patients were impaired at discriminating between repeated and manipulated scenes, and they identified many fewer of the manipulations than controls. In addition, across all manipulated scenes, controls tended to direct their viewing toward the region that had been changed (the manipulation effect), but the patients did not. Nevertheless, when eye movements were analyzed separately depending on whether participants were aware of the manipulation, MTL patients did exhibit the manipulation effect for the few scenes where they could identify what had changed (and the effect was absent when they could not identify what had changed). The manipulation effect is impaired in amnesia because the effect is observed only when participants are aware of the change and because memory-impaired patients are usually unaware of the changes. These findings are in agreement with the idea that awareness for what has been learned is a characteristic of hippocampus-dependent memory.

Title: Comparison of semi-automated hippocampal subfield segmentation methods in a pediatric sample

Authors: *M. L. SCHLICHTING[1], M. L. MACK[1], K. F. GUARINO[2], A. R. PRESTON[3]
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Loyola Univ. Chicago, Chicago, IL; [3]The Univ. of Texas at Austin, Austin, TX

Abstract: Episodic memory function has been shown to depend critically on the hippocampus. This region is made up of a number of subfields, which differ in both cytoarchitectural features and functional roles in the mature brain. Recent neuroimaging work in children and adolescents has suggested that these regions may undergo different developmental trajectories—a fact that has important implications for how we think about learning and memory processes in these

populations. Despite the growing research interest in hippocampal structure and function at the subfield level in healthy young adults, comparatively fewer studies have been carried out looking at subfield development. One barrier to studying these questions has been that manual segmentation of hippocampal subfields—considered by many to be the "gold standard" approach for defining these regions—is laborious and can be infeasible for large cross-sectional or longitudinal studies of cognitive development. Moreover, manual segmentation requires some subjectivity and is not impervious to bias or error. In a developmental sample of individuals spanning 6-30 years, we compared the performance of two semi-automated segmentation approaches, Advanced Normalization Tools (ANTs) and Automated Segmentation of Hippocampal Subfields (ASHS), to manual subfield delineation on each individual by a single expert rater. Across several quantitative metrics, we found negligible differences in subfield reliability across the child, adolescent, and adult age groups, suggesting that these methods can be reliability applied to developmental studies. We conclude that ASHS outperforms ANTs overall, and is thus preferable for analyses carried out in individual subject space. However, we underscore that ANTs is also acceptable, and may be well-suited for analyses requiring normalization to a single group template (e.g., voxelwise analyses across a wide age range). Previous work has validated the use of such methods in healthy young adults, as well as several special populations such as older adults and those suffering from mild cognitive impairment. Our results extend these previous findings to show that ASHS and ANTs can also be used in pediatric populations as young as six.

Title: Behaviorally relevant events modulate hippocampal representations and functional connectivity

Authors: *R. MOYAL[1], H. B. TURKER[1], A. PHELPS[1], W.-M. LUH[2], K. M. SWALLOW[1]
[1]Dept. of Psychology, [2]Cornell MRI Facility, Cornell Univ., Ithaca, NY

Abstract: Events that are relevant for task performance may be differently encoded and represented in episodic memory systems than those that are not. For example, recent data indicate that stimuli that require an overt or covert response, such as a target in a detection task, boost memory for unrelated background items and their spatiotemporal context. In this rapid

event-related fMRI study, we examined the neural mechanisms underlying the effects of target detection on episodic memory encoding. Participants viewed a series of briefly presented, masked images from six different categories (male and female faces, beaches, forests, cars, and chairs). Whenever an image appeared, a high-pitched tone, low-pitched tone, or no tone was played. Participants memorized the images and pressed a button only when the tone was of a predefined target pitch. After scanning, they completed a recognition test on the images. If responding to behaviorally relevant events enhances episodic memory encoding, then the functional connectivity between hippocampus and visual areas should be greater on target than on distractor or no tone trials. The patterns of activity in regions involved in representing the current situation should also differ between tone type conditions. Consistent with the first prediction, Generalized Psychophysical Interaction (gPPI) analysis indicated that hippocampal activity was more strongly correlated with activity in visual cortex when a target tone was presented than in other conditions. Functional connectivity between hippocampus, thalamus, and dorsal striatum was also stronger on target tone trials. In addition, representational similarity analysis revealed that tone relevance modulated patterns of activity in the hippocampus and in visual cortex. These findings indicate that the hippocampus encodes ongoing events differently when they are task relevant. They also suggest that the detection of relevant events promotes integrated processing in a functional network spanning areas implicated in low-level perception and memory.

Title: Measures of episodic recollection for real-world events in patients with medial temporal lobe damage

Authors: *N. HEYWORTH[1,4], L. R. SQUIRE[4,1,2,3]
[1]Psychiatry, [2]Neurosciences, [3]Psychology, Univ. of California San Diego, La Jolla, CA; [4]VA Med. Ctr., San Diego, CA

Abstract: Studies of autobiographical memory have typically depended on retrospective methods. We studied autobiographical memory prospectively by taking patients with medial temporal lobe (MTL) damage and two control groups (CON-1 and CON-2) on a guided walk during which 11 planned events occurred. Memory for the events was assessed immediately after the walk for the patients and for CON-1-immediate, after one month for CON-2-1 month, and again after 2.6 years for CON-1-2.6 yrs. At test, participants delivered 6-min narrative recollections about the walk, gave 1-min narrations in response to a cue about each event, and took a multiple-choice test about the events. Patients recalled fewer details than CON-1-immediate and a similar number of details as CON-2-1 month and CON-1-2.6 yrs. The quality of the recollections was assessed using measures of episodic richness and other features of narrative construction including parts of speech, word frequency, imageability, and coherence. Coherence reflects the continuity and organization of the narrative and was measured by quantifying time-and-place information, as well as the chronology and theme of the narrative. Coherence was lower in patients than in all control groups largely due to poor chronology (i.e, the events of the walk were not recalled in chronological order). For most other measures, the episodic recollections reported by patients were similar to controls tested after long delays (1 month and 2.6 years), suggesting that the quality of the recollections was related to the strength of memory rather than factors specific to MTL function.

Title: Hippocampal subfields show dissociable integration and separation signatures for overlapping memories

Authors: *R. J. MOLITOR, K. R. SHERRILL, N. W. MORTON, A. R. PRESTON
Univ. of Texas at Austin, Austin, TX

Abstract: The flexibility of episodic memory allows us to remember both the details that differentiate similar events as well as commonalities among overlapping experiences. These two functions are thought to arise through the formation of orthogonal memory codes via pattern separation and overlapping representations through memory integration, respectively. Empirical

research and computational modeling suggest that hippocampal subfields $CA_{2,3}$/dentate gyrus ($CA_{2,3}$/DG) are biased towards pattern separation, whereas CA_1 supports the formation of integrated memory codes. However, we have a limited understanding of the learning conditions that influence how highly similar memories are represented in hippocampal subfields. Here, we tested whether the formation of integrated and separated memories in hippocampal subfields depends on the strength of memory reactivation during learning. While some research suggests that reactivation may allow for the integration of new information into existing representations, other data suggest reactivation may lead to competition between co-active memories and require pattern separation to resolve interference. To adjudicate between these perspectives, participants studied a set of associations (AB pairs, either face-object or scene-object), and then were scanned with fMRI while they encoded overlapping associations (BC object-object pairs). Both before and after learning, participants were also scanned while viewing images (A and C) in isolation. Using multivariate techniques, we measured reactivation of related memories (A items) during overlapping event (BC) learning as well as the degree to which hippocampal activation patterns for indirectly related images (A and C) became less similar (i.e., separated) or more similar (i.e., integrated) after learning. We found evidence of a dissociation across hippocampal subfields, such that stronger reactivation led to the integration of overlapping memories in CA_1, and separation of those same memories in $CA_{2,3}$/DG. These findings provide insight into the basis of the complementary neural codes formed by the memory system and empirical support for computational learning models of the hippocampus.

Abstract: There is good agreement that theta oscillations in the human hippocampus play a central role for episodic memory formation. However, conflicting results have been reported on how theta power modulations are related to memory formation. Some studies reported theta power increases (putatively reflecting neural synchronization), whereas other studies reported theta power decreases (putatively reflecting neural de-synchronization) during memory formation. Therefore the question arises as to how theta power changes and neural synchronization processes underlie episodic memory formation in humans. To address this question we have recorded local field potentials and putative single-unit activity using microwire electrodes implanted in human patients suffering from epilepsy. Our results indicate that there is a significant band limited and sustained theta power increase during memory formation. This theta power increase, however, was limited to areas which also show an increase in firing rate during the task. Areas which do not show increased firing rates during the encoding task appear to show theta power decreases. Furthermore, our results suggest that in areas which show an increase in firing rate, the firing of neurons is weakly coupled to the phase of theta oscillations. These results suggest that both, theta power increases and decreases can be observed during memory formation, however, theta power increases are limited to areas which show an increase in firing rate. Theta power increases further might point towards neural synchronization processes in the service of memory formation. These results potentially resolve a current debate in the field in suggesting that whether we see theta power increases or decreases depends on whether recordings are obtained from areas which also show an increase in local spiking activity.

Title: Cardiorespiratory fitness predicts default mode network effective connectivity in young adults

Authors: *K. L. KERN[1], C. A. KRONMAN[2], R. K. NAUER[3], M. F. DUNNE[1], T. W. STORER[4], K. SCHON[1]

Abstract: Rodent and human studies examining exercise-induced changes in brain structure indicate that the hippocampus, a brain region critical for episodic memory, demonstrates striking plasticity in response to exercise. Human studies examining exercise-induced changes in behavior demonstrate that exercise affects broad cognitive domains reliant on large-scale brain networks not limited to the hippocampal memory system. Examining network activity in large-scale resting-state brain networks may provide a link between exercise-induced hippocampal plasticity and cognitive enhancement. Previously, cardiorespiratory fitness (CRF) has been associated with enhanced functional connectivity of the default mode network (DMN). However, how CRF affects strength and directionality of connectivity, or effective connectivity, between the hippocampus and other DMN nodes remains unknown. We used resting-state fMRI and Conditional Granger Causality Analysis (CGCA) to test the hypothesis that CRF positively predicts effective connectivity between the HC and other DMN nodes in healthy young adults. Twenty-five participants (aged 18-35 years) underwent a treadmill test to determine CRF and a 10-minute resting-state fMRI scan (Philips 3T Achieva) to examine DMN effective connectivity. The DMN was identified using group independent component analysis, and effective connectivity between nodes was examined using CGCA. Linear regression analysis demonstrated that CRF significantly predicts strength of effective connectivity from the hippocampus to multiple DMN hubs, including the medial prefrontal, posterior cingulate, and lateral temporal cortices. These findings suggest functional connectivity changes between the hippocampus and large-scale brain networks as a link between the exercise-induced hippocampal plasticity observed in rodents and the exercise-induced enhancement of broad cognitive domains observed in humans.

Title: Sharp wave ripple cross-structure phase locking to cortical oscillations predicts the modulation of cortical activity in human intracranial recordings

Authors: *I. SKELIN[1], J. ZHENG[2], H. ZHANG[4], B. L. MCNAUGHTON[5], J. LIN[3]
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Dept. of Biomed. Engin., [3]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; [4]Biomed. Engin., Univ. of California Irvine, Irvine, CA; [5]Dept. of Neurosci., The Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Hippocampal sharp wave/ripples (SWRs), cortical slow oscillations (SOs) and sleep spindles (SPs) have been proposed to support memory consolidation during the slow wave sleep (SWS). In particular, SWRs provide the time window for hippocampal memory reactivation and promote hippocampal-cortical communication supporting memory consolidation. However, it is less clear how hippocampal SWRs interact with cortical SOs/SPs during the SWS and how such interplay shapes cortical neuronal dynamics. To address this, we performed overnight intracranial electroencephalography recordings in 11 patients undergoing pre-surgical seizure localization. Specifically, we assessed the dependence between the cortical peri-SWR high frequency local field potential (HF-LFP; 300-900Hz) and SWR phase-locking to SOs and/or SPs in the same cortical location. Local field potential (LFP) was simultaneously recorded from the hippocampus, temporal, frontal and cingulate cortices. SWS periods were identified based on LFP delta (1-4 Hz) power in the frontal cortex. SWRs were identified based on double threshold of power in 80-150 Hz range (peak and duration). Periods surrounding interictal epileptic discharges (IEDs; +/- 1 s) were excluded from the analysis. Significance of HF-LFP response during -250 to 250 ms period surrounding the SWR peaks was based on the presence of significant difference from the baseline in at least two consecutive 25 ms time bins. Instantaneous phases of SOs and SPs at the SWR peak times were extracted from cortical LFP using the Hilbert transform. SWR-SO or SWR-SP cross-structure phase locking significance was assessed using Rayleigh test for non-uniformity of circular data. We found that the cortical locations showing significant HF-LFP response were more likely to show significant SWR phase locking to SOs or SPs, relative to cortical locations without significant HF-LFP response. This pattern was consistent for both anterior and posterior hippocampal SWRs (chi-square test; all p's < 0.02). These findings suggest that during SWS, SWR/SW/SP interactions orchestrate the dynamics of cortical HF-LFP, a proxy of multi-unit neuronal firing. This could represent an important mechanism for organizing hippocampal-cortical interactions supporting memory consolidation.

Title: Spontaneous generalized memory representations following paired-associates training

Authors: *S. ASHBY, C. R. BOWMAN, D. ZEITHAMOVA
Univ. of Oregon, Eugene, OR

Abstract: Memory studies typically focus either on memory for individual experiences (specificity) or the ability to link information across events (generalization). However, experiences in our daily lives are not neatly separated into specificity vs. generalization tasks. Instead, we have to make different judgments based on the same experiences. Do we spontaneously extract generalized knowledge even when the task at hand demands specificity? To answer this question, we assessed behavioral and neural measures of memory specificity and generalization during and after a task where participants learned face-name associations. Face stimuli were constructed as 50/50 blends of never-seen "parent" faces. Three parent faces were selected to determine category membership, presented as a family surname, and then blended with other parent faces. Each training face had a unique first name. As a result, the training faces had an underlying category structure that was incidental to the paired-associate learning as participants were instructed to memorize the full name for each face during fMRI. To measure specificity, participants completed a full name recall test and an old/new recognition task with novel face-blends as foils. Results showed good performance on both metrics, indicating that participants successfully acquired memory for specific faces. To measure generalization, participants made pairwise similarity ratings of faces before and after learning and made categorization judgments of novel face-blends. Results showed above-chance categorization of novel faces and greater perceptual similarity ratings for faces from the same category than different categories (controlling for physical similarity) that emerged after learning, indicating spontaneous acquisition of generalized knowledge. Neural pattern similarity analysis in the ventromedial prefrontal cortex (vmPFC) showed representations of individual items, but not categories, during the paired-associates training; category information was present in vmPFC during subsequent categorization but not recognition. These results indicate that vmPFC may flexibly access specific or generalized memory representations based on the current task demands. In contrast, perceptual regions like fusiform cortex showed category effects during both recognition and categorization, reflecting primarily perceptual information irrespective of

the task. This study demonstrates spontaneous formation of generalized knowledge even when task demands emphasized specificity and newly suggest a flexible role of vmPFC in representing both specific or generalized information in response to task demands.

Title: Hippocampal characteristics influence the structure of idle thought

Authors: *J. TSENG[1], J. POPPENK[2]
[1]Neurosci., [2]Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: We are estimated to spend up to half of our waking hours in idle thought. Is this experience similar for everyone? Recent research has found that hippocampal damage changes the content and form of mind-wandering. Although brain damage could influence cognition in many ways, this finding raises the interesting possibility that, among healthy adults, individual differences in memory recall that are supported by the hippocampus influence the nature of traversal through mental states. Accordingly, we explored the role of the hippocampus by correlating its characteristics with neural markers of mental state traversal.
We conducted our analysis on 815 healthy participants between the ages of 22 and 35 years from the Human Connectome Project (HCP) dataset. Each participant had one hour of resting state functional MRI data. The HCP conducted group functional connectivity analyses to identify a specified number of brain region networks or “nodes”. Then, a participant’s mental state could be characterized as the linear combination of the activity at each node. As the HCP generated these representations for multiple sets of nodes, we carried out our analysis on the 15-, 100-, and 300-node timeseries.
The node timeseries for each participant was fed into the t-distributed stochastic neighbour embedding dimensionality reduction algorithm, which produced a two dimensional trajectory of the participant’s resting state brain activity. Then, we calculated the Euclidean distance between successive points in the lower dimensional output. We defined the duration of a state as the number of consecutive timepoints whose Euclidean distance from the previous timepoint falls

under a reasonable threshold. Using this definition, we determined the average and maximum time spent in each mental state and the number of state transitions. This was repeated for all participants and all three node timeseries.
We discovered that the three characteristics had small but significant correlations with hippocampal volume. In particular, the average time spent in a state was correlated with the right hippocampal volume (rs > 0.12, ps < 0.001), and the right anterior hippocampus (rs > 0.09, ps < 0.032). The findings held across the 15-, 100-, and 300-node timeseries, as well as across varying distance thresholds used to define the state transitions.
These results suggest that the hippocampus serves a role not only in episodic memory processes, but also in the very structure of thought, perhaps influencing our thought trajectories by means of episodic reinstatement.

Title: Distinct connectivity patterns along the hippocampal anterior-posterior axis

Authors: *L. FRANK
Univ. of Oregon, Eugene, OR

Abstract: Recent work suggests that memories can be represented in the hippocampus at different levels of specificity. Hierarchical organization of memories may be supported by functional distinctions between the anterior and posterior hippocampus, such that detailed representations become increasingly more abstract as they move from posterior to anterior subregions. Animal studies have shown that the size of receptive place fields increase moving from dorsal (posterior) to ventral (anterior) hippocampus. In the episodic memory domain, human fMRI studies have shown small time-integration windows and sentence-level representations in the posterior, compared to larger time-integration windows and narrative-level representations in the anterior hippocampus. Additionally, we recently showed that activity in the anterior hippocampus uniquely reflected abstract concepts rather than specific category exemplars during a category generalization task. Given the different functions of the anterior and posterior hippocampus, we tested whether intrinsic functional connectivity differs between these hippocampal subregions. Similar to the proposed organization of the hippocampal axis, we

expected to see greater anterior hippocampal connectivity with medial prefrontal regions that are known to support generalizing across events and greater posterior hippocampal connectivity with lateral prefrontal regions involved with differentiation of overlapping events. We also tested how connectivity patterns may change or remain stable under varying levels of task engagement. Following category training, participants underwent fMRI, including a rest scan, two scans of passive viewing of category exemplars, and four runs of a category generalization task. Contrasts of anterior and posterior hippocampal connectivity revealed greater anterior hippocampal connectivity with the ventromedial prefrontal cortex, and greater posterior hippocampal connectivity with the dorsolateral prefrontal cortex and anterior cingulate cortex. These patterns remained stable across the three phases (rest, passive viewing, concept generalization), suggesting the organization of connectivity is relatively unaffected by level of task engagement. These results contribute to our understanding of functional organization along the long axis of the hippocampus, highlighting interactions with distinct prefrontal regions that contribute to differentiating details or finding commonalities respectively.

Title: Interactions of hippocampal characteristics with sleep structure in gist memory consolidation

Authors: *N. MATORINA, G. MARVEL, J. POPPENK
Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Recent research in animal models suggests that the hippocampus increases in spatial scale when moving from its dorsal to ventral segments, which is analogous to the anterior and posterior segments in humans. This functional specialization may relate to more general memory features, such that the anterior hippocampus is specialized for 'gist' memories, and the posterior for 'detailed' memories. Interestingly, a growing body of research suggests that sleep may be involved in the process of abstracting detail information into gist, or gist extraction. However, the role of the anterior hippocampus in the relationship between sleep physiology and gist memory is unknown.

In the current, pre-registered study, we collected sleep, memory and neuroanatomical data from 66 participants. The memory sessions took place in the evening before sleep, in the morning after sleep (12 hours later), and 7 days later. Participants wore a portable EEG device between the evening session and morning session that measured and classified sleep at home. We investigated two kinds of gist memory in a visual statistical learning (VSL) and a transitive inference (TI) task. For VSL, participants were tested on sequences of shapes. Some shapes were presented in the same order each time (detail sequences), while others were presented in the same order only 3/4 of the time (gist sequences). For TI, participants studied pairs of associates and were tested on studied pairs (detail pairs), as well as unstudied pairs that required inferences from studied pairs (gist pairs). Finally, neuroanatomical volumes were estimated through Freesurfer analysis of 0.7mm isotropic whole-brain T1w and T2w data, which were gathered using a 3T MRI scanner. To control for head size, we residualized the effects of intra-cranial volume.
We predicted that either more slow-wave sleep (SWS) or more rapid-eye movement (REM) sleep would improve gist memory over time. We also predicted that anterior hippocampal volume would moderate this relationship, such that those with more SWS or REM and larger anterior hippocampal volumes would have more improvement in gist memory over time. Using multi-level modelling, we found a variety of interactions. As predicted, SWS positively predicted gist memory over time in VSL for participants with larger left anterior and smaller left posterior hippocampi.
Conversely, in our TI task, right anterior hippocampal volume positively predicted gist memory only in participants with low levels of REM. This suggests that anterior hippocampal volume and SWS may be synergistic in consolidation of gist for extracting visual patterns, while REM may impede consolidation of gist for inferences.

Abstract: Over the last 15 years, the number of studies using high-resolution MRI to examine the structure and function of human hippocampal subfields has soared. However, the ability to compare findings across studies has been hampered by substantial differences in how subfields are segmented by different research groups. To remedy this issue, the Hippocampal Subfields Group (HSG) was formed in 2013 with the goal of creating a valid and reliable harmonized segmentation protocol grounded in robust histological standards. Over the past 5 years, our efforts have focused on developing a harmonized protocol for high-resolution T2-weighted 3T MRI. Our development approach consists of: 1) collecting histology samples labeled by multiple anatomists to guide the development of an MRI segmentation protocol, 2) holding working group meetings to develop different portions of the protocol (e.g., hippocampal body, head), 3) assessing HSG agreement with boundary rules via a series of online questionnaires, 4) revising boundary rules in response to questionnaire responses, and 5) testing reliability of each rule on multiple MRI data sets. Given substantial differences in the anatomy of the hippocampal head and body, we have approached these regions separately. For both the body and the head, we have completed steps 1 and 2, such that we have developed a preliminary subfield segmentation protocol for each region. Additionally, with respect to the outer boundaries of the body (i.e., the anterior/posterior, medial/lateral, and superior/inferior boundaries), we have completed steps 3 and 4 as well. An online questionnaire describing each of the outer boundary rules was sent to HSG members, with a total of 29 labs participating. Consensus agreement was reached for all rules included in the questionnaire, but slight modifications were made to select rules to improve clarity. We are now in the process of creating and administering additional questionnaires assessing agreement with the inner boundary rules for the hippocampal body (e.g., between the cornu ammonis fields) as well as the boundary rules for the hippocampal head. Upon completion of the assessment/revision process for each set of rules, the final phase - validation testing - will begin. Once completed, the harmonized protocol is expected to significantly impact the field by enabling cross-study comparisons and thus advancing our understanding of the structure and function of hippocampal subfields.

Title: Semantic learning in developmental amnesia: Can recognition facilitate recall?

Authors: *R. ELWARD[1], J. LIMOND[2], M. MISHKIN[3], F. VARGHA-KHADEM[4]
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Exeter, Exeter, United Kingdom; [3]NIMH, Bethesda, MD; [4]UCL Inst. of Child Hlth., London, United Kingdom

Abstract: Patients with developmental amnesia (DA) have suffered hippocampal damage in infancy and subsequently shown poor episodic memory (i.e. amnesia for the events of their life). Despite their high IQs, these patients underperform in school presumably because they do not remember their prior lessons and learning experiences, and must therefore rely on acontextual semantic knowledge which is accrued over time. It is not clear how patients with DA are able to amass this bank of general knowledge in the presence of episodic amnesia. One important factor is that patients with DA show well-developed recognition memory on multiple choice or true/false tests. These recognition abilities may support semantic learning. We provide data from three experiments designed to understand how patients with DA learn semantic information. The first experiment showed that multiple learning trials on new texts did not facilitate recall. In this study, patients were presented with four texts containing new knowledge. Each text was presented six times and followed by cued recall after each trial. Recall performance remained low (<40%) and plateaued after the 3rd trial. One week later, patients recalled only 35% of the contents (controls recalled 80%) in a cued recall test. In experiment two, the same knowledge test was presented to a new group of patients with DA via video. Each video was presented six times and after each trial, a multiple-choice recognition test was administered. Patients performed at 90% accuracy during these recognition tests. One week later, patients with DA

were able to recall 85% of the learned information in a cued recall test. These data show that multiple opportunities to recognise the new information led to good recall performance. Experiment three directly compared recognition learning versus recall learning. A patient with DA (aged 8 years) watched each video six times. Two videos were supported with cued recall tests and two were supported with recognition tests. One week later, cued recall performance was compared across the two learning paradigms. This showed a clear benefit of recognition learning compared to recall learning (35% vs. 76%). If this finding replicates in a larger group of patients, then it may provide a practical means of supporting the education of young people with DA. Furthermore, the data suggest that young people with extensive hippocampal damage indeed utilise their recognition memory to support the integration of new information into their semantic system.

Title: Similarities in perirhinal cortex response patterns related to decision outcome in recognition-memory judgments

Authors: *A. BLUMENTHAL[1], C. B. MARTIN[2], S. KOHLER[3]
[1]Univ. of Western Ontario, London, ON, Canada; [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [3]Univ. Western Ontario, London, ON, Canada

Abstract: The ability to determine whether objects and other entities in the environment are novel or familiar is known to depend on perirhinal cortex (PrC) in the medial temporal lobes. However, how PrC representations support item-based recognition-memory decisions is not fully understood at present. Previous fMRI work from our laboratory has revealed that PrC carries category-specific memory signals for a number of visual object categories, including faces, chairs, and planes. In the present study, we re-examined data from these studies to determine how such such signals relate to the decision outcome. Specifically, we asked whether patterns of activity in PrC reflect perceived or objective memory status, and how similarities in these patterns correspond to decision outcome. We found that pattern similarities in PrC were higher for items from the same category that had the same perceived memory status (familiar vs novel).

By contrast, similarities did not vary according to objective item status. This set of result did not hold for the hippocampus, whose patterns showed no relationship to perceived or objective memory status. We also found that PrC patterns associated with false alarms were more similar to hits than those associated with correct rejections were to hits (despite their shared objective memory status as novel). These similarity relationships, however, were only present when items from the same category were compared in the analyses. Critically, the latter result suggests that similarities in PrC response patterns for hits and false alarms during recognition-memory decisions are not tied to shared motor-responses. Instead, they appear to be tied to computations that inform the process of memory discrimination. Inasmuch as PrC is thought to contribute to discrimination through 'global matching', our findings suggest that this matching is constrained by category membership.

Title: Anterior and posterior hippocampal contributions to extraction of schematic information from naturalistic experiences

Authors: *J. POPPENK, N. DOAN, J. WASERMAN, I. PETRAR-SILCA
Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Interest has grown in functional subdivisions within the human hippocampus, with the anterior portion of the structure believed to feature a role in gist-like episodic memories, and the posterior a role in detailed episodic memories. While the hippocampus as a whole is believed to contribute to consolidation of episodic memories into more schematized forms over time, how these segments may individually contribute to this process is not well understood. Notably, the anterior, but not posterior hippocampus features direct connections to the anterior temporal lobe and ventromedial prefrontal cortex, two regions believed to feature schematic representations. We therefore predicted that the anterior hippocampus in particular, with its gist-like features, could feature a role in memory generalization, whereas discretized event data in posterior hippocampus may serve to feed such generalization.

To explore this possibility, we gathered memory and neuroimaging data from 66 healthy young adults (age 25-35). Participants viewed six 13-slide narrated slideshows, each comprising a short event. The first slide of slideshow was a "context" slide featuring a location for the event and corresponding soundscape. Immediately after seeing the slideshow as well as the next day, participants were cued with the context slide and soundscape and asked to recall the corresponding slideshow. Participants were given two minutes for recall of each slideshow, and were asked to verbally recall each event slide-by-slide, in order, and in as much detail as possible. On a later occasion, participants repeated this task with an additional six slideshows. These recall attempts were scored by raters for schematic elements, slide gist and slide detail content. At the end of our experiment, neuroanatomical volumes were estimated through Freesurfer analysis of 0.7mm isotropic whole-brain T1w and T2w data, which were gathered using a 3T MRI scanner. To control for head size, we residualized the effects of intra-cranial volume.
To link memory and brain data, we performed mediation analyses, investigating changes to memory representations after a delay as a function of hippocampal characteristics. These analyses revealed a positive relationship between the left pHPC/aHPC ratio and development of schematic memory representations in the delayed condition. *Post hoc* analyses revealed that, contrary to our expectations, the driver of this relationship was the left hippocampal tail. We speculate that these results reflect the posterior hippocampus's role in maintaining distinctive representations of events from which schematic representations may be generated.

Title: Grid realignment predicts human contextual memory

Authors: *L. C. SOMMER, J. B. JULIAN, C. F. DÖLLER
Kavli Inst. For Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: To guide spatial behaviour successfully, the brain must retrieve memories that are appropriately associated with different navigational contexts. Grid cells in the entorhinal cortex

(EC) may serve an important role in this function. Between navigational contexts, grid cells alter their firing patterns, a process known as grid realignment. However, the relationship between grid realignment and contextual memory is unclear. One possibility is that grid realignment is driven purely by changes to perceptual cues. Alternatively, grid realignment may reflect memory for navigational context *per se* that goes beyond sensory processing. To test the relationship between grid realignment and contextual memory, human participants learned the locations of target objects in two virtual reality arenas (Context A and B) distinguished by the shape of their boundaries (one square, one circle) and their distal orientational cues. Following training, participants underwent fMRI scanning while object location memory was tested in Contexts A and B, as well as in a third ambiguous half-square half-circle arena (Context AB). By comparing the recalled target object locations in Context AB to the correct target locations in Context A versus B, we could estimate which contextual memory (Context A or B) was reinstated in Context AB on a trial-by-trial basis. Preliminary results showed greater changes in the human EC fMRI grid-like signal across Contexts A and B than across different trials within the same context, consistent with contextual grid realignment in humans. Critically, we also found that the EC grid-like signal predicted contextual memory retrieval in Context AB. Together, these results provide the first evidence for grid cell involvement in contextual memory independent of sensory processing.

Title: Temporal mapping in the human entorhinal cortex

Authors: *J. L. BELLMUND[1], L. DEUKER[2], C. F. DOELLER[1]
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]Ruhr-University, Bochum, Germany

Abstract: Episodic memories are thought to be formed by binding events to their spatial as well as temporal context and medial temporal lobe structures have been implicated in the formation of such integrated memories. But which neural mechanisms allow us to remember when a specific

event occurred? Theoretical accounts and recent empirical evidence suggest that the entorhinal cortex provides a slowly varying temporal signal, which might enable the tagging of individual events in time; thereby allowing the formation of a temporal mnemonic map. Here, we probe the development of temporal representations in the entorhinal cortex through learning. We relate changes in multi-voxel pattern similarity in entorhinal cortex to temporal distances between events participants encountered through repeated navigation along a fixed route in a large-scale urban environment. FMRI data were acquired during isolated presentation of events in random order, indicating that the observed similarity structure reflects the reactivation of a learned temporal mnemonic map rather than time per se. Our findings speak to how the entorhinal cortex might provide temporal context information for episodic memory and elucidate the mechanisms underlying the mapping of time in the medial temporal lobe in general.

Abstract: Memory is affected when humans voluntarily modulate single neuron or neural population activity using neurofeedback. However, it is currently unknown whether memory is facilitated or impaired after such neural perturbations. In this study, participants memorized objects while we trained them to modulate their brain activity patterns in the medial temporal lobe (MTL), hereby creating an artificial memory context in the MTL while memorizing objects. The results revealed that the context created by neurofeedback caused interference with memory performance during a subsequent associative learning task. These results shed light onto how memory formation can be influenced by synthetic memory tags with neurofeedback, with

implications for our understanding of mnemonic coding in the MTL and possible applications in information technology as well as the clinic.

Title: Mapping the human navigation network with high-field fMRI: A voxel-wise encoding model

Authors: *M. NAU, T. NAVARRO SCHRÖDER, C. F. DOELLER
Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The brain's navigation system has been extensively studied over decades, yet on a population and systems level the underlying spatial codes remain poorly understood. Here, we used 7T-fMRI to monitor human brain activity at submillimeter resolution while participants navigated a virtual environment and performed an object location memory task. We predicted each voxel's time course by incorporating navigation behavior into computational models of neural tuning curves for which weights were estimated using cross-validated ridge regression. By iterating this procedure for a multitude of parameters (e.g. tuning width) and by predicting held-out data, this approach allows us to map each voxel's tuning and predictability across the cortex. Preliminary results point towards a wide-ranging network coding participants' virtual head direction and give new perspectives on grid-like fMRI signatures in the human mediotemporal lobe. While we implemented this model using human fMRI navigation data, it yields the potential to be used also for other human imaging techniques, cognitive domains or for data from other species.

Abstract: Spatially modulated cells in the hippocampus and medial enthorinal cortex (mEC) provide reliable information required for successful navigation in an environment. A lower information limit of these structures can be approximated by assessing the accuracy with which self-location can be decoded from the underlying neural activity. Most traditional decoding algorithms use spike sorting methods for detecting action potentials which are subsequently used for spatial decoding. However, spike sorting potentially introduces selection biases and methods limited to action potentials inevitably discard information contained in the local field potential (LFP). Here we decode self-location from wide-band (2Hz - 6000Hz) electrophysiological signals from regions CA1 and mEC in freely moving rats, using state-of-the art deep learning algorithms. We demonstrate that our model is able to extract spatially relevant features from wide-band traces and outperforms established location-decoding methods, such as a Bayesian decoder, trained on manually sorted spikes. We further investigated if this decoding architecture generalises to non-rodent data, specifically to human brain activity recorded using magnetoencephalography (MEG) during navigation in a virtual environment. This allows us to examine single-cell as well as population level activity underlying spatial navigation in rodents and humans within a single model.

Abstract: Grid cells in the rodent and human entorhinal cortex are a critical component of the brain's spatial coding system. In virtual-reality (VR) navigation tasks in humans, the fMRI BOLD signal in the entorhinal cortex exhibits hexadirectional modulations that may reflect population activity of grid cells. However, it remains unknown whether and how grid cell population activity specifically gives rise to this hexadirectional hemodynamic fMRI signal. Here we address this issue in two steps. First, we employed a VR navigation experiment using magnetoencephalography (MEG) in human participants and found hexadirectional signal modulations in the high-gamma band, source-localised to the medial temporal lobe. Next, we conducted analyses to test the relationship between grid cell activity and local field potential (LFP) recordings in freely moving rats. We found hexadirectional modulations in the same frequency band as in the human MEG navigation experiment. The orientation of this hexadirectional LFP modulation was aligned to the orientation of the hexagonally symmetric firing patterns of grid cells. Together, these findings describe new ways to measure grid cell population activity and their non-invasive source localisation using MEG. Crucially, we link grid cell activity to measures of population activity in rats and humans, thereby elucidating the physiological basis of non-invasive grid cell population measures previously revealed with fMRI. Since grid cell function is affected early in Alzheimer 's disease, understanding how to measure their activity with non-invasive methods is of high clinical relevance.

Title: Knowledge transfer between physical and conceptual spaces

Authors: *D. KUHRT, J. L. S. BELLMUND, C. F. DOELLER
Kavli Inst. For Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Spatial navigation is a basic cognitive process known to involve the hippocampal-entorhinal system. Research on spatial navigation in rodents has revealed a range of functionally defined cell types, among them place and grid cells conveying positional information. These studies typically investigate navigation in spaces based on the three physical dimensions by tracking movements through physical enclosures or virtual environments. Therefore, we will refer to these spaces as physical spaces. Intriguingly, recent studies have shown spatial processing mechanisms in abstract, conceptual spaces beyond navigation in physical space. This is in line with the notion that these conceptual spaces can be described by the same quantifiable features as physical space and further suggests that representations of abstract information in higher-level brain areas might follow coding principles identified in spatial navigation research. Here, we ask the question if knowledge acquired in physical and conceptual spaces is represented in a similar format, allowing knowledge transfer between spaces. To test this hypothesis, we created a 2D conceptual space and a corresponding virtual model of a physical space, carefully matching space-defining features such as dimensionality, size, underlying metric, shape and informational content. In an object-location memory paradigm, participants learned to navigate both spaces using the same controls and successfully created object-location associations. In a post-learning test, we probed participants' abilities to transfer knowledge between the two spaces. Behavioural results provide evidence for accurate representations of both spaces as well as for a transfer of knowledge between spaces. Future fMRI analyses will shed light on the representation of knowledge gained in physical and conceptual spaces in the brain's navigation system and the potential neural integration of information across spaces. Our initial behavioural findings speak to the growing body of evidence suggesting domain-generality of spatial coding principles in higher-level cognition.

Abstract: A hallmark of Alzheimer's disease (AD) is the impaired ability to find one's way through the environment. One of the first structures affected in AD is the entorhinal cortex (EC), a structure containing grid cells, known for their importance in the brain's spatial navigation system. Old transgenic EC-TAU mice express impairments in grid cell function. In humans, both old adults and healthy young participants with an increased genetic risk for AD, i.e., *APOE*-ε4 carriers, exhibit weaker hexadirectional entorhinal signals, understood to be an fMRI signature of grid cell population activity, compared to young controls. Carriers of this genetic risk factor differ from controls and apply a strategy characterized by reduced navigation in the central area of a virtual testing environment. Here, we investigate differences in navigational strategies in young and old healthy volunteers performing an object-location memory task, while undergoing fMRI, to gain insight into processes underlying cognitive ageing affecting spatial navigation and memory. Following an initial encoding phase, in which participants explored the locations of objects in a virtual environment, participants were cued to recall and further learn the object locations. Our findings indicate differences in navigational strategies between the age groups, with old adults navigating more frequently farther away from the centre of the environment, thereby indicating a surround navigational strategy compared to young participants. Further, our paradigm enabled dissociation of mnemonic strategies for positional learning through the movement of a local landmark in a subsequent memory test. Our behavioural findings will be complemented by analyses of neural representations during navigation contrasting the age groups. Understanding alterations in memory and navigation in healthy ageing may contribute to distinguish normal from pathological cognitive ageing in dementia diseases such as AD.

Additionally, it may enable investigations of AD pathology, as structures known to be important for memory and spatial navigation are affected at early stages of the disease.

Title: The role of hexadirectional coding in spatiotemporal integration

Authors: *I. POLTI[1], M. NAU[1], V. VAN WASSENHOVE[2], C. F. DOELLER[1]
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]CEA, DRF/Joliot, NeuroSpin; INSERM, U992, Cognitive Neuroimaging Unit, Univ. Paris-Sud; Univ. Paris-Saclay, Gif-Sur-Yvette, France

Abstract: The hippocampal-entorhinal network has been implicated in processing spatial as well as temporal information. Convergent evidence from single-unit recordings in non-human primates and fMRI in humans suggested that entorhinal cortex represents a grid-like map of visual space. This spatial code is hexadirectional, as reflected in a six-fold rotationally symmetry of neural activity as a function of gaze direction. However, the behavioural function of this code and whether and how it incorporates information about time into underlying computations remain elusive. Here, we designed a highly controlled visual tracking task in which participants fixated at a dot that moved on linear trajectories with different speeds within a circular boundary. Whenever the dot stopped moving, participants had to estimate the time-to-contact (TTC), i.e. the time point when the dot would have hit the boundary if it continued moving. This allowed us to examine TTC estimates as a function of gaze direction for a variety of target durations while participants' eye movements were monitored using high-resolution eye tracking. Preliminary results suggest that TTC estimates indeed depend on gaze-direction and that our task is well suited to examine time-judgement effects, such as scalar variability across the visual field. We now investigate whether participants' behavioural performance is related to fMRI activity in the hippocampal formation (HF), in particular entorhinal cortex. Our novel psychophysics approach has the potential to provide new insights into how space and time are processed dynamically

across the visual field and could help to unravel HF involvement in spatiotemporal integration and prospection.

Title: Mapping conceptual space

Authors: *S. THEVES[1], G. FERNANDEZ[1], C. F. DOELLER[2]
[1]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The hippocampal formation encodes maps of the physical environment. Whether its spatial coding principles provide a universal metric for organizing non-spatial information, such as conceptual knowledge, remains elusive. Here we investigate how the human hippocampus represents knowledge using a novel concept-learning paradigm combined with functional neuroimaging. Participants learned to categorize objects based on the relation of two abstract stimulus-feature dimensions that span a two-dimensional concept space with the diagonal as category boundary. We seek to investigate the neural representations of both, the conceptual space, as well as resulting categorical information. So far, we showed that following learning, two-dimensional distances between individual positions in concept space were represented in the hippocampal multi-voxel pattern as well as in the univariate hippocampal signal as indexed by fMRI adaptation. This suggests a map-like format of neural concept representations and supports the notion that the hippocampus computes domain-general, multidimensional cognitive maps along continuous dimensions.

Abstract: It has been proposed that sleep's contribution to memory consolidation is to reactivate prior encoded information. To elucidate the neural mechanisms carrying reactivation-related mnemonic information, we investigated whether content-specific memory signatures associated with memory reactivation during wakefulness reoccur during subsequent sleep. We show that theta oscillations orchestrate the reactivation of memories, irrespective of the physiological state. Reactivation patterns during sleep autonomously re-emerged at a rate of ~1 Hz, indicating a coordination by slow oscillatory activity

Title: Value inference across cognitive maps

Authors: *M. M. GARVERT[1], N. SCHUCK[2], C. F. DOELLER[3]
[1]Max Planck Inst. For Human Cognitive and Brain, Leipzig, Germany; [2]Max Planck Inst. For Human Develop., Berlin, Germany; [3]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: It has been suggested that the brain organises knowledge about the relationships between positions in space and non-spatial information in a cognitive map. Such a representation of events and knowledge may facilitate goal-directed behaviour by enabling the generalisation of value across related states. Here, we combine a novel virtual reality task with computational modeling to investigate whether humans generalise across related states to infer reward values that were never directly experienced. In this task, spatial relationships between stimuli learned on day 1 predict reward relationships in a decision making task on day 2. We find that participants not only update the stimulus-reward associations they experience directly, but also use their knowledge about the relationships between stimuli to predict outcomes of cues whose values were not experienced. Relational knowledge organised in cognitive maps can thus be used to extrapolate across related states and thereby facilitate novel inference. By including stimuli in the decision making task whose spatial locations are unknown, we further demonstrate that novel stimuli can be integrated into existing cognitive maps if their statistical structure is consistent with previously experienced regularities. Furthermore, the prediction errors subjects experience when they first learn about a stimulus position predict how much participants like stimuli at the end of the experiment, suggesting a close relationship between spatial learning and stimulus valuation. Using fMRI, we investigate the neural dynamics underlying the spread of values across cognitive maps in hippocampal-medial prefrontal networks. Together, our novel approach opens up the possibility to connect seemingly disparate fields of spatial coding, learning and decision behaviour.

Title: Temporal dynamics of event integration

Authors: *L. S. SCHURMANN[1], J.-M. SCHOFFELEN[1], S. H. COLLIN[2], B. MILIVOJEVIC[1], C. F. DOELLER[3]
[1]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Princeton Neurosci. Inst., Princeton, NJ; [3]Kavli Inst., NTNU, Trondheim, Norway

Abstract: Memory integration is a crucial building block of autobiographical memory. It enables us to weave individual events of our daily lives into coherent memory networks. Furthermore, it allows us to dynamically and flexibly reorganize these mnemonic networks when new information becomes available. Results from our previous fMRI study (Milivojevic et al., 2015) provided evidence for a central role of the hippocampal-prefrontal circuit in memory integration using life-like stimuli. However, while both areas are known to be involved, the contribution of individual regions and the related temporal dynamics remain unclear. In this study, we extended the life-simulating memory paradigm used in our previous studies (Milivojevic et al., 2015; Collin et al., 2015) in order to shed light on the temporal dynamics of hippocampal and prefrontal processing underlying memory integration. In a life-like narrative-insight task, we presented three seemingly unrelated events per narrative, which participants saw several times in a counterbalanced order during a pre-insight phase and a post-insight phase. Between these phases we showed a fourth event in isolation, which provided insight into which of the previously seen events belong together in a narrative and which event does not. This allowed us to track insight-triggered reconfiguration of these event networks. We extended the paradigm to include a behavioral relatedness judgment task, in which participants rated how related events were, both before and after the insight phase, for each of the 13 narratives they saw. This enables us to track the brain-behaviour relationship for each of the narratives in a within-subject design. Additionally, in order to examine hierarchical embedding of event networks into broader, across-narrative networks, we included a task designed to assess the relationship between the individual narratives. This task will give us novel insights into both behavioral and neural correlates of across-narrative integration, and extend our previous work on hierarchical memory networks (Collin et al., 2015). In addition, we optimized the paradigm to examine the temporal aspects of memory integration using MEG (data acquisition ongoing). A possible mechanism that might underlie memory integration is prefrontal-hippocampal theta coupling (Backus et al., 2016). Using representational similarity analysis, we will examine how memory integration varies on different temporal scales within and across trials. This study offers the opportunity to improve our understanding of how the human brain is able to apply prior knowledge to inform our behavior in new situations.

Title: Functional parcellation of the rodent and human hippocampus at 7T

Authors: *A. G. DAHL, S. A. HUBER, T. NAVARRO SCHRÖDER, C. F. DOELLER
Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The hippocampus is a region pivotally involved in spatial navigation and memory formation. While most of the tools available for functional magnetic resonance imaging (fMRI) analysis have been developed for human data, much of what we know about the underlying mechanisms for spatial navigation comes from rodent research. To facilitate translation between rodent and human research we take advantage of a novel, data-driven method from human fMRI analysis to estimate individual functional connectivity maps for each voxel within the rodent hippocampus. Computing the similarity between these 'fingerprints' results in a hippocampal map of functional connectivity similarity, which is then subjected to a manifold learning algorithm, yielding topographies of functional connectivity change across hippocampal voxels. Finally, by applying a clustering algorithm we identify functional subunits within the hippocampal formation based on their similarity in connectivity to the rest of the brain. We then compare the results with those obtained from applying the same method to a human 7T fMRI dataset, allowing us to investigate translational features between the functional connectivity of the rodent and human hippocampus.

Title: Evidence for a discretized organization of the hippocampal long-axis in humans

Authors: *S. A. HUBER[1,2], T. NAVARRO SCHRÖDER[1], A. KOBRO-FLATMOEN[1], J. SCHWARZBACH[2], M. P. WITTER[1], C. F. DOELLER[1]

Abstract: The hippocampus is a medial temporal lobe structure that is critically involved in numerous brain functions including memory formation, spatial navigation and emotional processing. Its involvement in this multiplicity of cognitive functions raises the question to what extent this diversity is reflected in the functional anatomy of the hippocampus. Previous studies point towards two opposing hypotheses, namely a smooth functional gradient versus discrete step-like transitions along the longitudinal axis of the hippocampus.
Here, we present evidence for a discretized organization of the hippocampal long-axis. Our findings are based upon a recently developed analysis algorithm applied to a high-resolution 7 Tesla functional magnetic resonance imaging (fMRI) dataset, incorporating 22 healthy adults. The algorithm consists of the following steps: First, the individual functional connectivity profiles of all hippocampal voxels to the rest of the brain are computed. Then, we estimate correlation coefficients between all pairs of voxel-wise connectivity 'fingerprints', yielding a functional connectivity similarity map of the hippocampus. This map is fed to a manifold learning algorithm to determine the topography of functional connectivity change within the hippocampus. Our results indicate that the dominant mode of functional connectivity change follows the hippocampal long-axis in a step-like, discretized manner. Finally, we used *k*-means clustering to parcellate the dominant mode of functional connectivity change into separate clusters.
Together with previous insights from gene expression studies, our findings support the hypothesis of a discretized organization of the hippocampal long-axis in humans.

Title: Memory interaction and integration in young and aged adults

Authors: *K. E. TOBIN[1], T. T. TRAN[2], A. R. PRESTON[3], A. BAKKER[1]
[1]Psychiatry and Behavioral Sci., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [3]Ctr. for Learning and Memory, The Univ. of Texas At Austin, Austin, TX

Abstract: Episodic memory formation is a dynamic process, where existing memories can be combined and updated with new and relevant experiences. The integration of prior experiences and new information allows us to create novel associations that support new inferences. This memory integration process requires both stable and reliable episodic memory representations as well as the flexibility to manipulate, combine, and incorporate new information.
Memory integration has been primarily examined in young adults but may play a significant role in age-related memory changes as well. Previous studies suggest that in older adults, episodic memories may be less stable and more prone to interference or be more rigid and less accessible for memory integration. The current study assessed memory integration and inferential reasoning in young adults and cognitively normal older adults using an associative inference paradigm. Our findings show that episodic memories remain stable in older adults but are inflexible with older adults showing difficulty integrating new information and generating new inferences when compared to young adults.

Title: Memory for Object identity and object positions in novel environmental scenes

Authors: *T. T. TRAN[1], K. E. TOBIN[2], V. PULIYADI[1], M. GALLAGHER[1], A. BAKKER[2]
[1]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Psychiatry and Behavioral Sci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Subregions of the medial temporal lobe are differentially affected in healthy aging and Alzheimer's disease. Notably, the lateral entorhinal cortex appears particularly vulnerable in both normal and pathological aging. The lateral entorhinal cortex is one of the first sites of tau neurofibrillary tangle accumulation, a biomarker of Alzheimer's disease. However, even in cognitively normal older adults, the lateral entorhinal cortex shows considerable neurofibrillary deposits compared to young adults, suggesting that even in healthy aging, lateral entorhinal cortex functioning may be affected.
Although previous behavioral and neuroimaging studies in humans have examined the role of lateral entorhinal cortex in object identity memory, there is limited work on object position memory. Single-cell recordings in rodents have implicated lateral entorhinal cortex in object position memory as well as tracking a change in the position of an object in an environment. The current study examined behavioral differences between young and older adults in recalling object identity or object position within a computerized novel spatial environment. Results show that age-related changes in the function of lateral entorhinal cortex are exhibited through both decreased object identity and object position memory in older adults compared to younger adults. These results suggest that even in healthy aging these aspects of memory that depend on the lateral entorhinal cortex can be observed.

Title: Medial temporal-medial prefrontal theta phase synchrony binds human associative memory

Authors: *H. ZHANG, J. ZHENG, J. LIN
Biomed. Engin., Univ. of California Irvine, Irvine, CA

Abstract: The hippocampus is critical for binding of distinct elements to form episodic memory. It has shown that theta rhythms in the hippocampus orchestrate the temporal coding of events but how hippocampal theta rhythm interact with other cortical and subcortical region such as the medial prefrontal cortex and amygdala to promote correct and incorrect associative memory is unknown. To investigate the amygdala-hippocampal-medial frontal prefrontal circuit dynamics during memory association, we recorded local field potential (LFP) simultaneously from the amygdala-hippocampus-orbitofrontal network in patients undergoing pre-surgical seizure localization. Patients performed a memory association task, in which they passively viewed pairs of images during the encoding phase, followed by the retrieval phase where the subjects were asked to discriminate whether the given pair is a correct association shown during the encoding phase.

We found that the hippocampal theta power significantly increased for success encoding compared to unsuccessful encoding (1s after stimulus onset, t-test $p<0.05$). To assess the connectivity in the amygdala-hippocampal-medial prefrontal circuit, we calculated the phase-locking value (PLV) and found distinct connectivity matrix for success encoding and unsuccessful encoding. Specifically, the medial temporal-medial prefrontal PLV in the theta band showed increased connectivity during correct encoding compared to incorrect encoding. In contrast, the connectivity between amygdala and hippocampus showed increased connectivity for incorrect versus correct associations. These findings demonstrate that although hippocampal theta synchrony is critical for associative memory, distinct cortical-subcortical circuit synchrony promotes correct and incorrect associations.

Title: Effect of repeated immediate reactivation on memory performance

Authors: *M. E. MONTCHAL, M. YASSA
UC Irvine, Irvine, CA

Abstract: Decades of memory research have underscored the importance of the hippocampus and medial temporal lobe cortex for memory retrieval. However, it remains unclear how memories and the brain networks supporting them change with time and experience. Converging evidence suggests that memories can shift from being dependent on the hippocampus to the cortex (Squire, 1992; Frankland and Bontempi, 2005). However, it is unknown how repeated retrieval events and the passage of time may interact to affect memory accuracy, especially of event details. Recent work has provided evidence that memory reactivation during sleep (Oyarzun, Moris, Luque, et al., 2017; Shimizu, Connolly, Cellini, et al., 2018) and during wakefulness (Tambini, Berners-Lee, and Davachi, 2017) can improve memory performance. Based on evidence-based models of memory, it is possible that memory reactivation can impair memory performance in certain circumstances. The Competitive Trace Theory (CTT) framework (Yassa and Reagh, 2013) holds that each reactivation of a memory causes it to become less episodic and more semantic. Taken to the extreme, this would mean that repeated reactivation immediately after a memory is formed would cause it to lose episodic detail and become more semantic. The current study aimed to test the influence of immediate repeated reactivation on memory for episodic details. Participants watched a video clip and were randomly assigned to either the reactivation group or the control group. The reactivation group viewed still frames from the video every 10 minutes and was instructed to imagine the scenes depicted. The control group viewed still frames from a video they had not seen. The extent of spontaneous reactivation was also measured using a questionnaire. We report accuracy for detailed and more generalized questions for both groups, elucidating the effects of repeated immediate reactivation on memory retrieval.

Title: Hippocampal cingulum white matter integrity contributes to spatial discrimination in older adults

Authors: *F. MARQUEZ[1], J. A. NOCHE[3], M. S. LARSON[3], D. DELISLE[3], E. MURRAY[3], L. MCMILLAN[3], M. WITBRACHT[2], S. SIRIVONG[2], J. GRILL[2], M. A. YASSA[3]

Abstract: Studies suggest that two neocortical systems interact with subcortical areas (including the hippocampus) to support memory for objects and memory for spatial navigation. The hippocampus is connected to other brain regions via two major limbic tracts: the fornix and the cingulum bundle, which includes the hippocampal cingulum and superior cingulum. In healthy adults (51.8 ± 18.9 years; MMSE: 29.02; RAVLT Delay: 11.52), significant relationships between chronological age and integrity of the hippocampal cingulum and fornix tracts have been described previously, and behavioral assays have shown a relationship between object discrimination and fornix integrity. While asymptomatic older adults have major deficits on object discrimination, they only show subtle deficits on the comparable spatial discrimination task when compared to young adults. If spatial discrimination is supported by hippocampal connections to a broader neocortical network, then deficits in spatial discrimination may be mediated by the integrity of limbic tracts. In this study, older adults (74.6 ± 7.5 years; MMSE: 27.94 ± 1.39 RAVLT Delay: 9.94 ± 4.46) underwent diffusion tensor imaging (2.2 mm nominal isotropic resolution) and completed the object and spatial mnemonic discrimination tasks. Behaviorally, we found a positive correlation between performance on RAVLT Delay and spatial discrimination (r^2=0.271, p=0.0054), but no relationship between performance on RAVLT Delay and object discrimination (r^2=0.002, p=0.80). Targeted tractography analyses revealed that hippocampal cingulum integrity (fractional anisotropy, mean diffusivity, and restricted diffusion) was significantly related to mnemonic discrimination for spatial memory, but not for object memory. These findings support the idea that deficits in spatial memory manifest due to hippocampal disconnection to neocortical systems via the hippocampal

cingulum. The results additionally suggest that the integrity of the hippocampal cingulum may be a biomarker that is associated with cognitive changes particularly related to spatial memory.

Title: Structural integrity deficits of uncinate fasciculus predict medial temporal lobe activity during an emotional pattern separation task

Authors: *S. J. GRANGER[1], S. L. LEAL[2], E. A. MURRAY[3], M. A. YASSA[3]
[1]Neurobio. and Behavior, Univ. of California, Irvine, Coto De Caza, CA; [2]Univ. of California, Berkeley, Berkeley, CA; [3]Univ. of California Irvine, Irvine, CA

Abstract: The medial temporal lobe (MTL) is well known for its role in contributing to the formation of lasting memories. Specifically, the dentate gyrus (DG) and CA3 subfields of the hippocampus are thought to contribute to a neural computation known as Pattern Separation which the brain uses to distinguish between highly similar items (known as “lures”) during recall. One version of the paradigm designed to tax the pattern separation process is known as the Emotional Pattern Separation task and has been employed to study the effects of emotional discrimination. Although the MTL’s functional activity has begun to be categorized during these Pattern Separation tasks, the role of the prefrontal cortex (generally thought to exert top-down influence over cognitive processes) in regulating pattern separation processes is still relatively unclear. The prefrontal cortex is structurally connected to the anterior MTL through a dense white matter bundle known as the uncinate fasciculus (UF). Deficits of the UF have been implicated in those exhibiting depressive symptoms and larger structural integrity measurements have been shown to positively correlate with memory performance in tasks involving highly similar items. It is possible that the UF is highly involved in top-down influence in both emotional and non-emotional memory discrimination affecting MTL subfield activity. Thus, we hypothesize that deficits in UF integrity might predict aberrant DG/CA3 activity during emotional lure discrimination performance and poorer measures of lure discrimination. Using high resolution fMRI and “model-free” tractography methods from diffusion weighted imaging

we found that structural integrity deficits of the left UF are associated with increased activity of DG/CA3 in the left hemisphere only during the correct rejections of emotional and not neutral items. Further, increased DG/CA3 activity during correct discrimination of negative lure items was associated with poorer negative lure discrimination. Finally, using a causal mediation analysis, we provide evidence for a marginal effect of DG/CA3 activity mediating the relationship between UF integrity and lure discrimination for negative items. Past studies have suggested that hippocampal hyperexcitability may be an aberrant condition that predicts mild cognitive impairment and poor memory performance, here we suggest that hyperactivity of DG/CA3 mediates the relationship between deficits in structural top-down inhibitory control and poorer lure discrimination. A larger sample size will allow us to further investigate this intricately interconnected system between brain structure, function and memory performance.

Title: Gamma power in the human medial temporal lobe and prefrontal cortex predicts error and learning in a spatial memory task

Authors: *R. F. STEVENSON[1], J. T. JANECEK[2], J. ZHENG[3], L. MNATSAKANYAN[4], S. VADERA[5], R. T. KNIGHT[6], J. J. LIN[4], M. A. YASSA[2]
[2]Neurobio. and Behavior, [3]Biomed. Engin., [4]Neurol., [5]Neurolog. Surgery, [1]Univ. of California, Irvine, Irvine, CA; [6]Univ. of California Berkeley, Berkeley, CA

Abstract: The ability to learn novel associations is thought to depend on local processing within the medial temporal lobe (MTL) and prefrontal cortex (PFC) as well as functional interactions between these two regions. However, the ways in which the MTL and PFC contribute to associative learning in humans as well as the dynamics of MTL-PFC interactions remain poorly understood. We tested pre-surgical epilepsy patients with depth electrodes implanted in both the MTL and PFC using a spatial memory task in which subjects attempted to learn object-location associations over the course of three training blocks. During encoding, patients were shown objects at random locations along the circumference of an invisible circle. For each training

block, the same objects were shown at the top of the circle and patients used a dial to rotate the object to where it appeared during encoding. After patients finished placing each object, the object was shown in the correct location for one second as feedback. Following the three training blocks there was a final test during which no feedback was given. Angular error between the correct location and the indicated location was recorded as a continuous measure of performance. At retrieval, we found greater gamma (40-100 Hz) power in the MTL and PFC for more precise trials (less error). The opposite pattern of activity was observed at feedback, with greater MTL and PFC gamma power for less precise trials (more error). Increased MTL and PFC activity at feedback also predicted greater decreases in error from one training block to the next, indicating that these error signals are involved in updating memory representations or modifying incorrect associations during learning. Together, these results suggest possible mechanisms for the learning of object-location associations.

Title: Interference resolution in memory: Beyond the medial temporal lobe

Authors: *C. CHWIESKO, M. A. YASSA
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: The Object Mnemonic Discrimination Task (MDT-O) is a task designed to test pattern separation (the ability to minimize interference across similar stimuli in memory). Overcoming mnemonic interference in this task has been associated with the integrity of hippocampal Dentate Gyrus and CA3, which are hypothesized to be particularly critical in supporting pattern separation. In line with this hypothesis, the decline in performance observed in older subjects in the MDT-O has been linked to aging-related structural and functional changes in these areas.
However, aging is also known to affect the function of the Prefrontal Cortex (PFC). In addition, the PFC, in particular the Anterior Cingulate Cortex and the Dorsolateral Prefrontal Cortex, have been shown to play a critical role in interference resolution. This raises the question whether the

PFC could also contribute to the ability to overcome interference in the MDT-O.
The present study investigated this question by assessing the performance of young (n=21, mean age: 21.3 years) and old (n=34, mean age 74.2 years) subjects in the MDT-O and in the STROOP task (sensitive to PFC function in the context of interference resolution). More precisely, the STROOP task measures one's ability to inhibit cognitive interference. As previously reported, older subjects showed a significantly worse performance in mnemonic discrimination and in the STROOP task. More interestingly, the ability to mnemonically discriminate between similar stimuli in the MDT-O and the PFC related ability to inhibit cognitive interference in the STROOP task was significantly correlated. The observed correlation seems to be specifically related to inhibitory control processes of the PFC, as other measures of executive function did not correlate with mnemonic discrimination. Overall, these findings indicate that overcoming mnemonic interference in the MDT-O may not solely rely on pattern separation in the Hippocampus, but also potentially on interference resolution through inhibitory control mechanisms in the PFC.

Abstract: Age-related neurobiological changes are observed in the hippocampus in experimental model systems as well as in elderly humans. Although regular exercise is thought to counteract these age-related changes in hippocampal structure and function, there is very little work examining the impact of low-intensity exercise on hippocampal memory. This is an important avenue, as low-intensity or mild exercise is practically applicable to elderly with low fitness levels. Recently, there has been increasing evidence indicating that mild exercise in rodents activates hippocampal neuron and enhances adult neurogenesis especially in the dentate gyrus (DG), which plays a key role in hippocampal memory formation. However, the impact of a short term mild exercise intervention on human DG structure and function has not been previously evaluated. A total of 49 healthy old adults (mean age 66 ± 5.6; 6 males) took part in the baseline assessment of this study. We examined associations among age, aerobic fitness, and hippocampal subfield volumes (left and right DG/CA3, CA1, and subiculum). To assess individual maximal aerobic fitness (VO_{2peak}), participants performed a graded exercise test with a recumbent ergometer. From this sample, seventeen older adults participated in the intervention, which was implemented by a fitness trainer and met three times per week for 6 weeks. A high-resolution structural MRI scan using a T1-weighted 1mm isotropic MPRAGE sequence was collected before and after the exercise program for hippocampal subfield segmentation. Examining the baseline data, we found that both DG/CA3 volume and aerobic fitness level were negatively associated with age, as one might expect. However, DG/CA3 volume was positively correlated with baseline aerobic fitness level. We have previously shown that aerobic fitness is associated with DG-mediated pattern separation performance (Suwabe et al., 2017). Further, we found that mild exercise training was associated with increased volume of the left DG/CA3. To our knowledge, this is the first empirical evidence that even short term mild exercise can potentially increase DG/CA3 volume. Future work will examine how long lasting these effects may be and correlate volume increases to memory enhancement.

Abstract: Individuals with Down syndrome (DS) are at increased risk for developing Alzheimer's disease (AD) and have earlier symptom onset at an average age of 55, compared to age 80 in the general population, indicating that they may represent a model of early susceptibility for AD. The additional copy of chromosome 21 contributes to increased levels of amyloid precursor protein and subsequent accumulation of Aβ peptides beginning at age 40. Previous studies in individuals without DS have shown that both Aβ positive cognitively normal older adults and Aβ positive older adults with mild cognitive impairment (MCI) have altered functional connectivity in the medial temporal lobe (MTL) and the hubs of the default mode network (DMN), but few studies have investigated functional connectivity in individuals with DS over the age of 40. We hypothesize that the functional connectivity profile of older individuals with DS will look similar to that of Aβ positive cognitively normal older adults and Aβ positive MCI individuals. In the present study, we examine reduced connectivity within the MTL and the DMN, as well as reduced connectivity between the MTL and the DMN.

Title: Neurite architecture of the planum temporale predicts neurophysiological processing of auditory speech

Authors: *P. FRIEDRICH[1], S. OCKLENBURG[1], C. FRAENZ[1], C. T. SCHLÜTER[1], C. BESTE[2], O. GUNTURKUN[1], E. GENC[1]
[1]Dept. of Biopsychology, Ruhr-University, Bochum, Germany; [2]Universitätsklinikum Carl Gustav Carus, Dresden, Germany

Abstract: The left-hemispheric advantage in speech perception is reflected in faster neurophysiological processing. Based on post-mortem data, it has been suggested that asymmetries in the organization of the intrinsic micro-circuitry of the posterior temporal lobe

may produce this leftward timing advantage. However, whether this hypothetical structure-function relationship exists in living human subjects has never been empirically validated.
To test this assumption, we used a diffusion MRI-based method called "neurite orientation dispersion and density imaging" (NODDI) to quantify micro-circuitry in terms of axon and dendrite complexity of the left and right planum temporale in 98 right-handed individuals. Furthermore, the cortical processing times of auditorily presented consonant-vowel syllables and white noise control stimuli were assessed via latencies of N1 event-related potentials in the EEG. We found that a higher density of dendrites and axons in the left planum temporale is associated with faster neurophysiological processing in the left hemisphere ($r = -.25$, $p < .05$), indicated by shorter N1 latencies. In contrast, N1 latencies after presentation of white noise were not associated with the planum temporale neurite architecture ($r = .01$, $p = .99$), indicating that the structure-function relationship is specific for speech-related stimuli.
Our results thus imply that a higher density and number of synaptic contacts in the left posterior temporal lobe increases temporal precision and decreases neurophysiological processing time during speech perception.

Abstract: Introduction There is growing interest in understanding how abstract concepts are represented in our brains. While some authors support the idea that all concepts are stored in a single hub in the anterior temporal lobe (ATL), others propose distinct regions specialized for different types of abstract concepts. A role of social and magnitude dimensions in the representation of specific classes of abstract concepts has been reported (Troche et al., 2014). While social concepts have been associated to the superior ATL, the right intraparietal sulcus (rIPS) has been linked to numerical magnitude and to arithmetic concepts. We investigated the causal role of the right sATL and rIPS in representing social and magnitude concepts, using a

state-dependent transcranial magnetic stimulation (TMS)-priming paradigm in healthy subjects. Materials & Methods Eighteen subjects took part in the study. Fifty-six nouns, 28 social and 28 magnitude words matched for letter and syllable number, frequency, familiarity, imageability, valence, and mean priming effect (all p>.59), obtained from a pilot study, were employed. Priming to a category name (either "SOCIAL" or "QUANTITY") was used with the objective of modulating the initial activation state of each region prior to application of TMS and the presentation of the target stimulus. The experiment involves 56 congruent (SOCIAL-social target, QUANTITY-magnitude target) and 56 incongruent (SOCIAL-magnitude target, QUANTITY-social target) stimuli pairs, repeated for each site, namely the right sATL, the rIPS and the sham-control site (Vertex). Subjects were asked to indicate whether the target belonged to the quantity or social category. Results To investigate whether TMS interfered with the priming effect, the difference between congruent and incongruent trials found in the Vertex stimulation site was compared with that of the other two TMS conditions for each category separately. Pairwise comparisons revealed a abolition of the priming effect in rATL only for social words (p= .013), whereas in the rIPS the TMS effect was significant for both types of words (p <.05). Discussion Our results suggest that distinct brain regions are specialised for the processing of different types of abstract concepts. The rIPS is involved in magnitude concepts processing, in line with its role in the abstract numerical magnitude representation. Social concepts are represented in both right sATL and rIPS, in agreement with their respective role in social cognition and person-related knowledge (Mitchell & al., 2002).

Title: Visual word recognition across the adult life span: A MEG study

Authors: M. KARADAG[1], C. WHITING[2], J. KLIMOVA[1], A. CLARKE[1], *L. K. TYLER[1], W. MARSLEN-WILSON[1]
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Although some cognitive processes decline with age, spoken language comprehension remains unimpaired. Little is known, however, about how reading skills change over the adult lifespan, and no research has been conducted using spatiotemporally resolved imaging methods. A recent MEG study using the CamCAN cohort (a population-representative sample, age-range 18-88), found significant slowing with age in early visual responses to simple visual forms. Reading, however, involves a complex series of low- to high-level analysis processes, distributed over the brain, where an early stage of orthographic processing of letter strings is followed by morphemic analysis and by lexical access to specific word meanings. Previous MEG studies with young adults characterise a set of regions in occipital, temporal and frontal cortex where these processes are localised (Whiting et al., 2014). The current study, using CamCAN cohort MEG data, investigates the relative timing and the location of these processes in the aging brain, testing three groups of participants (Young (n=25, ages: 22-38), Middle (n=25, ages: 46-60) and Older (n=25, ages: 70-88).
Participants read silently 380 visual stimuli: simple words (e.g., *biscuit*), consonant strings (e.g., *hywc*), and morphologically complex words (*jumped, darkness*). MEG data were pre-processed and source localised using each subject's structural MRI scans. We first computed early visual evoked responses for each age-group in the early visual regions. Parallel responses for each age group were seen bilaterally in the occipital pole, with slight slowing for the older participants (~10 ms). We then tested for differences between words and consonant strings to detect the onset of orthographic processing across age groups. The Young group showed orthographic effects from 150 ms in bilateral posterior regions, similar in onset and location to the earlier Whiting et al result. The Older group showed major slowing (65 ms) in the onset of orthographic processing with only right hemisphere effects. Focusing on the temporal lobe ROIs where Whiting et al (2014) saw lexical effects, we computed lexical processing effects for each group using Representational Similarity Analysis. Consistent with the previous study, the Young group showed lexical effects in the posterior superior temporal gyrus from 370 ms, the Middle group showed similar but weaker effects, but the Older group showed no consistent effects at any temporal ROIs. Although CamCAN behavioural data shows similar reading proficiency across the adult lifespan, these spatiotemporally resolved data suggest significant age-related divergences in the neural systems involved.

Title: Brain connectivity was modulated by sentence difficulty as revealed by fMRI-ICA in Chinese relative clause

Authors: *K. XU[1], Y.-Y. HUANG[2], J.-R. DUANN[1]
[1]Inst. of Cognitive Neurosci., Natl. Central Univ., Taoyuan, Taiwan; [2]Natl. Central Univ., Taiyuan, Taiwan

Abstract: Introduction: Relative clause is one type of sentence with embedded structure among languages. Previous studies have revealed that the essential roles of the left superior temporal and frontal gyri (LSTG and LIFG), which might subserve reordering and storage of linguistic components, in processing relative clause in Indo-European languages. However, it is unclear whether or how these brain regions are functionally connected in a typologically different language, like Chinese. On the other hand, there is the preference between two main types of relative clause, that is, subject relative clause (SRC) and object relative clause (ORC). The preference for SRC over ORC has been clearly established in English and other head-initial languages, but whether the same preference is observed in Chinese is still on a heated debate. Furthermore, there are few studies elucidating the neural mechanism underlying such preference. **Hypothesis:** LIFG and LSTG was involved in processing Chinese Relative clause, similar with English studies. As the difficulty of Chinese relative clause changed, the effective connectivity between LIFG, especially subareas of LIFG, and LSTG would be different. **Method:** In the present mixed-trial fMRI study, the MRI image was acquired using a 3T scanner with a 64-channel whole-head coil. Then, the functional MRI data was processed using independent component analysis (ICA) method. Afterwards, task-related time series of different functional brain areas were further examined using GCA based on a multivariate autoregressive model. **Results:** LIFG and LSTG exhibited higher activation in processing more difficult Chinese subject relative clause (SRC) compared to Chinese object relative clause (ORC). Moreover, the similar neural networks but with different effective connectivity between brain areas were identified in reading SRC and ORC. Specifically, when comprehending more difficult Chinese SRC, the effective connectivity from BA44/45 to BA47 then extent to LSTG was found to be significant, while reading the simple ORC, only the connectivity from LSTG to BA 47 without the involvement of BA 44/45 was shown to be evident. **Discussion:** The present study offered hemodynamic evidence for Chinese ORC preference, particularly in the processing mechanisms that are supported by LIFG and LSTG, which was consistent with previous findings in English. Moreover, the result not only confirmed the specific roles of LIFG and LSTG involved in processing relative clause, which subserved reordering and storage, but also demonstrated how the brain connectivity was modulated by sentence difficulty.

Title: Functional dissociation of language and working memory revealed by pattern analysis of subject-specific conjunction maps

Authors: *T. L. SCOTT[1], T. K. PERRACHIONE[2]
[1]Grad. Program for Neurosci., [2]Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: Separable brain networks with opposing functional specificity are thought to support language and working memory (WM) (Fedorenko et al. 2010; 2012). A consistent exception to this functional dissociation has been observed in neuroimaging of verbal working memory (VWM) tasks, which appear to recruit regions belonging to both networks. Here, we compare and contrast activation in the brains of individual subjects evoked during functional magnetic resonance imaging (fMRI) of language, VWM, and spatial working memory (SWM) tasks. We use novel analysis techniques designed to assess overlap and pattern similarity between tasks without requiring strict correspondence of voxel-based anatomical alignment between subjects. WM tasks contrasted maintenance of long vs. short sequences of auditorily presented digits (VWM) or visual spatial locations (SWM) to identify voxels responsive to WM load in individual subjects. The language task contrasted listening to clips of speech vs. unintelligible degraded speech (Scott et al. 2017). We identified eight brain areas where significant activity overlaps between language and VWM in a majority (> 80%) of participants. Patterns of activity evoked by the two tasks were only weakly correlated (median $r = 0.12$) in these regions. Only three brain regions were identified as showing overlap between language and SWM, but there was virtually no correlation in the patterns of task-evoked activation in these regions (median $r = -0.05$). Overlapping activity between VWM and SWM was found in 16 regions, with highly correlated patterns of activity across these tasks in each region (median $r = 0.44$). Two regions, left posterior middle frontal gyrus / precentral gyrus and left planum temporale were found to have significant overlap in all three comparisons. Ultimately, although several areas show classical conjunction between language and VWM task activation, our fine-grained analyses reveal that the patterns of activity in these conjoint regions are in fact relatively dissimilar. Conversely, pattern analysis of the conjunctions between verbal and spatial WM reveal highly convergent activation patterns. These results suggest a degree of functional segregation between language and WM computations, even in commonly-activated brain areas.

Title: Behavior, sex, and the brain: Relationships with dyslexia risk gene DYX1C1

Authors: *A. J. KRAFNICK
Psychology, Dominican Univ., River Forest, IL

Abstract: Twin studies have shown genetics to contribute between 30% and 70% of the chance of developing dyslexia (Scerri & Schulte-Körne, 2010). Specific genes linked with increased risk of dyslexia diagnosis include genes involved in neuronal migration during development (Galaburda et al., 2006). One specific gene, *DYX1C1*, has been shown to interact with estrogen receptors (Tammimies et al., 2012), and could help explain findings of sex differences in the brain profile of dyslexia (e.g. Evans et al., 2014). Here, using data from the Pediatric, Imaging, Neurocognition, and Genetics (PING) study, effects of genotype and sex on reading and brain phenotypes were investigated in group of typically developing children and young adults. 1199 subjects from PING (average age 12 years, range 3-21 years; 581 F) with imaging and genetic data were included in this study. Average cortical thickness and total surface area (generated by PING using Freesurfer; Fischl, 2012) of five left hemisphere posterior regions involved in reading (superior temporal sulcus, superior temporal gyrus, inferior parietal lobule, supramarginal gyrus, and fusiform gyrus) were investigated for sex and genotype effects from two *DYX1C1* SNPs (rs685935 and rs3742404). Sex and genotype effects of reading and vocabulary behavioral measures were also investigated.Reading and vocabulary scores showed significant effects of genotype for both SNPs (all p<0.05), and vocabulary scores showed a significant effect of sex in both models (p<0.05; higher scores in males). No genotype x sex interactions were observed. For average cortical thickness, no effects of genotype or genotype x sex interactions were found, but supramarginal gyrus showed a sex effect in both models (both p<0.05; thicker cortex in females). For surface area (controlling for total LH surface area), rs3742404 showed significant effects of genotype in superior temporal sulcus, inferior parietal lobule, and superior temporal gyrus (all p<0.05; AA > AC and CC). For surface area and rs685935, main effects of sex were observed for fusiform gyrus and supramarginal gyrus (both p<0.05; larger surface area in males) and a genotype x sex interaction was observed in superior temporal sulcus (p<0.05; virtually no difference amongst females, but larger surface area for GG compared to GA and AA in males). No genotype effects were observed for

rs685935 on surface area.These results provide evidence for sex and genotype effects for dyslexia risk gene *DYX1C1* related to reading ability. Differences in genotype effect by sex may help explain the different anatomical profiles of dyslexia observed at the volumetric level (e.g. Evans et al, 2014).

Title: Intrinsic connectivity within individuals reveals a distributed left-lateralized network that is language-responsive

Authors: *R. M. BRAGA[1,2], L. M. DINICOLA[1], K. R. VAN DIJK[3], J. R. POLIMENI[4], R. L. BUCKNER[1,3]
[1]Harvard Univ., Cambridge, MA; [2]Imperial Col. London, London, United Kingdom; [3]Massachusetts Gen. Hosp., Charlestown, MA; [4]Martinos Ctr. Biomed Imaging, MGH/Harvard Med. Sch., Charlestown, MA

Abstract: Group-averaged network estimation based on intrinsic functional connectivity (FC) often fails to delineate a left-lateralized network that is a clear candidate for supporting language function (but see Hacker et al., 2013 for an interesting exception). This has remained a puzzle because of the noted specialization for language. FC analysis of repeatedly scanned individuals has recently revealed that distinct, closely juxtaposed and interdigitated networks can be observed within canonical group-defined networks such as the default network (DN) and frontoparietal control network (FPN; Braga & Buckner, 2017). These networks were called DN-A, DN-B, FPN-A and FPN-B for convenience. A possibility is that blurring across individuals may obscure detection of a distinct, language-specialized network. Here, we explored the functional anatomy of individuals to determine whether a distinct candidate language network exists. Extensive resting-state data (>56 mins acquired at 3T, 2.4mm, 1.00s TR) were collected from each of 10 individuals, along with 40 mins of a language localizer task (Fedorenko et al., 2010). Data were registered to a subject-specific target and resampled to 1mm isotropic

resolution and smoothed at 2mm FWHM (yielding over 1.3TB of data per subject). Individual surface vertices were selected from the prefrontal cortex and used as seeds for the FC analysis. The resulting FC patterns identified distinct distributed networks. A putative language network within individuals was found consistently that is distinct from (but closely neighboring) other distributed association networks, particularly DN-B, FPN-A and FPN-B. This language network follows the broad distributed motif of other association networks (prefrontal, temporal, midcingulate and dorsomedial prefrontal cortices) but notably is absent a prominent posteromedial component. Fine-grained anatomical details of the distinct networks were explored in 3 subjects at high spatial resolution (24 mins acquired at 7T, 1.35mm, 1.49s TR). The language network could be identified in the volume with distributed components localized to the cortical ribbon that were distinguishable from adjacent networks on closely juxtaposed portions of the cortex. Finally, this distributed network overlaps with regions showing increased activation during a language localizer task, and its functional specificity forms part of ongoing investigation. Our results identify a clear candidate for a left-lateralized language network that is missed when data are averaged across subjects.

Title: Effects of the specific rehabilitation of defecit and pragmatic typo in patients with aphasia

Authors: *J. C. GALICIA, SR[1], M. A. MACÍAS[2], T. J. VILLASEÑOR[2], M. E. JIMÉNEZ[2], E. R. VILLUENDAS[3]
[2]Neurociencias, [1]Univ. de Guadalajara, Guadalajara, Mexico; [3]Facultad de Psicología Posgrado, Univ. Michoacána de San Nicolás de Hidalgo, Morelia, Mexico

Abstract: Introduction. Two approaches in rehabilitation of aphasia favorable results: the traditional or specific treatment of the deficit TED (which addresses the recovery of a particular linguistic function) and pragmatic or functional therapy TPF (aimed at improving communication skills). **Objective.** To compare the effects of TED and TPF in patients with aphasia and their language skills and communication. **Method.** 12 adults patients (66.7% W 33.3% M) with aphasia (9 Broca, 2 Wernicke and 1 Global) secondary to EVC, all preferably manually right, selected by convenience, crossover design (ABAB) single case, with two intervention groups (1 and 2) which includes two types of treatment five evaluation periods. Instruments: The evaluation periods were performed with the Boston Test for the Diagnosis of

Aphasia (TBDA) and the Protocol for the Evaluation of Communication of Montreal (MEC). Procedure: The rehabilitation program consists of two different treatment techniques, with 20 sessions of 1 hour, divided into four periods of treatment according to the intervention group. Evaluations were presented before and after each treatment period. **Results.** Visual analysis of the data showed in both treatment groups an upward shift in the expressive components (CEL), Listening (CCAL) and language proficiency rate (ICL). Also in the pragmatic tasks of conversational speech (DC), the interpretation of speech acts (IAH) and interpretation of metaphors (IM). Statistically significant differences by type of treatment in improving some language skills (ICL) and communication (DC) patients, after 20 treatment sessions were found. **Conclusions.** The results suggest that patients improved their language skills and communication are similar in both intervention groups, but by type of treatment differences. It is possible that increased communication skills attributable to TED results from the combination of specific exercises with words or family prayers used by patients premorbid form.

Title: The neural representation of number-noun phrases: An ECoG study

Authors: *V. C. CARUSO[1], G. B. COGAN[2], J. M. PEARSON, 27705[3], T. OVERATH[3], M. M. HAGLUND, 27705[3], S. R. SINHA, 27705[3], C. MUH, 27705[3], J. M. GROH[3]
[1]Ctr. For Cognitive Neurosci., [2]Dept. of Neurosurg., [3]Duke Univ., Durham, NC

Abstract: Speech entails the combination of words into structured phrases and sentences. Thus, a first essential step in understanding how speech meaning is encoded in the brain is to determine the neural responses of words uttered in combination. We focused on two-word spoken phrases consisting of a number followed by a concrete noun (such as “two books”). We recorded ECoG data from 7 participants undergoing pre-surgical monitoring for pharmacologically resistant epilepsy. In particular, we took an approach similar to single cell electrophysiology and tested whether the response to the noun is modulated (e.g. monotonically or in a tuned fashion) by the numerical quantity indicated by the preceding number. We recorded ECoG data while participants actively listen to two-word number-noun phrases (‘two’, ‘three’, ‘four’, ‘eight’, ‘ten’, and ‘book’,’chairs’,’dogs’). We quantified the neural response as the magnitude of the ECoG signal in the high gamma range (70 to 150Hz), because this has been proven to correlate strongly with the local neuronal population spiking activity. We report here preliminary data

from two subjects. We found that in the majority of the sound-responsive channels, the high gamma response during the second word was significantly modulated by the preceding number, as indicated in a two-way ANOVA by either a main effect of number or an interaction. This was still true in sites for which the activity during the number presentation and the delay time between the words was not modulated by the number. More data are needed to establish whether the trend is significant, determine the exact shape of the interaction and its time course, and test whether there is a spatial segregation between sites that show interaction vs. main effect of number. Investigating the neural representation of short phrases consisting of a limited number of stimuli provides a useful bridge between the tuning curve approach of single unit auditory neurophysiology and the higher level approaches of language studies.

Title: EEG correlates of natural, narrative speech processing at the level of phrases

Authors: J. HOOGENDOORN[1], M. P. BRODERICK[2], G. M. DI LIBERTO[3], *E. C. LALOR[4]
[2]Neural Engin., [1]Trinity Col. Dublin, Dublin, Ireland; [3]DEC, École Normale Supérieure, Paris, France; [4]Univ. of Rochester, Rochester, NY

Abstract: One fascinating aspect of language is recursion**;** technically, you could keep adding in phrases to create a never-ending sentence. Although humans do tend to finish their sentence eventually, listeners are left with the task to identify which words combine into a phrase. Recent research has begun to provide evidence for neural signals that may reflect this process. In particular, high gamma power activity from intracranial recordings has been shown to monotonically increase with each additional word in a phrase, and to drop at phrase ending. And EEG alpha power has been suggested to reflect syntactic processing, with reports of a power increase within a clause, followed by a drop in power at the end of the clause. This suggests that there is a build-up of neural activity during a phrase, or during a clause, relating to a hierarchical parsing of syntactic structure. While these results are compelling, they have typically been shown only in the context of experiments involving presentation of isolated sentences. Indeed even these sentences often have very specific and predictable structures. Thus, it remains

possible that the reported neural signatures of phrasal processing may be somewhat confounded by attentional fluctuations based on the constrained and predictable nature of the stimuli. Here, we aim to explore if some of these neural measures still reflect syntactic processing while subjects listen to more natural, narrative speech. Ten subjects listened to a ninety-minute segment of an audiobook while their EEG was being recorded using 128 channels. Alpha power (between 8 and 12Hz) was extracted from the EEG signal. We derived a measure that models the build-up over phrases by identifying the start and end of the verb phrases within our speech stimuli, and modelled this build-up over a verb phrase as a saw tooth wave. Using a stimulus-response mapping technique known as the Temporal Response Function (TRF), we fit a model based on this quantity and the alpha power of the recorded EEG. We use this model to predict EEG in a leave-one-out cross validation analysis. We found significant prediction accuracies over left temporal channels, which were consistent across subjects. This indicates that EEG may track the syntactic build up over the length of a phrase. Having such a measure would allow for studying syntactic processing under more naturalistic conditions of natural, narrative, continuous speech, using EEG.

Title: Performance to verbal learning and verbal semantic predict based on resting state neural oscillations pattern

Authors: *V. OSWALD[1], Y. ZEROUALI[3], A. BOULET-CRAIG[4], P. JOLICOEUR[2], S. LIPPÉ[3], K. JERBI[2], P. ROBAEY[2]
[1]Univ. de Montréal, Montreal, QC, Canada; [2]Univ. de Montréal, Montréal, QC, Canada; [3]Univ. de Montreal, Montréal, QC, Canada; [4]Univeristé de Montreal, Montréal, QC, Canada

Abstract: Objective: In this study, we used resting state MEG (and not a task paradigm) to explore neural oscillations patterns correlated with the performance in a standardized verbal learning test. **Participants and methods**: We recorded 5-min eyes-open resting-state MEG data and administered the California Verbal Learning Test-II (CVLT-II) in 28 healthy subjects. In the CVLT-II the subject was asked to recall words from a list read aloud over five learning trials (List A), then from another List B presented once. A free-recall of List A was tested immediately and again after 20 min. A T1-weighted MRI images was used to generate a cortical surface model. Forward modeling of magnetic field activity was performed. We calculated means of

Power Spectrum Density for different frequency bands (delta, 1-4Hz; theta, 4-8Hz; alpha, 8-13Hz; beta, 13-30-Hz; gamma, 30-120Hz) and correlated normalized MEG power in each frequency band with the performance in the CVLT-II across trials, and trial by trial. In order to control multiple comparisons, we used a non-parametric cluster mass approach. **Results:** Based on the sequential detection of clusters for each trial, we identified three sets of correlations between CVLT performance and (1) auditory associative areas for the gamma band, (2) auditory associative and premotor areas for lower frequencies (mainly alpha and beta), (3) auditory associative and parietal areas across all frequencies. The first type of correlation clusters was mostly detected during List A trials 2 to 4, the interference List B trial, and the long-delay free recall trial. The second type was observed in trial 3 of List A, and in the short- and long-delay free recall trials. Finally, the third type was detected in trials 3 and 4 of List A. **Conclusions:** Resting state MEG can identify different processes involved in verbal learning, including semantic processing in the auditory associative areas and subvocal rehearsal distributed between the parietal and the premotor areas.

Title: Saccadic corruption of the top-down hypothesis for visual processing

Authors: *A. CURTIS[1], C. M. KADIPASAOGLU[2], K. FORSETH[4], N. TANDON[3]
[1]Rice Univ., Houston, TX; [2]Neurosurg., [3]Neurolog. Surgery, Univ. of Texas Med. Sch. at Houston, Houston, TX; [4]UT Hlth. Sci. Ctr. In Houston, Houston, TX

Abstract: Top-down visual object recognition in the orbitofrontal cortex (OFC) has been proposed to drive rapid processing of simple images in higher-level visual regions. Event-related long-range connectivity between OFC and fusiform, quantified with phase locking value (PLV) in the low gamma band (40 - 80 Hz), has been argued to constitute crucial evidence for this perspective. However, PLV in the gamma band can be contaminated by cranial and optical muscle artifacts in EEG recordings. Intracranial electrodes, including both surface grid electrodes (n = 467, 3 patients) and penetrating stereotactic depth electrodes (n = 547, 3 patients), were implanted for electrocorticographic (ECoG) pre-surgical evaluation of epilepsy. Furthermore, each of these patients was monitored with concurrent extracranial electrodes.

Patients completed a picture naming task in which they quickly and accurately articulated common object names. In this task, a third of the visual stimuli were rendered incoherent and patients responded with “scrambled.” We leverage this unique opportunity with paired intra- and extracranial EEG recordings of an essential language task to isolate the influence of non-neural signals (e.g. saccadic eye movements) on a prominent connectivity measure - PLV.Using non-parametric cluster based time-frequency statistics, we find that trials lacking saccade artifact in extracranial EEG also lack the corresponding low gamma band PLV increase (200 - 300 ms post-stimulus) in ECOG. We observed this same dissociation in the response to both coherent and scrambled pictures. Therefore, we demonstrate that the well-characterized saccadic spike potential can induce artificial PLV in EEG, which can sometimes be mistaken for neuronal activity in the low gamma band.The confounds introduced by saccadic spike potentials confounds crucial evidence for early top-down modulation of visual object recognition. Our findings help identify and characterize the saccadic artifact in ECoG experiments as well as differentiate it from true functional connectivity between cortical regions.

Title: Evidence-accumulation models confirm the epistemic property of writing: A predictive coding and active inference study of writing to learn

Authors: A. M. SILVA[1], *R. LIMONGI[2]
[1]Sch. of Pedagogy, Pontifical Catholic Univ. of Valparaíso, Valparaíso, Chile; [2]INACAP Online, Technological Univ. of Chile, Santiago, Chile

Abstract: Writing plays a prominent role in both academic achievement and professional success because it allows to gain information, reduce uncertainty, and boost curiosity. This is, writing has an epistemic property. It is uncontested that writing enhances learning. However, what neural mechanisms underlie the learning effects of writing and how we could measure such effects are open questions. This paper proposes a new (Bayesian-brain) theoretical perspective about how writing affects learning and cognition: the predictive coding and active inference approach. Furthermore, it proposes an experimental task and a data analysis strategy to disambiguate the predictions of the dominant cognitive-psychology perspective of written composition and the emergent Bayesian perspective. In a simple experimental paradigm, participants read short passages, wrote or spoke a summary, and performed an episodic-memory recognition task. Reaction time of correct responses was shorter in the written condition than in the spoken condition. Furthermore, evidence-accumulation models revealed that writing optimized the prior beliefs that participants deployed when they summarized texts. Visual dynamic simulations of the competing evidence accumulation models show how a higher starting point value leads to a faster evidence accumulation towards the decision threshold. These findings support a Bayesian theory of brain function that regards epistemic writing as a specific case of active inference. Moreover, the results show a remarkable correspondence between the phenomenological notion of epistemic writing stated in the educational, linguistic, and psychology-of-writing fields and the neurocomputational formulations of predictive coding and active inference. Finally, the dynamic simulations provide tools for a visual and heuristic understanding of the complex neural process that underlies the effect of writing on memory.

Title: Functional connectivity in the language network in response to syntactic complexity and acoustic degradation: A functional near-infrared spectroscopy study

Authors: *B. E. WHITE, C. LANGDON
PhD in Educational Neurosci. (PEN) Program, Gallaudet Univ., Washington, DC

Abstract: INTRODUCTION: Behavioral and neuroimaging research suggests that processing degraded acoustic information creates a cascading effect on the mechanisms underlying speech comprehension (Peelle, 2018). Here, using a plausibility judgment task and functional near-

infrared spectroscopy (fNIRS), we aim to dissociate motivated listening and its modulation of language processing in response to increased demands on executive functioning. Hypotheses. H1: Compared to simple, clear speech, the processing of complex and degraded speech increases demands on domain-general cognitive resources. P1: The functional connectivity between the posterior superior temporal gyrus (pSTG) and areas in the frontal and right temporal lobes will be stronger for more difficult speech. H2: Alternatively, the processing of complex and degraded speech increases demands on language networks primarily in the left temporal regions. P2: Functional connectivity will be stronger between the left pSTG and other left hemisphere language areas for more difficult speech. METHODOLOGY: Participants. Monolingual, English-speaking adult participants (N=4; ages 24-37) with clinically-defined typical hearing. Procedures. Participants complete a battery of language and cognitive assessments. The fNIRS task presents participants with 192 sentences for a plausibility judgment task. The sentences vary linguistically (i.e., simple subject-relative and complex object-relative clause structures) and acoustically (i.e., clear speech and 8-channel, noise-vocoded speech). RESULTS: Using the left pSTG as a seed region for functional connectivity analysis, we observed (1) stronger left inferior frontal gyrus (LIFG) and left anterior middle frontal gyrus (aMFG) connectivity in syntactically simple and noise-vocoded speech, (2) reduced overall connectivity for syntactically complex compared to syntactically simple grammar for both speech conditions, and (3) stronger LIFG, but weaker right hemisphere connectivity, for syntactically complex and noise-vocoded speech. CONCLUSION: While the syntactic complexity condition fails to indicate support for either hypothesis, functional connectivity with the left pSTG is distinctly modulated by acoustic degradation and indicates support for the hypothesis that increased demands are placed on attentional resources (H1).

Title: In search of the cognitive abilities required for comprenhension of indirect request in Spanish speking young adults

Authors: *G. L. LICEA HAQUET[1], M. GIORDANO[2]
[1]Inst. De Neurobiología UNAM, Queretaro, Mexico; [2]Inst. de Neurobiología UNAM, Queretaro, Mexico

Abstract: Even though language allows us to say exactly what we mean, we often use language to say things indirectly, in those instances verbal comprehension represents only the starting point for an inferential process that results in the attribution of speaker´s meaning that involves recognition of speaker´s intentions. An indirect request is a common form of nonliteral language that can be understood either as literal, or as figurative requests for an action to be carried out. For example, the utterance "Can you open the door?" can be interpreted as an indirect request for the door to be opened. Or, taken literally, as "Are you physically able to open the door?"(Sperber & Wilson, 2002). There are different theories about how listeners identify speaker´s meaning, some studies suggest that listeners first compute the literal meaning, and if it is inappropriate to the context they infer the speaker's communicative intention. In contrast, other studies indicate that indirect requests are processed early on, even before the end of the sentence is heard (Coulson & Lovett, 2010). Based on empirical studies of populations suffering from various pathologies, it has been proposed that the recognition of the speaker´s intentions requires the integrity of other cognitive process such as executive functions and theory of mind, however, there are few studies in healthy controls. The aim of this work was to study the relation between the comprehension of indirect request and executive functions and theory of mind in a neurologically intact sample of native Spanish speakers. We translated and adapted to Spanish the stimuli used by van Ackeren, et. al.(2012), One hundred images and sentences were selected to design a decision task which evaluated indirect request identification using PsychoPy (Pierce, 2008). The participants (n=20, 21-35 years old) were indicated to see the images and read the sentences and indicated if they thought that somebody was making a request. The task was designed with two SOAs of 0.5 and 1.5 seconds to explore if the process is automatic or requires an inferential process. Participants also answered a psychometric battery that included executive functions and theory of mind tests. We found that participants showed worse performance in indirect requests than control trials, both with short and long SOAs. Only response time on a general cognitive ability task, explained the variance in reaction time for indirect requests. The behavioral tasks are currently being adapted to be used during acquisition of structural and functional images to determine the neural correlate of indirect request identification.

Title: Differential involvement of the left and right hemispheres on the processing of verbs and pseudo-words

Authors: G. L. LICEA HAQUET[1], M. GIORDANO[1], *A. REYES AGUILAR[3,2], B. I. ARCE LÓPEZ[2]
[1]Univ. Nacional Autónoma de México, Querétaro, Qro., Mexico; [2]Neurosci., Univ. Nacional Autónoma de México, Mexico City, Mexico; [3]Inst. of Neurobio., Univ. Nacional Autonoma de Mexico, Queretaro, Mexico

Abstract: Language “comprehension” requires pre-lexical, and lexical-semantic processing. The neurobiological substrate in charge of these processes, according to the dual stream model, involves two networks with a common origin, the sensory/phonological system in the temporal and occipital cortices. According to this view, the dorsal stream would be connected to the motor-articulatory systems in the left frontal regions, while the ventral stream would connect to the conceptual-semantic systems in the ventral temporal cortex bilaterally. Verbs are a class of words that express action, occurrence, or mode of being. We were interested in evaluating the functional dissociation between pre-lexical and lexical-semantic processing of pseudowords and verbs, and their relation with language skills using functional magnetic resonance imaging (fMRI). We selected 112 verbs based on their psycholinguistic properties according to linguistics corpora. After validation of the stimuli in a behavioral study, we included three categories in the fMRI study: symbols, pseudo-words, and verbs in a one-back detection task. Twenty-four right-handed, young participants, gave written informed consent. Participants were scanned in a 3T GE MR750 scanner, and were requested to complete the vocabulary subtest of the WAIS, and verbal fluency tasks outside the scanner. Our results indicated that, in comparison to symbols, verbs recruited bilateral parietal, temporal and frontal regions, while pseudo-words showed involvement of the left hemisphere language network. Finally, verbs in contrast to pseudo-words, recruited right temporal and frontal areas. Region of interest analysis showed that vocabulary and verbal fluency performance was negatively correlated with the hemodynamic response in the left brain areas in the contrast verbs versus all other stimuli categories, and positively correlated with the hemodynamic response in the right posterior temporal region in the contrast pseudo-words vs symbols. These results suggest that pre-lexical processing evoked by pseudo-words, is lateralized to the left, and could reflect the attempt of the motor-articulatory system to recognize the stream

of letters. While lexical-semantic processing recruited bilateral fronto-parieto-temporal regions. Language proficiency, as measured by vocabulary and fluency tests, was related to less involvement of the left lexical-semantic system for verbs, and more involvement of the right motor-articulatory system for pseudo-words.

Title: Semantic and phonological errors described by a hierarchical computational model of speech production

Authors: M. TOPALIDOU[1], E. NEFTCI[1], *G. S. HICKOK[2]
[1]Univ. of California Irvine, Irvine, CA; [2]Univ. California, Irvine, CA

Abstract: Dell et al. (1997) implemented a hierarchical model of three layers (semantic, lexical, and phonological) to explain semantic and phonological speech errors for aphasic patients. Through a series of papers, Dell and his colleagues identify the strength of the connections between the units of the semantic and lexical, and the lexical and phonological layers as the main element for the variety of errors in aphasic patients during picture naming experiments (Foygel and Dell, 2000). Later, Walker and Hickok (2015) based also on the Hierarchical State Feedback theory (Hickok et al., 2011), extended the model by dividing the phonological layer to auditory and motor, to explain better conduction aphasia. However, none of the models include a internal feedback mechanism at the phonological level that can detect and correct phonological selection errors prior to overt speech output (Hickok, 2012). Our goal was to implement a mechanism that can achieve internal speech error detection and correction during multi-syllables production. We used the architecture proposed as one level in the Hierarchical State Feedback Control (HSFC) model as described in Hickok, et al. (2011) with the addition of a semantic level as in Dell's model. The network comprises five structures: semantic, lexical, auditory-phonological, motor-phonological, and auditory-motor intermediary (Spt) levels. The lexical level is bidirectionally connected to the semantic, auditory and motor levels. The two latter structures are connected to each other also via the Spt auditory-motor interface level. Our model does not separate the sequence of the phonemes in onsets, vowels and codas as in previous models. The needed information of the sequence is provided by the connections weights between the word (in the

lexical level) and the phonemes (in auditory and motor level). Internal error correction is hypothesized to occur via auditory-motor interaction in cases where the motor plan does not match the lexical and auditory targets (Hickok, 2012). Analysis of network behavior showed that motor errors can be corrected by Spt driving the correction. Another outcome of the analysis was that word sharing of semantic features is enough to produce occasional/rare semantic errors. One prediction of the model based on these results is that the more semantic features two word share, the more likely is the wrong word to be produced. On the contrary, the phonological errors should be less frequent, because of the internal feedback mechanism at the phonological level; a component that the semantic level lacks.

Title: Subtle emotional distinctions in primate vocalizations (chimps and vervets) can be recognized by naive humans; evolution of proto-language in left hemisphere and musical scales (ragas) in the right hemisphere - mediated by a primordial emotional language of intonation and prosody via ultra normal peak-shift

Authors: *V. S. RAMACHANDRAN, S. KANDALAFT, K. VAYYALA, C. CHUNHARAS, Z. MARCUS
UCSD, La Jolla, CA

Abstract: Two great enigmas are the evolution of music and of language; both of which require retracing the sequence of steps through the fitness landscape. A key idea is the deployment of the peak shift principle and ultra normal stimuli in perception that amplify otherwise marginal selection pressures for markers and trigger features (including facial expression, gestures and emotional vocalization).
We suggest early in primate evolution grunts, barks, screams, hoots, growls, howls screeches - formed an early emotional vocabulary (meaning inferred by ethologists based on social context). Intriguingly we have preliminary evidence that naive humans can, in a binary choice task, identify better than chance even subtle distinctions e.g. dominance vs aggression (gorillas), anger vs fear (chimps), separation vs aggression (vervets), even though they diverged from us 6 to 15 million years ago (vervets also appear to use onomatopoeia for birds vs. leopards). The emotional vocabulary then evolved via ‘peak shift’ and ultra normal (‘gull chick striped beak’;

exploiting idiosyncratic aspects of brains wiring for feature detection) principle, into an entirely novel "primordial language " of emotions - prosody and intonation which we find can convey a surprising range of emotional subtleties (e.g. REALLY. can be ironic, incredulous, skeptical, etc; there are 17 meanings. Another example NO. See website CBC). This preceded left-hemisphere language, but in parallel it evolved, via peak shift/ ultra normal modulation, into musical scales exemplified in Indian ragas, or, scales. Thus, the separation cry of a baby chimp morphed into Darbari Kanada (a scale) for existential angst of separation from God. (untutored westerners can distinguish ragas evoking closely related emotions - e.g. “personal present anguish” vs “our race has gone through great pain”; (mukhari and nagagandhari). Meanwhile the left hemisphere evolved Chomskys recursiveness, hierarchical embedding, but borrowed intonation from the right, so we don't sound like R2D2 or Siri.

Title: Onset-driven activation of lexico-semantic cohorts dynamically activates bilateral fronto-temporal language systems

Authors: *A. CLARKE, L. K. TYLER, B. RANDALL, E. KOCAGONCU, W. MARSLEN-WILSON
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Recognising spoken words requires the transformation of acoustic signals into a meaningful representation. Models of spoken word recognition propose that upon hearing the initial phoneme of a spoken word, there is rapid activation of the lexical and semantic properties of word candidates that match the initial sensory input. While recent research shows the STG analyses the phonetic features of speech inputs (Mesgarani et al., 2014), and MEG studies show how later stages of lexical and semantic cohort competition converge on the semantics of the target word (Kocagoncu et al., 2017), little is known about the neural dynamics of how auditory and phonetic inputs initially activate the lexical cohort. Here we use representational similarity analysis (RSA) of MEG data to reveal how the different aspects of spoken words are integrated into the recognition process from word onset. Participants heard 218 spoken nouns. We characterised the acoustic properties of each word from the sound recordings, and its phonological properties according to its phonetic features. To define the lexical candidates of the cohort, an independent set of participants performed a word gating study. Participants were presented with sound fragments of differing lengths and had to guess what the word was. The guesses represent the candidate set of likely words given the sound fragment, and the cohort size was the number of unique candidates. We defined the semantic properties of the cohort as the average of the Baroni and Lenci (2010) co-occurrence semantic feature vectors for each cohort member. RSA models were constructed for these acoustic, phonetic, lexical, and semantic dimensions. Spatiotemporal searchlight RSA was applied to source reconstructed MEG signals aligned to word onset. Early model-fit related to the loudness of the acoustic signal is seen in bilateral STG at 50 ms, along with model fit driven by the phonetic features of the word-initial phoneme. This onset-related phonetic model fit spread rapidly through STG and MTG, with bilateral frontal engagement within 150 ms. Cohort size showed effects starting at 80 ms but later than phonetic model fit in STG and moving into MTG within 200 ms, while cohort semantic effects appeared after 150 ms in STG/MTG. The prolonged and widespread model fit for the first

phoneme RSA suggests that speech onsets immediately trigger cascaded processing of lexical and semantic properties of word candidates in bilateral fronto-temporal language systems. Our results track the flow of information from pre-lexical properties of spoken words to abstract lexical and semantic representations, directly captured as spatio-temporally distributed activity patterns.

Title: End-to-end decoding of speech from human cortex

Authors: *J. G. MAKIN[1], E. F. CHANG[2]
[1]Ctr. for Integrative Neurosci., Univ. of California, San Francisco, San Francisco, CA;
[2]Neurosurg., UCSF, San Francisco, CA

Abstract: We aim to decode speech from cortical activity, an enterprise with both scientific and practical implications. In our case, data come from human electrocorticography (ECoG) recordings from from peri-Sylvian speech cortices. Taking a cue from recent advances in machine translation and automatic speech recognition, we implement and train a recurrent neural network (RNN) that maps from high-gamma activity directly to linguistic outputs, either words or full sentences. The RNN uses an encoder-decoder framework in order first to build abstract sentence representations from ECoG data, and then to decode these representations into text sentences. The network is trained to reduce the cross-entropy of the next word, given its current state and the previous word, and then evaluated on word-error rates for full sentences. We also show how to use *transfer learning* to overcome limitations on data availability; in particular, we show that decoding performance can be improved by training the network on multiple patients, despite very different electrode coverage. We likewise explore the usefulness of pre-training the network on different translation tasks.

Title: Spatiotemporal characteristics of semantic processing: An fMRI and EEG study of sentence comprehension

Authors: *K. S. ABOUD, L. E. CUTTING
Vanderbilt Univ., Nashville, TN

Abstract: In order to understand a sentence, a person needs to (1.) retrieve the meaning of a word from long-term memory ("semantic retrieval), and (2.) unite incoming word meanings into a coherent, internal representation of the text ("semantic integration"). While single modality neuroimaging studies have identified key brain areas that support these processes, there is still considerable debate over the specific roles these areas play during semantic cognition. Multimodal imaging techniques provide a powerful way to convergently identify the neural mechanisms of semantics. However, no studies to date have used multimodal imaging techniques to quantitatively compare the spatiotemporal signatures of retrieval versus integration networks. In the current study, we used functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) to examine typical adult readers (n = 30) as they performed a novel sentence reading paradigm. In order to isolate areas specific to semantic retrieval and integration, sentences were manipulated to have variable word- and/or sentence-level semantic coherence. Findings revealed that semantic retrieval and integration independently map on to distinct neural routes in the bilateral fronto-temporal language system, and these circuits correspond with differential characteristics of the N400 temporal component. This is the first study to use fMRI/EEG to provide a unified spatiotemporal characterization of semantic sub-processes. Future studies will examine how these spatiotemporal signals correspond with individual differences in comprehension ability.

Title: Pauses and neural indicators during speech: English (l1/l2), Spanish (l1/l2), and Heritage Spanish

Authors: *N. ENRIQUEZ[1], F. LLORELLA[2], J. CRUZ[1], L. DIAZ[3]
[1]Univ. of Houston, Houston, TX; [2]Univ. of Gerona, Gerona, Spain; [3]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: In this paper we present a study on processing problem indicators in oral production in both Spanish and English in a simulated transaction task. Subjects are native English, native Spanish and heritage Spanish speakers. The aim was to describe the role of speech pauses as processing indicators in oral production as a communication strategy and their differences between groups of speakers and the language used in the simulation.
Hypotheses: i) pauses are different quantitative and qualitatively depending on the speaker's competence; ii) familiarity with the situation in the target language affects the patterns of occurrences of pauses; iii) the speaker's role in the task (operator or costumer) affects the number and function of pauses and iv) pragmatic and cultural aspects do play a role in the amount and type of pauses in each language.
In order to test these hypotheses, we gathered two different corpora. StopELE/SP (6031 tokens) which consists of a sample of 18 dialogues in Spanish (6 native, 6 heritage and 6 non-native) and StopELE/EN (5562 tokens) which contains 18 dialogues in English (6 native, 6 heritage and 6 non-native). The speakers played both roles in both languages.
We report preliminary findings on EEG data (64 channels, 500 Hz) during oral production. The bandpower in EEG data during 36 speech pauses was compared to baseline, where the subjects relaxed and looked at a blank paper in front of them for 1 min. The data was preprocessed by using the H-inf filter to remove eye-related artifacts, band-pass filtering the signal between 0.3 and 50 Hz, using the PREP pipeline for robust re-referencing, and ASR for removal of artefactual power bursts. At the onset of the speech pauses we found statistically significant ($p<0.01$) modulation in the left frontal areas for the delta band (1-4Hz), and activation of central-left regions in the alpha (8-12 Hz) and gamma (30-50 Hz) bands. The pattern was found both in English and Spanish speech production, with pre-frontal bandpower deactivation in the English task.
Linguistic data confirms the role of pauses as indicators of the difficulty of the task itself and the linguistic difficulty in carrying it out in L2, and by role, as stated in hypothesis (i), (ii) and (iii) above. The study also reveals significant differences between native, heritage and non-native

speakers, related to hypotheses (i) and (iv). Specifically, in native speakers, pauses are indicators of difficulty in management decisions, while in non-native speakers pauses indicate difficulties with syntax, verb inflection and information management.

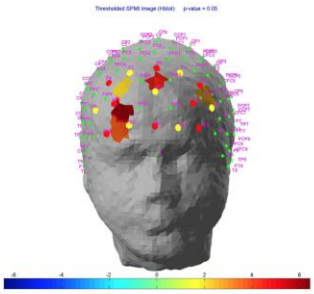
Title: Language proficiency and executive function: An fNIRS study

Authors: *V. DARGAM[1], M. BARALT[1], A. DARCY MAHONEY[3], R. JUNG[2], A. K. THOTA[2], L. RINCON GONZALEZ[1], C. MYLAND[1], V. LEON[1]
[2]Biomed. Engin., [1]Florida Intl. Univ., Miami, FL; [3]The George Washington Univ. Sch. of Nursing, Washington, DC

Abstract: Robust empirical evidence continues to show a bilingual 'edge'; in executive functioning. However, to date, no research has explored the potential for a bilingual edge in executive functioning with heritage speakers, who may have learned Spanish first as children, but who are now dominant in English and who have receptive knowledge only in Spanish (e.g. Montrul, 2004). The present study aims to contribute to this gap in the literature by comparing the executive functioning of 1) monolingual, 2) fully productive bilingual, and 3) heritage speakers (understand Spanish but do not productively speak it) of English and Spanish. 45 adults ages 18-25 participated in the study (25 were females). Participants performed two tasks that measured executive function: the Dimensional Card Change Sort Task (DCCS) and the Go/No-Go task, with simultaneous brain imagining via Functional Near-Infrared Spectroscopy (fNIRS). Preliminary fNIRS data revealed that bilinguals demonstrated greater neural recruitment efficiency than the monolinguals and the heritage speakers. Monolinguals and bilinguals shared some areas of neural recruitment while performing the tasks, whereas heritage speakers did not. For both the DCCS and Go/No-Go tasks, heritage speakers had the slowest reaction times when compared to the other groups; the bilinguals were the fastest. These data indicate two key results. First, bilingualism results in enhanced executive functioning in the brain. Second, this bilingual benefit requires full *productive* capacity in two languages, not just receptive knowledge, as is the

case for the heritage learner profile. The implications of our study suggest that bilingualism can lead to enhanced executive functioning, but that daily oral use is required to reap the benefits of bilingualism. We conclude with implications for bilingual education in the U.S., and in particular, with a discussion on the unique linguistic profile and needs of heritage speakers.

A General Linear Model was used to find contrast SPM image to find similar areas of neural activation per language groups. Hbtotal statistically significant t-statistic values compared No-Go to Go task per participant. Monolinguals and bilinguals had common areas of neural activation while heritage speakers did not.



Example of a **Monolingual's** SPMt image.

Title: Proficiency in a second language modulates the engagement of the first language network

Authors: *Y.-C. LIN[1], F.-H. LIN[2], W.-J. KUO[1]
[1]Inst. of Neurosci., Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Inst. of Biomed. Engin., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: During the second language (L2) learning, neural circuits need to be rewired to process new statistical structure and grammatical properties. Therefore, the learning performance, i.e. L2 proficiency, must couple with the functional changes of the brain network for L2 processing. This study investigates changes in brain networks for L2 spoken sentences

processing. Two groups of native Mandarin speakers participated in an functional magnetic resonance imaging (fMRI) experiment. The two groups differed in L2 proficiency (High- and Moderate-proficiency, henceforth: H-group and M-group, respectively) meanwhile had similar educational history and learned English as their L2 after the age of seven (late learners). Their language skills and learning history were evaluated via an online questionnaire. In the fMRI experiment, participants passively listened to sentences in the native language (L1), L2, and Wolof (served as an unknown control language to the participants). The online questionnaire showed that the H-group had better L2 skill than the M-group, implying that the H-group understand L2 materials better. Our fMRI results showed that when listening to spoken sentences in L2, the H-group recruits the language network resembling the network elicited by L1. On the contrary, the M-group shows compelling different activity patterns when listening to spoken sentences in L1 and L2. Significant activations in the bilateral temporal regions were only found in the L1 but not L2 condition. Surprisingly, we found that, from moderate to proficient of L2, the cortical areas covary with L2 proficiency levels migrate from language areas related to higher levels to lower levels processing. In the M-group, we found L2 proficiency positively correlated with the cortical response in the middle temporal gyrus and bilateral angular gyri, which were found to be related to semantic and syntactic processing. In the H-group, the positive correlation was revealed in the left early auditory cortex and the left superior temporal gyrus which was identified to play a central role of identifying spoken word forms. Our results suggest that the brains in different status of L2 proficiency might underwent various stages of functional improvement to grow the efficiency of spoken sentence comprehension. In summary, by contrasting participants with different L2 proficiency, we successfully identified distinct brain regions recruited for supporting the comprehension of spoken sentences in different stages of L2 learning.

Title: Assessment of neural networks related to post-stroke aphasia with the EEG phase synchrony index

Authors: *T. KAWANO[1,2,3], N. HATTORI[2,4,1,3], Y. UNO[3], M. HATAKENAKA[1], H. YAGURA[1], H. FUJIMOTO[1], T. YOSHIOKA[1], M. NAGASAKO[1], H. OTOMUNE[1], H. MOCHIZUKI[2], K. KITAJO[3], I. MIYAI[1]

Neuroengineering, Global Ctr. for Med. Engin. and, Osaka Univ., Osaka, Japan

Abstract: Objective: Neural network function can be assessed by the EEG-based synchrony analysis. We have reported that the EEG phase synchrony index (PSI) between specific electrodes showed correlations with various impairments in post-stroke patients. The aim of the current study was to assess networks related to aphasia by using the PSI.
Methods: Twenty-four first ischemic stroke patients presenting aphasia with left hemispheric lesions (all right handed, mean age: 67.4, median post-stroke days: 37.5) and age-matched 22 healthy volunteers were enrolled. Patients were assessed using two subscore sets (speech score: 0–70; comprehension score: 0–50) of the Standard Language Test of Aphasia. We obtained 2.5 minutes of eye-closed EEG data with electrodes placed according to the international 10–20 system, and computed the PSIs in six frequency bands (δ, θ, α, β1, β2, and γ). Then we calculated the PSIs of following four electrode pairs associated with language networks: 1 bilateral inferior frontal lobes (F7F8), 2 bilateral superior temporal lobes (T5T6), 3 ipsilesional front-temporal lobes (F7T5), and 4 contralesional front-temporal lobes (F8T6). We evaluated abovementioned networks by correlations between the PSIs and clinical scores. Spearman's rank correlation coefficient with Bonferroni correction was used for the correlation analysis.
Results: 1: The interhemispheric PSIs were positively correlated with clinical scores, whereas the intrahemispheric PSIs were negatively correlated with clinical scores. 2: In all electrode pairs, the PSIs were correlated with speech score (F7F8: P=0.034; T5T6: P=0.035; F7T5: P=0.0035; F8T6: P=0.035). 3: In electrode pairs not including left inferior lobe (T5T6/F8T6), the PSIs were correlated with comprehension score (T5T6: P=0.038; F8T6: P=0.005). 4: Correlations were observed in distinct frequency bands (F7F8: β1, T5T6: β1, F7T5: β2, F8T6: σ). 5: Additionally, F8T6-PSI was significantly larger than that of normal control (P=0.004, Mann-Whitney U-test).
Conclusion: Existence of both positive (interhemispheric PSIs) and negative (intrahemispheric PSIs) correlations suggested different roles of these networks. In addition, the PSIs including left inferior frontal lobe were correlated with speech score, but not with comprehension score, in accordance with the role of this area (speech production). Furthermore, elevated F8T6-PSI compared with normal control suggested active role of the contralesional hemisphere in the post-acute aphasia. Taken together, we concluded that the EEG PSI helps us understand the mechanisms of post-stroke aphasia from a network point of view.

Title: Effects of categorical cues on naming

Authors: *R. TANAKA[1], Y. ITAGUCHI[3], C. YAMADA[4], K. FUKUZAWA[2]
[1]Waseda Univ., Tokyo, Japan; [2]Waseda Univ., Shinjuku-ku, Japan; [3]Dept. of Syst. Design and Engin., Keio Univ., Kanagawa, Japan; [4]Waseda Univesity, Tokyo, Japan

Abstract: Effects of categorical cues on naming Ryoko Tanaka, Yoshihiro Itaguchi, Chiharu Yamada, Kazuyoshi Fukuzawa Keywords: naming, picture naming, name agreement, category, language production The present study investigated effects of categorical cues on the performance in a picture naming task. Impairment in naming is one of the most common symptoms in aphasic patients. Although previous studies reported that categorical cues facilitate the performance in picture naming tasks, the effects of categorical cues in a naming task for Japanese healthy adults have never been investigated. We thus conducted an experiment to test the hypothesis that categorical cues improve naming performance also in Japanese healthy participants. Twenty university students participated in a picture naming task. In the experiment, participants were asked to name line drawings presented on a display as quickly as possible. We used 10 drawings for each of eight categories: vegetables and fruits, instruments, processed food (e.g. doughnuts, sandwiches), animals, commodity, vehicles, colors, and body parts. Participants were assigned to one of two groups: in one group they were given categorical cues and the cues were not given to the control group. For the group given a categorical cue, a name of a category was visually provided before drawings of the category were shown. One experimenter counted the number of correct responses and the reaction time was registered by a computer. We performed independent t-tests to compare the number of correct responses and the reaction time between the groups. The number of correct responses did not differ between the groups, maybe due to a ceiling effect. However, the reaction time was significantly shorter in the group with categorical cues. The results for the first time confirmed that categorical cues facilitated efficiency of naming in Japanese population.

Title: Stress alters functional connectivity in language processing regions of the brain during verbal fluency tasks

Authors: *N. NAIR[1], J. P. HEGARTY, II[3], B. J. FERGUSON[4], S. J. HOOSHMAND[2], P. HECHT[5], M. R. TILLEY[6], S. E. CHRIST[7], D. Q. BEVERSDORF[8]

For Autism, Columbia, MO; [5]Avanir Pharmaceuticals Inc., Aliso Viejo, CA; [6]Central Methodist Univ., Columbia, MO; [8]Dept Radiol, Neurol, Psychol Sci, DGS of INP, [7]Univ. of Missouri Columbia, Columbia, MO

Abstract: Psychological stress has deleterious effects on cognitive performance, especially in tasks that require searching through multiple, distributed networks. For example, verbal fluency tasks require rapid access to distributed lexical and semantic networks and our lab has previously shown that stress impairs performance in these tasks. This has implications for conditions such as public speaking and test taking anxiety. However, the neural correlates of the effects of stress during such language processing tasks are not well explored. This study explored stress effects on functional connectivity (FC) in specific language processing regions of the brain while performing verbal fluency tasks. Since serotonin transporter gene (5-HTTLPR) polymorphisms (S-allele and L-allele) and gender are known to influence stress susceptibility in individuals, we additionally explored the role of these two factors on the effect of stress on FC during task. Forty-five healthy volunteers attended two functional magnetic resonance imaging (fMRI) sessions. During the sessions, they performed two runs each of letter and category fluency tasks, interposed with either the Montreal Imaging Stress Test to induce stress or a no-stress control task. fMRI data was analyzed using FSL (FMRIB Software Libraries) software. The a priori regions of interest (ROIs) were the left and right inferior frontal gyri, left middle temporal gyrus, left parietal lobe and left fusiform gyrus. Significant regional variations in FC strength were noted between the a priori ROIs while performing verbal fluency tasks under stress. Overall, males displayed regional increases in functional connectivity strength over long and short distances during task under stress while S-allele participants, irrespective of gender, showed regional decrements in FC strength. This study is the first to explore the neural correlates of stress effects on language processing. Previous work from our lab has shown the potential for

specific therapeutic agents to overcome the cognitive deficits associated with stress. Larger studies examining neural correlates of stress susceptibility, its effect on task performance combined with therapeutic agents to reverse these effects could help pave the way towards targeted therapeutic interventions.

Title: Wernicke aphasia patients do not understand that they do not understand language: An initial case study

Authors: *E. L. ALTSCHULER
Physical Med. and Rehabil., Metropolitan Hosp., New York, NY

Abstract: In 1874 Carl Wernicke described a novel form of aphasia whereby patients spoke fluently but (1) the speech was often simply gibberish, and (2) the patients did not often understand what was said to them. Wernicke described a third feature of the syndrome which remains of great interest and still not understood today: the patients do not seem bothered by the fact that they do not understand what others say, and that what they say cannot be understood. An outstanding question is whether or not Wernicke aphasia patients (WAP) appreciate, or not, their lack of understanding of language (or the intelligibility of their own speech). Recently we have described a method to answer this question (Hartman et al., and ELA, J Undergrad Neurosci Educ. 2017;16(1):E5-E12). In brief: As a control WAP are shown pictures of someone "speaking in pictures," that is, a cartoon of a person with a speech bubble containing a picture. For example, the picture might be of a bone. Then there are given three choices (also in pictures): a cat, a dog and a collection of question marks. The target answer is the dog. As reasoning appears to be intact in WA patients they should answer these questions on target all or most of the time. A subsidiary set of questions is next needed to establish that the WAP will choose the answer '????' on target, for example when asked to pick a picture of the weather outside given a picture a room with a shade covering the window. Finally, the patients are asked the original questions but now posed in words not pictures, e.g., 'bone'/'dog,' 'cat,' '????' . If the WAP knows she does not understand language, she will chose '????', but if the WAP does not know she does not understand language, she will randomly pick an answer. We have used this method in an initial case study of a patient with moderate WA (and expressive aphasia)

following stroke. For no question would the patient chose '????', so we had to modify our approach somewhat. When asked simple arithmetic questions written out in numerals the patient chose the correct answer at a level three standard deviations above chance. However, when asked the same questions written out in words (answers in words as well), the patient performed at chance. Finally, we interspersed questions with no correct answer. When the questions (and answers) were given as numerals, the patient got visibly perturbed and started gesticulating at the examiner, but when questions were posed as words the patient did not exhibit this behavior. In this case it thus appears that a WA patient does not appreciate their lack of language understanding. Further studies are warranted.

Title: Behavioral and electrophysiological evidence of incidental learning, generalization and retention of speech categories from continuous speech

Authors: *C. WU[1], R. LIU[3], S.-J. LIM[4], L. L. HOLT[2]
[1]Psychology, [2]Carnegie Mellon Univ., Pittsburgh, PA; [3]MARi, Washington, D.C., DC; [4]Speech, Language and Hearing Sci., Boston Univ., Boston, MA

Abstract: Speech segmentation and speech category learning are each been described in rich literature. Yet, few studies have examined how these two challenges affect learning in the same context. In the current study, native English participants played a video game shown in prior work to encourage incidental learning of speech categories, even in the context of fluent speech requiring segmentation. Here, 4 acoustically-variable Mandarin keywords were embedded in 4 distinct sentences uttered by 4 talkers (2 female). Unknown to participants, the presence of a keyword in the continuous Mandarin speech was associated with functionally- relevant actions and events in the game. During training, participants were not informed about the keywords, made no overt categorization decisions, and received no feedback. An overt post-training categorization test demonstrated robust incidental keywords learning that persisted even 10 days after training, and generalized to novel utterances and talkers. Further, the N100 response in the frontal and central EEG electrode (Fz and Cz) evoked by keyword onsets within continuous Mandarin speech during passive listening was greater post-training compared to pre-training. This enhancement was not observed for Mandarin words that were frequency-matched but not functionally paired with a visual referent in video game training.

Title: Developmental changes in speech perception at the syllable, word and sentence level

Authors: *O. B. KOLOZSVÁRI[1,2], W. XU[1,2], N. LOULELI[1,2], N. AZAIEZ ZAMMIT CHATTI[1], J. A. HÄMÄLÄINEN[1,2]
[1]Dept. of Psychology, Univ. of Jyväskylä, Jyväskylä, Finland; [2]Ctr. for Interdisciplinary Brain Res., Jyväskylä, Finland

Abstract: During auditory speech perception, the brain extracts speech sounds and their sequences from the incoming auditory signal, which then activate the meaning of the word. Using EEG and MEG, acoustic-phonetic features of speech have been found to modulate activity in the auditory cortices as seen in the N100m response around 50-100 ms. Language-specific phonetic-phonological analysis has been shown to start 100-200 ms following stimulus onset. From 200 ms onwards studies have found sensitivity to lexical-semantic manipulations in the superior temporal areas.
In our study, we wanted to investigate the developmental changes of evoked fields reflecting speech perception in children (between ages of 5 and 8). As the first step of analysis, we investigated differences in sensor-level responses, with a focus on event-related-fields to syllables and words. In the future we will also examine source level responses and neural entrainment at the word and sentence level.
Here, we report data from 11 five-year-old (4 boys) and 23 eight-year-old (11 boys) Finnish children. Participants were measured with a whole-head 306 channel Elekta Neuromag TRIUX MEG device. Planar gradiometer data were transformed into combined planar gradients and used in the analyses. Pre-processing was done using MNE for Python and analyses were done using FieldTrip toolbox for MatLab.
During the measurement, participants were asked to listen to syllables (18 repetitions of /ka/, /pa/ and /ta/), words (starting with the syllables, 18 different words for each syllable) and sentences (1 sentence for each word) presented through earphones while looking at a fixation cross. Their task was to repeat out loud what they had just heard when a cue (a parakeet) was presented on the screen. 54 stimuli per type of stimuli were presented in random order.

Permutation tests with channel and time point clustering were carried out. (Time window of analysis: 0 - 500 ms, cluster α level .05, number of permutations 3000.)
Our permutation tests showed significant differences between age groups to Syllable stimuli in the P1-N1 (p=0.011), N2 (p=0.021) and N4 (p=0.021) time-windows in the fronto-central channels and to Word stimuli in the P1-N1-N2 (p = 0.006) and N4 (p = 0.007) time-windows in the front-central channels.
Our findings show significant differences between the two groups, in case of both types of stimuli. The N1m response was larger for 8-year-olds than for 5-year-olds when presented with syllables or words. These differences seem to be robust and they appear to reflect developmental changes in speech perception between the two age groups.

Title: Effects of early sign language use on anatomical structures of visual regions: Surface-based and DTI analyses

Authors: *Q. CHENG[1], D. KLEIN[2], J.-K. CHEN[2], E. HALGREN[1], R. I. MAYBERRY[1]
[1]UCSD, La Jolla, CA; [2]McGill Univ., Montreal, QC, Canada

Abstract: Sign language is a visuospatial language that requires motion processing, and often involves more peripheral visual processing for proficient signers. Previous studies find that deaf people with early sign language often show better peripheral vision, and also show more activation of the left middle temporal and medial superior temporal (MT/MST) regions when processing motion (Bavelier et al. 2001, 2006; Bosworth & Dobkins 1999). It is unclear whether these enhancements come from compensatory plasticity for auditory deprivation, or from extensive early sign language use. Early sensory and language deprivation during a critical period often have a significant impact on brain development (Hensch 2005; Mayberry et al 2011, 2018). By investigating the brain structures of deaf individuals with various ages of sign language onset, the present study explicitly examines the effects of age of sign language acquisition (AoA) on brain plasticity in visual regions. A group of 22 deaf signers with varying AoAs but similar years of sign language use participated in the study. Structural T1 and diffusion-weighted data were collected and corrected using in house pipelines and FSL (Smith et

al. 2006). For T1 data, we used a topographical visual map (Wang et al. 2015) to parcellate the visual regions in Freesurfer (Fischl et al. 2002). For DTI data, we used the group connectometry analyses in DSI Studio (Yeh et al. 2015). Using gender and age as covariates, the surface-based analyses showed a significant negative AoA effects on volume at one lateral-temporal region, MST ($t = -4.71$, $p < 0.001$), where neuronal firing encodes coherent motion, and significant negative effects ($p < 0.01$) at several ventral-lateral regions (V2v, V3v, PHC1). For the DTI analyses, also with gender and age as covariates, we found AoA to be significantly related to decreased fiber connectivity in the left inferior longitudinal fasciculus, especially in the lateral portion near the middle temporal lobe. These findings suggest that early sign language experience is crucial for neural plasticity in regions for para/peripheral vision and motion processing in deaf brains. Missing the critical time window for sensory-linguistic input has an irreversible impact on brain structures that support sign language learning and processing, which may partially explain the disrupted language outcomes of these deaf individuals (Boudreault & Mayberry 2006).

Title: Brain responses to native and non-native syllables in typical readers and in children with reading or attentional problems

Authors: *N. AZAIEZ ZAMMIT CHATTI, O. H. LOBERG, N. LOULELI, O. B. KOLOZSVÁRI, J. A. HÄMÄLÄINEN, P. H. LEPPANEN
Univ. of Jyväskylä, Jyväskylä, Finland

Abstract: Previous research has demonstrated that speech perception is linked to basic reading skills. In this study, we explored this link in school children with dysfluent reading or attentional problems using a cross-linguistic approach. Brain event-related potentials (ERPs) of 138 sixth grade Finnish children were recorded with a high-density Electroencephalography (EEG) system (128 electrodes) in three groups: 86 typical readers, 26 dysfluent readers and 17 children with attentional problems. Participants were exposed to native (Finnish) and non-native (English) language stimuli in an auditory oddball paradigm presented in two different blocks. In the first

block, Finnish syllables were used as stimuli, /suu/ as standard (80%), /sai/ and /sii/ as deviant stimuli (10% each). In the second block, non-native phonologically matched syllables were used instead, /shoe/ (80%), /shy/, and /she/ (10% each). Cluster-based permutation statistics for ERP waveforms and topographic maps were calculated between the different conditions and between the different groups. Our results showed that ERP responses were different between languages (Finnish vs English) and within language: in Finnish (/sai/ vs /sii/) and in English (/shy/ vs /she/) for the three groups. The brain responses to the non-native syllables were different compared to the responses observed with the native stimuli. Moreover, ERP amplitudes, latencies and topographical distribution were different between the three groups. The participants with attentional problems and dysfluent readers showed atypical brain activities compared to the typical readers. Overall, these atypical responses suggest less specific phonemic representations and more reliance into stimulus features during passive auditory processing. Next steps involve further investigation of these neural signatures by localizing their sources and examining their correlation to behavioral measures.

Title: Morphological representations in pre-school children with and without risk for dyslexia

Authors: *N. LOULELI[1], L. NIEMINEN[2], N. AZAIEZ ZAMMIT CHATTI[1], O. B. KOLOZSVARI[1], J. A. HÄMÄLÄINEN[1], P. H. T. LEPPÄNEN[1]
[1]Dept. of Psychology, Univ. of Jyvaskyla, Jyvaskyla, Finland; [2]Ctr. of Applied Language Studies, Univ. of Jyvaskyla, Jyvaskyla, Finland

Abstract: Phonological processing and speech perception difficulties have been associated with dyslexia, but there is considerable diversity across dyslexics in their cognitive skill profiles (e.g. dyslexics with and without phonological difficulties). While the morphological representations are closely linked to phonological representations and speech perception, it is possible that a subgroup of dyslexics have problems primarily with morphological processing. This study aims to investigate the connection between phonology, morphology and dyslexia in Finnish language by testing pre-school children using magnetoencephalography (MEG). Event-related fields

(ERFs) were measured from 37 pre-school 6.5-7 year-old Finnish children consisting of two groups: 20 typically developing control children without risk and 17 with familial risk for dyslexia. Children were auditorily presented with a morphological task during MEG recording: 108 pairs of sentences, consisting of a verb and its stem with the derivational suffix -jA, which transforms a verb into a noun (Hän johtaa. Hän on johtaja - He leads. He is a leader.). The derivational nouns were also divided into two subcategories, legal and illegal forms. Illegal word forms were the same as legal word forms (johtaja), but with a morpho-phonological change in the last vowel before the derivational suffix (johtija). The morphologically legal and illegal forms produced distinct ERFs for both groups, but the timing of the brain responses and the topography of the brain activation differed between the groups. Right hemispheric activation was more dominant in the control group, whereas bilateral hemispheric activation was observed in the group at-risk for dyslexia. Furthermore, the effect of the morphological manipulation was 250 ms delayed in children at risk for dyslexia compared to the control children. These findings suggest differences in decoding of the morphological information, already before school entry, in children at risk for dyslexia.

Title: Children with Down syndrome anticipate information

Authors: *N. ARIAS-TREJO[1], A. A. ANGULO-CHAVIRA[2], J. B. BARRÓN-MARTÍNEZ[1]
[1]Facultad de Psicología, Lab. de Psicolingüística, UNAM, Mexico City, Mexico; [2]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Under typical development, children and adults employ linguistic information to anticipate information. Whether children and young people with an intellectual disability that impairs language anticipate information based on verbal cues remains unspecified. This research investigates if children and young adults with Down syndrome are able to anticipate information based on the semantic information of verbs. People with this genetic syndrome tend to exhibit problems at producing language; however, their comprehension remains optimal according to their mental age. However, although their comprehension is explored for all grammatical categories when using parental reports, it is generally restricted to the quantification of nouns

when observational or experimental studies are employed. Thus, we employed a preferential-looking study presented by means of an eye-tracker to explore whether beyond problems to produce words, particularly verbs, children and teenagers employ the meaning of verbs to anticipate a target, in the same fashion as typically-developed children do. Therefore, we compared their performance to a control group matched by mental age. In ten trials, the participants saw two images -target and distractor-, while they heard a phrase containing a semantically informative verb (e.g., 'eat') or an uninformative verb (e.g., 'see'). The results showed that the two groups of children, matched for a mean mental age of 5.48 years, were able to anticipate the target upon hearing an informative verb, moreover prediction skills were positively correlated with mental age in those with Down syndrome. As expected, when exposed to uninformative verbs, participants were unable to systematically anticipate a target. This work demonstrates that children and teenagers with Down syndrome are capable of predicting information based on the semantic information of verbal cues. We also show that sentence processing in this population, as in typical development, is driven by predictive relationships between verbs and arguments.

Title: An fMRI study of the cerebellum during reading in children and adults

Authors: *S. ASHBURN[1], L. D. FLOWERS[1], E. M. NAPOLIELLO[1], G. F. EDEN[2]
[2]Ctr. for the Study Learning, [1]Georgetown Univ., Washington, DC

Abstract: It is well established that left inferior frontal, temporo-parietal, and occipito-temporal cortices play a role in reading (Pugh et al., 2001). A meta-analysis of brain imaging studies of reading in adults found convergence of activity in these areas, but also in bilateral cerebellum (Martin et al., 2015). However, the cerebellum was not observed in children, raising the question whether it is specifically involved in experienced adult readers. Here we approached this question by examining *activation* as well as *functional connectivity* (FC) in *typically reading adults* (n=35, age 23.02 ± 3.2). We contrasted an implicit word reading task with a pseudofont control task (Price et al., 1996) and expected the cerebellum (1) to be *active during reading*, and (2) have *functional connections* with those cortical regions known to be involved in reading. We

also compared a subset of these adults (n=20, age 24.61 ± 2.7) with children (n=20, age 9.80 ± 1.9) matched on IQ, and expected *greater activity and FC in adults compared to children*.
First, the *activation* analyses examined (a) whole cerebellum as well as (b) six cerebellum sub-regions (left and right crus I, crus II, and lobule VI; p-FWE < .05, height threshold < .001) using SUIT, within SPM12. Both analyses revealed no cerebellar activation in the full sample of adults. As such it was not surprising that when comparing the subset of adults with the children, there were no between-group difference in either direction (even though, unexpectedly, in children the within-group subregion analysis revealed left lobule VI activation). Since the meta-analysis (Martin et al., 2015) had used low-level baselines, we also compared our reading task with a fixation baseline and again found no between-group differences for either whole or subregion cerebellar analyses.
Second, we performed ROI-to-ROI *generalized psychophysiological interaction FC* analyses with the CONN toolbox in both groups, with the 6 subregions as seeds, and 7 cortical regions known to be active during reading as target ROIs (seed-level corrected p-FDR <.05). In the full sample of adults we found only de-correlation between left crus I and left superior parietal lobule. We found no between-group differences when comparing the subsample of adults with the children (and there was no FC in the group of children).
Overall, our results suggest that in adults the cerebellum is not involved in single word processing and there is no positive FC between the cerebellum and cortical regions known to be involved in reading during word reading. We also found no differences between adults and children, together suggesting that an adult-specific role of the cerebellum for reading is not likely.

Title: Functional MRI of language lateralisation in developmental amnesia

Authors: *S. M. BUCK[1], T. BALDEWEG[2], R. ELWARD[5], D. CARMICHAEL[3], F. VARGHA-KHADEM[4]
[1]Inst. of Child Hlth., London, United Kingdom; [2]Cognitive Neurosci. and Neuropsychiatry,

[3]Developmental Imaging and Biophysics, [4]UCL Inst. of Child Hlth., London, United Kingdom; [5]Cognitive Neurosci. and Neuropsychiatry, UCL Instite of Child Hlth., London, United Kingdom

Abstract: Introduction Evidence suggests that despite their close interaction, the hippocampal network serving cognitive memory, and the neostriatal-prefrontal network serving speech and language are distinct in their functions. A theoretical question is whether early damage to the hippocampus alters not only the fMRI activation of cognitive memory, but also, indirectly, that of the speech and language network. Functional MRI study of patient Jon, who has developmental amnesia (DA) caused by bilateral hippocampal atrophy consequent to neonatal hypoxia-ischaemia, showed that similar to controls, he successfully retrieved autobiographical memories using both medial and lateral brain regions. However, unlike controls who showed left-sided activation, Jon showed bilateral activation of this network which includes several regions involved in speech and language functions (Maguire et al., Brain, 2001). Here, we used fMRI to ascertain the status of language lateralisation for encoding and retrieval of auditory verbal stimuli in patients with DA compared to controls. **Methods** Functional MRI correlates of language lateralisation were acquired on a 3T Siemens system in five patients with DA (n = 5, age range 8-40 years), and healthy controls (n = 27, age range 8 to 18 years). Language lateralisation was assessed through verb generation, where nouns were heard one at a time (one every 4 sec) and participants required to overtly generate a verb for each noun (*e.g.* hear "cake", generate "eat"). **Results** In the controls, block-wise comparisons for the language task demonstrated activations in left Broca's, and Wernicke's areas ($p<0.05$, FWE; Laterality Index Broca's area = 0.79). Consistent with this finding, patients with DA showed activation in left Broca's area, albeit with some weaker activation in the homologous region in the right hemisphere ($p<0.05$). Bilateral representation of language was seen only in one patient. **Discussion** Consistent with the pattern of activation in healthy controls, patients with DA showed left lateralisation of language function, although this was weaker than the activation in healthy controls' left hemisphere. This pattern of results suggests that early bilateral hippocampal damage that reportedly alters the functional organisation of the autobiographical retrieval system, does not substantially modify the lateralisation of the speech and language network, thereby providing further evidence for the distinct functions of the two systems in relation to their neural substrates.

Title: Linguistic skills and brain electrical activity during auditory processing in typically developing children

Authors: *V. V. MORALES- GARCÍA, I. G. GALÁN LÓPEZ
UNAM, Mexico City, Mexico

Abstract: Understanding the neural basis of language processing helps characterize normal functioning in typically developing children and allows early identification of developmental delays.
Only few studies have characterized normal language development by means of the association between linguistic skills and brain electrical activity. The aim of this study was to explore this relationship.
Methods
Sixty healthy Spanish native speakers aged 5-7 living in Mexico City, with Full-Scale IQ scores ranging 80-120 (obtained from WISC-IV) were recruited.
Language skills comprising auditory perception, comprehension, repetition, oral expression and metalinguistic performance, were assessed using "ENI" battery. EEG activity was recorded by 16 electrodes placed according to the International 10-20 system during two conditions: resting state (RS), where children remained calmed for 3 min, and auditory stimulation (AS), composed by 8 blocks of 15 repetitions of the monosyllable /ta/. The FFT was applied on 1s epochs to obtain absolute power (AP) of theta (θ 4-8Hz), alpha (α 8-13Hz), and beta (β 13-30Hz). AP mean of each electrode was compared between the two conditions to measure changes in brain oscillations during AS. To identify hemispheric differences in AP, electrodes were clustered into two regions (left vs right) and the mean was compared. This was done for both conditions. Correlation analysis was made between language skills and the difference in AP obtained when comparing both conditions.
Results
Twelve boys and 8 girls (mean age: 6.35 years) were included.
A significant increase in AP for θ and α bands was seen in almost every electrode site during AS. Concerning β band, only O2 exhibited a significant increase.
Left hemisphere showed significantly greater θ AP in the RS condition. No other significant difference was observed during inter-hemispheric comparison.
Negative correlations were found between θ AP and linguistic skills. Both α and β power exhibited positive correlations between frontocentral regions and language skills.
Conclusion
The absence of significant differences between RS and AS in β band, may be explained by the lack of maturation in children concerning higher frequency bands.
Moreover, the lack of inter-hemispheric difference during AS could indicate these networks are not yet completely specialized.
Negative correlations in θ band suggest lower efficiency in linguistic skills when AP increases. A decrease in slow activity is expected in normal maturation process, however children of this age range still show high values in θ band.
An increase in fast activity was also present and positively related to successful language skill performance.

Title: A novel long noncoding RNA essential for human neural progenitors cells differentiation links two pathways of inherited dyslexia

Authors: *B. PRAJAPATI[1], M. FATIMA[1], M. FATMA[1], R. MIDHA[1], S. DEVASENAPATHY[1], T. NASKAR[1], R. KUMARI[2], M. MUKERJI[2], M. FARUQ[2], N. SINGH[1], P. SETH[1], S. SINHA[1,3]
[1]Natl. Brain Res. Ctr., Gurugram, India; [2]Inst. of Genomics & Integrative Biol., New Delhi, India; [3]All India Inst. of Med. Sci., New Delhi, India

Abstract: Dyslexia is a neurodevelopmental disorder with a strong familial component and complex and heterogeneous inheritance. 38 members of a large, affected multigenerational family from an endogamous group were subject to exome sequencing and validation. We identified the homozygous recessive association of a dinucleotide GT insertion at 5p15, in the 5' overlapping region of two genes transcribed in opposite directions - a novel brain expressed lncRNA LOC285696 (referred as BASP1-AU1) and BASP1. Neuronal differentiation of human Neural Progenitor Cells (hNPCs), resulted in lncRNA and BASP1 showing an initial increase followed by a sharp decline. Knockdown reduced BASP1 RNA and impaired the neural differentiation of hNPCs. BASP1-AU1 RNA, BASP1 gene, and a transcription factor TCF12 formed a molecular complex. TCF12 is located in the DYX1 locus that has been earlier extensively replicated in inherited dyslexia. Knocking down either BASP1 or TCF12 also abrogated hNPC differentiation and affected a set of genes common to BASP1-AU1 knockdown. The functions of the two distinct loci for inherited dyslexia converge during hNPC differentiation via the novel lncRNA and its interacting partners.

Title: Functional connectivity in Portuguese-English bilingual-biliterate adolescents without and with developmental dyslexia: Studying the role of orthographic depth

Authors: *E. BRIGNONI-PEREZ[1], A. FAY[2], N. BIANCHINI[2], A. BUCHWEITZ[2]
[1]Georgetown Univ., Washington, DC; [2]PUCRS, Porto Alegre, Brazil

Abstract: More than half of the world's population is bilingual-biliterate; however, there is a paucity of research on bilingual development, especially on the neural bases of reading, limiting our understanding of the brain's functional organization subserving successful biliteracy. Critically, there has been minimal attempt to extend the findings on the brain bases for word reading in monolingual children with developmental dyslexia (DD) to bilingual children with DD. Reading involves the coordination of numerous neurobiological mechanisms to produce fluent letter-to-sound mapping (or grapheme-to-phoneme conversion, GPC), resulting in accurate and fluent whole word reading. The functional brain system for reading in typical monolinguals, predominantly English speakers, has been exhaustively studied using functional magnetic resonance imaging (fMRI). These studies led to a prominent model that designates left-hemisphere temporo-parietal cortex (TPC) for GPC, occipito-temporal cortex (OTC) for orthographic (letter/word) processing, and inferior frontal cortex (IFC) for semantic and phonological processing. Although seen as the quintessential brain model for reading, it is limited in generalizability to all readers. It has proved to be modulated by multiple factors, including orthographic depth (OD) (i.e., the consistency of GPC). However, the specific effect of OD on brain function in bilingual children without and with DD is unknown. Previous studies have focused on detection of the different activating regions related to the written language's orthographic depth. It is critical, however, to understand how OD modulates the brain system for reading at the network level, since it is a system of intercommunicated regions rather than isolated regions working independently. We tested whether word reading in a semi-deep (Portuguese) versus a deep (English) alphabetic orthography relies on different functional connectivity between Portuguese-English bilingual-biliterate adolescents without (i.e., typically developing, TD) and with DD. Performing a seed-to-voxel approach, we found that word reading in Portuguese relies on greater correlation between regions in OTC and IFC in the TD group, and none in the DD group. Contrastingly, word reading in English relies on greater correlation between regions in OTC and TPC in the TD group, and greater correlation between regions in TPC and IFC in the DD group. Together, to our knowledge, these findings are the first evidence

showing an interaction effect between orthographic depth (semi-deep versus deep) and reading development (typical versus non-typical).

Title: Brain responses to letters and speech sounds and their correlations with cognitive skills related to reading in children

Authors: *W. XU[1,2], S. P. MONTO[1,2], O. B. KOLOZSVÁRI[1,2], J. A. HÄMÄLÄINEN[1,2]

Abstract: Letter-speech sound (LSS) integration is crucial for initial stages of reading acquisition. However, the cortical organization for supporting LSS integration and its relationship with reading skills and cognitive skills underlying reading in early readers remain unclear. In the present study, we measured brain responses to Finnish letters and speech sounds from 29 (6-11 years, mean age 8.17 years, SD: 1.05 years, 19 girls, 10 boys) typically developing Finnish children in a child-friendly audiovisual integration experiment using magnetoencephalography (MEG). Cortically-constrained and depth-weighted L2 minimum-norm estimate (wMNE) was used for the MEG source analysis. Brain source activations in response to auditory, visual and audiovisual stimuli as well as audiovisual integration response were correlated with cognitive skills predictive of reading development and reading skills after controlling for the effect of age. Regression analysis showed that out of all the brain measures, the auditory late response around 400 ms showed the largest association with phonological processing and rapid automatized naming (RAN) abilities. In addition, the audiovisual integration effect, as revealed by cluster-based permutation test, was most pronounced in the left and right temporoparietal regions and the activities in several of these temporoparietal regions correlated with reading and writing skills. Our findings indicated the important role of temporoparietal regions in the early phase of learning to read and their unique contribution to reading skills.

Title: Neurobiological underpinnings of rapid white matter plasticity during intensive reading instruction

Authors: *E. HUBER, J. YEATMAN
Psychology, Univ. of Washington, Seattle, WA

Abstract: Experience can modify the microstructure of the white matter over remarkably short timescales. The majority of past work examining white matter plasticity in humans has relied on metrics derived from diffusion MRI (dMRI) and the diffusion tensor model, which can be influenced by several distinct biological properties of the white matter. Broadly, these properties can be characterized as features of axons, such as their caliber, packing density, coherence, and myelination, or features of the extra-axonal space, such as the number and/or size of glial cells, and constituents of the extracellular matrix. Here we use diffusion kurtosis imaging (DKI; Jensen et al., 2005) and a biophysical model (white matter tract integrity, WMTI; Fieremans et al., 2010, 2011) to test whether microstructural changes during an 8-week, intensive reading intervention are best interpreted as rapid, experience-dependent changes in myelination, or as changes to the extra-axonal space. Behavioral measures and multi-shell dMRI data were collected at regular intervals during the intervention in a group of 32 children, ranging in age from 7-12 years. In the intervention group, but not in a group of age-matched controls, we observed large-scale changes in mean diffusivity throughout a distributed system of white matter tracts. We then examined axon water fraction and the extra-axonal axial and radial diffusivities derived from the WMTI model in the same anatomical pathways. Extra-axonal radial, but not axial, diffusivity was reduced in a large collection of tracts, including but not limited to those considered to be part of the ‘core reading circuitry’ (Vandermosten et al., 2012; Yeatman et al., 2013). AWF remained stable throughout the intervention. Although extra-axonal radial diffusivity can be impacted by myelination, a large change in myelin would also be expected to alter axon water fraction, by reducing the volume of the extra-axonal space. We therefore conclude that the rapid and widespread changes occurring in the white matter during learning are likely to reflect changes in the composition of the extra-axonal space, including changes in the size or distribution of glial cells.

Title: Exploring the link between age-related hearing loss, resting-state network connectivity, and speech comprehension in older adults

Authors: *M. C. FITZHUGH[1], L. C. BAXTER[2], C. ROGALSKY[1]
[1]Speech and Hearing Sci., Arizona State Univ., Tempe, AZ; [2]Neuroimaging Res., Barrow Neurolog. Inst. and St. Joseph's Hosp. and Med. Ctr., Phoenix, AZ

Abstract: As many as one-third of older adults without dementia experience communication difficulties that are not fully explained by hearing loss. Research suggests that as we age, the typical frontotemporal language network may not be sufficient for everyday speech comprehension, thereby requiring additional domain-general resources. The present study uses resting-state fMRI to examine how hearing loss and functional connectivity of domain-general brain networks are related to sentence comprehension in older adults. Twenty participants (60-80 years old, native English-speaking, right-handed, without cognitive impairment) completed a sentence-picture matching task, resting-state fMRI, and pure tone audiometry. The sentences varied by structural complexity (canonical and noncanonical) and background noise (multispeaker babble, broadband noise, and silence). The CONN Toolbox and SPM12 were used to compute 1) average functional connectivity between networks of interest (frontoparietal, salience, default mode, dorsal attention, and language networks) and 2) network functional connectivity correlated with participants' hearing ability. Multiple regression models were used to determine the relationship between functional connectivity measures and sentence comprehension performance in each condition. Age, vocabulary, and processing speed measures were included in the models as covariates. Results include: 1) reaction time to sentences in multispeaker babble was significantly positively correlated with functional connectivity between the portions of the salience and language networks; reaction time for noncanonical sentences was significantly positively correlated with the functional connectivity between the frontoparietal and language networks. 2) Poorer hearing correlated with reduced connectivity between the salience network and portions of the default, dorsal attention, and language networks. These functional connectivity reductions did not significantly predict reaction time in any sentence comprehension condition. These initial results suggest that that increased effort during sentence comprehension (i.e. longer reaction times) in older adults is not explained by network changes related to hearing

loss, but instead may be related to greater network connectivity between the language network and specific domain-general networks. It also is noteworthy that the background noise and structural complexity manipulations of sentence difficulty are differentially taxing the frontoparietal and salience networks.

Title: Aging modulates the effects of cognitive demands on brain-wide network architectures

Authors: *Q. ZHOU, L. LIU, H. LI, Y. ZHANG, C. LU, G. DING
Beijing Normal Univ., Beijing, China

Abstract: **Introduction**: Several studies have shown that aging affects brain-wide network properties at rest (Geerligs et al., 2015) and during cognitive tasks (Sheppard et al., 2011). It is also reported that task-related brain architectures differ from the intrinsic brain architectures in terms of connectivity patterns and network topology (Bolt et al., 2017), suggesting the brain network is modulated by cognitive demands. However, it is still unclear whether and how the modulation of cognitive demands on brain network changes along aging. **Methods**: In the current study, we used functional magnetic resonance imaging (fMRI) technique to record the brain activities when 26 young (12F, age = 20.23) and 25 old (14F, age = 64.20) participants performed a spoken word comprehension task (Task-on), which alternated with a baseline block of passively viewing a scrambled picture (Task-off), and when at rest (resting state). The three different states require decreasing cognitive demands. Brain activation was first analyzed and compared between the two groups. Then graph theoretical analyses were conducted with a whole-brain atlas (Power et al., 2011). Several global metrics (global efficiency, local efficiency, small-world, and modularity) were computed, and repeated-measures ANOVA was performed. We repeated this analysis over a range of sparsity thresholds (from 0.1 to 0.16) and computed the area under the curve (AUC) for each network. **Results**: Behavior results show that young adults have better performance on the spoken word comprehension task than old adults, with higher accuracy and shorter reaction time. Interestingly, brain activation analysis doesn't show any differences between the two groups. However, group differences are found in the graph analysis. To be brief, here we only present the result of the AUC, which is representative of each sparsity. For the global efficiency, we only find a significant main effect of group. While for the other

three indexes, the results show significant main effects of states and group and also the interaction between them. The simple effects analysis of network properties further revealed that young group shows no difference between the task-on and task-off condition, but old group shows significant decline in these three indexes from the task-off state to task-on state. Resting-state network shows a trend that it has higher network properties than the other two states in both groups. **Conclusion**: Our graph theory analysis reveals that the characteristics of whole brain network of older adults change enormously with different cognitive demands while those of young adults could almost keep stable across the three states.

Title: Theta phase sychrony in a spatial cognitive control network

Authors: *L. K. CHINN[1], J. MYERS[2], E. J. GOLOB[2]
[1]Tulane Univ., New Orleans, LA; [2]Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Direct recordings from the anterior cingulate cortex (ACC) in primates suggest that theta oscillations (3-8 Hz) increase power during the control of attention. Measured with EEG in humans, frontal midline theta power also increases during cognitive control, supporting evidence that neurons in this area synchronize during cognitive control. Although the ACC is thought to be a major source of cognitive control in the brain, less is known about how it communicates with other regions on a millisecond basis to form the functional connectivity underlying cognitive control. To address this question, we measured neural coherence (i.e., phase synchrony) during an auditory Simon task where subjects (N = 47) pressed a left or right button in response to sounds on each trial to indicate which of the two possible sounds were presented. On half of trials, the sounds were presented in the earphone ipsilateral to the correct response (i.e., compatible trials). For the other half of trials, the sound was presented contralateral to the correct response, leading to stimulus-response conflict (i.e., incompatible trials). Theta coherence was measured between independent components localized near the ACC, primary motor, and superior parietal lobe in each subject. Results indicated that theta coherence between dorsal and ventral ACC was highest when an incompatible trial was preceded by a compatible trial ($p < 0.001$, $\eta^2 = 0.297$). Compatible-then-incompatible trial sequences have been shown to maximize stimulus-response conflict, thus requiring more cognitive control than other sequence conditions.

During the average behavioral response time (350-550 ms), theta coherence also increased between the dorsal ACC and the primary motor cortex, suggesting that the ACC might communicate conflict information to motor regions in order to avoid errors ($p = 0.008$, $\eta^2 = 0.190$). Coherence between the dorsal ACC and the right superior parietal lobe also maximized for compatible-then-incompatible sequences, but was minimal when both the current and previous trials were compatible ($p = 0.006$, $\eta^2 = 0.176$). Results provide evidence that the ACC is part of a sensorimotor and attentional network that appraises stimulus input to optimize selection of correct behavioral responses during cognitive control.

Title: Phase-locking of neurons in human medial frontal cortex to hippocampal theta is engaged by declarative memory-based decisions

Authors: *J. MINXHA[1], R. ADOLPHS[1], A. MAMELAK[2], U. RUTISHAUSER[3]
[1]Caltech, Pasadena, CA; [2]Cedars Sinai, Los Angeles, CA; [3]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Decision-making relies on the accumulation of evidence in favor of a particular choice. While this process is relatively well understood for perceptual decisions, little is known about decisions that rely on internal representations. Here, we tested two types of decisions that depend on two types of an internal representation: a recognition memory (depends on declarative memory) and a categorization decision (depends on high-level semantic knowledge). We recorded from 360 neurons in amygdala and hippocampus (MTL), and 399 neurons in dorsal anterior cingulate cortex and pre-supplementary motor area (MFC) in nine neurosurgical epilepsy patients. Subjects were shown single images of objects from 4 categories and asked to respond to one of the above two questions (in blocks of 40 trials). In MFC, we identified 78 cells that signaled the choice made (yes or no) only on the memory (n=40/78), the categorization (n=29/78), or both trials (n=9/78), but invariant to the type of choice action (button press or saccade) and not coding motor response (as a control, we also asked subjects to respond with a

button press or a saccade). MFC cells that encoded memory-based choices showed strong modulation of their spike-field coherence with local field potentials in the theta range recorded in the MTL, but only when making a memory-based decision. By contrast, the MFC cells that signaled categorization-based choices showed no modulation of spike-field coherence. Our findings show that (i) there are distinct populations of cells in the MFC encoding recognition memory or categorization based choices, (ii) visually-selective MTL cells are insensitive to such task conditions, and (iii) spike-field coherence between field potentials in the MTL and action potentials in the MFC are enhanced based on task demands and may thus facilitate integration of memory-based information to make decisions. A further lag analysis of spike-field coherence between the two areas revealed that MTL theta leads (i.e. entrains) spiking activity in the MFC. These results support a model according to which memory representations are conveyed from the MTL to the MFC, dynamically routed as a function of the demands of the task, and that specific neuronal populations within the MFC may then abstract category membership from such memory representations.

Title: Neural representation of the target selection “to buy” in the human EEG

Authors: *H. SAWAHATA, Y. NAKAMURA, R. P. HASEGAWA
Human Informatics Res. Inst., AIST, Tsukuba, Japan

Abstract: Neuromarketing is expected to reveal the neural basis of the decision-making processes of consumers that reflect both a conscious and unconscious intentions to purchase products. It is, however, still unclear how such an intention is represented by brain activity. In this study, we used our custom-made BMI system, the Neurocommunicator® to record EEG activities from the normal subjects (n=12) during a cognitive task as a model of shopping behavior in order to explore the neural indicator of the intention to buy. The task was based on the sequential delayed matching-to-sample paradigm, in which the subject looked for one of eight visual stimuli (pictures of products such as chair, cake, dress, etc.). EEG signals were recorded from 8 electrodes around the top of the head (FC1, FC2, C3, Cz, C4, CP1, CP2, and Pz)

while subjects silently counted the times of presentations of the product ('target to buy') that the subjects most wanted to buy out of 8 products in a group. As a control, we also tested the subjects the same task except that the target was the product ('target NOT to buy'), which they never wanted to buy. As the results, we observed the greater event-related potentials (ERPs) responded to the target than that to the nontarget in both 'to buy' and 'NOT to buy' conditions, replicating the previous studies. The magnitude of the response to the 'target to buy' was, however, greater than that to the 'target NOT to buy' especially during the period of 250-550 ms after stimulus onset. Such an enhanced response to the 'target to buy' around the similar period was also observed by the short-time Fourier transformation method. In fact, the power to the 'target to buy' was more increased than that to the 'target NOT to buy' in the low-gamma frequency band (32-48 Hz). These results suggest that strong ERP response and large low-gamma power become a candidate of the neural indicator of the purchasing intention, which could be useful not only for a neuromarketing tool but also an EEG-based shopping aid of patients with severe motor deficits.

Title: Electrophysiological and hemodynamic correlates of self-committed and observed decision monitoring

Authors: *M. PEREIRA, N. FAIVRE, I. ITURRATE, L. SERAFINI, S. MARTIN, A. DESVACHEZ, O. BLANKE, M. WIRTHLIN, D. VAN DE VILLE, J. DEL R. MILLÁN

Abstract: Humans can monitor their own mental lives and build knowledge about themselves. This capacity to introspect and report one's own mental states, or in other words "knowing how much one knows", is termed metacognition. Here, we assessed the contribution of motor signals to metacognition by identifying the behavioral and neural correlates for monitoring self-committed vs. observed decisions. We recruited twenty healthy volunteers for a simultaneous EEG-fMRI experiment, in which they had to decide which of two stimuli contained the more dots by pressing a key (first-order task, active condition), or to observe the computer deciding for them (observation condition). Subsequently, they had to indicate their confidence in the choice made (second-order response). Metacognitive performance, defined as the extent to which confidence tracks first-order performance, was better in the active compared to the observation

condition, indicating that the monitoring of motor actions occurring in the active condition improved the sense of confidence. During the active condition, EEG over the parietal and frontal midline of the scalp predicted confidence as early as 100 ms after the response, while in the observation condition this prediction was shifted in time to around 350 ms after the observation of the response. We then used the single-trial EEG predictions of confidence as parametrical regressors to model the blood-oxygen-level dependent (BOLD) signal. We found that for the active condition, early EEG correlates of confidence (between 50 and 250 ms after the response) were explained by supplementary motor area and inferior frontal gyrus BOLD activations. In both conditions, late EEG correlates (250 to 450 ms) were explained by supplementary motor area and inferior parietal BOLD activations. Interestingly, Fronto-polar (BA10) regions better explained late EEG activity in the active than in the observation condition. Based on these results, we discuss how the computation of confidence may be grounded onto action monitoring, in line with recent theoretical frameworks suggesting that predictions about bodily signals shape cognition.

Title: Neurophysiological underpinnings of the diminished capacity for regulating speed-accuracy tradeoffs in older age

Authors: *J. DULLY[1], G. LOUGHNANE[2], S. KELLY[3], R. G. O'CONNELL[4]
[1]Trinity Col. Inst. of Neurosci., Dublin, Ireland; [2]Trinity Col., Dublin, Ireland; [3]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland; [4]Trinity Col. Dublin, Dublin, Ireland

Abstract: The ability to adjust decision making strategies to account for changing demands for speed versus accuracy is an essential component of adaptive choice behaviour. It has consistently been observed that older adults have diminished flexibility in this regard but it is unclear how this manifests in neural signatures of decision formation. In the present experiment, healthy older adults (65 - 80 years) and younger adults (18 - 35 years) engaged in a two-alternative contrast discrimination task (n = 60), consisting of discrete trials featuring two superimposed

leftward/rightward gratings which gradually changed in relative contrast. Stimuli were presented under two conditions emphasising accuracy versus speed, imposed via verbal instruction to participants as well as feedback in the form of points. Instructions to switch between tasks were given on a block-by-block basis. Continuous 128-channel EEG data were also recorded, to allow for probing of the distinct stages of the sensorimotor hierarchy (sensory encoding, evidence accumulation, and motor preparation). In keeping with the findings of previous studies, older adults were less amenable to speed accuracy manipulations at the behavioural level. Although the age groups were matched for accuracy and reaction time when accuracy was emphasised, the reaction times of older adults were significantly slower than those of younger adults when speed was emphasised and consequently earned fewer points in this regime. Analysis of beta band activity indicated that this effect was at least partly attributable to differences in the adjustments that were made at the level of motor preparation. While young participants exhibited markedly greater motor preparation at trial onset under speed compared to accuracy emphasis, this modulation was less pronounced among the older adults. However, further neurophysiological analyses highlighted a number of additional age-related effects manifesting at other processing levels. Older adults exhibited stronger sensory evidence encoding signals (Steady State Visual Evoked Potentials), with an accordingly faster build-up of evidence accumulation, indexed by the centro-parietal positivity (CPP). These compensatory mechanisms may account for the comparable accuracy across age groups. These results add insight to performance differences between younger and older adults, and contribute to our understanding of the limitations faced by older adults in the domain of decision making.

Title: Cortical electroencephalographic activity in the different phases of decision-making

Authors: *J. P. GARCÍA HERNÁNDEZ[1,2], P. M. CORTES-ESPARZA[2], M. L. RAMÍREZ-RENTERÍA[2], M. A. GUEVARA[2], M. HERNANDEZ-GONZÁLEZ[2]

Abstract: Decision-making has been divided into 3 stages based on distinct functionalities, as follows: 1) forming preferences; 2) executing action(s); and 3) experiencing the outcome. This division also has a basis in the different cerebral structures involved in each stage. Among the

areas involved in the different phases, the parietal and frontopolar cortices participate in evaluating the stimuli and the perception-action cycle that is required to correctly perform decision-making. Against this background, the objective of this study was to characterize the electrical activity of the parietal and frontopolar cortices during the different phases of decision-making. Subjects in this study were 30 healthy, right-handed men aged 20-35. Electroencephalographic activity (EEG) was recorded from the frontopolar (Fp1-Fp2) and parietal (P3-P4) cortices during phases 1, 2 and 3 of a decision-making task. Absolute power (AP) as well as interhemispheric EEG (Fp1-Fp2 and P3-P4) and intrahemispheric EEG (Fp1-P3 and Fp2-P4) correlations were analyzed in the following EEG bands: delta (1-3.5 Hz), theta (4-7.75) Hz), alpha1 (8-10.5 Hz), alpha2 (11-13.5 Hz), beta1 (14-19.5 Hz), beta2 (20-30 Hz) and gamma (31-50 Hz). A lower AP of the alpha1 and alpha2 bands was observed in frontopolar areas during stage 2, whereas during stage 3, a higher AP in the delta and theta bands was obtained with respect to the other two stages. In parietal areas, a higher AP in the slow bands (delta and theta) and a lower AP in the fast bands were obtained in stage 2 compared to stages 1 and 3. During stage 2, the degree of interhemispheric EEG synchronization between areas Fp1-Fp2 showed a lower EEG correlation from the delta to beta1 bands, but a higher correlation in the gamma band, compared to stages 1 and 3. Also in stage 2, a higher correlation from the theta to gamma bands was obtained between areas P3-P4. The intrahemispheric EEG correlation showed a decrease in the delta, beta1, beta2 and gamma bands in stage 2, with respect to the other stages. These EEG data
show that the activation and degree of functional coupling between the parietal and frontopolar cortices change during the decision-making process. Taken together, our findings suggest that frontopolar activity is related to the adequate stimuli-processing phase, while the parietal cortex is involved primarily in the action-execution components of decision-making.

Dublin, Dublin, Ireland

Abstract: Electrophysiological recordings from rodents, monkeys and humans have demonstrated that decisions are formed by accumulating sensory evidence up to an action-triggering bound. Evidence accumulation signals have been identified in several fronto-parietal regions governing visual attention & premotor processes, yet it is unclear how decision-relevant information is efficiently communicated across these separate areas to facilitate speeded perceptual reports. Here, neural metrics of evidence accumulation were isolated in human participants using EEG, and related to both diffusion and resting state (rs)-MRI. The rate of evidence accumulation mediated the relationship between white matter structural organisation of the dorsal branch of the superior longitudinal fasciculus (projecting to the dorsal attention network; DAN), and the speed of perceptual reports. rs-MRI analyses confirmed that faster rates of evidence accumulation were related to stronger premotor-DAN connectivity. These results demonstrate that connectivity within the DAN influences interindividual variability in the rate of human evidence accumulation.

Title: Neural responses to heartbeats impact value encoding in subjective, preference-based decision-making in ventro-medial prefrontal cortex

Authors: *D. C. AZZALINI, S. PALMINTERI, C. TALLON-BAUDRY
Dept. d'études cognitives, Lab. de Neurosciences Cognitives, École Normale Supérieure, Paris, France

Abstract: Preference-based decisions rely on subjective values: whether you prefer wine or beer is solely determined by your own experience, and this preference is only accessible to you. In the field of decision-making, the subjective status of preferences has not been highlighted thus far. On the other hand, subjectivity has been a long-standing issue in consciousness research. Neural responses to heartbeats (aka heartbeat evoked responses) have been recently proposed as a candidate mechanism to generate a self-centered reference frame to which subjective processes would be bound. Here, we tested whether neural responses to heartbeats distinguish decisions that are based on internally generated evidence - hence self-centered - from those based on external evidence.
21 healthy human participants performed preference-based and perceptual choices on pairs of movie titles while their brain and cardiac activities were recorded with magneto-encephalography (MEG) and electrocardiography (ECG), respectively. The type of decision to be performed was indicated at the beginning of each trial by a geometrical cue (a square or a diamond) presented on the screen for a fixed delay of 1.5 s. After the cue, two movie titles of slightly different luminance were displayed on a light gray background. In preference-based choices, subjects had to indicate which movie they liked more, whereas in perceptual choices, which title looked darker. After response and a variable delay, the next trial began. The exact same pairs of titles were presented twice, once per decision type.
Our results show that, during cue presentation (hence, before options are displayed), neural responses to heartbeats in the rostral part of vmPFC are larger when subjects have to prepare for preference judgment as compared to perceptual choice. During option presentation, the chosen value in preference decisions is encoded in caudal vmPFC, in agreement with the fMRI literature. Our analyses further reveal that value encoding in caudal vmPFC is enhanced for trials in which neural responses to heartbeats during task preparation are larger. On the contrary, in perceptual decisions, the luminance value of the chosen title is encoded in a posterior network of brain regions, and is not modulated by the amplitude of neural responses to heartbeats.
We thus show here that preparing for a preference-based judgment enhances responses to heartbeats in (rostral) vmPFC, and that those responses to heartbeats modulate the strength of subsequent subjective value encoding in (caudal) vmPFC.

Title: STN-DBS, not L-DOPA, restores the contextual regulation of perceptual decisions

Authors: *L. J. RONDOT[1], M. ULLA[2,3], V. WYART[4], J.-J. LEMAIRE[2,5], J.-C. DREHER[6], F. DURIF[2], P. DOMENECH[1,7]

Cognitives Marc Jeannerod, CNRS, Bron, France; [7]DHU PePSY, Dept. of Functional Neurosurg. and Psychiatry, Henri Mondor Hosp. (AP-HP), Créteil, France

Abstract: Perceptual decision-making can be described as a process by which sensory evidence is accumulated until a decision threshold (DT) is reached. This DT is adaptively tuned to its context, such as the probabilistic regularities of the environment. Here, we consider two types of contextual information: (1) the predictive information (PI), which is the log probability ratio of an event occurring given a previous event, relative to its frequency and (2) the contextual uncertainty (CU) which is the prior entropy over an events' occurrence given a previous event. This study aims at specifying how patients suffering from Parkinson's disorder (PD patients) adjust their DT to contextual information compared to healthy matched controls (HC) and how does levodopa (L-DOPA) treatment affect this adjustment compared to deep-brain stimulation of the subthalamic nucleus (STN-DBS).
14 PD patients performed a simple perceptual decision making task under 4 pseudo-randomly ordered conditions: ON or OFF L-DOPA treatment and ON or OFF STN-DBS. 31 HC subjects also performed the task once. In the task, the subjects pressed a button to match the shape presented on screen. Transitions between shapes were controlled to systematically manipulate contextual information. The electroencephalography of patients was also recorded in each condition.
L-DOPA reduced both PD patient's RTs (F (11) = 129.73, $p < .0001$) and performance (F (11) = 7574.2, $p < .0001$), suggesting a shift in the speed-accuracy trade-off. This deleterious effect was significantly limited with STN-DBS, both in RTs (F (11) = 101.75, $p < .0001$) and performances (F (11) = 8201.5, $p < .0001$). RTs in HC decreased with PI (Z = 4.076, $p < .0001$) and increased with CU (Z = - 4.292, $p < .0001$). There was no significant effect of PI nor of CU on RTs of untreated patients. The effects of both PI (Z = 2.746, p = .006) and CU (Z = - 2.275 ; p = .023) on RTs was restored when patients were OFF L-DOPA + ON STN-DBS and there was no significant difference in the effects compared to HCs.
These preliminary behavioural results suggest that L-DOPA treatment has a deleterious effect on simple perceptual decisions causing a shift of the speed-accuracy trade-off toward impulsivity, which is somewhat rectified by STN-DBS. Moreover, the use of contextual information (both PI and CU) is deteriorated in untreated PD patients but this impairment is fully rectified through STN-DBS, but not L-DOPA.

Title: Insula processes salience prediction error for primary reinforcers

Authors: *J.-C. KIM, L. HELLRUNG, M. GRÜSCHOW, E. KAPETANIOU, A. BAGAINI, D. HINZ, P. N. TOBLER
Univ. of Zurich, Zurich, Switzerland

Abstract: Salience guides attention and accelerates behavior. In a formal definition of salience as absolute value, salience increases both when reward or punishment surprisingly occur and when they surprisingly fail to occur. Thus, even though reward occurrence and punishment absence have positive value whereas reward absence and punishment occurrence have negative value, all four outcome types commonly have higher salience than the occurrence or absence of a neutral event. In this study, we designed a novel task that controlled for the absolute value of primary reward and punishment in the form of appetitive and aversive liquids and investigated salience processing in the fMRI scanner. We individualized the liquid types and concentrations to each of the 50 participants' tastes. For example, we used fruit juices and milk drinks as rewards, saline and bitter solutions (PROP) as punishments. Distilled water with the main ionic components of saliva served as neutral liquid. Each participant performed a calibration session during which we individualized appetitive and aversive liquids and two fMRI sessions for the main task. Before starting the main task, participants learned to associate three distinct visual cues with one of three different liquids (appetitive, aversive, or neutral). For each of the three cues, liquid delivery occurred at p=0.5. In the main task, each trial started with the presentation of a visual cue. After a variable delay (mean 1.5 s), the fixation cross changed color, the participants received liquid or no liquid and rated the outcome. The absolute value of reward did not differ significantly from that of punishment ($t=1.8277$, $p=0.1182$) but was higher than that of the neutral liquid (appetitive: $t=3.2020$, $p=0.0116$; aversive: $t=2.1291$, $p=0.0773$). Preliminary analyses at the neural level suggest that the surprising absence of both appetitive and aversive liquids activated the left insula and the amygdala more than the surprising absence of neutral liquid ($p<0.001$, uncorrected). Moreover, the left insula (and to a lesser degree the amygdala) also showed stronger activation to the surprising delivery of appetitive and aversive liquids compared to neutral liquids. These data suggest that the insula processes a salience prediction error.

Title: Predictive coding depends on causal inference and NMDA receptor-mediated feedback in the brain

Authors: ***S. MOHANTA**[1], D. POLYAKOV[2], M. J. REDINBAUGH[3], N. A. KAMBI[3], J. M. PHILLIPS[3], S. TANABE[2], W. FILBEY[2], J. KILDOW[2], S. TWADELL[2], J. L. AUSTERWEIL[3], R. D. SANDERS[2], Y. B. SAALMANN[3]
[2]Anesthesiol., [3]Psychology, [1]Univ. of Wisconsin, Madison, Madison, WI

Abstract: Predictive coding is the ability to make predictions about upcoming events in our sensory environment based on prior experience, allowing efficient processing of sensory input. According to this framework, predictions are sent from higher-order to sensory cortex along feedback pathways. Such feedback is often associated with neural processing in alpha/low beta frequencies. Recent evidence suggests that feedback also involves NMDA receptors. However, it is unclear if these neural mechanisms contribute to predictions.
To test mechanisms of predictive coding, we used an audio-visual learned-association task, in which subjects (n=25; 13 female) indicated whether the initial sound and subsequent image matched. Importantly, we manipulated subjects' predictions by varying the probability of an image appearing after its associated sound. We conducted a hierarchical drift-diffusion analysis of subjects' reaction times, in which the drift rate and bias depended on the evidence for a causal relation. To investigate the underlying neural processes, we recorded EEG signals using a 256-channel array. We also aimed to pharmacologically manipulate predictions, by administering sub-anesthetic doses of ketamine, an NMDA receptor blocker, or dexmedetomidine, an α2-adrenergic receptor agonist.
Subjects' reaction times were faster when sounds had greater predictive value in the audio-visual task. The hierarchical drift-diffusion analysis shows that causal inference (which accounts for how often a particular image follows its associated sound, and how often that image follows other sounds) predicted reaction times better than transitional probabilities (how often a particular image follows its associated sound only). During the delay period, prior to image

onset, occipital alpha power correlated with predictions.
Preliminary pharmacology results suggest that ketamine, but not dexmedetomidine, blocks predictions: predictive value did not influence reaction times. When we incorporated these pharmacological interventions into the drift-diffusion model, causal inference failed to predict reaction times for ketamine; but causal inference could predict reaction times for the control, dexmedetomidine. Ketamine also reduced prediction-correlated delay period alpha power in occipital electrodes.
Taken together, this suggests that predictions depend on causal inference, and not just transitional probabilities. Because NMDA receptors have been reported to contribute to feedback processes, our data are consistent with a role for NMDA
receptor-mediated feedback from higher-order to sensory cortex as a key mechanism enabling predictive coding.

Title: Examining the interaction between striatal dopamine and externalizing behaviors on prediction errors during decision making

Authors: *E. A. NEWELL, K. A. BYRNE
Clemson Univ., Clemson, SC

Abstract: Externalizing behaviors affect between 8-9% of Americans annually (Insel & Fenton, 2005). Two externalizing behaviors that share a common heritable liability are disinhibition and substance abuse (Krueger & Markon, 2006). Prior research suggests that genetic variation in striatal dopaminergic function contributes to general proneness to externalizing problems (e.g., Derringer et al., 2010; Krueger & Markon, 2006). Moreover, striatal tonic dopamine levels also affect phasic reward prediction error dopamine responses, which is critical to reward learning and decision-making (Cools & D'Esposito, 2011; Evers et al., 2016). Thus, dopaminergic variation is independently associated with both a general liability for externalizing behaviors and reward prediction errors. However, it is unclear how variation in striatal dopamine modulates the

relationship between externalizing behaviors and reward prediction errors during decision-making. This study investigated the interaction between striatal dopamine and externalizing behaviors on prediction errors during decision making. Participants (*N*=104) self-reported problematic substance use and disinhibition behaviors using the Externalizing Spectrum Inventory Brief Form (Patrick et al., 2013). Participants then performed a novel four-choice reward-based decision-making task in which they chose an option, estimated their expected reward, and then received feedback on the reward amount they actually earned. Striatal tonic dopamine levels were operationalized using spontaneous eye blink rate. The outcome measure, prediction errors, was computed as the average difference between the reward estimated and the reward received. Hierarchical regression results revealed main effects of substance abuse and striatal dopamine in which high striatal dopamine and higher levels of problematic substance use predicted larger magnitude negative prediction errors, and thus an overestimation of expected rewards. A significant interaction between striatal dopamine and disinhibition was also observed in which more impulsive individuals with high levels of striatal dopamine made more negative prediction errors. This suggests that variation in striatal tonic dopamine modulates the effect of disinhibitory tendencies on decision-making, which is consistent with previous work in our lab (Byrne et al., 2016). These findings underscore the importance of considering individual differences in dopaminergic functioning to determine cognitive correlates of externalizing proneness.

Title: Does dopamine modulate the willingness to exert cognitive control?

Authors: *L. HOFMANS[1,2], D. PAPADOPETRAKI[1,2], R. VAN DEN BOSCH[1,2], J. I. M. MÄÄTTÄ[1,2], B. I. H. M. LAMBREGTS[1], A. WESTBROOK[1,2,3], R. COOLS[1,2]

Abstract: Brain dopamine has long been implicated in working memory and cognitive control (Sawaguchi et al., 1991; Cohen et al., 2002). Moreover, dopamine is important for motivation

and decision making, as evidenced by effects of dopaminergic drugs on physical effort-based decision making (Treadway et al., 2009; Salamone et al., 2016). We aim to integrate these lines of evidence and ask whether dopamine also plays a role in cost-benefit decision making about cognitive control. To address this question, we combined PET, psychopharmacology and a cognitive effort-discounting choice procedure with a classic delayed response task of working memory. In this placebo-controlled, double-blind, cross-over design, 50 healthy participants (25 females) completed a working memory task as well as a subsequent preference task on 3 sessions: once after intake of placebo, once after a low oral dose (20mg) of the catecholamine reuptake blocker methylphenidate and once after intake of a low oral dose (400mg) of the selective dopamine receptor antagonist sulpiride. All participants also underwent an [^{18}F]DOPA PET scan to quantify their baseline dopamine synthesis capacity. This allowed us to ask whether their willingness to perform a cognitive task for reward varies with (i) individual differences in striatal dopamine synthesis capacity and (ii) dopaminergic drug administration, perhaps interacting with baseline synthesis capacity. Analyses of blinded data, collapsed across all three sessions, do not demonstrate a relationship between individual variation in dopamine levels and willingness to perform the task. However, preliminary exploratory analyses revealed an interesting pattern of results as a function of session, with willingness to perform the task declining with session, despite, if anything, increases in performance. Critically, dopamine synthesis capacity predicted the degree to which willingness to perform the task decreased from the first to the last session. Participants with higher levels of dopamine synthesis capacity exhibited a greater reduction in willingness to perform the task across sessions than did low dopamine participants, supporting a role for dopamine in cognitive effort-based decision-making (Froböse et al., 2017). We will further investigate these preliminary between-subject effects of dopamine by examining the within-subject drug effects on willingness to perform the task, as a function of baseline dopamine synthesis capacity.

Title: Corticostriatal representation of information value during ambiguous decision-making

Authors: *U. R. KARMARKAR[1,2], S. YE[3], V. RIMEIKYTE[4], E. KASTMAN[5], J. W. BUCKHOLTZ[6]

[1]Rady Sch. of Mgmt., LA Jolla, CA; [2]Sch. of Global Policy and Strategy, UCSD, La Jolla, CA; [3]Harvard Business Sch., Cambridge, MA; [4]Human Develop., Cornell Univ., Ithaca, NY; [5]Harvard Univ., Boston, MA; [6]Harvard Univ., Cambridge, MA

Abstract: The economic definition of ambiguity refers to uncertain situations in which both the outcomes, and the probabilities of the outcomes are unknown. Thus people have to make choices with incomplete information, which is generally found to be aversive, and to have negative effects on decision-making. In this work, we focus on how people use the partial information they do have. In particular, we examine how incremental information that is favorable or unfavorable to a desired outcome influences valuation of an ambiguous financial prospect and how this information is represented in the brain. We collected behavioral and fMRI data from 34 participants who received varying levels of valenced information about financial gambles. In this "Pro/Con" task, participants indicated their willingness to purchase fixed-price tickets for several independent gambles, each representing a poker chip being randomly drawn from a bag of exactly 100 red and blue chips. The underlying composition of the bag differed on each trial, and participants were given partial information about the amount of red chips and blue chips it contained. (The number of chips remaining unidentified was also indicated.) A red chip draw resulted in a monetary payout; a blue chip resulted in no payout. Thus the number of red chips revealed represented the amount of favorable information while the number of blue chips revealed represented the amount of unfavorable information. Both types of information were parametrically varied between 0 and 50. Behaviorally, increasing the amount of information revealed (regardless of valence) increases participants' willingness to engage in the gamble. In addition, we find an asymmetric influence of favorable over unfavorable information on willingness to purchase, replicating our prior research. Whole brain analyses reveal that activity in dlPFC, IFG, striatum, and areas in OFC significantly correlate with the amount of information (favorable+unfavorable) revealed. However, when considering the relative representation of favorable and unfavorable information, striatal activity was more strongly correlated with increasing amounts of unfavorable information. By contrast, OFC and dlPFC activity varied more according to the degree of favorable information. Collectively we find that under ambiguity, the amount of information that is available is tracked by reward-related circuitry, and there are differences in this representation for favorable and unfavorable information.

Abstract: Serotonin signaling is implicated in major psychiatric disorders such as depression, anxiety disorders, and anorexia. It is also thought to play a major role in decision-making in the healthy, yet its computational roles remain murky. To delineate this further, we have modified cyclic voltammetry techniques for use in human subjects undergoing electrode implantation surgery for deep brain stimulation treatment for Parkinson's disease or essential tremor (Kishida et al., 2016; Moran et al., 2018). These voltammetry measurements, taken while subjects carry out simple economic games, allow the detection of sub-second dopamine and serotonin signals related to computational variables defined by the tasks. Here we extend these results to serotonin signaling in humans engaged in active social exchange. Specifically, we examine serotonin signaling while subjects played a well-characterized multi-round trust task (N= 20; see Hula et al., 2018). We model subjects' behavior using an interactive partially observable Markov decision problem framework (iPOMDP; Hula et al., 2018) and derive a first-order inter-personal prediction error: the ongoing difference between a partner's action and what this action was expected to be. Serotonin fluctuations at the revelation of the partner's action are negative for positive first-order errors and positive for negative first order errors; thus, even in this complex, socially-defined, exchange, serotonin is apparently opponent to dopamine, which typically reports prediction errors with the opposite (i.e., normal) sign. These results suggest that the idea that serotonin is an opponent to dopamine can be extended in a principled computational way to social situations.

Title: The relative frequency of neuronal perikaryal sizes differentiates five classes in higher-order nuclei of the human thalamus

Authors: *E. ARMSTRONG, G. KAHVECI, S. LAGO, J. LENCHNER, M. ROBINSON, E. SEVER
Lake Erie Col. of Osteo. Med., Greensburg, PA

Abstract: The relative frequencies of neuronal perikaryal sizes were analyzed in different human thalamic nuclei. The data are from a normal human brain that is part of the Yakovlev Collection. Neurons were identified by their full, round nucleoli and an eye-piece micrometer measured two axes, the longest and the second at right angles to that. It is assumed that shrinkage is common throughout the thalamus and measurements were made systematically in all three dimensions of the nuclei. Although exact functional associations of soma size are not known, size is thought to reflect attributes of how information is delivered rather than of content.
Higher-order thalamic nuclei; the pulvinar (N=422), the lateral posterior nucleus (N=85), and the medial dorsal nucleus (N=242), were characterized by having a population of small neurons (400-1200 μm^3) and a larger range of intermediate sized neurons (2000-6000 μm^3). There was a scattering of a few larger perikarya in all these nuclei (>5800 μm^3). All higher-order nuclei had very few neurons in the size range (1200-2000 μm^3). The intermediate cell groups formed four distinct local maxima that overlapped each other, suggesting a concurrence of modulating properties for corticothalamic afferents. Despite their different content, each peak may form a single class. The limbic nuclei, anterior principalis (N= 70) and lateral dorsalis (N=46), resembled higher-order nuclei in having few neurons in the 1200-2000 μm^3 range, but differed, by having a single peak of intermediate sized soma.
Sensory nuclei showed a different distribution. Intermediate sized neurons in the ventroposterior lateral and medial nuclei (VPL+M; N=238) had a unimodal distribution, resembling those of motor nuclei, ventrolateral oralis (N=85) and ventrolateral caudalis and medialis (N=283), but differ in having large neurons as well. Distributions in both geniculate bodies (LGBm N=72, LGBp N=155; MGBm N=31, MGBp N=150) had local maxima and minima with little overlap, suggesting that geniculate neurons modulate according to local demands and do not form a single class.

Title: Alpha-band phase coherence modulation at right fronto-central region reflects a sustained proactive control mechanism involved in a stop-signal task

Authors: *W. LEE, E. JEONG, M.-S. KANG
Psychology, Sungkyunkwan Univ., SEOUL, Korea, Republic of

Abstract: Proactive control mechanism reflects a sustained, top-down maintenance of a goal representation in advance of task-related events while reactive control mechanism reflects a transient, bottom-up goal reactivation in response to task-related events (Braver, 2012). We designed a manual stop-signal task to isolate neural representations specifically involved in proactive control mechanism. Subjects performed a choice reaction time task but had to withhold their response to an infrequent stop-signal. We manipulated stop-signal probability (30% vs 10%) over different blocks of trials so that different proactive control levels were sustained within each block. In addition, we obtained EEG responses locked with the fixation onset to isolate neural representations of proactive control mechanisms because the fixation is uninformative to subsequent events and, thus, neural responses accompanied with the fixation onset reflect the cognitive state sustained throughout each block.

26 subjects' data (12 female, mean age 23.5) were analyzed. Reaction times (RTs) increased and erroneous responses after the stop-signal decreased with stop-signal probability, indicating that subjects changed their behavioral strategy proactively. When we analyzed the trials without stop signals in conjunction with a non-parametric permutation test and cluster-based correction, a significantly higher alpha-band inter-trial phase coherence (ITPC) modulation was identified at the right fronto-central electrode (FC6) within 400 to 800 ms after the fixation point from the 30% stop-signal block in relative to 10% block. We then conducted an inter-site phase clustering (ISPC) analysis by using the FC6 signal as a seed because previous studies have shown that frontal cognitive control mechanism impacted the target processing by modulating neural responses at the posterior and occipital areas (e.g. Zanto & Gazzaley, 2011). We found a significant theta-band ISPC modulation from occipital areas (O1 and Oz) prior to the target onset. To see whether this ISPC modulation at occipital electrodes does impact visual processing, we obtained target-locked ERPs and found a significant posterior N2 modulation between the two probability blocks. Taken together, we concluded that right fronto-central area plays an important role in adaptive behavior in advance of task-related events.

Title: EEG gamma activity is altered in working memory during test recall

Authors: J. G. FOY, S. M. MCQUADE, L. M. KEARNS, C. DE PIEROLA, *M. R. FOY
Dept. of Psychology, Loyola Marymount Univ., Los Angeles, CA

Abstract: An electroencephalogram (EEG) measures changes in brain electrical activity, with wireless EEG systems being particularly useful in establishing high ecological validity. In the current study, we identified EEG activity changes while participants completed a series of standardized and challenging performance-based cognitive tasks (NIH Toolbox). Wireless EEG scalp recordings (B-Alert x10 Headset, Advanced Brain Monitoring) corresponding to a wide spectrum of signal frequencies (alpha, beta, delta, gamma, sigma, theta) were recorded from 29 undergraduate participants during 1.5 hr recording sessions. Power spectral densities (PSD) were computed following artifact decontamination and data smoothing (AcqKnowledge 4.4; B-Alert Software, Biopac). Here we report the results of gamma frequency band (25-40 Hz) PSD during

an episodic working memory task (Picture Sequence Memory Test, NIH Toolbox). Gamma activity was obtained in 1 sec epochs during memory practice vs. memory task phases at 9 electrode sites (Pz, Fz, Cz, P3, P4, F3, F4, C3, C4). A repeated measures ANOVA revealed statistically significant ($p<.001$) main effects of phase and electrode site. Post-hoc tests revealed significantly increased gamma PSD during the memory task phase compared to memory practice phase at all of the electrode sites. Gamma PSD was also found to be highest at right frontal (F4) and right central (C4) electrode sites compared to all other electrode locations for both phases of the study. Our results confirm prior research that associates gamma activity with attention and memory demands. Also, our results show that increased gamma activity during the cognitive task is distributed across all electrode sites from which recordings were obtained, with highest activity recorded in right hemisphere.

Title: Dissociable roles for theta and beta frequency neural oscillations in cognitive control

Authors: *D. A. VOGELSANG[1,2], J. RIDDLE[2], K. HWANG[2], D. CELLIER[2], M. D'ESPOSITO[2]
[1]Dept. of Neurosci., D'Esposito Lab., Berkeley, CA; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Cognitive control is the ability to organize thoughts and actions according to internal goals. Mechanisms of cognitive control can be revealed by manipulating the rules subjects use to evaluate a stimulus and make an appropriate response. This type of rule learning requires flexible cognitive control, which relies on being able to execute simple concrete rules as well as more complex abstract rules. For example, a simple concrete rule is one that explicitly maps a stimulus to a response, whereas a more complex abstract rule is one where the stimulus response mapping depends on contextual factors. Cognitive control also relies on the ability to hold a number of these rules in mind simultaneously. Therefore, in addition to varying the level of abstraction, the number of rules can be increased within a single level of abstraction (set size). Previous research has found that both neuronal oscillations in theta (Voytek et al. 2015) and beta (Wutz et al. 2018)

frequencies are associated with various types of top-down cognitive control, however whether these two frequency bands play a similar or distinct roles in cognitive control remains unknown. The current EEG experiment (n=31) investigated whether the level of abstraction of a rule, and number of rules that must be maintained, are supported by neuronal oscillations in different frequency bands. Results of the time-frequency analysis in frontal electrodes showed an increase in theta power for increased set size that positively correlated with changes in reaction time, whereas a decrease in beta power was associated with increased abstraction and negatively correlated with reaction time. Our results suggest that there are distinct neural oscillatory mechanisms that underlie different aspects of top-down cognitive control. <!--EndFragment-->

Title: No-go specific EEG activities during response inhibition training associated specifically with subsequent chocolate eating behavior

Authors: *K. YAMANAKA
Showa Women's Univ., Tokyo, Japan

Abstract: Previous studies suggested that training to inhibit food-related responses has a potential to help modulate excessive or impulsive eating behavior. However, there are considerable inter-individual differences and food-specificity in the effectiveness of the response inhibition training. It’s partly due to a large variety of their approach to the response inhibition training and/or property of the target food. Therefore, we investigated the relationship between cortical activities during the training and subsequent food consumption of different target food. For the response inhibition training, we used a go/no-go task, in which go or no-go signal was simultaneously presented with one of the images of chocolate, manju (Japanese sweets), sio-sembei (Japanese salty snack) on the plate, or empty plate. In this study, participants were assigned to chocolate-no-go condition (n = 12) or manju-no-go condition (n = 10), in which no-go signal consistently presented with the chocolate or manju image. Before the training, an eating-related questionnaire (Dutch Eating Behavior Questionnaire: DEBQ) and subjective assessment of appetite and preference for the 3 types of foods used in this study (visual-analog

scale: VAS) were conducted. During the training, surface electroencephalogram (EEG) was recorded and traditional event-related potential (ERP) waveforms were calculated. After the training, participant was instructed to eat the 3 types of foods as she would like in a sham taste test. And finally, the number of pieces they ate was calculated for each food separately and for all 3 foods together. As a results, there was no significant difference in DEBQ score, VAS scores, and food consumption between chocolate-no-go and manju-no-go conditions. However, in both condition, manju and sio-sembei consumption positively correlate, but chocolate consumption does not correlate, with total consumption, suggesting a chocolate-specific eating behavior. Moreover, in chocolate-no-go condition, amplitude of negative ERP peak (N2) in no-go trials, which reflect response inhibition, significantly correlate with amount of chocolate intake. On the other hand, in manju-no-go condition, there was no significant correlation between amplitude of no-go N2 and manju intake. These results indicate that 1) the participants who inhibit a chocolate-related response more strongly in no-go trials eat less chocolate, and that 2) the food-related response inhibition training has an effect specific for chocolate eating behavior.

Title: The strategy in the brain: The micro-structural correlations predict the hyper-direct pathway and ‘hub’ in the reactive inhibition

Authors: *F. ZHANG[1,2], S. IWAKI[1,2]
[1]Natl. Inst. of Advanced Industrial Sci., Tsukuba, Japan; [2]Univ. of Tsukuba, Tsukuba, Japan

Abstract: A open question in the brain research is how the structural networks influence the functional interactions.The research in reactive inhibition, which triggered by the stop signal, has provided the detailed information of underlying neural system. The stop signal is received and processed by frontal cortical regions, then the command is sent to the basal ganglia to prepare or inhibit the response. Furthermore, there are increasing evidences that the hyper-direct pathway(cortico-subthalamonigral) , which is critical in quickly response inhibition by bypassing the striatum and connecting the cortex and subthalamic nucleus directly, is involved in the motion information processing. In our research, we investigated the inter-tract correlation of fractional anisotropy(FA) between cognitive control network including inferior frontal cortex(IFG), presupplementary motor area (preSMA) / supplementary motor area (SMA),

putamen, Thalamus, primary motor cortex (M1) and subthalamic nucleus, and found the involvement of hype-rdirect pathway. Furthermore, we also combined micro-structural correlation with the effective connectivity of cognitive control network, and confirmed the existence of hyper-direct pathway in both structural and functional connectivity. Meanwhile, we also proved the basal ganglia as a 'hub'in the cognitive control network. Taken together, our research provided the new perspective to investigate the influence of structure network on functional interactions, and how the function emerges from structural network in reactive inhibition.

Title: Neural oscillatory correlates of effort based influences on proactive inhibition

Authors: *T. TSUCHIYA[1], J. M. FINE[2], M. SANTELLO[2]
[2]SBHSE, [1]Arizona State Univ., Tempe, AZ

Abstract: Research on reinforcement-based decisions presumes that the option with the highest expected value is chosen. Furthermore, when deciding between two options with similar reward, there is typically a preference towards action with the least effort cost. There are also scenarios where one must choose between engaging (Go) in an action with some probability of reward and abstaining (No-Go) from action and without reward. Given a fixed reward, one would anticipate that increasing effort would increase inhibition over 'Go' decisions as this alone incurs a physical cost. However, the behavioral and neurophysiological indices related to effort-based choices of action engagement (Go/No-Go) remain unknown. The current study aimed to fill this gap by examining behavioral responses and EEG-based oscillatory activity while human subjects (n=13) performed a novel anticipatory stopping task. Subjects used a robotic manipulandum to perform reaching movement and hit a target location if they believed it was a Go trial. Endpoint movement occurred simultaneously with a moving bar to gain reward. In all trials, the moving bar was displayed as a specific color that was linked to the bar's probability of stopping (Pstop: 0.15, 0.4, 0.6, and 0.85) before the target. Both correct Go and No-Go responses were rewarded. In Go trials, subjects took 700 ms to reach the target. In Stop trials, the bar stopped at 475 ms. In the first block of trials, subjects' proportion of 'Go' responses matched the probability of the 'Go' cue. In the second block, we used a novel effort manipulation (3 effort levels) by implementing a velocity-dependent force field. In this effort manipulation block, we found an asymmetric effect of effort wherein the proportion of Go responses increased and decreased in trials with high and low Go probability, respectively. When comparing probability of responding in block 1 vs block 2 (with effort), higher Go probability trials (Pstop: 0.15 and 0.4) revealed larger tendencies to Go despite a higher effort in block 2, rather than decreasing these responses. This indicates that effort did not have the anticipated effect of globally decreasing Go responses, but rather increased the tendency to Go when Pstop was low and decreased it when Pstop was high. Our EEG results examined during response preparation revealed medial frontal (MF) theta power increased with Pstop (blocks 1 and 2), while MF alpha power increased by the inclusion of effort (block 2) independent of Pstop. These findings extend previous work by revealing that separate MF frequencies may represent distinct variables impinging on decision making and response inhibition.

Title: EEG signature of instructed sensory-motor mapping implementation

Authors: *M. SENOUSSI, D. TALSMA, T. VERGUTS
Exptl. Psychology, Ghent Univ., Gent, Belgium

Abstract: Humans can create arbitrary associations between stimuli and actions (sensory-motor mappings). These mappings allow us to flexibly implement complex behavior depending on context or instructions. On short time scales these mappings cannot be subtended by structural changes in neural networks, but must instead be created through functional networks built on the fly. In this study we investigated the electrophysiological signature of preparing sensory-motor mappings instructed on a trial-by-trial basis. We recorded EEG with 64 electrodes while participants prepared instructed sensory-motor mappings to perform a 2-Alternative Forced Choice orientation discrimination task on one of two gratings using either their left or right hand (depending on the instruction). Each trial started with instructions in the form of two letters, one above and one below the fixation cross. These letters were either 'L' (for Left) or 'R' (for Right) and instructed participants which grating was the target (letter above the fixation cross), and which hand to use to report the tilt direction (letter below the fixation cross). Instructions were followed by a variable-duration interval (1700-2200ms) to prepare the instructed mapping. Then two gratings were presented, one on each side of the fixation cross. Tilt level was titrated to reach ~75% accuracy for each participant before the experiment. To uncover neural activity selective to the preparation of the different sensory-motor mappings we used a Linear Discriminant Analysis classifier based on spatial patterns of EEG activity. As inputs to the classifier we used either scalp potentials (for each time point and electrode) or spectral amplitude (for each time point, oscillatory frequency, and electrode). Using scalp potentials we were able to classify the mapping during the preparation interval. Classification accuracy reached 45% (chance level 25%) and was sustained above chance level between 170ms to 950ms. Classification on spectral amplitudes revealed selective classification accuracy up to 52% between 600ms and 1500ms in alpha (8-12hz) and beta (13-30hz) frequencies. This demonstrates that sensory-motor mapping information is present in the EEG signal extremely rapidly and before stimulus onset.

Abstract: Inhibitory control over impending or ongoing actions is essential for success in activities of daily living. Response inhibition has been studied extensively using the 'stop signal task' (SST) where subjects cancel actions in response to an infrequent stop cue. Correlational studies (EEG, fMRI), lesion studies, and neuromodulation studies (TMS) have identified a reactive stopping network involving pre-SMA, subthalamic nucleus, and *pars opercularis* in the right inferior frontal gyrus (rIFG), with rIFG being the area most repeatedly linked to inhibition. With regard to neuromodulation studies, offline TMS protocols have provided mixed results by revealing increased or decreased stopping performance dependent on the stimulation protocol. One issue with TMS is that it can potentially elicit neural activity in several neighboring areas. Because these TMS investigations are applied offline and induce large artifacts in electrophysiological measures of cortical activity (e.g., EEG), online neural measures and TMS have not been paired. Thus, it is unclear how rIFG TMS effects on inhibition translates into neural processes implicated with response inhibition, and therefore evidence from human studies remains correlative. Here we examined the role of rIFG during a SST (35% stop trials) using MRI stereotaxically-guided 0.5 MHz transcranial focused ultrasound stimulation (tFUS). tFUS has several advantages over all other non-invasive stimulation methods, including (1) the beam is precise within a 5-mm^2 region, allowing us to specifically target *pars opercularis*, and (2) there are no current spread or artifacts, allowing us to simultaneously stimulate and measure EEG. We used 4 levels of stop-signal delay determined as percentages of baseline of 'Go' reaction time distribution from all trials. During tFUS trial, the stimulation trains lasted 300 ms and were applied at either visual Go or Stop signal onset. tFUS improved the proportion of correctly inhibited responses (18% improvement), but only when tFUS was applied coincident with the Stop signal. Importantly, this effect of tFUS was not found in a control group (tFUS over ipsilateral S1). EEG analysis of rIFG group data revealed tFUS increased theta and beta activity measured over preSMA and rIFG. Surprisingly, tFUS increased directed-phase connectivity from preSMA to rIFG, but not vice versa. These results provide strong support for the role of *pars opercularis* in reactive inhibition, and provide the first demonstration that tFUS can be used online to identify key neural nodes for cognitive and executive functions in humans.

Title: Electrophysiological evidence for common processing of task-switching and novelty processing

Authors: *T. R. DYKSTRA, E. HAZELTINE, J. R. WESSEL
Univ. of Iowa, Iowa City, IA

Abstract: Orienting attention to salient events and using feedback to adapt ongoing behavior are critical components of cognitive flexibility. Research suggests that cued task-switching and processing infrequent events may rely on a common cognitive system, indexed by a frontocentral P3 wave (Barcelo et al., 2006). Here we investigate the relationship between novelty detection and *feedback-driven* switching by measuring frontocentral P3 amplitude in three paradigms requiring varying degrees of task-switching and novelty detection. In this way, we also test a possible shared network for stimulus-driven (e.g., novelty) and feedback-driven (e.g., switching) behavioral adaptation.

Participants completed a feedback-driven task-switching paradigm in which switches occurred by changing response mappings rather than changing the relevant stimulus dimension. Subjects also completed a separate task containing irrelevant infrequent stimuli but no switches. Finally, participants performed a combined infrequency/switch task where comparing feedback to response determined the correct response mapping for the next trial, but irrelevant infrequent events were also present.

We applied ICA to the novelty task portion of the EEG dataset to identify a frontocentral P3 component, which showed increased activity on novel vs. standard trials. We then investigated the activity of this component in the task-switching tasks and observed increased activity on switch vs. repeat trials. We observed the same pattern of results when repeating the analysis and identifying a frontocentral P3 component from the task-switching portion of the EEG dataset and comparing to the novelty tasks.

Our results imply that behavioral adaptations during task-switching and novelty detection may be implemented via a common neural network. Theoretical accounts propose that this network may involve the subcortical subthalamic nucleus (STN; Wessel & Aron, 2017). Therefore, we collected intracranial recordings from Parkinson's patients undergoing implantation of deep brain stimulators in the subthalamic nucleus during the task-switching task. Preliminary results

show sustained increases in STN β-power for switch as compared to repeat trials, confirming a potential involvement of the STN.
We extend previous work on task-switching to show that the link between novelty and switching based on stimulus dimension also applies to switching with respect to response mappings. Moreover, our results suggest a common network for stimulus- and feedback-driven behavioral adaptation, as suggested by prior work. Lastly, our results provide first evidence for the subcortical STN in task-switching.

Title: Successfully stopping a movement has global motor effects as evident in a pause of tonic EMG of a task-unrelated effector

Authors: *S. JANA, A. R. ARON
Dept. of Psychology, Univ. of California San Diego, San Diego, CA

Abstract: Rapid stopping of action is an everyday requirement. In the lab, it is often studied using the Stop Signal or Go/NoGo tasks. Rapid action stopping appears to have global motor effects as demonstrated by several studies that have measured corticospinal excitability with Transcranial Magnetic Stimulation (TMS). When one effector is stopped (such as voice or eyes) there is decreased corticospinal activity for a task-unrelated effector (such as hand or leg) (Badry et al. 2009; Cai et al. 2012; Majid et al. 2012; Wessel et al. 2013). This global motor effect correlates with signals recorded from the subthalamic nucleus (Wessel et al. 2016), and may reflect the operation of a prefrontal-subthalamic nucleus 'hyperdirect' pathway (Nambu et al. 2002) which has a broad suppressive effect on the basal ganglia output. Yet further investigations of this global suppression are hampered by the method of using TMS to measure corticospinal excitability. Not only is this inconvenient for many labs, but it also requires an exorbitant number of trials to map the temporal profile.
Here we tested a novel approach of studying the temporal profile of global motor suppression by measuring electromyography activity (EMG) in a task-unrelated muscle. We asked subjects to perform the Stop Signal task with their right hand while they continuously pressed a squeeze ball between their left hand thumb and forefinger. We measured EMG activity from the first dorsal

interosseous muscle of the left hand using surface electrodes. In accordance with the findings from TMS, and in two separate experiments (each N = 20), we observed a decrease in the task-unrelated tonic EMG activity for Correct Stop trials compared to both Correct Go and Failed Stop trials. This decrease was quite rapid (~80 after the Stop Signal) and transitory, lasting until about the Stop Signal Reaction Time, a metric of the time taken to stop a movement. Further research will investigate the effectiveness of this method in elucidating global suppression in error and conflict scenarios.
Global motor suppression is a proxy for a fast stopping process, and possibly a proxy for a hyperdirect frontal-subthalamic circuit with a global impact on basal ganglia output. This EMG approach provides a novel method for easily testing whether and when global motor suppression occurs in different task contexts.

Title: Hypoxic exercise-induced cognitive fatigue depends on arterial oxygen desaturation: A neuroimaging study

Authors: *G. OCHI[1,2], H. SOYA[1,2]
[1]Lab. of Exerc Biochem & Neurosci, Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Dept. of Sports Neuroscience, Advanced Res. Initiative for Human High Performance, Univ. of Tsukuba, Tsukuba-Shi, Japan

Abstract: Exercise-induced fatigue consists of central fatigue, such as reduction of central motor command, and the peripheral fatigue in muscle. This exercise-induced central fatigue may also deteriorate executive function mediated by prefrontal cortex (cognitive fatigue) and worse athletic performance. We found that 10 min moderate exercise under moderate hypoxic condition (FIO_2 = 0.13) lowers dorsolateral prefrontal cortex (DLPFC) activity and decrease executive function (Ochi et al., *NeuroImage*, 2018). Although mechanisms behind cognitive fatigue are still unclear, cerebral hypoxia caused by decreasing arterial oxygen saturation (SpO_2) is thought as one of the important factor of exercise-induced cognitive fatigue. Thus, the purpose of this study was to clarify the effect of arterial desaturation during hypoxic exercise on

cognitive fatigue by using our special hypoxic exercise model and to clarify the underlying neural mechanisms by using multichannel functional near-infrared spectroscopy (fNIRS). Fourteen healthy subjects underwent moderate intensity exercise (50%VO_{2peak}) under two conditions: moderate (FIO_2 = 0.13)(MOH) or mild hypoxic conditions (FIO_2 = 0.16)(MIH). All subjects performed color-word Stroop task (CWST) before and after exercise under moderate hypoxic condition (FIO_2 = 0.13). Cognitive performance was assessed by reaction time (RT) of CWST. The difference in RT between incongruent and neutral trial of CWST was calculated as $RT_{interference}$ to determine executive function. fNIRS probes were put over the forehead during the CWST and we monitored brain activity in left sides of the DLPFC what plays a crucial role in executive function. Task-related oxy-Hb concentration change was used as an indication of brain activity. Arterial oxygen saturation (SpO_2) were monitored during experiment. As the results, SpO2 significantly decreased during exercise in MOH compared with MIH (MIH: 88.4±1.7%; MOH: 79.5±3.6%). On the other hand, there was not significant difference on SpO_2 during CWST between both conditions (MIH: 89.2±2.0%; MOH: 88.6±1.6%). Regarding $RT_{interference}$ and brain activity, two-way ANOVA showed significant interactions between time (pre/post) and condition (MOH/MIH). Post-hoc analyze revealed that delayed $RT_{interference}$ and decreased task-related oxy-Hb concentration change in left DLPFC in MOH compared with MIH. These results indicate that negative effect of hypoxic exercise on executive function was cancelled by suppressing SpO_2 reduction during hypoxic exercise. Hypoxic exercise-induced arterial desaturation lowers task-related prefrontal activity and deteriorate executive function.

Title: Preparing to stop and preparing to go have dissociable signatures in sensorimotor beta and mu

Authors: *V. MURALIDHARAN[1], X. YU[1], M. X. COHEN[2], A. R. ARON[1]
[1]Dept. of Psychology, Univ. of California San Diego, La Jolla, CA; [2]Radboud Univ., Nijmegen, Netherlands

Abstract: We are interested in how people proactively set their motor system into a suppressed state so that they can stop better in the future. Here we used scalp EEG to test the hypothesis that

this proactive suppressive state might correspond to increased beta band power. Human subjects performed a task which required them prepare to stop an action in the future. On each trial, a cue instructed them to prepare to stop the left or right hand, or to prepare to move the left or right hand. After a delay of 1000 ms they had to make a bimanual movement, and, on a minority of trials to try to stop the earlier cued hand while continuing with the other. We analyzed scalp EEG data in 16 subjects using Generalized Eigenvalue Decomposition (GED). This looks for a subspace of weights which optimally separates signals from two conditions (here, the 1000 ms cue period where they prepared to stop the left or right hand). In all subjects, we found components with a contralateral sensorimotor topography in the beta frequency (12-20 Hz). Importantly, power in this component correlated trial-by-trial with the ability to selective suppress when required (Prepare to Stop Right: $r = -0.13$, $p<0.05$; Prepare to Stop Left: $r = -0.15$, $p<0.05$). Interestingly, doing a similar analysis in the cue period for preparing to move a hand (as opposed to preparing to stop) now revealed sensorimotor components at a lower frequency (mu) (Average preparing to Go: 10.40 Hz; Average preparing to Stop: 15.03 Hz). We thus show that preparing to stop a particular hand has an EEG signature of increased beta band power in contralateral sensorimotor regions. The degree of power in this component relates to the ability to subsequently selectively stop a response. Moreover, this suppressive state has a different signature from preparing to go. These findings raise interesting questions about the physiology of sensorimotor circuits for stopping and going, prove the utility of the GED method as an effective spatial filter for response control, and pave the way for real-time feedback approaches.

Title: Preventing a thought from coming to mind elicits increased right frontal beta just as stopping action does

Authors: *A. CASTIGLIONE[1], J. WAGNER[2], M. C. ANDERSON[3], A. R. ARON[4]
[1]LA Jolla, CA; [2]Dept. of Psychology, Univ. of California San Diego, La Jolla, CA; [3]Med. Res. Council, Univ. of Cambridge, Cambridge, United Kingdom; [4]UC San Diego, La Jolla, CA

Abstract: How do we stop thoughts and memories from coming to mind? It is possible that preventing retrieval recruits a similar stopping mechanism as motor stopping. Rapidly stopping

action requires the integrity of the right inferior frontal cortex, for which, for the stop signal task, a specific electrophysiological signature is increased beta band power for successful vs. failed stop trials, before stop signal reaction time. Here we tested whether the same signature would be elicited by the requirement to prevent an unwanted thought from coming to mind.
We recorded scalp EEG during a Think/No-Think behavioral paradigm and a subsequent stop signal task, in each of 42 participants. In the first phase of Think/No-Think participants learned word pairs. In a second phase, they were presented the left-hand word as a cue, and asked to either think about (Think trial) or not to think about (No-Think trial) the target right-hand word. At the end of each trial, they were also asked whether they had experienced an intrusion. In a final phase, they were given the cue and asked to recall the target word.
Behaviorally, we reproduced the standard finding of worse final recall for items always presented in No-Think trials, and of decreased intrusions with increasing practice for No-Think trials. For EEG, we reproduced the finding that rapid action stopping elicited increased right frontal beta power, greater for successful vs. failed stop trials, before stop signal reaction time. Critically, we observed that No-Think vs. Think trials also elicited increased right frontal beta power, within about 200ms of the No-Think cue, and this was also greater for No-Think trials where there was not a reported intrusion.
Our findings show that the requirement to prevent a thought from coming to mind quickly recruits a similar EEG signature as stopping action. This is consistent with the theory that a prefrontal stopping system also affects long term memory retrieval.

Title: Decision related signals at single-neuron resolution in human motor cortex

Authors: *S. N. FLESHER[1,2], C. CHANDRASEKARAN[2], F. R. WILLETT[1,2], S. D. STAVISKY[1,2], M. WANG[3], P. G. REZAII[1], L. R. HOCHBERG[8,9,11,12,10], J. M. HENDERSON[1], K. V. SHENOY[2,4,5,6,7]

Abstract: Considerable work recording intracortically in animal models and non-invasively in human participants has demonstrated the involvement of sensorimotor brain areas in decision making. This activity has not yet been observed in human motor cortex at single-neuron resolution. In a brain-computer interface (BCI), in which a user's motor intention is estimated, the presence of cognitive signals in a region that is being used for motor control could pose problems for accurately estimating user intention. Here, we sought to identify activity related to decision making during movement in human motor cortex with single-unit resolution.
We recorded from intracortical electrode arrays chronically implanted in the hand region of a BrainGate2 pilot clinical trial participant's (T5) motor cortex during a perceptual decision making task (Chandrasekaran et al. Nat Comm 2017). The participant observed a red and green colored grid and determined if the grid contained more red or green squares. The participant reported his decision as soon as he decided, with either an overt head movement to the target of the corresponding color, or by moving a BCI-controlled cursor to the target.
The color coherence of the grid ranged from 0.44% to 80%, and the participant's unsigned coherence threshold was found to be less than 10%, which is consistent with previously established NHP and human thresholds on the task. The recorded neurons exhibited decision-related activity in the form of sustained activity before movement onset that was separable by intended target, task coherence (difficulty) and reaction time. This sustained, pre-movement activity that encodes stimulus characteristics provides the first evidence with single-neuron resolution for decision-related activity in human motor cortex.
The presence of decision-related signals in human motor cortex both enables the opportunity to study single-neuron population dynamics in sophisticated decision tasks and highlights the necessity of taking these signals into account. More specifically, decision-related signals could otherwise appear as uncontrolled neural variability, potentially interfering with BCI control in settings with multiple potential goals. Furthermore, once identified as such, decision-related signals could be used to augment BCI control.

Title: Declining RNA integrity is associated with selectively weakened detection of mitochondrial pathway genes in human cadaver brain tissue samples

Authors: *E. S. JOHNSON, K. HARGIS-STAGGS, E. M. BLALOCK
Dept. of Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: RNA degradation can be influenced by many factors, including *post-mortem* interval and tissue pH. The degree to which RNA is degraded prior to quantification affects downstream measurement (e.g., *in situ* hybridization, RT-PCR, transcriptional profiling). Agilent Technologies introduced the RNA Integrity Number (RIN) in 2006, and over the last decade RIN has become widely adopted as a *de facto* standard to quantify RNA degradation across samples and labs. Recent studies have shown that RIN (ranging from 1- worst, to 10- best) influences mRNA levels, though relatively little work has been done to determine whether that RNA damage is random or is targeted to certain biological pathways. We hypothesized that RIN's influence on gene expression would:
a) show a strong positive correlation in control tissue (degrading RNA signal as RIN declines)
b) show a robust effect across independent studies
c) target mRNA in specific pathways
To test this, we identified and downloaded four publically available human post-mortem transcriptional profiling datasets that included disambiguated RIN scores for each array, used Affymetrix transcriptional profiling technology, and examined *post-mortem* human frontal cortex samples. To isolate RIN-selective effects, only the profiles of control samples from within each study were examined. RIN was tested for correlation with each gene's relative expression level within each study. In general, RIN correlations to gene expression in individual studies showed False Discovery Rates in the 0.15-0.3 range, indicating a relatively strong 'RIN Effect'. To determine whether this RIN Effect was robust across studies, the two studies with the strongest RIN Effects were statistically analyzed for similarity. We report a consistent and selective correlation between worsened RIN and declining mitochondrial gene expression, suggesting that

pockets of subcellular RNA close to mitochondria may be more adversely affected during the course of RNA degradation in human brain tissue. Our results further indicate that this RIN-gene expression correlation becomes pronounced when RIN < 7.5. Finally, these results indicate that this RIN Effect may create transcriptional pathway-specific blind spots that are not amenable to downstream RIN-correcting strategies.

Title: Machine learning for genome based diagnosis and mechanism discovery in autism spectrum disorder

Authors: *D. N. AMATYA[1], S. T. SCHAFER[1], G. MCVICKER[2], T. O. SHARPEE[3], S. NAVLAKHA[5], F. H. GAGE[4]
[1]Lab. of Genet., [2]Integrative Biol. Lab., [3]CNL-T, [4]LOG-G, Salk Inst., La Jolla, CA; [5]The Salk Inst., La Jolla, CA

Abstract: Background:
Autism Spectrum Disorder (ASD), is a heritable neurodevelopmental condition that is defined by social, behavioral, and cognitive deficits. Affecting 1 in 68 children in the US, it is among the most devastating disorders of childhood in terms of prevalence, morbidity, and impact on society. An open problem in ASD is the lack of clinical grade biomarkers that can aid in diagnosis, as well as an incomplete understanding of disease mechanisms at the molecular level. Standard genome-wide association studies have struggled to solve this problem, because of the limited effect size of individual variants. Instead, we propose to use machine learning algorithms that are capable of considering the combinatorial effects of numerous genes simultaneously.
Methods:
In this work, we describe the application of machine learning to the genetic and clinical data contained in the Autism Speaks MSSNG database, currently the largest repository of ASD genomic data. Specifically, 1) we construct a novel representation of an individual genome as a vector of mutation burden across all genes, 2) detail the construction of classifiers (e.g. logistic regressor, random forest, support vector machines, artificial neural network) that are capable of inputting these genomic vectors and outputting the likelihood of ASD diagnosis, and 3) apply methods for “reverse engineering” these classifiers to identify individual and population ASD

risk genes.
Results:
Genomic data were acquired for 7,500 control and ASD subjects. Variant calls were parsed and scored to create genomic vectors for each subject, resulting in an efficient and informative data representation for machine learning. Using standard training and cross-validation techniques, a variety of classifiers were trained to identify ASD genomes with high accuracy (greater than 90%). In comparison to linear classification methods, such as Naive Bayes, these methods demonstrated superior performance. Finally, examination of salient genes used by the classifiers revealed overlap with known ASD genes, as well as novel potential ASD genes.
Conclusions:
Modern machine learning methods, which are capable of learning complex nonlinear functions, are able to identify patterns of mutation with diagnostic relevance in ASD. The potential impact of this work is significant, as pre-symptomatic diagnosis could facilitate the preventative management of ASD, thereby affording patients the best chance for normal development. Additionally, the discovery of new ASD related gene patterns could inform novel biological experimentation to trace disease mechanisms and therapeutic targets.

Title: Exploring differences in hippocampal gene expression across three different animal models of mood disorder: Prototyping a meta-analysis pipeline

Authors: *H. KHALIL[1], M. H. HAGENAUER[2], C. AYDIN[3], Q. WEI[4], F. MENG[1], B. S. MCEWEN[5], C. NASCA[6], S. J. WATSON, Jr.[2], H. AKIL[2]
[1]The Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI; [3]molecular and behavioral neuroscience institute, Universty of Michigan, Ann Arbor, MI; [4]Mol. & Behav. Neurosci. Inst., Univ. of Mich., Ann Arbor, MI; [5]Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY; [6]Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: The Hope for Depression Research Foundation (HDRF) focuses on the neurobiology of mood disorders and brings together five research groups which have been using transcriptomic studies to gain insight intoanimal models of depression.Since each animal model typically represents one dimension of the plethora of changes that might be occurring within the brains of depressed individuals, integrating the results from across these studies is essential for gaining a better understanding of the biology of mood disorders. However, analyzing the results of experiments across all these studies is statistically challenging given the different species, platforms, technologies, experimental designs and statistical methodologies used. Here we developed an analysis pipeline and meta-analysis technique in order to extract consistent gene expression signatures across animal models and platforms. We tested this pipeline using five data sets from three animal models: selectively-bred high responder (HR) and low responder (LR) rats, Flinderssensitive and resistant rats, and mice with glucocorticoid receptor overexpression (early life and lifetime). The whole hippocampus or dentate gyrus was analyzed in these studies using either microarray or RNA-Seq. In order to ensure comparability, the raw data from each study was first run through our proposed pipeline for annotation, quality control, and data preprocessing. We calculated the effect size (Hedge's *g*) for each gene from each study from the moderated t-statistic obtained as the result of a differential expression analysis conducted within the limma or limma-voom pipeline. This effect size was then used within a multi-level, random effects meta-analysis model which allows grouping of the experiments by biologically relevant variables, such as species. Interestingly, we find that preliminary results point to several hundred candidate genes which show similar differential expression in the hippocampus across these animal models of mood disorder despite the fact that a superficial comparison indicated minimal intersection between the top results from each individual study. These differentially expressed genes are enriched within particular biological pathways: down-regulated genes are enriched within pathways related to synaptic function, and upregulated genes are enriched within pathways related to cell adhesion, vascular development, extracellular matrix, methylation, and inflammation. We conclude that it is beneficial to integrate results from various different models in order to understand the neurobiology of mood disorder.

Abstract: Several neurobehavioral disorders are often marked by genetic heterogeneity, suggesting networks of genes contributing to symptoms presented by patients. This is especially true in autism and heritable ataxias; both conditions are associated with disparate phenotypes and gene markers in many brain regions. In this work we built multiple networks from gene expression studies in mouse and performed network meta-analyses to characterize brain network changes in 20 brain regions. We captured correlated genes in regions from thousands of publicly available RNA-Sequencing studies to provide robust evidence of weighted gene co-expression networks in mammalian brain tissues. Within each region of interest, we also created gene co-expression networks from RNA in-situ hybridization from the Allen Brain Atlas to correlate genes' spatial expression. Hierarchical clustering based on dissimilarity and topology were used to create densely connected modules within each brain-region and experimentally based network. Permutation tests were used to ensure the statistical stability of modules. Valid modules were functionally characterized by pathway enrichment analyses, multiple species phenotype enrichment and the semantic similarity of module genes' ontological annotations. Several modules were enriched with neurobehavioral phenotypes presented by humans diagnosed with spinocerebellar ataxias and on the autism spectrum. To further prioritize novel genes within these communities, these phenotypes were individually diffused throughout modules onto neighboring genes via random walks with restart in diffusion kernels. This enabled us to rank genes by their degree of co-expression, a guilt-by-association approach, with other genes in modules already enriched with patient relevant phenotypes. To validate our predicted genes associated with autism phenotypes, we have obtained patient data from the Simmons Foundation for Autism Research Initiative. Using the Neuro Behavioral Ontology, we have annotated patients' clinical outcomes to phenotypes discovered in the cohort. Future work is performing genome association studies for each phenotype encoded as above, and we will use these data as validation of our prioritized gene/phenotype associations relevant for autism. Ultimately, this study will present communities of genes associated with brain region-specific behavioral traits, and provide a ranking of both known and predicted genes which contribute to said traits. Using phenotype ontologies as our predictive ground truth will facilitate confirmation of predicted gene/trait associations by in-vivo experimentation in mouse.

Title: Deconvolvution of bulk rna sequencing data to estimate neuron type abundance across human cortical regions

Authors: *R. J. LOUGHNAN, T. DONOGHUE, B. VOYTEK, E. A. MUKAMEL
Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Single cell RNA sequencing (scRNA-Seq) is a valuable tool for classifying cell types based on gene expression. However, current scRNA-Seq datasets from the human brain are limited to a sparse subset of cortical regions. By contrast, RNA-Seq data from samples of whole brain tissue, also called bulk RNA-Seq, has been generated across many human brain regions and multiple developmental time points. Differences in gene expression across human brain regions have been related to spatial variability in physiological measures from functional brain imaging data, and to regional differences cortical architecture. These data suggest specific genes that are implicated in functional differences throughout the brain, but they do not give insight as to the neuron cell types driving these differences. By creating a human neuron cell type atlas with high spatial sampling, we could enable a molecular interpretation of cell types driving topological differences found in structural and functional brain imaging. Here, we present a method for estimating cell type proportions at over 100 locations across the human brain by combining single-cell RNA-Seq data with spatially resolved bulk transcriptomes.
Our method uses single cell and single nucleus RNA-Seq data from human cortex to create prototype gene expression profiles for cell types, including glial cells and excitatory and inhibitory neuronal sub-types. Graph-based Louvain clustering was used to define cell types. We integrated these single cell data with bulk RNA-seq from 120 locations sampled in 2 post mortem male human brain donors (ages 24 and 39 years; Allen Institute for Brain Science, 2013). By fitting a generalized linear regression model with non-negative coefficients for each cell type, we are able to deconvolve the bulk RNA-Seq data and estimate the proportion of each cell prototype contributing to the bulk sample.
The estimates of cell type proportions are stable and reproducible within technical replicates of the same cortical brain region within a donor. We validated our deconvolution results by repeating the analysis using independent subsets of genes. Deconvolution of bulk RNA-Seq data using prototype transcriptomes from single-cell RNA-Seq data is a promising approach to

estimate cell type proportions across brain regions. This technique could be applied in situations where single-cell RNA-Seq may be challenging, such as analysis of frozen or archived brain samples.

Title: Variation among intact tissue samples reveals the core transcriptional features of human CNS cell classes

Authors: *K. W. KELLEY[1], H. NAKAO-INOUE[2], A. V. MOLOFSKY[2], M. C. OLDHAM[3]
[2]Psychiatry, [3]Neurolog. Surgery, [1]Univ. of California San Francisco, San Francisco, CA

Abstract: It is widely assumed that cells must be physically isolated to study their molecular profiles. However, intact tissue samples naturally exhibit variation in cellular composition, which drives covariation of cell-class-specific molecular features. By analyzing transcriptional covariation in 7221 intact CNS samples from 840 individuals representing billions of cells, we reveal the core transcriptional identities of major CNS cell classes in humans. By modeling intact CNS transcriptomes as a function of variation in cellular composition, we identify cell-class-specific transcriptional differences in Alzheimer's disease, among brain regions, and between species. Among these, we show that *PMP2* is expressed by human but not mouse astrocytes and significantly increases mouse astrocyte size upon ectopic expression *in vivo*, causing them to more closely resemble their human counterparts. Our work is available as an online resource (http://oldhamlab.ctec.ucsf.edu) and provides a generalizable strategy for determining the core molecular features of cellular identity in intact biological systems.

Title: Translating ribosome affinity purification (TRAP) molecular profiling of CNS cell types: A data resource for the neuroscience community

Authors: *J. P. DOYLE[1,2], J. A. VEKICH[1], K. BOBKOV[1], C. S. HOLUB[1], D. DAS[1], R. YAMASHITA[1], M. EKSTRAND[1], A. AMADOR[1], E. BOSHOFF[1], P. TASKAR[1], H. SCHIFFER[1,2], J. ATIENZA[1], J. SERRATS[1], N. CHEN[1], E. YOO[1], G. CORBETT[3], J. POWELL[3], N. BRICE[3], N. KAUSHAL[1,2], W. J. RAY[1,2]
[1]Takeda California, San Diego, CA; [2]Envoy Therapeut., Jupiter, FL; [3]Takeda Cambridge, Cambridge, United Kingdom

Abstract: The Translating Ribosome Affinity Purification (TRAP) methodology was developed in the labs of Nathaniel Heintz and Paul Greengard at Rockefeller University in order to overcome the inherent complexity of brain tissues and to obtain cell-type specific translational profiles of critically relevant neural cell types (Doyle et al., Heimann et al., Cell, 2008). Using bacTRAP transgenic mouse lines licensed from Rockefeller University or generated in-house, we have collected a large amount of both microarray and RNAseq TRAP data for numerous neural cell types, both in a basal state as well as in animal models relevant for autism, schizophrenia, Alzheimer's disease, Parkinson's disease, and cognitive function. This data is an invaluable resource for identification of potential disease targets and biomarkers, as well as for elucidating the mechanism of action for neurological disorders and drugs targeting the CNS. The existing TRAP datasets cover three general areas: 1. Baseline data, collected from unperturbed transgenic bacTRAP mice, targeting specific cell types (neuronal, glial, microglial) in several brain regions (cortex, striatum, thalamus, hippocampus, hypothalamus). 2. Data from disease model studies (Alzheimer's disease, schizophrenia). 3. Data from MOA studies with existing or newly developed drugs for neurological disorders (schizophrenia, autism, Parkinson's Disease). In order to make best use of these existing datasets, we are making these data available to the greater neuroscience community. In addition to the microarray and RNAseq data, we have access to many Rockefeller TRAP lines which have been extensively backcrossed by us to the Bl6/J mouse strain, and a number of new bacTRAP transgenic lines generated in-house. The lines can be obtained from Jackson labs either through an MTA with Rockefeller University, or an MTA with Takeda Pharmaceuticals. Details of data and transgenic mouse lines will be available at this poster session.

Title: Integrating gene and protein data into SenseLab databases for neuroinformatics-driven discovery

Authors: *M. SURLES-ZEIGLER[1], T. M. MORSE[3], R. A. MCDOUGAL[2], G. M. SHEPHERD[4]
[1]Ctr. for Med. Informatics, [2]Neurosci., Yale Univ., New Haven, CT; [3]Neurosci., Yale Univ. Sch. Med., New Haven, CT; [4]Dept. Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Neurons are often categorized by their wide range of properties, including, but not limited to, their morphology, location, and physiology. It is often challenging to identify commonalities and differences between these cells because individual papers and/or databases

frequently tend to focus on a single property. To solve this problem, NeuronDB (senselab.med.yale.edu/neurondb) has been created to aggregate neuronal information from multiple resources; this facilitates the integration and comparison of various cell types and properties for building computational models. NeuronDB currently provides unique tools to enable users to integrate data about the spatial expression of receptors and channels in individual neurons. Adding gene and protein expression data to the database is essential to increase understanding and comparison of neurons. We have begun to address this need with a data acquisition protocol, focusing on highly studied cells, initially cells of the hippocampus (cells of the dentate gyrus and regions CA1, CA3, and CA4). We systematically searched PubMed for combinations of cell types and well-known techniques. Papers and abstracts meeting a set of inclusion criteria were manually reviewed to identify the gene and protein expression data and the associated metadata (species, species strain and age, and technique used to identify data). This data is now available through NeuronDB and an interactive microcircuit viewer. This microcircuit viewer enables interoperability between the SenseLab databases' (e.g., NeuronDB, ModelDB) neuronal properties, with links to other properties such as electrophysiological data as tracked by associated databases such as Neuroelectro (http://neuroelectro.org). We will demonstrate this incorporation of protein and gene expression data into NeuronDB and show how it can accelerate basic science and modeling research, assisting in the exploration of experimental studies and models of neurons and their ion channels and receptors.

Title: A novel high-content platform for evaluation of dendritic spines in late-stage preclinical drug discovery

Authors: C. A. SHANKULA[1], J. K. ALEXANDER[2], K. KORJENIC[1], *C. S. REX[3]
[1]Afraxis, Inc., San Diego, CA; [2]Alexander Scientific Analysis and Programming, L.L.C., Austin, TX; [3]Dept of Neurobio., Afraxis Inc., San Diego, CA

Abstract: CNS drug discovery imposes unique barriers to rational drug evaluation - central to these are a lack of fundamental understanding of information processing in brain that gives rise

to affective and cognitive states. It is expected that these states emerge from the coordinated activities of individual synaptic contacts within and across distributed brain regions. Therefore, phenotypic analyses of synpatic activities should simultaneously assess broadly and at high resolution (single synapses). Here we describe the development of a scalable platform technology to evaluate individual dendritic spine morphometries from neuroanatomically precise samples across large numbers of distributed neurons within intact mammalian brain. We introduce a novel seeded image segmentation analysis method for semi-automated morphometry conducted on Airyscan super-resolution micrographs. This approach permits acquisition of >10,000 dendritic spines per animal within a reasonable cost-per-unit and timeframe for drug discovery. As a proof-of-principle, we evaluated the effects of low doses of ketamine on broadly distributed dendritic spines in young adult mice and rats, including locii of previously established effects (e.g. medial prefrontal cortex). We confirmed and optimized segmentation results against human observer results. We also introduce a novel statistical tool for nested parametric evaluation of non-parametric, multi-dimensional distributions of fundamental dendritic spine measures. This approach, we believe, will increase the reproducibility of dendritic spine analysis as well as permit assessment of inter-animal variances from fundamental morphometric measures - both advances are likely necessary for drug screens using dendritic spine analysis. Together, the novel assemblage of optimized assay utilities form a powerful late-stage preclinical CNS drug evaluation tool that can be deployed to probe responses of broadly distributed individual synapses in conjunction with in vivo pharmacology and introduce a level of scalability to whole animal drug testing that is typically reserved for high-throughput or high-content analysis.

Title: Predicting pathogenicity of structural variation in neurodevelopmental disorders using machine learning

Authors: *P. TANDON, O. SHANTA, D. ANTAKI, W. BRANDLER, M. KLEIBER, O. HONG, J. SEBAT
Psychiatry, UCSD, San Diego, CA

Abstract: Structural Variants (SVs) are genetic mutations that consist of changes in the copy number or arrangement of DNA sequences (> 50 bp) and include deletions, duplications, and inversions. Previous studies have shown that gene-disrupting SVs contribute to elevated risk for a variety of neurodevelopmental disorders including Autism Spectrum Disorders (ASD), Developmental Disorders (DD), and schizophrenia (SCZ) (Malhotra and Sebat 2012; Walsh et al. 2008). Despite continued success in identifying SVs that confer risk, current analytical approaches have been limited to investigations of the genome-wide burden of SVs or the enrichment of large gene-disrupting SVs at individual loci. Limited progress has been made in identifying smaller causal variants within individual genes or in regulatory regions of the genome that may affect risk.

This study seeks to develop more accurate pathogenicity prediction and functional interpretation tools for SVs using an integrative machine learning approach. The study develops a machine learning pipeline to fuse multiple biological functional annotations into a single pathogenicity score for a structural variant to assess risk for neurodevelopmental disorders. The trained classifier can distinguish deleterious SVs from neutral variants on a variety of data types including next-generation, whole genome sequencing, and clinical microarray data. On National Institute of Health (NIH) ClinVar data, the trained predictor can leverage multiple functional constraint predictors to predict the pathogenicity of an SV accurately, even in the absence of any previously-implicated highly-constrained gene (i.e. ExAC probability loss of function (pLI) score = 0.5).

The developed SV pathogenicity scoring system is used to investigate the unexplained genetic basis of psychiatric disease in SCZ and ASD. The predictor is more accurate than previous methods for scoring medium to large (10^5-10^6 bp) deletions in the Psychiatric Genomics Consortium (PGC) data (Wilcox $p < 0.01$). Emphasis in our study is placed on exploring the contribution of SVs that overlap non-coding regulatory elements to disease risk. The predictor utilizes fetal brain enhancer and promoter annotations (derived from Epigenetic Roadmap Project data) in an explicit non-coding classifier to improve prediction performance for non-exonic SVs. On Simons Simplex Consortium (SSC) data, our approach improves significance for non-coding variants in ASD patients (Wilcox $p < 0.01$).

Abstract: We introduce a web-based viewer for integration of two-dimensional (2D) *in situ* hybridization (ISH) images with three-dimensional (3D) gene expression image datasets located in the standard MRI coordinate. We configurated the viewer for 2,810 para-sagittal sectioned mouse brain ISH images of the BrainTx database (http://www.cdtdb.neuroinf.jp), 3D gene expression image datasets, which were made using a microtomy-based microarray assay system, Transcriptome Tomography, and archived in the ViBrism DB (http://vibrism.neuroinf.jp), and MR images of the mouse standard coordinate space, Waxholm space (WHS, https://www.nitrc.org/projects/incfwhsmouse). Each ISH image was linearly transformed into each of a series of para-sagittal MR image slices of the WHS, and he best-fit slice were identified by calculating the similarity metric value (δ). We parallelized this computation framework, using the IPython cluster package, and implemented it on the PC cluster provided for the Brain

Atlasing Hackathon (BAH) activity hosted by Neuroinformatics Japan Center in Japan. Transformed 2D images to the best-fit MR image were visualized in the BAH viewer using a Web-GL based back-projection methods along with 3D gene expression images of ViBrism DB. Three types of data, produced with different modalities and originally located in different dimensions, were successfully compared in the viewer.

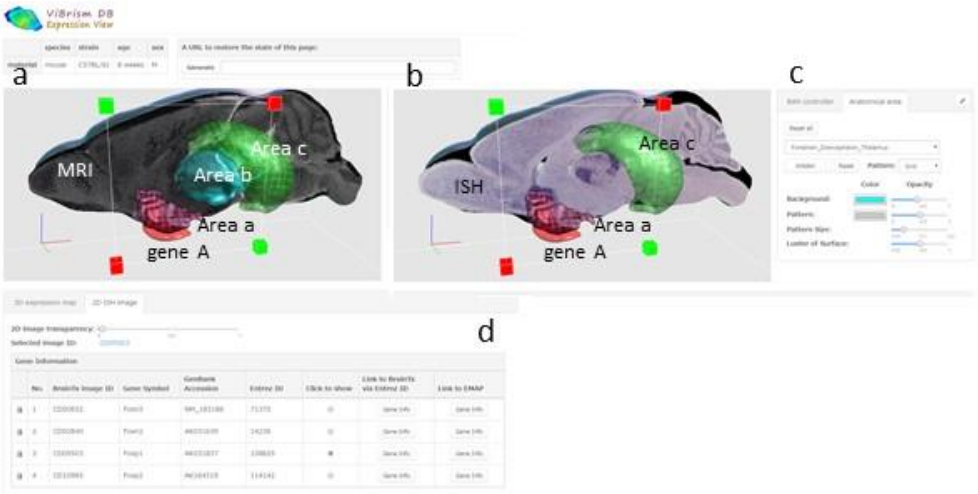

Fig.1 Example views of images in BAH Viewer and BAH control panels

Title: *In vivo* morphological imaging of brain cancer using Gaussian weighted Laplace prior regularization

Authors: H. HUI[1], X. YANG[1], *J. TIAN[2]
[1]Key Lab. of Mol. Imaging, CAS, Inst. of Automation, Chinese Acad. of Scienc, Beijing, China; [2]Key Lab. of Mol. Imaging, CAS, Beijing City, China

Abstract: Bioluminescence tomography (BLT) is a powerful non-invasive molecular imaging tool for in vivo studies of glioma in mice. However, because of the light scattering and resulted ill-posed problems, it is challenging to develop a sufficient reconstruction method, which can accurately locate the tumor and define the tumor morphology in three-dimension. In this work, we proposed a novel Gaussian weighted Laplace prior (GWLP) regularization method. It considered the variance of the bioluminescence energy between any two voxels inside an organ had a non-linear inverse relationship with their Gaussian distance to solve the over-smoothed tumor morphology in BLT reconstruction. We compared the GWLP with conventional Tikhonov and Laplace regularization methods through various numerical simulations and in vivo orthotopic glioma mouse model experiments. The in vivo magnetic resonance imaging (MRI) and ex vivo GFP fluorescent images and H&E stained images of whole brain cryoslicing specimens were utilized as gold standards. The results demonstrated that GWLP achieved the highest accuracy in tumor localization and tumor morphology preservation. This study achieved accurate BLT morphological reconstruction of orthotopic glioma without using any segmented tumor structure from any other structural imaging modalities as the prior for reconstruction guidance. This enabled BLT more suitable and practical for in vivo imaging of orthotopic glioma mouse models.

Title: Using the open metadata Markup Language (odML) and Semantic Web methods to facilitate interoperability of diverse neurophysiology data

Authors: *J. L. TEETERS[1], P. JEŽEK[2], M. SONNTAG[3], Y. SHALIVSKYY[3], A. KOUTSOU[3], J. GREWE[4], F. T. SOMMER[1], T. WACHTLER[3]
[1]Redwood Ctr. for Theoretical Neurosci., UC Berkeley, Berkeley, CA; [2]Dept. of Computer Sci. and Engin., Univ. of West Bohemia, Pilsen, Czech Republic; [3]G-Node, Dept. Biol. II, Ludwig-Maximilians-Universität München, Planegg, Germany; [4]Inst. for Neurobio., Eberhard-Karls-Universität, Tübingen, Germany

Abstract: In order to efficiently find and use shared scientific data, the metadata describing the data must be detailed and standardized to be machine readable. Currently, for neurophysiology data, this is often not the case. Many labs still use custom formats to store data. Multiple standardized formats (such as Kwik [1], NEO [2], NIX [3] and NWB [4]) have been recently developed which store metadata in a consistent manner. However, the diversity of the experiments often requires metadata elements that are not included in any existing standard. Moreover, neurophysiology metadata are still stored in a multitude of incompatible formats, and thus cannot be processed consistently by software tools.
As a step towards solving the problem of diversity in metadata representation, we present an approach which combines the use of the open metadata Markup Language (odML) [5] with Semantic Web methods. The approach was developed using datasets stored in CRCNS.org and the G-Nodes's GIN [6] data repositories and can be used by labs and data repositories to make their shared data easier to find and interoperable between datasets and repositories. The odML format is highly suitable for representing metadata from heterogeneous datasets, because it provides a standardized, machine-readable representation of metadata without constraining the content. While converting metadata to odML puts the metadata in a common format, there can still be differences between datasets in the organization of the same type of metadata within the odML structure. To reduce these differences we proposed and provided odML Terminologies [7] as optional templates for common metadata use cases. The Semantic Web methods are harnessed through software we have developed which converts odML-formatted metadata to the Semantic Web Resource Description Framework (RDF) data model. The RDF representation allows metadata from multiple sources to be combined into a common graph and searched using the SPARQL query language, and thus facilitates interoperability of diverse neurophysiology data across repositories.

Title: KRSA: A user-friendly tool for identifying significant differences in kinase activity from kinome array data

Authors: *E. DEPASQUALE[1,3], E. BENTEA[2,1], N. NAWREEN[2,1], J. L. MCGUIRE[2,1], J. MELLER[3,1], R. E. MCCULLUMSMITH[2,1]

Abstract: As an important mechanism of post-translational modification, phosphorylation by serine/threonine kinases is critical for altering protein function. In order to examine differences in kinase activity on a large scale, kinase substrate arrays (or kinome arrays) have been developed that allow for testing of differential phosphorylation between conditions across many different serine/threonine kinases. We utilized the kinome array platform to discover differences in kinase activity from dorsolateral prefrontal cortex (DLPFC) between male (n=3) and female (n=3) subjects, with a sliding fold change cutoff for identifying significantly different peptide phosphorylation levels. As a replication study, DLPFC from control males (n=10), control females (n=10), schizophrenia males (n=10), and schizophrenia females (n=10) were pooled by group and kinase activity was assessed using the kinome array. To identify which kinases were targeting these peptides, we developed a new application: Kinome Random Sampling Analyzer (KRSA) using the Shiny platform in R. This application takes mappings of protein kinases predicted to target the peptides used in the kinome array from publicly-available databases, enforces optional quality control constraints on the data, then performs resampling analysis to identify kinases that phosphorylate the peptides at a greater frequency than would be expected by chance. From the KRSA results, signaling network models linking the kinases identified in the resampling analysis were constructed using known interactions in the Ingenuity database. Previous studies performed in our laboratory using KRSA confirmed the predictive accuracy of the method through PCR, western blots, and kinome arrays with inhibitors of the affected kinases. Through these studies, significant kinase activity differences between males and females in both unaffected brain tissue and affected tissue were identified and the intersection between the two phosphorylation networks was examined to glean knowledge on how sex differences may play a role in the molecular underpinnings of disease.

Title: New and improved CrePortal, a comprehensive recombinase expressing mice resource at Mouse Genome Informatics (MGI: www.infomatics.jax.org)

Authors: *H. ONDA, E. S. MAYOTTE, L. BECHTEL, S. A. MURRAY, C. L. SMITH
Mouse Genome Informatics, The Jackson Lab., Bar Harbor, ME

Abstract: Since the introduction in early 1980s, over 20,000 “conditional-ready” mice containing recombinase recognition sites have been generated. The technology is based on the mutant mice expressing site specific recombinase, notably Cre, but also Flp, Dre, phiC31, paired with mice containing two DNA recognition sites in their genome. To realize full utility of those “conditional ready” mice, spatial and temporal specificity of recombinase activities in cognate recombinase-driver mice need to be fully characterized. There have been large bodies of published results indicating recombinase activities in the intended tissue or cell type. However, negative results or spurious activities of those recombinase in other tissues or time points are often overlooked or omitted from reporting, thus not easily available to potential users in search of appropriate recombinase driver lines. The CrePortal (*www.informatics.jax.org/home/recombinase*) catalogues published and unpublished researcher-submitted recombinase driver mouse lines to facilitate identification of the most suitable mouse lines for conditional mutagenesis experiment by providing a centralized, comprehensive set of well-annotated recombinase driver mouse lines in easy to search database. It currently provides data for over 2,900 transgenes and knock-in recombinase driver alleles. Recombinase activity is annotated not only on its reported activity, but also for activity not-detected. We have improved the database in our new release by enabling a search for mice with activities detected in specific anatomical structure and nowhere else. In addition to this new search capability, the recombinase summary now displays a new matrix of gene expression data and recombinase activity data side-by-side to easily visualize comparison of endogenous driver expression and reported recombinase activities in various structures/tissues. The search results summary page now shows sortable columns of: a list of drivers, icon linking to matrix views, allele symbols, organ systems activity detected, organ systems activity not detected, inducing agent, link to International Mouse Strain Resource (IMSR, *www.findmice.org*), link to references, and allele synonym(s). Here, we describe new features found in the CrePortal from the Mouse Genome Informatics (MGI,

www.informatics.jax.org), and encourage you to explore this resource for recombinase allele information for the scientific community.

Title: The international neuromodulation registry: A graph database representation of patient-specific data with combined predictive modeling for neuromodulation therapies

Authors: *D. HEDGES[1], G. DUFFLEY[3], R. GOURIPEDDI[2], C. R. BUTSON[1]
[1]SCI Inst., [2]Biomed. Informatics, Univ. of Utah, Salt Lake City, UT; [3]Bioengineering, Univ. of Utah Dept. of Bioengineering, Salt Lake City, UT

Abstract: Neuromodulation therapies such as deep brain stimulation (DBS) and transcranial magnetic stimulation (TMS) have provided symptomatic relief and improved quality of life for certain patients with movement disorders and psychiatric conditions. Unfortunately, the effects of neuromodulation therapies can be highly variable and difficult to quantifiably predict for individual patients. To enhance the accuracy of predictive models, we have created a novel, metadata-driven informatics mechanism to incorporate data from hundreds of patients into predictive computational models. This platform is integrated into the International Neuromodulation Registry, housed at the University of Utah. Within the framework of this patient registry, this informatics platform provides the means to quantitatively combine seemingly disparate data types such as neuroimaging, genetics, demographics, and rating scales for both quality of life and disease severity. The data are organized using the Neo4j graph database management system and can either be uploaded from the University of Utah electronic medical record or from external collaborators. In addition to storing and allowing data retrieval, this system can display and discover complex data relationships. We have paired this database with an analysis pipeline that generates patient specific models of deep brain stimulation (DBS). When data from a patient is uploaded into the registry, a computational model of the patient's DBS implant is generated and sent back to the user. The user can then explore the model via an iOS device such as an iPad, using ImageVis3D Mobile, an app freely available from the iTunes App Store. The model contains individual patient imaging, anatomy, and predictions of the volume of tissue activated (VTA). The model allows the clinician to adjust simulation settings

and visualize the spatial changes of activation from both 2D and 3D views. Given the potential for this platform to improve both translational research and patient care via data-driven predictive analysis, we believe that this next-generation clinical database will play a pivotal role in advancing the field of neuromodulation.

Title: Liquid crystal polymer-based multichannel depth probe with polymeric optical fiber for optogenetic stimulation and electrical recording of CaMKIIα expressing CA1 pyramidal cells of mouse

Authors: C. KIM[1], S. SHIN[1], J.-H. KIM[2], S.-H. LEE[2], *S. KIM[1]
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]KAIST, Daejeon, Korea, Republic of

Abstract: With optogenetic approach, genetically modified target cells can be stimulated or inhibited in timescale of millisecond, which is ideal for studying brain circuitry. For optogenetic stimulation and simultaneous electrical recording, we developed a depth probe comprising a liquid crystal polymer (LCP)-based tetrode and a polymeric optical fiber.
The LCP-based tetrode has four working electrodes at the tip of the shank, a ground electrode at the front of the shank, and a polymeric optical fiber at the back of the shank. The tetrode was fabricated using MEMS process, thermal lamination, and laser machining. The dimension of the shank is 300μm-thickness, 300μm-width, and 10mm-length. The electrodes were fabricated by electroplating gold. The working electrodes was shaped as two adjoining rectangles having size of 10μm-thickness and 50μm-width. The average electrical impedance of the working and ground electrode of 10 fabricated devices were 161+67kΩ and 10.3+3.3kΩ. The polyimide-coated, multi-mode optical fiber with diameter of 125μm was buried in the back side of the tetrode. For the optogenetic experiment, mouse transgenic line of CaMKIIa-cre and DIO-ChR2-EYFP were mated to produce transgenic line of CaMKIIa-ChR2-EYFP. The fabricated optrode was inserted to hippocampal CA1 area and blue laser (473nm wavelength) with power of 1.5mW was irradiated through the optical fiber. The electrical signal was recorded at working electrodes using Intan amplifier. The raw trace was further processed to get the peri-stimulus time

histogram and rastor plot. The result clearly showed the optogenetic experiment was successful. In summary, we developed the LCP-based optrode having four working electrodes at the tip of the shank, and successfully conducted optogenetic experiment on CA1 pyramidal cells using the fabricated optrode. We are currently developing the LCP-based optrode to have more number of electrodes and the distance from the electrodes to be close to the tip of optical fiber.

Title: All-optical screening of near-infrared genetically encoded voltage indicators

Authors: M. MATLASHOV[1], *C. SONG[2], M. COLAVITA[2], M. MONAKHOV[3], D. M. SHCHERBAKOVA[1], S. D. ANTIC[4], V. V. VERKHUSHA[1], T. KNOPFEL[2]

Abstract: Development of better performing genetically encoded voltage indicators (GEVIs) has been ongoing for the last several decades, yet its progress is limited by the low throughput of testing rationally designed new variants and screening high diversity libraries. Currently, single cell patch-clamp electrophysiology provides excellent data quality, and field stimulation techniques have reasonable throughput. We recently developed near-infrared (NIR) GEVIs that can be combined with blue light-controlled optogenetic membrane voltage actuation. This opens the path for an efficient all-optical screening approach for optimisation and evolution of new NIR GEVI variants. We generated a human embryonic kidney 293 (HEK293) cell line that constitutively expresses the blue-shifted cation channel opsin CheRiff (to enable a blue-light stimulation) and the potassium channel Kir2.1 (to achieve a sufficiently negative baseline membrane potential). Using patch-clamp electrophysiology, we verified that flashes of blue light drive the membrane potential from a baseline level (about -90 mV) close to the opsin reversal potential (about 0 mV). Transient expression of NIR GEVI variants in this cell line allowed determining their voltage sensitivity using an all-optical technique. Based on the same principle, we tested a series of NIR GEVI variants that emerged from the HEK293 cell-based screening in primary neuronal cultures. Action potentials were evoked either by a current injected through the patch-clamp pipette or by a CheRiff-mediated photocurrent. Cell-to-cell and construct-to-construct variations of the action potential-reporting optical signal were comparable between the two stimulation methods. All-optical testing largely increased the throughput of this secondary screening method. This screening approach can now be applied in multi-well format and microfluidics approaches.

Title: Multifunctional neural probe development via thermal drawing

Authors: *A. CANALES[1], S. PARK[1], M.-J. ANTONINI[1], C. LU[2], P. ANIKEEVA[1]
[1]MIT, Cambridge, MA; [2]Applied Materials, Santa Clara, CA

Abstract: Seamless integration of neural probes still presents many challenges despite advances in the materials and fabrication methods used. This is particularly relevant when combining multiple modalities of interacting with the brain, such as electrical recording and stimulation, and optical stimulation. Bi-directional communication with the brain, however, is crucial in furthering our knowledge of neural circuits in health and disease.
In order to address these challenges, we have used a thermal drawing process to develop multifunctional neural probes. Using soft materials, such as polymers and composites, and metals, we have fabricated flexible probes that provide co-localization of the different functionalities included. These probes can be used to record neural activity, for optical stimulation, and to deliver drugs or viruses at a region of interest. Furthermore, these probes have been successfully used in both the brain and the spinal cord of mice.
Using one of these probes, we developed a one-step optogenetics procedure. In this process, the virus carrying the gene expressing the light-sensitive protein was injected using the same device that was later used to provide the optical stimulation, and to record the neuronal response. These measurements were done in freely behaving mice, and we were able to observe changes in mice behavior correlated with the optical stimulation. These probes were able to record single unit activity, and to track it over at least 3 months.
We have also used elastomers to fabricate a stretchable probe. The mechanical flexibility of these probes makes them suitable to be used in environments with large amount of moving and stretching, such as the spinal cord. We used these probes to optically stimulate and record neural activity from the spinal cord of freely moving mice. We also correlated the electromyography measured in the leg to the optical stimulus delivered in anesthetized mice.

Abstract: As neuronal migration is crucial for brain development, unveiling its mechanism contributes to understanding of neurodevelopmental disorders. To observe behavior of cells *in vitro*, we have developed a portable *in vitro* cell imaging system based on a direct contact imaging by using a CMOS image sensor. To acquire bright field images of cells, we just directly put a culture dish on a CMOS image sensor of this imaging system. The developed imaging system is integrated with green and blue LEDs. When bright field images are acquired, The green LED is used to acquire bright field images illuminated, while the blue LED is used to stimulate cells optically. The size of the CMOS image sensor is so large that it can take image in a large area without sifting it. In addition, the package of this imaging system is so compact that it can be laid in typical CO_2 incubators without removing the shelf.
By using this portable *in vitro* cell imaging system, we first observed behavior of Neuro2a cells under normal condition. To observe cellular migration, we performed scratch wound healing assay and we could acquire the time-lapse images of cellular migration. Next, we transfected Channelrhodopsin 2 to Neuro2a cells and performed time-lapse imaging of scratched dish under photo-stimulated condition. We successfully acquired the time-lapse images of cellular migration, and the behavior of cells was almost the same as in the normal condition. In addition, apoptosis was not observed, suggesting that the LED light intensity is not harmful to cells and suitable for photo-stimulation.
The combination of this portable *in vitro* cell imaging system and light-sensitive channels can help to reveal the migration mechanism in future.

Title: Fast-decay red fluorescent genetically-encoded calcium indicators

Authors: *S. KERRUTH, C. COATES, K. TÖRÖK
Mol. and Clin. Sci. Res. Inst., St George's, Univ. of London, London, United Kingdom

Abstract: The time-course of intracellular Ca^{2+} transients is hard to assess due to buffering and signal integrating interactions. Genetically-encoded calcium indicators (GECI) have proven useful for monitoring Ca^{2+} transients in living cells and organisms. However, Ca^{2+} indicators with high Ca^{2+} affinity and slow decay kinetics themselves integrate Ca^{2+} signals, and furthermore may become saturated before peak [Ca^{2+}] is reached. Thus, for more faithful tracking of rapid Ca^{2+} dynamics, probes with faster off-kinetics are required[1,2]. Red-fluorescent GECI have been developed with the view of multicolour imaging and optogenetic applications[3]. Here we report novel fast-decay variants of red-fluorescent genetically-encoded Ca^{2+} indicators jRGECO1a and jRCaMP1a[3] with up to 8-fold ($t_{1/2}$ of 6.4 ms) and 13-fold ($t_{1/2}$ of 33 ms) faster *in vitro* decay kinetics (37 °C), respectively. Fast-decay jRGECO1a and jRCaMP1a variants retain comparable fluorescence brightness and dynamic range values to their parent proteins. The fluorescence dynamic range of the brighter mApple-based jRGECO1a variants is stable between pH 6.5 and 7.5, but declines above pH 7.5 to a Ca^{2+}-independent fluorescent state. In contrast, the less bright jRCaMP1a variants, based on mRuby, are stable over the pH range of 6.5 to 10. Red-fluorescent GECI, like their green-fluorescent counterparts, are characterised by high cooperativity to Ca^{2+}, and complex kinetic patterns of Ca^{2+}-dependent fluorescence response with a limiting *on*-rate. However, the fast-decay variants of jRGECO1a and jRCaMP1a reveal 8-fold faster ATP-evoked Ca^{2+} transients compared to their parent proteins in HEK293T cells, showing the benefits of fast-decay red-fluorescent GECI indicators for monitoring Ca^{2+} dynamics in living cells.

Abstract: Neuroscientists are paying increasing attention to fiber photometry techniques to record neural activity of genetically-targeted populations in behaving animals[1-3]. However, light scattering and absorption confine the recording volume addressed by conventional approaches to the vicinity of the fiber tip (~300μm). To circumvent this limitation, we propose tapered optical fibers (TFs) as photometry probes to collect fluorescent photons originated at depth. We measured light collection diagrams for TFs, TFs with micro-structured optical windows[4-6] and flat cleaved fibers (FFs) in semi-transparent and turbid medium. To do this, we used a two-photon microscope to measure the intensity collected by the waveguide surface when a focal spot is raster scanned in its proximity. We reconstructed the distribution of light delivered by the TF using a de-scanned pinhole imaging system. The combination of light collection and illumination diagrams led us to calculate the optical photometry efficiency of our devices. This led us to demonstrate that TFs collect photons from their whole optically active region, covering depths that depend on the fiber NA, core size and taper angle (Fig.1a). Despite collecting less photons overall, TFs are better suited than standard fibers to interface with extended and deep regions (Fig.1b). We also found that light collection can be localized to cellular volumes at specific depth by micro-structuring optical windows on the surface of TFs coated with a metallic layer (Fig.1c a diagram of the device and collection volumes of a 45 μm × 45 μm window as a function of the fraction of all collected photons). In light of these results, we view TFs as a complementary tool for fiber photometry experiments in cortical and sub-cortical regions.

Title: Diverse mechanisms of glutamate sensing by chemically labelled and genetically encoded fluorescent protein probes

Authors: C. COATES, N. HELASSA, *K. TÖRÖK
SGUL, London, United Kingdom

Abstract: Protein-based fluorescent glutamate sensors have the potential for real-time monitoring of synaptic and cellular glutamate concentration changes. We have developed both genetically encoded and chemically labeled fluorescent glutamate sensors and characterised their mechanisms of glutamate sensing. Fluorescence enhancement of genetically encoded probes $iGlu_u$ and $iGlu_f$ (Helassa *et al*., *Proc. Nat. Ac. Sci. USA, in press* (bioRxiv 233494; doi:

https://doi.org/10.1101/233494)) is based on two flanking portions of the bacterial periplasmic glutamate/aspartate binding protein (GluBP) reattaching on glutamate binding and thereby correcting the structure of circularly permuted EGFP (Marvin *et al*., 2013). Apo-iGluSnFR has low fluorescence; to achieve a highly fluorescent state, reconstitution of GluBP is required, stabilized by bound glutamate. Ultrafast sensor iGlu$_u$ first binds glutamate, which is not sufficient for fluorescence enhancement. Binding is followed by a conformational change (the reattachment of GluBP fragments) during which the highly fluorescent state develops. This step limits the rate of the fluorescence response. A novel variant, iGlu$_m$ with mM affinity for glutamate, follows an alternative kinetic path whereby reattachment of GluBP fragments occurs first, accounting for 15% of the fluorescence enhancement; glutamate binding to the reformed complex causes 85% of the fluorescence enhancement. Fl-GluBP, a glutamate sensor generated by fluorescent derivatization of GluBP with a synthetic fluorophore yields 90% of its fluorescence enhancement in the initial glutamate binding phase. The rate of fluorescence response by Fl-GluBP is faster, with a diffusion limited rate constant. Thus, while iGlu$_u$ signals the glutamate *on*-process by a concentration-independent rate, iGlu$_m$ and Fl-GluBP fluorescence response rates are glutamate concentration-dependent. The *off*-rates of all three probes allow sub-millisecond detection, at 34 °C. Through their broad affinity range and mechanistic variety, the above selection of genetically encoded and chemically labeled fluorescent glutamate sensors are suitable for monitoring the different processes that glutamate undergoes in neurotransmission and cellular homeostasis.

Title: Analyzing the two-photon absorption of red fluorescent genetically-encoded calcium ion indicators

Authors: *R. MOLINA[1], Y. SHEN[2], Y. QIAN[2], R. E. CAMPBELL[2], T. E. HUGHES[1], M. DROBIZHEV[1]
[1]Cell Biol. & Neurosci., Montana State Univ., Bozeman, MT; [2]Chem., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Genetically-encoded calcium ion indicators (GECIs) illuminate brain activity in model organisms. The basic design consists of a Ca2+ binding domain attached to a fluorescent protein

in such a way that the binding of Ca2+ modulates its fluorescence. The current favorite GECI is the green GCaMP6, due to the large increase of fluorescence upon binding Ca2+ (up to a 50-fold change). However, red fluorescence scatters less than green fluorescence, which is especially desirable for deeper imaging in tissue. Although there are red fluorescent GECIs available, they are less popular for reasons that include a smaller change in fluorescence. Three factors can contribute to the change in fluorescence: 1) different quantum yields of the Ca2+-bound and Ca2+-free forms; 2) different extinction coefficients or cross sections, in one- or two-photon imaging, respectively; and 3) a redistribution of the neutral and anionic forms of the chromophore in the presence of Ca2+. The third factor was previously shown to be the predominant mechanism for modulating the fluorescence of GCaMP6. We present a thorough analysis of the one-photon and two-photon properties of several red GECIs and use this data to determine the main factor(s) contributing to the increase in fluorescence upon binding Ca2+, particularly under two-photon excitation. In most cases we observe both the change of the maximum two-photon cross section and the shift of equilibrium between the neutral and anionic forms of the chromophore upon binding Ca2+. Quantitative analysis of the two-photon absorption properties can tell us about changes in the electrostatic environment around the chromophore and can potentially direct mutagenesis efforts towards creating red GECIs with a larger Ca2+-dependent fluorescence increase.

Title: Sensing Ca^{2+} without perturbing neurons: The design, validation and applications of GCaMP-X

Authors: *X. LIU[1], Y. HE[2], Y. LIU[2], P. LI[1], S. YUE[1], Y. YANG[1,2]
[1]Beihang Univ., Beijing City, China; [2]Dept. of Biomed. Engin., Tsinghua Univ., Beijing, China

Abstract: GCaMP, one popular type of genetically-encoded Ca^{2+} indicators, has been associated with various side-effects. Here we unveil the intrinsic problem prevailing over different versions and applications, showing that GCaMP containing CaM (calmodulin) interferes with both gating and signaling of L-type calcium channels (Ca_V1). GCaMP acts as impaired apoCaM and

Ca^{2+}/CaM both critical to Ca_V1, which disrupts Ca^{2+} dynamics and gene expression. We then design and implement GCaMP-X, by incorporating an extra apoCaM-binding motif, effectively protecting Ca_V1-dependent excitation-transcription coupling from perturbations. GCaMP-X resolves the problems of detrimental nuclear accumulation, acute and chronic Ca^{2+} dysregulation, and aberrant transcription signaling and cell morphogenesis, while still demonstrating excellent Ca^{2+}-sensing characteristics partly inherited from GCaMP. In summary, CaM/Ca_V1 gating and signaling mechanisms are elucidated for GCaMP side-effects, while allowing the development of GCaMP-X to appropriately monitor cytosolic, submembrane or nuclear Ca^{2+} (Yang *et al.* Nature Communications 2018), which is also expected to guide the future design of CaM-based molecular tools. In addition, some recent progress in applying GCaMP-X to elucidate biophysical and physiological mechanisms in neurons will be discussed.

Abstract: In eukaryotic cells, the endoplasmic reticulum (ER) is the largest continuous membrane-enclosed network which surrounds a single lumen. Using a new genetically encoded voltage indicator (GEVI (named Aahn)), we applied the patch clamp technique to cultured HEK293 cells and neurons and found that there is a very fast electrical interaction between the plasma membrane and internal membrane(s). This discovery suggests a novel mechanism for interaction between the external membrane and internal membranes as well as mechanisms for interactions between the various internal membranes. The ER may transfer electrical signals between the plasma membrane and other internal organelles. The internal membrane optical signal is reversed in polarity but has a time course similar to that of the plasma membrane signal.

The optical signal of the GEVI in the plasma membrane is consistent from trial to trial. However, the internal signal decreases in size with repeated trials suggesting that the electrical coupling is degrading and/or the resistance of the internal membrane is decaying. Recently, we have tested the second generation of Aahn which appears to give only an internal signal.

Title: A red shifted GEVI that can resolve population signals in slice

Authors: *B. KANG[1,3], B. YI[1,3], S. LEE[2,4], B. J. BAKER[5,3]
[2]Ctr. for Functional Connectomics, [1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Bio-Medical Sci. and Technol., UST, Daejeon, Korea, Republic of; [4]Dept. of Trans-Disciplinary Studies, Seoul Natl. Univ., Suwon, Korea, Republic of; [5]KIST Korea Inst. of Sci. & Tech., Seoul, Korea, Republic of

Abstract: A genetically encoded voltage indicator (GEVI) with bright emission in a red shifted spectra was developed by modifying the combination of Bongwoori voltage-sensing domain (VSD) and the red fluorescent protein (FP) dTomato. Dimerization of the FP has been shown to be critical in the mechanism of the voltage-dependent optical signal which led to the use of the very bright FP dTomato. Improvements were made by manipulating charges in the dimer interface between the red FPs and altering the linker between the VSD and FP. The resulting GEVI, called Ilmol (Korean for sunset), shows that directed mutagenesis from a mechanistic approach can successfully create probes capable of resolving action potentials in neurons and population recordings from slice.

Abstract: Genetically encoded voltage indicators (GEVIs) convert voltage change into a fluorescence signal. GEVIs have improved, showing promising results in characterizing mammalian neuronal circuit. We recently developed a GEVI, Bongwoori-R3, that is optimized for visualizing action potential spikes in neurons. To optimize its expression in transmembrane regions thereby improving the signal-to-noise ratio, we introduced Golgi-to-plasma membrane trafficking and ER export signals. The signal sequences were introduced separately or in combination to ascertain effects on Bongwoori-R3 membrane expression. The ER export signal increased the ΔF/F but made the voltage-dependent optical signal slower. Placing spacers in between Bongwoori-R3 and the ER signal sequence alleviated this effect while keeping the improved ΔF/F size. A novel strategy to only activate the GEVI molecules in certain area was also investigated using photoactivation. We developed a photoactivatable Bongwoori-R3. After the photoactivation, this variant successfully showed voltage-dependent fluorescence signal from a mammalian cell type. In this presentation, we will also discuss strategies that we adopted and newly introduced to expand applicability of GEVIs.

Title: Multifunctional tapered optical fibers for optical excitation and electrical extracellular recording using direct laser writing and two-photon lithography

Authors: *A. BALENA[1,2], A. RIZZO[1,2], E. D. LEMMA[1,2], F. PISANO[1], M. PISANELLO[1], L. SILEO[1], M. DE VITTORIO[1,2], F. PISANELLO[1]

Abstract: Tapered optical fibers (TF) are a versatile tool for spatially selective activation or inactivation [1] of genetically defined set of neurons at depth [2]. TFs are based on multimodal optical fibers (core size 50 - 200 µm) and a sub-µm tip for smooth insertion into the brain [2-4]. Light delivery can be confined to small apertures along a metal-coated taper by acting on the light coupling angle into the fiber. We propose a system that combines Direct Laser Writing (DLW) and 3D Two Photon Litography (TPL) to fabricate a single integrated probe capable of both optical stimulation and electrical extracellular recording. Our DLW-TPL system consists in two parallel paths that exploit an ultraviolet and an infrared laser focused on TF surface (Fig.1a). The TF is connected to a four-axis piezoelectric stage (Fig.1b) by a custom fiber holder, allowing for translation and rotation around the TF axis. The system is controlled with custom LabView software. The DLW path ablates the metal coating to obtain optical apertures all along and around the TFs [5] (Fig.1c-d). The TPL path allows for the implementation of positive photoresist patterning techniques for the realization of µ-electrodes by subsequent metal deposition and lift-off steps (Fig.1e-g). Our system exploits the advantages of TPL in terms of 3D sub-micrometer pattering on the highly non-planar surface of the fiber. Potentially, this technique can be used to fabricate µ-electrodes and mm-long conductive tracks of different size and shape. We view the proposed method as a fast and powerful technique to fabricate multifunctional neural interfaces for optogenetic applications with customized light delivery geometries and extra-cellular recording from multiple sites.

Abstract: Microglia are central nervous system (CNS)-resident macrophages that regulate and maintain CNS homeostasis during development and in healthy and disease states. The observation of microglia is predominantly restricted to either histopathological techniques utilizing post-mortem CNS tissues or fluorescent imaging using knock-in or transgenic mouse lines that express fluorescent proteins in microglia lineages. Therefore, efforts have been dedicated to generating or identifying biomolecules or small chemical probes that target microglia population *in situ* and *in vivo*. Through a thorough structure-activity relationships study, we developed a microglia-specific probe, CDr20, which can be applied both to *in vitro* and *in vivo* imaging. CDr20 selectively stained microglia in both cultured cells and in the rodents' brains. We confirmed that intravenously delivered CDr20 labeled cortical microglia if and only if the blood brain barrier was compromised using LPS injected animals, mild ischemia and Alzheimer's disease model animals. Through a genome-scale CRISPR-Cas9 screening, we found that Ugt1a7c turns on the fluorescence of CDr20 by enzymatic glucuronidation reaction in microglia. Since the target enzyme of Ugt1a7c was the only type of Ugt genes highly enriched in microglia, this research will lead an interest its functional role in the brain, and Ugt1a7c can be used as a novel marker of microglia.

Title: Serotonin imaging using serotonin-imprinted fluorescent polymer nanoparticles as a probe

Authors: *R. MORI, K. UMETA, Y. KATSUMATA, S. ISHIDA, Y. YOSHIMI
Shibaura Inst. of Technol., Koto-ku, Toyosu, Japan

Abstract: A Molecularly Imprinted Polymer (MIP) is a polymer that has been processed using the molecular imprinting technique which leaves cavities in polymer matrix with affinity to a chosen "template" molecule. Thus, we attempt to develop a probe tracing neurotransmitter using a fluorescent nanoparticle of MIP (fMIP-NP) of the target neurotransmitter as a template. In this study, serotonin was chosen as the target neurotransmitter. Serotonin was immobilized on glass beads via silane coupler. The beads were fluidized in a solution of a functional monomer which has affinity with serotonin, a crosslinking monomer, a fluorescent monomer and a radical polymerization under UV irradiation. The synthesized copolymer was removed from the beads by washing with acetonitrile. After evaporation of the acetonitrile, the copolymer was dispersed as fMIP-NP in 0.1 M phosphate buffered saline at pH 7.4. The radius and fluorescent intensity of fMIP-NP were sensitive to serotonin but were insensitive to L-tryptophan (The results will be presented in this meeting separately). A 0.1 mM serotonin solution was injected into the fMIP-NP dispersion under observation with a fluorescent imaging system (MiCAM02, Brainvision Inc.). The fluorescent intensity was increased by 2.6% with a time lag of several-ten milliseconds. The result indicates that the fMIP-NP can work as a rapidly responsive probe. A cerebral ganglion of Aplysia was stained by immersion in an artificial sea water dispersed with the fMIP-NP for 24 hours. The ganglion was observed by the fluorescent imaging system. As a result, only one neuron in the vicinity of the serotonergic neurons (MCC) indicated spiked change of 0.05 % in the fluorescent intensity an interval of 50 ms. Those results indicate that the fMIP-NP of serotonin is feasible for detection of serotonin secreted in living nervous system. Molecular imprinting technology can target many kinds of chemicals, then fMIP-NP would contribute to elucidate the roles of each neurotransmitters in nervous systems.

Title: Development, characterization, and deployment of a new generation of genetically encoded voltage indicators

Authors: *F. ST-PIERRE[1,2], Z. LIU[2], Y. GOU[1], S. GUAN[1], X. LU[2], J. LEE[2], J. YANG[2], P. SUZUKI[2], S. CAO[2], A. TOLIAS[1]

Abstract: A longstanding goal in neuroscience is to understand how spatiotemporal patterns of neuronal electrical activity underlie brain function, from sensory representations to decision making. An emerging technology for monitoring electrical dynamics is voltage imaging using Genetically Encoded Voltage Indicators (GEVIs) — light-emitting protein indicators whose brightness directly reports voltage. GEVIs are promising tools for monitoring voltage dynamics at high spatiotemporal resolution in genetically defined cell types *in vivo*. Indicator performance has steadily progressed since GEVIs were first reported; they have also been deployed in multiple animal systems. For example, we have recently demonstrated two-photon voltage imaging in organotypic slice cultures and in *Drosophila* with millisecond-timescale precision, subcellular resolution, and the ability to simultaneously monitor spatially-segregated locations. However, despite significant progress made so far by the GEVI community, the performance of current voltage indicators is usually insufficient for robust single-trial two-photon imaging of voltage dynamics of many individual neurons in behaving rodents. As a result, GEVIs have yet to be broadly adopted. The mechanisms of voltage indicators are insufficiently understood to enable purely rational engineering of new GEVIs with predictable outcomes, motivating the evaluation of many candidates to identify improved variants. As screening by patch-clamp electrophysiology can only evaluate fewer than ~10 new candidates per day, we are developing a pipeline for high-throughput screening of GEVI libraries, followed by detailed characterization of the most promising candidates. Here, we will present our ongoing efforts to develop improved methods for screening variants of the Accelerated Sensor of Action Potential (ASAP) voltage indicator family. We also present promising candidates identified during our screens. We anticipate that these efforts will ultimately produce high-performing indicators of broad utility for imaging spontaneous voltage dynamics in the brains of behaving animals.

Abstract: Genetically encoded voltage indicators (GEVIs) allow for optical recordings of membrane potential from genetically defined cell populations. Recently developed GEVIs have dramatically improved signal-to-noise ratios that increase the fidelity of measurements of neuronal activity *in vitro* and *in vivo*. However, there is limited *in vivo* data from transgenic mice expressing GEVIs in targeted cell populations. Here we used Cre/tTA dependent expression of the GEVI ArcLight to generate knock-in transgenic mice with different expression patterns in the olfactory bulb. Odor-evoked optical signals were detectable in single trials using both widefield epifluorescence and 2-photon imaging. Our results demonstrate that the ArcLight transgenic line is a flexible genetic tool that can be used to record neuronal electrical activity of a variety of cell types with a signal-to-noise that is comparable to previous reports using viral transduction.

Title: Biophysical approaches for designing voltage-sensing probes

Authors: *M. J. IWANICKI, J. A. MANCINI, S. MUKHERJEE, C. C. MOSER, B. Y. CHOW, B. M. DISCHER
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neurons transmit information to other neurons by utilizing voltage signaling, and by imaging these signals on faster timescales, a greater understanding of interneuronal communication can be achieved. Organic voltage-sensing probes were first developed to measure voltage signaling in neurons. While many organic probes have been developed to detect signals with fast temporal resolution, they cannot be targeted to a specific cell or membrane. Genetically-encoded voltage indicators (GEVIs), which typically includes a voltage-sensing domain of a natural protein, were engineered to improve genetic targetability. However, GEVIs tend to be slower, dimmer, and not as sensitive as organic voltage-sensing probes. Here, we present our progress on the development and characterization of *de novo* designed GEVIs based on artificial 4-α-helical bundle proteins, called maquettes. Maquettes have been designed to be able to attach various natural cofactors and can either be water-soluble or transmembrane constructs. We are developing two classes of maquette GEVIs. The first class involves covalently attaching a fluorescent cofactor to the core of the maquette. We are using a direction evolution approach in order to improve its fluorescent signal and quantum yield. The second class is a fusion construct of a maquette and a fluorescent protein, whose fluorescence can be modulated by the redox state of heme. Energy transfer between the fluorescent protein and the maquette has been demonstrated upon heme reduction. Our current GEVI prototypes have been expressed in *E. coli* and characterized *in vitro*. The modular nature of these probes allows us to optimize the intensity and to tune their speed to be within the desirable range. We are also optimizing the sequences for plasma membrane trafficking in hippocampal neurons to validate the *in vitro* biophysical approach in mammalian cells.

Abstract: Genetically encoded voltage indicators (GEVIs) can be used to image neuronal activity *in vivo*. GEVIs detect neuronal membrane voltage changes, including action potentials and subthreshold activity. Moreover, the activity of distinct neuron subtypes can be followed by expressing GEVIs using cell type-specific promoters. However, current GEVIs exhibit relatively low sensitivity, inefficient membrane expression, and poor photostability, which limit their utility for *in vivo* imaging of neuronal populations. To improve GEVI performance, we created libraries of novel variants by structure-guided or unbiased mutagenesis and assayed activity using high-throughput screening. We used tissue culture cells for screening that can be induced to spike from a resting membrane potential by electrical field stimulation. These cells stably express voltage-gated sodium and inwardly rectifying potassium channels and are readily transduced with GEVI constructs. This enables a throughput of ~10^4 constructs screened per year in replicate. Fluorescence imaging was performed on a motorized microscope in an automated manner. Promising constructs were further tested in cultured neurons in response to action potentials or voltage steps. In order to improve sensor membrane expression, the membrane trafficking of the best variants was quantified in relation to the response amplitude by epitope labeling of surface versus internal membrane-expressed sensor proteins. We report on the higher sensitivity, faster kinetics, and shifted voltage range of new variants of the existing GEVIs: ArcLight, MARINA, ASAP, and the novel chemigenetic GEVI, Voltron. These next generation GEVIs will be useful for the correlation of neuronal activity *in vivo* with animal behavior.

Electrical Engineering,, Columbia Univ., New York, NY; [4]Columbia Univ., Dept. of Electrical Engin., New York, NY

Abstract: Optogenetics has revolutionized the investigation of neural network function. In many experiments, especially those coupled with electrophysiology, a single optical fiber is used to flood a large area of the brain with light, limiting the ability to activate neurons with high spatial resolution in vivo. Here we develop an active nanophotonic multi-beam probe integrated with recording electrodes which enables deep brain neural activation and extracellular spike recording with high fidelity in space and time. The active silicon photonics technology overcomes the limited reconfigurability of traditional optics and results in an unprecedented amount of optical control, matching the scale and resolution currently achieved by silicon probes for electrophysiological recordings. The demonstrated probe employed a 1x8 multipoint-emitting nanophotonic switch leading to an array of grating emitters (emitter size: 20 x 20 μm, 125 μm inter-beam distance) and platinum recording electrodes (size: 30 μm diameter) within 20 μm of each emitter. The nanophotonic switching electronics and the recording electrodes were co-fabricated on the same metal layer and insulated using SU8. Using an optimized nanophotonic architecture, we were able to achieve ON/OFF switch ratios of greater than 50:1. In this work, we injected AAV-EF1a-DIO-ChETA-eYFP virus (ChETA, a channelrhodopsin-2 variant which enables ultrafast optogenetic control) into the visual cortex of Gad2-IRES-Cre transgenic knock-in mice, and implanted the 8-beam nanophotonic probe into the visual cortex in anesthetized mice. By applying voltages to the nanophotonic switch network, we routed 473 nm blue light to 8 output grating light emitters and independently activated individual ChETA-expressing Gad2 interneurons across layer 2-6 of visual cortex with customer programmed patterns. In conclusion, we show that the nanophotonic platform can be successfully integrated with high-density electrical recording sites to create or edit complex neural activity. Scaling it up to a larger number of beams (e.g.128) is expected to be straightforward since these devices are defined lithographically, enabling high spatiotemporal resolution optical stimulation in deep brain regions.

Title: Engineering of voltage sensing domains for optical resolution of differing neuronal activities

Authors: *A.-R. JUNG[1], J. CHOI[2], E. HWANG[2], B. J. BAKER[1]
[1]KIST Korea Inst. of Sci. & Tech., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: To optically resolve different types of neuronal activities, we have developed several types of genetically encoded voltage sensing indicators (GEVIs). To develop GEVIs that can only resolve hyperpolarization (inhibition), we manipulated movement of the voltage-sensing domain with tryptophan residues. Our data suggest that several positions of Tryptophan inhibit the movement of S4 during membrane depolarization. To make stronger and a better for the signal to noise ratio inhibition probe, we inserted several Tryptophan's into the voltage sensing domains. Insertion of a tryptophan residue in the S1 or/and S4 α-helix dramatically reduced the optical signal for depolarization while maintaining the fluorescent response during hyperpolarization of the plasma membrane. As a result, the optical activities of some probes are biased towards optically resolving neuronal inhibition.

Abstract: Serotonin (5-HT) is an important monoamine neuromodulator in the nervous system, critical for learning, appetite control, sleep regulation, and many other cognitive functions. Malfunctions of 5-HT regulation are associated with several neurological diseases including depression, addiction and compulsivity. Despite its importance, deciphering the physiological function and regulation of 5-HT are currently hindered by the lack of non-invasive methods with good spatiotemporal resolution in tracking 5-HT dynamics *in vivo*. Here we successfully developed a novel genetically-encoded fluorescent 5-HT sensor ($GRAB_{5\text{-}HT}$), through coupling of a conformationally sensitive circular-permutated EGFP with an endogenous 5-HT sensing GPCR. We show that $GRAB_{5\text{-}HT}$ enables *in vivo* cell-specific monitoring of odor-evoked 5-HT secretion in *Drosophila*, as well as tracking dynamic changes of dorsal raphe 5-HT levels during reward conditioning in freely moving mice. Finally, $GRAB_{5\text{-}HT}$ could be long-term expressed, up to 6 months, in non-human primates without noticeable toxicity, and is capable of reporting specific changes of 5-HT concentration under two-photon imaging condition. These data together demonstrate $GRAB_{5\text{-}HT}$ is a useful and broad applicable probe for understanding the physiological and pathophysiological function of 5-HT in diverse model organisms.

Lab. for Optoelectronics, Wuhan, China; [6]Sch. of Med., Univ. of Virginia, Charlottesville, VA

Abstract: Norepinephrine (NE) and epinephrine (Epi), important biogenic monoamine neurotransmitters, are involved in many crucial physiological processes in diverse organs.

However, the precise function and regulation of adrenergic and noradrenergic transmission in the majority of tissues remains poorly understood due partly to the limitations of the available techniques for monitoring their release. Here we developed a G-protein-coupled Receptor Activation-based Epi/NE sensor ($GRAB_{NE}$). $GRAB_{NE}$ sensor responds to exogenous NE and Epi with $\Delta F/F \sim 200\%$ and no apparent ectopic activation of downstream G protein and β-Arrestin pathways. $GRAB_{NE}$ preserves the ligand binding pocket of endogenous adrenergic receptors and has an EC_{50} to NE ~1 μM. $GRAB_{NE}$ sensor specifically detects both exogenous and endogenous NE in brain slices under 2-photon microscopy. *In-vivo* application of $GRAB_{NE}$ sensor in awake zebrafish and behaving mice unravel their capacity and robustness in specifically revealing endogenous NE dynamics. Thus, $GRAB_{NE}$ sensor provides a new genetically-encoded tool for dynamically monitoring adrenergic and noradrenergic transmission during physiological and pathological processes.

Abstract: Acetylcholine (ACh) regulates a diverse array of physiological processes throughout the body, yet cholinergic transmission in the majority of tissues/organs remains poorly understood due primarily to the limitations of available ACh-monitoring techniques. By tapping into the native ACh sensing GPCRs, we here developed a family of G-protein-coupled receptor activation-based ACh sensors (GACh), with high sensitivity, specificity, signal-to-noise ratio, kinetics and photostability suitable for monitoring ACh signals in multiple preparations

including cultured cells and acute slices *in vitro* and living *Drosophila* and mice *in vivo*. Taking advantage of the novel GACh sensors, we successfully tracked the dynamics of endogenous ACh in real-time, revealing presynaptic regulation as well as firing-pattern dependent of cholinergic transmission. Furthermore, we recently developed newer GACh sensors with even larger dynamic range, offering improved probes to resolve physiological ACh levels. In sum, GACh sensors provide a convenient, broadly applicable tool for monitoring cholinergic transmission underlying diverse biological processes.

Title: A toolbox of genetically-encoded fluorescent sensors for monitoring purinergic neurotransmitters

Authors: *Y. LI[1,2,3,4], H. WANG[3,4], Z. WU[3,4], H. WU[5], L. DONG[2,4], K. HE[5], M. XU[6,7]
[1]Peking Univ., Beijing, China; [2]Peking-Tsinghua Ctr. for Life Sci., Beijing, China; [3]State Key Lab. of Membrane Biol., Peking Univ. Sch. of Life Sci., Beijing, China; [4]PKU-IDG/McGovern Inst. for Brain Res., Beijing, China; [5]Sch. of Life Sci. Tsinghua Univ., Beijing, China; [6]Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China; [7]Chinese Acad. of Sci. Ctr. for Excellence in Brain Sci. and Intelligence Technology, Chinese Acad. of Sci., Shanghai, China

Abstract: Purinergic molecules, e.g. ATP, ADP, AMP and adenosine, are playing important roles in a plethora of physiological processes, including sleep-wake control, learning and memory, as well as cell proliferation, cardiovascular activity and immune response. Malfunction of purinergic signaling is implicated in diseases such as pain, migraine, epileptic seizures and drug addiction. A major obstacle to decipher physiological and pathophysiological function of purinergic transmission is the lack of direct, sensitive, and non-invasive method to monitor and discern structural similar purinergic neurotransmitters, ideally with high spatial and temporal resolution *in vivo*. Here by tapping into naturally evolved adenosine receptors and purinergic

P2Y receptors, we developed a toolbox of distinct genetically-encoded fluorescent sensors, with unique molecular specificity for adenosine, ADP, ATP and UTP. These novel fluorescent sensors utilize metabotropic GPCR receptors as ligand sensing modules and circular-permutated GFPs as optical outputs. They have good membrane localization and exhibit robust fluorescence increase (~ 100% dF/F or more) upon cognate ligand application when expressed in cultured HEK239T cells. In addition, these sensors have nano- to micro-molar affinities to distinct purinergic molecules, very similar to native adenosine and P2Y receptors. Using these sensors, we successfully monitored neuronal- or glial- derived extracellular adenosine levels upon electric or high KCl stimulation. In addition, using fiber photometry, we are able to observe sleep-awake relevant changes of adenosine levels in mice *in vivo*. The development of these genetically-encoded purinergic neurotransmitter sensors provides a critical tool for better understanding of purinergic signaling in physiological and pathological processes with molecular specificity.

Abstract: Dopamine (DA) is a central monoamine neurotransmitter involved in many physiological and pathological processes. A longstanding yet largely unmet goal is to measure DA changes reliably and specifically with high spatiotemporal precision, particularly in animals executing complex behaviors. Here we report the development of novel genetically-encoded GPCR-Activation-Based-DA ($GRAB_{DA}$) sensors that enable these measurements. In response to extracellular DA rises, $GRAB_{DA}$ sensors exhibit large fluorescence increases ($\Delta F/F_0$~90%) with sub-second kinetics, nanomolar to sub-micromolar affinities, and excellent molecular specificity. Importantly, $GRAB_{DA}$ sensors can resolve a single-electrical-stimulus evoked DA release in mouse brain slices, and detect endogenous DA release in the intact brains of flies, fish, and mice. In freely-behaving mice, $GRAB_{DA}$ sensors readily report optogenetically-elicited nigrostriatal DA release and depict dynamic mesoaccumbens DA changes during Pavlovian conditioning or during sexual behaviors. Thus, $GRAB_{DA}$ sensors enable spatiotemporal precise measurements of DA dynamics in a variety of model organisms while exhibiting complex behaviors.

Title: Electrophysiological phenotype characterization of human iPSC-derived dopaminergic neuronal lines by means of high-resolution microelectrode array

Authors: *M. FISCELLA[1,2], N. LEARY[1], S. RONCHI[1], A. HIERLEMANN[1]
[1]ETH Zurich, Basel, Switzerland; [2]MaxWell Biosystems AG, Basel, Switzerland

Abstract: High-resolution-microelectrode-array (HD-MEA) technology enables to study neuronal dynamics at different scales, ranging from axonal physiology to network connectivity

[1]. We have used this HD-MEA technology to characterize and compare the electrical phenotypes of commercially available human dopaminergic neurons (iCell DopaNeurons, MyCell DopaNeurons A53T α-synuclein, Cellular Dynamics International, Madison, WI, US). Furthermore, we have studied the effect of human astrocytes (iCell Astrocytes, Cellular Dynamics International, Madison, WI, US) on neural-culture development. Astrocyte/neuron co-cultures showed higher signal amplitudes and higher firing rates than neural cultures without astrocytes. Adding astrocytes to neural cultures changed the whole culture morphology by promoting cell clustering. Interestingly, astrocyte/neuron co-cultures showed a lower sample-to-sample variability across multiple HD-MEA recordings compared to neural cultures without astrocytes. We compared action potential propagation velocities along axons between dopaminergic A53T α-synuclein neurons and the wild-type isogenic control cell line. We found that in both, wild-type and disease-model neurons, axonal action potential propagation velocities were lower than in rat primary cortical neurons [2]. Furthermore, we found different axonal-action-potential-velocity-development profiles of A53T α-synuclein dopaminergic neurons and the wild-type counterpart. Finally, we were able to precisely evoke action potentials in individual single human neurons by subcellular-resolution electrical stimulation. HD-MEA systems enable to access novel electrophysiological parameters of iPSC-derived neurons, which can be potentially used as biomarkers for phenotype screening and drug testing.

Abstract: Human iPSC-derived neurons are expected to be applied to toxicity evaluations in nonclinical studies. One of the major toxicities of the central nervous system in clinical trials is convulsions. Multi-electrode array (MEA) systems have recently attracted attention as useful for evaluating convulsions because they can non-invasively measure the electrophysiological activities of neural networks. We have previously reported the electrophysiological responses to several convulsive compounds using MEA in cultured hiPSC-derived neurons. However, the identification of analytical parameters to detecting epileptiform activities remains an important issue. In this study, we developed a novel analytical method to quantify the periodicity of synchronized burst firings as one of the effective parameters for detecting epileptiform activities. We also identified the parameter sets that can separate the responses between convulsive drugs and negative control acetaminophen, and the responses among the several convulsants with different action mechanism using principal component analysis of 10 parameters. The parameters related to periodicity including new method developed by us were effective for the separation of convulsants and negative control. In this principal component analysis method using the identified parameter set, reproducibility was also confirmed in data of different samples. These our analysis method will be effective for detecting convulsive response and predicting mechanism of action of convulsive drugs.

Title: An *in vitro* 3D platform for functional and structural interrogation of neuronal circuits

Authors: B. M. MOLINA[1], P. D. JONES[2], L. JENTSCH[1], *P. CESARE[3]
[1]Neuro Microphysiological Systems, [2]Microsystems and Nanotechnology, [3]NMI, Reutlingen, Germany

Abstract: In the quest for developing new therapies for neurological disorders, researchers are still largely dependent on 2D in vitro experiments and animal models. Poorly representing the multifaceted nature of neurodegenerative processes in the human brain, these approaches have shown low predictive value in clinical studies.
To fill this gap, several public and private initiatives are focusing on the development of so called organs-on-chips. By combining advanced microfabrication and 3D cell culture technologies, these are expected to better recapitulate the physiology of the brain and capture its complexity at both structural and functional level, which may eventually lead to more relevant in vitro models of human neuronal disorders and consequently to a more efficacious drug discovery process.
However, despite the recent progresses in this field, none of the currently available technologies has the capability to directly measure electrical excitability of individual neurons synaptically connected in 3D neuronal circuits.
To address this need, our group is developing a novel phenotypic platform based on the integration of microfabrication methods, electrode arrays and microfluidics to reconstruct, record and image 3D brain circuits non-invasively in a high-throughput format.
For this purpose, mouse primary hippocampal neurons are grown embedded within hydrogel scaffolds to recreate 3D multicellular architectures inside microfabricated, pump-free bioreactors. Microelectrode arrays are then integrated into the microfluidic design and used to monitor the electrical activity of enclosed neuronal cells at different time points and in response to a range of neuroactive compounds. In parallel, morphological and 3D structural information of neurons can be collected at high-resolution by confocal microscopy following transduction with AAV particles encoding for fluorescent proteins. To meet the throughput requirements associated to pre-clinical research, up to twelve independent experiments can be carried out simultaneously on a single device having a footprint of only 49 x 49 mm. Future developments

may include integration of such technology into a format compatible with multi-well plates. Collectively, such technology has the potential to introduce a new paradigm in basic and applied neuroscience by providing a novel ground-breaking platform for investigating 3D neuronal circuits in vitro. By enabling a more physiologically relevant disease modelling, this will lead to: i) better understanding of basic neuronal mechanisms; ii) refinement of pre-clinical research methods; iii) reduction in the number of animal studies.

Abstract: Multi-electrode (MEA) assays using human induced pluripotent stem cell (hiPSC)-derived neurons are expected to predict the convulsion, which is one of severe neurotoxicity in drug development. However, an evaluation index of toxicity and differences in responsiveness depending on the convulsant type are not well known. In this study, we aimed to develop an analytical method enabling the evaluation of toxicity and the classification of action mechanism of convulsants using deep learning. hiPSC-derived cerebral cortical neurons were cultured on MEA chips, and the pharmacological responses of 17 drugs in spontaneous firings were obtained by the 24-wells MEA system (Presto). We constructed the raster plots of spontaneous firing and the divided image data. The 4096 feature quantities of the divvied image data in raster plots were extracted by unsupervised learning. Next, feature quantities and drug name were learned by deep learning. Using this learned neuronal network, we have succeeded in separating the responses between non-convulsive drugs and convulsants, the dose-responses, and classifying the action mechanism of convulsive drugs. We also found that there is an effective bin size of image data in raster plots for separating action mechanisms. The artificial intelligence analysis method of

image data in raster plots are useful for an evaluation index of toxicity and classification of action mechanism in MEA data of in vitro cultured hiPSC-derived neuronal networks.

Abstract: Human induced pluripotent stem cell (iPSC)-derived neurons are promising for evaluating the toxicity of pharmacological agents in nonclinical studies. One of the major

adverse events affecting the central nervous system observed during clinical trials is convulsions. We previously reported the convulsive response using Multi-electrode array (MEA) in cultured hiPC-derived neurons. Although the balance between excitatory and inhibitory inputs is important in convulsive seizure, the optimal proportion of excitatory and inhibitory neurons of human iPS cell-derived neurons in the evaluation assay of drug-induced convulsion toxicity is not known. In this study, we aimed to examine the feature of spontaneous firings and the drug - induced seizure activities depending on the ratio of excitatory/inhibitory neurons in human iPSC-derived neurons. hiPSC-derived cortical neurons, in which the ratio of Glutamatergic and GABAergic neurons are from 8 : 2 to 2 : 8 were cultured on MEA chips, and the spontaneous firings and pharmacological responses of convulsants were obtained by the 24-wells 384 ch MEA system (Presto). The neuronal network with a high percentage of excitatory neurons showed short synchronized burst firings (SBFs) at high frequencies and the firing rate other than SBFs was also high. On the other hand, the network with high inhibitory neurons showed the SBF with long period. In drug-induced seizure activities, there was no remarkable dose responses in high percentage of excitatory neurons, the network with high inhibitory neurons also showed significant activity changes in convulsants other than the inhibitors of GABA receptor. The network with high inhibitory neurons also showed activity change at low concentrations. These results suggest that a higher proportion of GABA neurons is more effective in detecting drug-induced seizure toxicity.

Title: Real-time measurement of dopamine release in cultured human iPS cell-derived dopaminergic neurons using carbon nanotube MEA system

Authors: *S. NOJI[1], N. MATSUDA[1], A. ODAWARA[1,2,3], I. SUZUKI[1]
[1]Tohoku Inst. of Technol., Sendai-Shi, Japan; [2]Aimr, Tohoku Univ., Sendai-Shi, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Multi-electrode (MEA) assays using human induced pluripotent stem cell (hiPSC)-derived neurons are expected to predict the toxicity and the pharmacological effects. If we can measure the release of neurotransmitter using this MEA, it is possible to evaluate the drug related to release of neurotransmitters, and it is expected to improve the accuracy of medicinal effects. In this study, we aimed to develop the carbon nanotube (CNT) MEA chip, which enables real-

time measurement of neurotransmitters by electrochemical reaction. The CNT-MEA chip was fabricated by electro-plating method. Detection sensitivity to dopamine (DA) in the fabricated CNT-MEA chip was examined by electrochemical measurement method. The change of DA release to methamphetamine (MTH) were measured using mounted striatal slice of 6 weeks old mice and cultured human iPSC-derived dopamine neurons on CNT-MEA. As a result of the electrochemical measurement, an oxidation peak current was observed at 0.25 V, and the detection limit and linearity of DA was less than 5 nM. We have succeeded in real time detection of DA release using striatal slices and human iPS cell derived DA neurons, and detected the changes in the amount of DA release depending on MTH dose. Furthermore, in the human iPSC-derived DA neuron, a change of spike pattern at MTH administration was detected by conventional filed potential measurement. In summary, we developed a novel CNT-MEA chip having high sensitivity to DA and enabling the detection of DA release from brain slices and cultured hiPSC-derived neuronal networks. We also found that CNT-MEA is possible to both electrochemical measurement of DA release and conventional field potential measurement. CNT-MEA is expected as a new MEA measurement method that improves the accuracy of toxicity prediction and the pharmacological effects.

Title: Trial for drug-induced seizure liability evaluation using microelectrode array and primary rodent neurons: Multi-site pilot study ofHESI NeuToxMEA subteam

Authors: *N. MIYAMOTO[1], A. OJIMA[2], S. INABA[2], T. YOSHINAGA[1]
[1]EISAI Co., Ltd., TSUKUBA, Japan; [2]Tsukuba branch, Techno Pro R&D company, Techno Pro Inc., Tsuchiura, Japan

Abstract: Drug-induced seizures are a serious cause of drug withdrawal from the market. There is no good non-clinical *in vitro* model to predict seizure liability of drug candidates. Translational Biomarkers of Neurotoxicity (NeuTox) Committee of Health and Environmental Science Institute (HESI) initiated the NeuTox Micro-Electrode Array (MEA) Subteam to investigate use of MEA technology for the prediction of seizure liability of drugs. The team launched a multi-site pilot study and is promoting engagement in scientific discussion utilizing the results of the multi-site pilot study. Because the experimental protocol and significant assay

endpoints have not been standardized yet, each facility is making a presentation in support of the discussion one at a time. Primary cortical neurons were prepared from fetal Wistar rats 18 days post-coitum and seeded on 48-well Classic MEA plates and 24-well MED-Q2430M plates for extracellular recording using Maestro and Maestro Pro or using MED64-Prest respectively. Twelve compounds (pentylenetetrazole; PTZ, picrotoxin; PT, 4-aminopyrdine; 4-AP, linopyridine; LP, amoxapine; AXA, strychnine; SC, pilocarpine; PC, amoxicillin; AXI, chlorpromazine, enoxacin, phenytoin and acetaminophen) were added to the cells (n = 6) at 5 concentrations for each compound to see phenotypic changes on spontaneous electrical activity in neural networks consisting of action potential spikes and organized patterns of synchronized bursts after 19 days of culture. Using data from Maestro and Maestro Pro, we examined 12 metrics: weighted mean firing rate (MFR), number of bursts (NB), burst duration, number of spikes per burst (NS/B), number of network bursts (NNB), network burst duration (NBD), number of spikes per network burst (NS/NB), inter-spike interval coefficient of variation (ISICV), inter-burst interval (IBI), IBI coefficient of variation, network IBI coefficient of variation, etc., to assess the degree of significance for assay endpoints, which are correlated across seizurogenic compounds in the test set. Specific enhancements were observed in MFR, NS/B and NS/NB for $GABA_AR$ inhibitors (PTZ and PT); in MFR, NB and NNB for K^+ channel inhibitors (4-AP and LP); in MFR, NS/B, NS/NB and ISICV for AXA; in NS/B, NS/NB and ISICV for SC; in NBD for PC and in IBI for AXI. In conclusion, there wasn't a common significant endpoint for all seizurogenic compounds, but it seems that there was a specific combination of endpoints for each type of seizurogenic compound. Principal component analysis for several burst parameters, using MED64 Prest data, is underway with the goal of finding useful endpoints for drug-induced epileptogenic phenotype classification.

Abstract: Human induced pluripotent stem cell-derived neurons are promising for use in toxicity evaluations in nonclinical studies. One of the major adverse events affecting the central nervous system observed during clinical trials is convulsions. Micro-electrode array (MEA) systems have recently attracted attention for use in evaluating the convulsion potential of a drug because they non-invasively measure the electrophysiological activity of neural networks at multiple sites in a high-throughput manner. MEA subteam of Neurotoxicity (NeuTox) Committee in Health and Environmental Science Institute (HESI) initiated the NeuTox Micro-Electrode Array (MEA) Subteam started pilot study using MEA for the prediction of seizure liability of drugs. Human iPSC-derived cortical neurons (Axol) were cultured on 24-wells MEA plate for extracellular recording using Presto. Twelve compounds (pentylenetetrazole, picrotoxin, 4-aminopyrdine, linopyridine, amoxapine, strychnine, pilocarpine, amoxicillin, chlorpromazine, enoxacin, phenytoin and acetaminophen) were tested at 5 concentrations for each compound. Using spontaneous firings data to drug administration, we identified the parameter sets that can separate the responses between convulsive drugs and negative control, and the responses among the several convulsants with different action mechanism using principal component analysis over 10 parameters. We also extracted the 4096 feature quantities from a image data in raster plots by unsupervised learning and constructed the artificial intelligence, in which feature quantities and drug name were learned by deep learning. Using this learned neuronal network, we have succeeded in separating the responses between non-convulsive drugs and convulsants and classifying the action mechanism of convulsive drugs. These our analysis method will be effective for detecting convulsive response and predicting mechanism of action of convulsive drugs.

Abstract: Few methods are available to quantify local glutamate release dynamics in animal models of disease, especially long term. An enzyme-based platinum microelectrode array (Pt-MEA) built on a ceramic probe has improved spatiotemporal resolution v. single-site probes and microdialysis. We produced Glu microprobes by coating R1 (CenMeT) Pt-MEAs with L-glutamate oxidase (GluOx), bovine serum albumin, and glutaraldehyde and then electrochemically depositing m-phenylenediamine, a size-exclusion polymer for blocking interferents (cycled 20 min, +0.25 V to +0.75 V, 50 mV/s). GluOx produces at the Pt electrode when Glu diffuses out of active synapses; the resulting current from H_2O_2 evolution was plotted in real time. Microprobe performance was tested by electrically stimulating release of Glu from mouse brain slices. Brains were harvested according to an approved IACUC protocol. Single, coronal slices were placed in a brain slice chamber. Microprobes were placed into neocortical locations or CA1 and 100-μA direct current pulses were delivered to tissue within 300 μm of the microprobe. Current returned to baseline between pulses. The peak current for single 1-s pulses was ~70 pA and 100 pA for paired pulses 2 s apart. Current was consistent at each pulse width and scaled with pulse width (Fig 1). This novel Glu microprobe facilitates real time measurements of extracellular Glu level dynamics and will be useful for understanding physiological processes. Next, we will optimize and modify the microprobe for studying glutamate and other neurochemical dynamics *in vivo*.
Funding from NSF EPSCoR RII-2 FEC OIA1632891
Fig 1. Current versus time for 3 stimulations at 3 pulse widths (one channel shown). Peak current scaled with pulse widths from 1 s (not shown) through 25 ms and was consistent at each pulse width. The 10-ms pulses did not elicit measurable glutamate release. The 25-ms pulses resulted in a mean ± SEM peak current of 3.56 ± 0.10 pA. Based on a calibration curve established prior to the measurements, this current corresponds to 468 ± 13 nM glutamate.

Abstract: Micro-electrode arrays (MEAs) are an established instrument for measuring neuronal and cardiac electrophysiological activity in vitro. The power of MEAs lend themselves to applications that can be applied to drug discovery, safety pharmacology, and toxicology screening. The present study demonstrates the power of a high-sensitivity MEA engineered for acute brain slices in improving the efficacy and accuracy of neurotoxicity screening in acute hippocampal slice preparations from mice. We demonstrate the capabilities of the highly

sensitive MED64-Quad system, a novel medium-throughput MEA engineered for acute or cultured slice applications in assessing neurotoxicology risk from acute mouse brain slices. Acute hippocampal slices from 6-8 week old mice were assessed for seizurogenic -like activity in response to compounds that are likely to elicit synchronized network activity typical of seizure-like activity (convulsants). We measured network burst activity and decomposed frequency analysis of field potential oscillations (analogous to EEG) in response to compounds known to elicit seizure-like activity. Spontaneous firing rate, synchronized network bursts, and the decomposed frequency component of the local field potential were measured in response to 4-Aminopiridine, Pentylenetetrazole, Picrotoxin, Pilocaprine and Strychnine. We demonstrate the power of the MED64-Quad system in detecting several measures of synchronized burst activity including the duration of synchronized bursts, total spikes within a burst, inter-burst interval, co-efficient of variation for the inter-peak interval of bursts, and the co-efficient of variation for the speak spikes of synchronized bursts. The results of this study indicated that the MED64-Quad system increases throughput while maintaining high enough sensitivity to detect spontaneous spiking, synchronized network bursts, and epileptiform activity in response to convulsants. The MED64-Quad MEA is a useful tool for improving the accuracy, efficacy, and throughput of drug discovery, target validation, safety pharmacology, and toxicology screening.

Abstract: When recording or modulating activity in neural networks it is of great advantage to obtain precise information about soma location, about subcellular compartments and about putative synaptically connected cells.
Here we present an algorithm for automated identification of cell locations in ex vivo retinal

networks and in dissociated neuronal cultures. The two neural systems were interfaced to high-density CMOS-based MEAs. The algorithm computes the spike triggered average (STAs) electrical image and performs a classification of the electrical images during the experiment. This enabled us to selectively stimulate cells at user-specified locations.
Two types of artificial stimulation will be presented. First, electrical stimulation was performed using a subset of 1024 available stimulation sites of the CMOS MEA. Stimulation waveforms could be selected to either activate axons or to avoid this activation. Secondly, optogenetic stimulation of channelrhodopsin-transduced cells revealed precise spiking. Precise adjustment of the stimulation intensity could be used to selectively stimulate cell subpopulations. The presented experiments demonstrate the power of electrical imaging using high-density microelectrode arrays prior to artificial stimulation.

Title: PEDOT polymer electrodes for non-invasive 8 channel full band DC EEG recordings from freely moving piglets and sports horses

Authors: *N. V. DE CAMP[1,2], J. BERGELER[3]
[1]Vet. Medicine,Physiology, Free Univ. Berlin, Humboldt Univ. Berlin, Berlin, Germany; [2]Physiol., Med. Ctr. of the Johannes Gutenberg Univ. Mainz, Mainz, Germany; [3]Vet. Medicine, Physiol., Free Univ. Berlin, Med. Ctr. of the JGU Mainz, Berlin, Mainz, Germany

Abstract: We invented the first non-metallic, self-adhesive and dry biosignalling electrode. The Poly(3,4-ethylenedioxythiophene) (PEDOT) polymer electrode changes its aggregate state and conductivity by light curing. The electrode can be applied underneath hair without shaving. With the aid of blue light, the electrode can be hardened within a few seconds at the desired location. The cured polymer electrode is highly conductive and can be applied on a very small location. Unlike other EEG electrodes, our electrode does not lose conductivity upon drying. The electrode strongly bonds to skin and does not require any additional adhesive. Short circuits due

to an outflow of gel are prevented with this technique. Therefore, the PEDOT polymer electrode is extremely well suited for applications that, up to now, have been challenging, such as non-invasive EEG recordings from awake and freely moving animals, EEG recordings from preterm babies in the neonatal intensive care unit or long-term recordings in the case of sleep monitoring or epilepsy diagnostics. We tested the PEDOT Polymer electrode with sleep recordings from piglets and sports horses. Typical patterns like spindle bursts and K-Komplexes can be identified with the new technique.

Title: Long-term high-density extracellular recordings enable studies of muscle cell physiology and pathology

Authors: M. LEWANDOWSKA[1], E. BOGATIKOV[1], A. HIERLEMANN[2], *A. R. PUNGA[1]
[1]Neurosci., Uppsala Univ., Uppsala, Sweden; [2]Dept. of Biosystems Sci. and Engin., ETH Zürich, Basel, Switzerland

Abstract: Skeletal (voluntary) muscle is the most abundant tissue in the body, thus making it an important biomedical research subject. Studies of neuromuscular transmission, including disorders of defective ion channels or receptors in autoimmune or genetic neuromuscular disorders, require high spatial resolution and an ability to acquire repeated recordings over time in order to track pharmacological interventions. Preclinical techniques for studying diseases of neuromuscular transmission can be enhanced by physiologic *ex vivo* models of tissue-tissue and cell-cell interactions. We present a method, which we used to follow the development of primary skeletal muscle cells from myoblasts into mature contracting myofibers over more than two months. In contrast to most previous studies, the muscles do not detach from the surface but instead form functional networks between the myofibers, whose electrical signals we observed over the entire culturing period. Primary cultures of mouse myoblasts differentiated into contracting myofibers on a chip that contains an array of 26,400 platinum electrodes at a density of 3,265 electrodes per mm^2. Our ability to track extracellular action potentials at subcellular resolution enables discovery of the origin of possible failure mechanisms in muscle diseases.

This system in turn enables creation of a novel electrophysiological platform for establishing *ex vivo* disease models.

Title: Sensory percepts elicited by macrosieve stimulation of peripheral nerve: A rat behavioral model

Authors: N. S. CHANDRA[1], W. M. MCCARRON[3], H. BURTON[4], *D. W. MORAN[1], L. S. GREEN[2], W. Z. RAY[5], M. R. MACEWAN[5]
[1]Dept. of Biomed. Engin., [2]Dept. of Psychological and Brain Sci., Washington Univ., Saint Louis, MO; [4]Neurosci., [5]Dept. of Neurosurg., [3]Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The macrosieve electrode (MSE) is a highly stable implant that interfaces with peripheral nerve and uses advanced current steering to selectively recruit subfascicular axon clusters with wide nerve coverage. The MSE might be an optimal platform for introducing sensory feedback (via interfaced peripheral nerve) that originates in embedded sensors in a prosthetic limb. To investigate this possibility, we developed a rat behavioral model to evaluate the MSE's ability to elicit sensory percepts at low current amplitudes without damaging nerve tissue over multiple activation cycles. Six adult, male Lewis rats learned a go/no-go auditory detection task. Training occurred in a sound- and light-attenuating Skinner box equipped with a house light, tone generator (2,900 Hz), snout detector and food-dispenser. Each rat learned to initiate trials by inserting its snout into the detector. The rat had to maintain snout insertion for a randomized interval (4 ± 2 s) to receive an auditory stimulus. Next, the snout had to be withdrawn from the detector within 500 ms of stimulus onset to receive reinforcement. Premature withdrawal (prior to stimulus onset) extinguished the house light for a 10 s time out as punishment. Late withdrawal (> 500 ms after stimulus onset) resulted in a 5-s inter-trial interval. After successfully learning to detect the auditory stimulus, five of the rats underwent a sterile surgery for implantation of an MSE. After induction of anesthesia, we exposed the right sciatic nerve, transected it, and sutured the proximal and distal stumps into a pair of silicone guidance conduits affixed to a prepared MSE/Omnetics assembly. The Omnetics connector, with trailing

microwires, was routed subcutaneously to the skull, passed through a scalp incision, and embedded in an acrylic head-cap. The connector provides an external interface to the MSE during behavioral experiments. Rats with implanted MSEs remained stable for 4-12 months following surgery; this interval is sufficient for relearning a go/no-go analog of the auditory detection task by attending stimulation of the sciatic nerve now activated through the implanted MSE. Current success with an implanted MSE in several rats will advance the development of sensory feedback originating from embedded sensors in prosthetic limbs and represent the potential of a clinically viable sensory interface.

Title: Reliability and acute *in vivo* testing of the lyse-and-attract cuff electrode

Authors: *C. LARSON, S. ELYAHOODAYAN, A. COBO, K. SCHOLTEN, D. SONG, E. MENG
Biomed. Engin., USC, Los Angeles, CA

Abstract: A major obstacle barring clinical implementation of peripheral nerve (PN) interfaces is the dual requirement to maintain long-term health of the nerve while still targeting specific nerve fibers. Our minimally invasive approach integrates microfluidic channels into an extraneural PN cuff for targeted delivery of a lyse-and-attract drug regimen to intact nerve. Collagenase delivery lyses connective tissue layers then neurotrophic growth factor induces sprouting of nerve fibers. The anticipated result is proximity of the nerve fibers to the electrodes for increased selectivity and signal fidelity without invading the PN bundle.
The lyse-and-attract cuff electrode (LACE) is microfabricated as a compliant sheet of Parylene C polymer with embedded platinum electrodes. Integrated design features include microfluidic channels with embedded electrodes and a ratchet-type locking mechanism to secure the cuff around the nerve. We evaluate reliability of the LACE under simulated *in vivo* conditions and report preliminary results from acute *in vivo* animal studies, including the first report of localized lysing of epineurium on live nerve through an extraneural cuff.
LACE were soaked in phosphate-buffered saline at 37 °C (one month) to simulate *in vivo* conditions. Periodic electrochemical impedance spectroscopy and interelectrode crosstalk testing

was performed. After two weeks, electrode impedance at 1 kHz decreased from 2.5 to 2.1 kΩ, while average signal leakage between electrodes remained below 10%. After one month, impedance decreased to 1.0 kΩ and signal leakage ranged from 10 to 63%, suggesting some delamination of the insulation. This suggests suitability of the current design for in vivo studies up to two weeks and that additional improvement to the fabrication process is required to achieve chronic reliability attained in neural interfaces of similar construction.
LACE were applied *in vivo* to rat sciatic nerve. Compound action potentials (CAP) were recorded by LACE arising from monophasic bipolar stimulation (200 μs, 5–150 μA) applied using implanted needle electrodes. Stimulation was repeated following application of lidocaine. Recordings prior to lidocaine captured CAP, but after lidocaine captured only the stimulus artifact. For lysing, 1 μL of collagenase was delivered through the LACE at 100 μL/min. Each nerve was then explanted, sectioned, and imaged. Histology sections near the microchannel outlets revealed lysed regions of the epineurium while sections away from the outlets showed no evidence of lysing. These results successfully demonstrate the functionality of the LACE device and potential of the LACE drug delivery approach.

Title: Functional electrical stimulation of ischemic stroke rat

Authors: *C. SONG, C. YEO
DGIST, Daegu, Korea, Republic of

Abstract: Rehabilitation effects of functional electrical stimulation have been studied in animal model and human, for treating various diseases such as spinal cord injury (SCI) and stroke disease. Percutaneous and implant FES configuration capable of activating deep muscles and placing electrodes in same position repeatedly and appropriately, has been spotlighted to improve the effectiveness of FES. However, the validation from animal experiment is essential because these invasive approaches are hard to apply human directly. Although rodent model has been used with low cost and easy to access, most of the studies focused on SCI rodent model. The studies for stroke rodent model are relatively less. Most FES studies with rodent model

showed therapeutic effectiveness of electrical stimulation rather than function stimulation to assist their voluntary mobility. The goal of this study is to develop FES pattern capable of inducing gait motion in ischemic stroke rat model, with percutaneous FES configuration. The Animal Experiment Ethics Committee of Daegu Gyeongbuk Institute of Science and Technology approved the experimental protocol (approval no. DGIST-IACUC-17102520-00). All ischemic stroke rats were induced by the surgery of middle cerebral artery occlusion. In hind-limb stimulation, the electrodes were inserted into quadriceps and hamstring muscles on left and right legs to induce walking motion. In upper-limb stimulation, the electrodes were placed only on left side induced ischemic stroke. For shoulder movement, unilateral spinodeltoideus and supraspinatus were stimulated. To induce elbow and digit movement, the electrodes were inserted in triceps/biceps and extensor digitorum communis/flexor digitorum profundus muscles. Electrical parameters were set to biphasic asymmetric wave, frequency of 75 Hz, pulse widths of 200 usec/phase, and pulse with of 0.25 ~ 1 mA. When the movement induced by FES are compared between before and after stroke, stiff movement after stroke was shown because of hemiplegia. It requires accurate parameter tuning for assisting more natural movement in step with rat's intention. We try to find optimal stimulation parameters and conditions for inducing natural movement. These works may contribute to the studies of implant FES system and neuronal stimulation for stroke rehabilitation of human.

Title: A transdural very-near field wireless power and data link for implantable neural interfaces

Authors: *M. P. POWELL[1], D. A. BORTON[1,2,3]
[1]Sch. of Engin., [2]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [3]Ctr. for Neurorestoration and Neurotechnology, Dept. of Veterans Affairs, Providence Med. Ctr., Providence, RI

Abstract: Traditional microelectrode arrays (MEAs) capable of electrical access to the brain with single cell resolution must communicate with external electronics via a wire tether through the dura matter. This physical connection is non-trivial to implant, results in chronic perforation of the dura, and may affect the stability of neural recordings as the tether mechanically perturbs the MEA. Completely untethered, "floating", neural interfaces have been developed but are often

limited in their ability to transfer sufficient power to the implant while maintaining high data rates for transmitting neural data. Improving the performance of the wireless link will enable higher channel counts and the ability to include more advanced electronic payloads allowing for new experimental paradigms. To address these challenges, a very-near field transdural wireless link is proposed for communicating power and data to an untethered floating neural implant. Inductive coupling is commonly used to power biomedical implants, but link design often focuses on optimizing power transfer over long distances and in weakly coupled systems. By reducing the wireless transmission distance, link performance and efficiency can be improved over such designs. We present a system capable of delivering 15 mW of power to a centimeter scale device with 57% efficiency. Additionally, the link is robust to coil misalignments of up to 3 mm. Power management circuitry provides a constant DC voltage supply for on-board components. To stream full broadband neural data from the implant, a previously designed RF application specific integrated circuit (ASIC) was used in conjunction with a field programmable gate array (FPGA) and a software defined radio (SDR) based receiver. Data rates of approximately 4.3 Mbps were achieved. Improvements on the data transmission circuitry are proposed with a target data rate of &gt10 Mbps. In addition, a circuit design is presented that can extract a clock from the power signal, preventing the need for on-implant clock synthesis. An optimized power amplifier will improve overall system efficiency for wireless power delivery and amplitude modulation can be used at the transmitter to deliver forward data to the implant. By implementing a very-near field wireless link, many of the traditional design limitations for a floating implant are lifted enabling, for example, on-implant recording, stimulation, and signal processing capabilities for low latency closed loop experiments. Other system architects could leverage the designs presented here to develop low power, untethered neural technologies without sacrificing advanced features.

Title: Transparent graphene electrodes for high resolution *in vivo* optical and electrophysiological mapping of epileptic networks

Authors: *N. DRISCOLL[1], H. TAKANO[3], B. MURPHY[4], R. VISHNUBHOTLA[5], D. A. COULTER[3], A. JOHNSON[5], B. LITT[4], F. VITALE[2]

Abstract: Of the estimated 50 million people worldwide currently living with epilepsy, approximately one-third do not achieve seizure freedom from antiepileptic drugs. For these patients, the only hope is highly targeted clinical intervention either with resective surgery or neuromodulation therapy. Yet, there are not currently robust methods for mapping epileptic circuits *in vivo* at high resolution and correctly identifying the areas to resect or stimulate. Events such as spikes and high frequency oscillations (HFOs) inform clinical decision making in identifying epileptic networks and seizure onset regions, but their actual size and dynamics are not well understood, particularly down at the cellular level. Experiments with high resolution electrophysiology and optical imaging in animal models have begun to shed light on these network dynamics, but they are limited: optical methods, like calcium imaging, can identify activity at the cellular level, but their temporal resolution is not sufficient to record epileptic biomarkers, such as HFOs. Electrophysiology has superior temporal resolution, but tissue sampling is limited to the regions around individual electrodes.
In this work, we present a platform for simultaneous *in vivo* optical and electrical recording based on transparent, flexible graphene electrode arrays and apply our technology to map epileptic networks, HFOs and seizure spread in an acute murine model of epilepsy induced by application of 4-aminopyridine (4-AP). The micro-electrode arrays demonstrated here consist of a 3x3 grid of 50x50 μm^2 graphene contacts embedded in a parylene-C substrate. The devices are >90% optically transparent across the visible and NIR spectrum, and chemically doped to achieve 1 kHz impedance of 1.34 ± 0.22 MΩ. We recorded 4-AP-induced seizure activity simultaneously on the graphene electrodes and through calcium epifluorescence imaging in anesthetized GCaMP6-exresssing mice (Jax #025776, Jackson Laboratory). We observed localized foci generating interictal HFOs and analyzed their spatio-temporal relationship to seizure onset and spread *in vivo*. We also detected on the electrodes spatial patterns of seizure onset and propagation corresponding to patterns of activity emerging in calcium imaging, and distinct electrographic patterns corresponding to different spatial patterns of seizure propagation, including planar and spiral waves. We plan to expand on this work by performing cellular-resolution imaging using two-photon imaging to elucidate the dynamics of seizure dynamics at the cellular level.

Abstract: Penetrating electronics have been used for treating epilepsy, yet their therapeutic effects are debated largely due to the lack of a large scale, real-time, safe recording/stimulation. Here, our proposed technology integrates ultrathin and flexible epidermal electronics into an electrocorticography (ECoG) array, therein simultaneously sampling brain signals in a large area for diagnostic purposes and delivering electrical pulses for treatment. The system was empirically tested to record the ictal-like activities of the thalamocortical network in vitro and in vivo using our epidermal electronics. Furthermore, the electronics selectively diminished epileptiform activities but not normal signal transduction. We propose that this technology heralds a new generation of diagnostic and therapeutic brain-machine interfaces. Such an electronic system can be applicable for several brain diseases such as tinnitus, Parkinson's disease, Huntington's disease, depression, and schizophrenia

Abstract: We built a rig to perform paired patch-clamp and extracellular recordings from the same neuron *in vivo.* In this setup, the axes of two micromanipulators are precisely aligned and their relative position is tracked in real-time by Bonsai software, allowing us to accurately target patch-clamp recordings to neurons near the extracellular probe. We used this approach to generate a publicly-available dataset where a cortical neuron's spiking activity is recorded on a dense CMOS probe and compared to its counterpart acquired through a patch-clamp electrode. "Ground-truth" datasets of this kind are rare but valuable to the neuroscience community, as they power the development and improvement of spike-sorting and analysis algorithms, tethering them to empirical observations. First, we describe our approach and report exploratory and descriptive analysis on this dataset. We study the detectability of patch-clamp spikes on the extracellular probe, manual clustering of paired spikes based on ground-truth features, within-unit reliability of spike features and spatiotemporal dynamics of the action potential waveform. Second, we propose a GitHub-based platform to host, accelerate and improve further work undertaken by others and ourselves on this dataset, including but not restricted to spike-sorting algorithm benchmarking. We suggest guidelines and best-practise workflows in a guise to stimulate transparency, replicability, real-time peer-review and accurate credit assignment.

Title: Fabrication, testing, and refinement of a silicon-based cochlear nucleus array

Authors: *N. NOLTA[1], P. GHELICH[1], M. JACOBS[1], D. B. MCCREERY[2], M. HAN[1]
[1]Biomed. Engin. Dept., Univ. of Connecticut, Storrs, CT; [2]Neural Engin. Program, Huntington Med. Res. Inst., Pasadena, CA

Abstract: In this poster we describe the fabrication, *in vivo* testing, and ongoing refinements of a silicon-based neural recording and stimulation electrode array. The array has iridium electrode sites, metal interconnects, and silicon oxide/silicon nitride passivation layers. Deep reactive ion etching is used to define electrode shanks. Backside thinning by reactive ion etching allows the probes to be released from the silicon-on-insulator wafer. Mechanical grinding of the probe tips results in a sharp, pointed tip, rather than a vertical wedge. Finally, cleaning, packaging, and sterilization complete the device. *In vivo* testing efforts have focused on using this array as part of an auditory brainstem implant in cats. The sharp tips and sturdy shanks facilitated successful implantation into the cochlear nucleus and inferior colliculus with an inserter tool. The 3D multi-shank layout of the electrode sites allowed for tonotopic stimulation at different locations in the cochlear nucleus. The arrays have performed successfully *in vivo* for over one year. These studies suggest the arrays could be used in a hearing prosthesis for people with deafness who cannot benefit from a cochlear implant due to ossified cochlea or damaged auditory nerves. Other applications could include closed-loop deep brain stimulation, spinal cord stimulation, and other difficult-to-reach anatomical targets where 3D multi-shank layout, mechanical robustness, and stable long-term performance are desired. Finally, we present preliminary work on novel refinements in the fabrication process such as recessed metal interconnects.

Abstract: Electrical stimulation of peripheral nerves is an effective method to influence, modulate, or change the function of the nervous system in a controlled and timely manner. The technique holds great potential to treat various conditions, and to change/improve normal cognitive functions such as learning, memory and decision-making. Vagus nerve stimulation (VNS) is perhaps the most widely used, but the underlying mechanisms of action are not well understood. Here, we present the first steps toward the development of a comprehensive approach to study the neurobiological mechanisms underlying VNS in a non-human primate preparation. One Rhesus monkey (Macaca mulatta, 6.5 yrs old) weighing 11.8 kg was induced with ketamine (10 mg/kg), intubated and anesthetized with 1.5% isoflurane for the duration of the experiment. The local IACUC approved all procedures. Buprenorphine (0.01 mg/kg) was given prior to surgery for analgesia. Heart rate, respiratory rate, blood pressure, oxygen saturation and temperature were monitored throughout the procedure. Under sterile surgical conditions, the cervical vagus nerve was exposed using blunt dissection and separate stimulating (2mm ID, 7mm inter-electrode spacing, LivaNova Inc) and recording (2mm ID, 2mm inter-electrode spacing) bipolar, cuff electrodes were implanted (1.5cm separation). A pair of needle electrodes implanted in the sternocleidomastoid (SCM) monitored electromyographic (EMG) activity evoked by stimulation. Following surgery, the subject was placed prone to facilitate measurement of pupil fluctuations resulting from VNS using an Eyelink 1000Plus (SR Research). Electrical stimulation of the vagus was performed using trains of 16 biphasic (cathode leading) pulses (0.8mA, 100us per phase) at five frequencies ranging from 7Hz to 110Hz. We observed a reliable, stimulation locked decrease in respiration rate and modulation in SCM EMG in response to VNS verifying engagement between the stimulating electrode and nerve. Importantly, these responses were eliminated by transecting the nerve proximally and distally to the cuff electrodes. Future work will examine the effects of VNS on compound nerve action potentials and pupil diameter fluctuations in awake, behaving subjects.

Title: Evaluation of neural interfaces for electrical stimulation of the rat trigeminal nerve

Authors: *A. J. SUMINSKI[1], J. P. NESS[2], W. ZENG[3], J. NOVELLO[2], S. K. BRODNICK[2], J. PISANIELLO[2], A. M. DINGLE[3], S. O. POORE[3], W. B. LAKE[1], J. C. WILLIAMS[2]

Abstract: Over the past decade, electrical stimulation of various cranial nerves has been shown to be an effective adjunctive therapy for many diseases including epilepsy and depression. Furthermore, these techniques hold great promise to treat other conditions and modulate cognitive functions such as learning, memory and decision-making. While the vagus nerve has traditionally been the target of these therapies, recent preclinical data suggests that the trigeminal nerve may present an alternative option due to is superficial course and integration with the sympathetic and parasympathetic nervous systems. However, the mechanism of action trigeminal nerve stimulation (TNS) remains in question. In this work, we describe the development and evaluation of a neural interface targeting the rat trigeminal nerve with the goal of enabling future mechanistic research on TNS. Fifteen (n=15) Lewis rats we used in experiments designed to: 1) identify the best stimulation target(s) for TNS in the rat and 2) evaluate the ability of a cuff electrode to stimulate the nerves. Using fresh cadavers (n=5), we investigated the course and measured the size of each branch of the trigeminal nerve, and found that both the V1 (supraorbital) and V2 (infraorbital) branches were best candidates for a neural interface to their accessibility and size (0.57 +/- 0.14 mm and 2.83 +/- 0.22 mm diameter, respectively). To evaluate the methodology to engage the branches of the trigeminal nerve, Lewis rats were anesthetized with isoflurane (1-2.5%) and implanted with a custom bipolar cuff electrode on the infraorbital nerve distal to the infraorbital foramen (1.5mm ID, 0.05mm wire diameter; n=5) or supraorbital nerve (0.75mm ID, 0.05mm wire diameter; n=5). Electrical stimulation was performed using single, monophasic or biphasic (cathode leading) pulses (50-800uA, 100-300us per phase) initiated at pseudorandom intervals (varying between 3-4 seconds). We measured changes in cortical activity in the barrel cortex elicited by infraorbital stimulation using a custom 16 channel uECoG array (200um site diameter, 500um inter-electrode spacing). Similarly, we measured changes in the orbicularis oculi electroromyogram elicited by infraorbital stimulation to verify engagement of the supraorbital nerve. In both cases stimulation evoked activity increased monotonically until saturation with increases in stimulation current and activation thresholds decreased with increases in phase duration. These preliminary results suggest that supraorbital and infraorbital nerve interfaces are suitable candidates for examining the neural mechanisms of TNS in the rat.

Title: Development of nanoelectrodes array using iridium oxide/gold nanowires for fast imaging of neural network

Authors: *H. YOON, M. H. KIM, A. SHIMKEVITCH, S. HAN, M. FREEMAN
Norfolk State Univ., Norfolk, VA

Abstract: It is critically important to develop highly and reliably performing electrodes for fast imaging of neural activity using electrical impedance tomography in chronic experiments. For fast electrical impedance tomography (fEIT) imaging of neural network, electrochemical properties of electrodes including impedance spectrum determines spatial and temporal resolution of imaging. In this research, vertically aligned iridium oxide/gold nanowire (IrOx/AuNW) electrodes with low impedance values were developed with the diameters of 280 μm for temporal resolution of 30 msec and 200 μm resolution imaging in the brain. For testing of long term stability of electrodes, electrochemical impedances were measured under 1 million cycles of current injection with 1725 Hz frequency and their variation of electrochemical properties was analyzed to determine effect of current injection on developed electrodes. The results show the stability of electrodes up to the level of 1 mA current injection, which is a sufficient level of electrode performance for fEIT. In addition, electrode potential drift effects were also measured and analyzed with various current injection conditions. This research demonstrated that novel IrOx/AuNW electrodes array can highly perform fEIT imaging for neural network in the brain for long term.

Abstract: Ultra-small, flexible neural electrodes with diameters the size of individual cells significantly increase the quality and longevity of neural recordings by reducing neural injury during chronic implantation. However, these flexible electrodes are traditionally difficult to implant and position without causing acute damage. Researchers typically apply stiffening agents that temporarily increase the overall size and rigidity of the electrode in order to overcome the buckling force upon implantation, but these methods increase the electrode footprint and cause increased acute damage and potentially chronic damage. Previously, we have demonstrated a novel, minimally invasive method of implanting flexible electrodes through the use of a fluidic microdrive designed to prevent buckling and drive electrodes into the brain without the need for stiffening agents. Using specially designed vent channels and viscous drive fluid, we are able to minimize the amount of fluid directed towards the brain, preventing additional trauma during implantation. Here, we show improvements upon the original design of the microdrive which allow for preconnected multi-channel flexible electrodes to be implanted into the rat brain without the need for stiffening agents or rigid shuttles. Current work focuses on comparing long term immune response and unit stability of flexible electrodes implanted with the fluidic microdrive versus more traditional methods.

Title: Neural implant insertion system using ultrasonic micro-vibration to improve penetrating microelectrode array insertion mechanics: *In vitro* and *in vivo* evaluations

Authors: *R. S. CLEMENT, N. N. TIRKO, J. K. GREASER, C. A. SCRUGGS, T. J. HIGGINS, R. B. BAGWELL
Res. and Develop., Actuated Med. Inc., Bellefonte, PA

Abstract: Penetrating electrode arrays provide localized access to neural stimulation and recording sources, and are a valuable neuroscience research tool. Neuroscientists and researchers developing future clinical applications continually seek to increase information transfer potential by implanting electrode arrays with higher numbers of shanks at greater density. Successful insertion of penetrating electrode arrays into brain tissue remains a significant challenge, and outcomes are often heavily reliant on surgical skill and technique. During insertion, electrode arrays apply forces to the neural tissue resulting in significant compression (dimpling) at the implant site and strain on local tissues. Shallow insertions (< 1 mm) targeting the upper cortical layers are especially difficult. The electrode array may need to be over-inserted past the target depth to ensure puncture of meningeal membranes, or be fired in at very high velocity, limiting implantation accuracy and possibly increasing implantation trauma. To combat these challenges, we have developed a penetrating electrode array inserter that utilizes ultrasonic micro-vibration to improve insertion mechanics. The inserter system incorporates a piezoelectric transducer, operated in an axial resonant mode, which transmits high-frequency micro-vibrations to an attached electrode array via a reversible coupler mechanism. Previously we have demonstrated the system could insert custom-built 2x4 fixed microwire (dia: 50 µm) arrays with lower peak forces (~78% difference) in agar brain model and *ex vivo* rodent brain, and with lower dimpling (~80% difference) of brain surface *in vivo*, as compared to non-vibrated insertion (speed= 50 µm/s). The ultrasonic micro-vibration does not appear to be harmful to neurons, as neural activity can be recorded immediately post-insertion and for weeks following implant. More recently we have evaluated the system for insertion of 2x8 microwire (dia: 65 µm) arrays obtained from a commercial provider (Tucker-Davis Technologies). Ultrasonic micro-vibration enables the reliable insertion of the arrays even through the dura, significantly simplifying surgical procedures. High quality neural recordings are observed immediately and for weeks following implant surgery. Ongoing studies are evaluating the performance of arrays implanted with ultrasonic micro-vibration for up to 4-6 weeks, followed by an assessment of post-implant histology. Reducing array implantation trauma and improving the electrode placement process is critical to maximize chronic neural interface performance, and future clinical translation of neural implant systems.

Title: Effects of cerumen and electrodermal response on in-ear electroencephalography

Authors: *A. PAUL[1], S. R. DEISS[2], D. TOURTELOTTE[3], G. CAUWENBERGHS[4]
[1]Univ. of California San Diego, La Jolla, CA; [2]Inst. for Neural Computation, UC San Diego, La Jolla, CA; [3]Starkey Hearing Technologies, Eden Prairie, MN; [4]Dept. of Bioengineering, UCSD, La Jolla, CA

Abstract: Conventional electroencephalography (EEG) requires placement of several electrode sensors on the scalp and, accompanied by lead wires and bulky instrumentation, makes for an uncomfortable experience. Recent efforts in miniaturization and system integration have enabled smaller systems, such as wearable, in-ear EEG devices that are gaining popularity for their unobtrusive form factor. Although in-ear EEG has been demonstrated in recent works, dynamics of the ear and ear canal that directly effect electrophysiological measurements have been largely ignored. Here, we present a quantitative analysis of electrode-skin impedance for in-ear EEG that accounts for cerumen (earwax) and electrodermal response. Custom fitted earmolds with 16 embedded electrodes were developed to map the skin conductance in the ear canal of 3 subjects. In the presence of cerumen, the calculated average conductivity of the ear canal was 73% less than canals removed of cerumen. Electrodermal activity was also found to play a role in electrode-skin impedance, increasing SC by up to 300% in response to certain stimuli. The better understanding of the dynamics of in-ear conditions may improve consistency and accuracy of in-ear electrophysiology.

Title: Low-cost, mobile, and wearable eeg

Authors: *N. BELKAYA, A. RAMAKRISHNAN, M. L. PLATT
Univ. of Pennsylvania, Philadelphia, PA

Abstract: There is a growing interest in the mobile, wearable, and low-cost electro-encephalogram (EEG) devices that can provide research grade signals regarding the brain states of individuals. While scalp EEG has long been the default approach to non-invasively diagnose epilepsy and traumatic brain injury, there is no viable way to continuously tract patients' EEG activity - other than long hospital stays in the wired EEG long-term monitoring unit (LTM), which is expensive and impractical. Aside from diagnosis, mobile EEG devices can lead to the development of continuous healthcare monitoring applications, personalized treatment protocols in medicine and optimal training programs in sports to name a few. With that purpose in mind, we have assembled a new EEG device with novel, flexible, dry electrodes -- that are capable of maintaining electrical contact with the subject's skin in the absence of electrolytic gel. The novel electrodes exhibited minimal signal loss at EEG-level voltage and frequencies. Signals obtained from our dry electrodes were matched in quality with those obtained from the current "gold standard" Ag/AgCl wet electrode. In the long run, as the gel dried up, while the wet electrode signal quality deteriorated, signals from the new electrodes were unaffected. Furthermore, the flexible nature of the electrode helped the sensor adhere to the skin preventing relative electrode-skin movements, which greatly reduced motion artifacts. These features have opened up the avenue to monitor brain states during highly mobile, naturalistic interactions, which are being tested currently. Based on these observations, we believe that the novel technology would be useful to several clinical applications, consumer research, and could open up new markets hitherto unexplored.

Title: Multi-day 24-hour recording from single units in human cortex

Authors: *C. ZAWORA[1], J. H. WITTIG, JR[2], K. A. ZAGHLOUL[3]
[1]Surgical Neurol. Br., NINDS, NIH, Silver Spring, MD; [2]NINDS, Bethesda, MD; [3]Surgical Neurol. Br., Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Recent advances in human micro-electrode array technology and fully-automated spike sorting methods have opened the door to new analyses of how human neurons respond during cognitive tasks. Despite these breakthroughs, a basic understanding of how soon after implant one should expect to see single units and how the quality and yield of isolated units changes over the course of a typical hospital stay is lacking. Here we recorded spiking neuron activity from microelectrode Utah arrays (Cereplex I; Blackrock Microsystems Inc.) implanted in the surface of the human temporal lobe in 10 epilepsy patients undergoing intracranial monitoring for up to 3 weeks. We first confirmed that a widely-used automated spike-sorting algorithm (Mountainsort, Chung et al. 2017) applied to this unique dataset successfully mimicked manual sorts made on a subset of the data. Next, we used a high-performance computing cluster to sort all recorded channels (either 96 or 192 electrodes), collected 24-hours a day, and applied machine learning algorithms to track whether identified units were dropped or new units were found during the course of the recording (Frasier and Schwartz 2012). Here we present the evolution of single-unit isolation quality and quantity for the first 3 weeks following implantation in a human participant. We evaluate whether population spike rate changes systematically over the days following implantation, and lastly, whether isolation quality, quantity, and spike-rate vary with each participant's circadian rhythm.

Title: The cell cycle-related genes as biomarkers for schizophrenia

Authors: *S. OKAZAKI, S. BOKU, I. OTSUKA, N. EGUCHI, I. SORA, A. HISHIMOTO
Dept. of Psychiatry, Kobe Univ. Grad. Sch. of Med., Kobe, Japan

Abstract: Background: Recent studies suggest that genomic abnormalities such as single nucleotide polymorphisms (SNPs) and copy number variations (CNVs) may elevate the risk of schizophrenia. Such genomic abnormalities often occur during chromosomal DNA replication in the S phase of cell cycle. In addition, several studies showed that abnormal expressions of several cell cycle-related genes are associated with schizophrenia. Therefore, here we compared mRNA expression levels of cell cycle-related genes in peripheral blood cells between patients with schizophrenia and healthy controls.
Methods: mRNA expression levels of cell cycle-related genes in peripheral blood cells from patients with schizophrenia and healthy controls were measured with quantitative reverse transcription polymerase chain reaction (Q-RT-PCR). The discovery, replication and intervention studies with Q-RT-PCR were performed as follows: discovery (40 cases and 20 controls), replication (82 cases and 74 controls) and intervention (22 cases and 18 controls).
Results: Nine genes were identified in the discovery and replication stages as schizophrenia-associated genes. Moreover, the combination of mRNA expression levels of *CDK4*, *MCM7*, and *POLD4* was identified as a potential biomarker for schizophrenia with multivariate logistic regression analysis. The intervention stage revealed thatthe mRNA expression levels of these three genes were significantly decreased in the acute state of schizophrenia, and *CDK4* was significantly recovered in the remission state of schizophrenia.
Conclusions: The combination of mRNA expression levels of three cell cycle-related genes such as *CDK4*, *MCM7*, and *POLD4* is expected to be a candidate for useful biomarkers for schizophrenia. Especially, the mRNA expression changes of *CDK4* may be potential as both trait and state markers for schizophrenia.

Title: Plasma brain-type fatty acid-binding protein is a potential candidate biomarker for psychiatric disorders

Authors: *M. KOGA[1,2], S. NAKAGAWA[3,2], A. SATO[2], Y. WAKATSUKI[2], K. KITAGAWA[2], R. KAMEYAMA[2], N. UDO[2], S. ASAKURA[2], Y. FUJII[2], Y. KAKO[2], K. ITO[2], N. MITSUI[2], H. NARITA[2], K. TOYOSHIMA[2], A. KATO[2], I. KUSUMI[2]

Abstract: There is urgent need to understand the pathophysiology of psychiatric disorders. To support this, biomarkers correlated with those disorders and symptoms must be identified. Since the organs primarily involved in psychiatric disorders are the brain, a tissue biopsy is generally impossible. Identifying molecules which are released from the abnormal organ and detectable in peripheral tissue such as blood, urine, etc. is a useful approach. However, such kinds of molecules have been poorly identified in psychiatric disorders. Previous studies have reported that elevated serum levels of brain-type fatty acid-binding protein (B-FABP) were observed in patients with dementia and ischemic stroke, thus suggested that B-FABP may be a useful biomarker for neurological disorders and cerebrovascular disorders. Relations between serum or plasma B-FABP levels and psychiatric disorders have not been reported. Although not as obvious levels as in neurodegenerative diseases, an involvement of nerve cell loss and cell death in the pathophysiology of mental disorders have also been reported. We hypothesized that B-FABP would also be a biomarker for psychiatric disorders. Patients with schizophrenia (n=30), bipolar disorder (n=29), depression (n=35), and subjects without a history of a mental disorder (n=40) were recruited. Patients with schizophrenia were evaluated through the Positive And Negative Syndrome Scale (PANSS), and patients with bipolar disorder and depression were evaluated with the Hamilton Depression Rating Scale (HAM-D) and the Young Mania Rating Scale (YMRS). Significantly elevated plasma B-FABP levels were observed in the schizophrenia group (4.87 ± 0.25 pg/mL*), the bipolar group (5.63 ± 0.26 pg/mL*) and the depression group (5.87 ± 0.24 pg/mL*) compared to the control group (2.74 ± 0.22 pg/mL). (*$p<0.0001$ by Tukey-Kramer test). PANSS score was correlated with the plasma B-FABP concentration in the schizophrenia group ($r^2=0.33$, $p=0.0008$). However, HAM-D and YMARS scores in the bipolar

disorders and depression showed no correlation with plasma B-FABP levels. Although the present study suggested that B-FABP may be a useful biomarker for psychiatric disorders, plasma B-FABP concentrations were higher in the all disease groups studied in this study than in the control group, suggesting that it reflects the pathophysiology common to these diseases. Further study would be to clarify the symptoms of psychiatric disorders correlated with plasma B-FABP concentration. This study was approved by the Ethics Committee of Hokkaido University Hospital.

Title: New measurement system for prepulse inhibition of acoustic startle response in common marmosets

Authors: *K. HAZEHARA, K. NAKAMURA
Primate Res. Institute, Kyoto Univ., Inuyama/Aichi, Japan

Abstract: Prepulse inhibition (PPI) is a neurophysiological phenomenon in which a weaker stimulus (prepulse) reduces the startle reflex to a subsequent intense stimulus (pulse). PPI usually occurs when the prepulse precedes the pulse by 30 - 500ms and 60 - 120ms intervals is reported to produce maximal inhibition in rodents and humans. Since PPI deficits in schizophrenia patients was reported in 1978, PPI is used as a biomarker for abnormalities of sensory-motor gating that underlies sensory flooding and cognitive fragmentation in schizophrenia. Common marmosets are suitable as nonhuman primate models concerning human neurologic diseases and psychiatric disorders. Hence objective behavioral indices are necessary to quantitatively assess the severity of symptoms in such models. However, so far, there are no methods to measure acoustic startle response and PPI in marmosets. The appropriate method varies among animal species (e.g., electromyography for orbicularis oculi muscle in humans, accelerometer for whole-body movement on all fours in rodents, and accelerometer in a sitting position in other nonhuman primates). Therefore, we had to choose an appropriate methodology for common marmosets. At first, we chose the method used in nonhuman primate research for marmosets to

quantify acoustic startle response and PPI. However, we failed to measure their startle response. Then, we applied whole-body protocol used in rodent research for marmosets. Our new apparatus consisted of 2 components: a startle response measuring device with a pressure transducer and a cage attached to the device. The device was filled with water. When a marmoset moved in the cage, their startle response was transmitted via water to the pressure transducer. First, we examined whether common marmosets show acoustic startle responses with a sound of 120dB. Of 5 marmosets tested, 4 marmosets but one showed startle responses. We regarded the one marmoset that did not show a startle response as a non-responder. Then, we tested whether the marmosets showed PPI. The 4 marmosets were presented in 4 kinds of trials (pulse-alone, prepulse-alone, PPI at 60ms intervals, PPI at 120ms intervals). 2 marmosets showed significant decreased startle responses in the PPI trials. These results suggest that PPI probably occurred at least in these 2 marmosets. The remaining 2 marmosets may also have shown PPI if we used an appropriate interval in PPI trials or paradigm. Further experimentation is needed to investigate appropriate inter-stimulus intervals for PPI in marmosets. We conclude that we have developed a new measuring system for PPI in common marmosets.

Title: Altered cerebrospinal fluid levels of matrix metalloproteinases in mood disorders and schizophrenia

Authors: W. OMORI[1], K. HATTORI[2], M. OKADA-TSUCHIOKA[1], K. ITAGAKI[1], N. KAJITANI[1], H. ABE[1], H. KUNUGI[2], *M. TAKEBAYASHI[1,3]

Hosp., Tokyo, Japan; [3]Dept. of Neuropsychiatry Fac. of Life Science, Kumamoto Univ., Kumamoto, Japan

Abstract: [Background] Matrix metalloproteinases (MMPs) are extracellular proteases involved in neuron / glia plasticity and inflammatory processes. We found a significant alteration of serum levels of MMP-2 in a state-dependent manner among patients with major depressive disorder (MDD) (Shibasaki et al., 2016). However, whether blood concentrations of MMP reflect the function in the brain is unclear. Therefore, MMPs in mood disorders and schizophrenia were examined using cerebrospinal fluid (CSF) in the current study. [Method] CSF was obtained from Japanese patients with MDD, bipolar disorder, and schizophrenia (SCZ) and from age- and gender-matched healthy controls (HC). First, MMP-1, 2, 3, 7, 8, 9, 10, 12, 13 were measured using Bio-Plex Pro Human MMP Assays (9-Plex) in small samples. Since MMP-3, 9, 12, 13 levels were almost equal to zero, CSF levels of the remaining MMPs, MMP-1, 2, 7, 8, 10, were measured in patients with MDD (n = 90), bipolar disorder (n=59), SCZ (n = 86), and HC (n = 106) using Bio-Plex Pro Human MMP Assays (5-Plex). Depressive symptoms were evaluated using the Hamilton Depression Rating Scale score. Psychotic symptoms were evaluated using Positive and Negative Syndrome Scale. The ethics committee of the national center of neurology and psychiatry (NCNP) and national hospital organization (NHO) Kure medical center approved the protocol of this study. All participants provided written consent. [Results] CSF level of MMP-2 was detectable in all samples, but MMP-1 level was almost equal to zero while the MMP-7, 8, 10 levels were much lower (average 14.5pg/ml, 19.4pg/ml, 28.9pg/ml, respectively) compared to MMP-2 level (average 5.96ng/ml). Therefore, we focused on MMP-2 level. In all samples, the correlation between MMP-2 level and age ($p<0.001$) was positive, and the difference between men and women ($p<0.001$) was significant. Thus, we compared the MMP-2 level while adjusting for age and gender between groups. As a result, a significant increase was found in patients with MDD (average 6.20ng/ml, $p=0.023$) and with SCZ (average 6.15ng/ml, $p=0.030$) compared to HC (average 5.57ng/ml). Additionally, a significant positive correlation emerged between MMP-2 level and depressive symptoms in MDD ($p=0.045$) while MMP-2 levels and psychotic symptoms in SCZ did not correlate ($p=0.174$). Finally, correlation between MMP-2 levels and imipramine equivalent doses of antidepressants in patients with MDD was non-significant ($p=0.691$). [Conclusion] We found a significant increase of CSF levels of MMP-2 in a state-dependent manner among patients with MDD, suggesting that MMP-2 may be related to the pathophysiology of MDD.

Title: The potential usefulness of long noncoding RNAs as biomarkers of major depressive disorder

Authors: *T. SEKI, H. YAMAGATA, S. UCHIDA, C. CHEN, K. HARADA, K. MATSUO, Y. WATANABE, S. NAKAGAWA
Yamaguchi Univ. Sch. of Med., Ube Yamaguchi, Japan

Abstract: There is growing evidence suggesting that aberrant transcription regulation plays a critical role in the pathophysiology of major depressive disorder (MDD). Although long noncoding RNAs (lncRNAs) have important functions in the chromatin structure, gene expression, and subsequent manifestation of various biological processes in the central nervous system, it is still unclear whether the aberrant expression of lncRNAs is involved in MDD. We therefore investigated the usefulness of lncRNAs as biomarkers of MDD. In Experiment 1, using gene expression microarray analysis, we comprehensively searched gene expressions that are changing in a stress-dependent manner in the hippocampus, the prefrontal cortex and the blood of chronically stress-loaded BALB / c mice. In Experiment 2, we compared the expression of lncRNAs in the blood of 29 currently depressed human patients suffering from MDD with 29 health controls, who were matched for age and sex. This study was approved by the Institutional Review Board of Yamaguchi University Hospital and written informed consent was obtained from all participants after providing them with a complete description of the study. We measured the expression levels of 84 lncRNAs in the blood leukocytes of depressed patients and healthy controls using a quantitative real-time PCR analysis. The results of the two experiments indicated several differentially expressed lncRNAs in stressed mice and depressed patients as compared to control mice and human subjects. Thus our data support the usefulness of blood lncRNAs as potential biomarkers for MDD.

Title: Serine racemase knockout mice demonstrate schizophrenia-like EEG biomarker deficits

Authors: *D. D. AGUILAR, M. R. ZIELINSKI, J. M. MCNALLY
Psychiatry, VABHS, Harvard Med. Sch., West Roxbury, MA

Abstract: Many noninvasive techniques are being explored as potential biomarkers for developing psychosis. Abnormalities in spontaneous and task-evoked gamma oscillations, sensory gating, processing of a deviant stimuli [(mismatch negativity (MMN)] and/or entrainment to a 40Hz auditory stimulus [auditory steady state response (ASSR)] have been observed in schizophrenia (Sz) patients and in others with clinical high risk to transition to psychosis. Further, a number of these biomarkers are associated with cognitive processes impaired in this disorder. Converging evidence suggests NMDA receptor hypofunction is central to the pathophysiology of Sz and other severe psychiatric disorders, and likely contributes to impairments in these translationally relevant biomarkers. NMDA receptor function has been indirectly linked to abnormalities in MMN, ASSR, and spontaneous gamma power, but their underlying mechanisms are not completely understood.

Here we have examined this relationship utilizing the serine racemase knockout (SR KO) mouse model, which has been shown to demonstrate Sz-like NMDA receptor hypofunction, and a variety of cognitive impairments. Adult male SR KO mice (n=4) and WT controls (n=3) were used for *in vivo* EEG/EMG recordings to test the translationally-relevant biomarkers listed above. EEG electrodes were stereotaxically implanted above the frontal and parietal cortices. In brief: 40 Hz ASSR was evoked using 1 second 90 dB click trains (100 repetitions), sensory gating used paired 4 kHz tones (50ms each, 500ms apart, 100 repetitions), and MMN used a 1Hz train of 9 identical tones (2 kHz pitch) followed by a deviant tone (4 kHz, 100 reps).

In the ASSR, a 40Hz auditory stimulus evoked an increase in 40Hz cortical power for WT but not SR KO mice. In sensory gating, the second tone had a reduced attenuation in gamma power in KO animals (32% attenuation of 1st tone) compared to WT (57%). In the MMN, the deviant tone evoked a large evoked response potential around 150ms in WT but not SR KO mice. We observed no changes in spontaneous gamma oscillation power.

In conclusion, SR KO mice demonstrated a variety of Sz-like deficits in EEG biomarkers, creating a logical association between these biomarkers and impaired NMDA receptor function. Interestingly, certain phenotypes like increased spontaneous gamma band connectivity are observed in first episode stages of psychosis but may be less common with disease progression (*Di Lorenzo et al 2015 Front Hum Neurosci*). These mice could be useful for exploring the underlying mechanisms behind these biomarkers and testing potential therapies for the cognitive and auditory deficits associated with these abnormal biomarkers.

Title: An *in vivo* automated functional screening method identifies modulators of neural activity for accelerated drug discovery

Authors: *R. LAGOY, D. ALBRECHT
Biomed. Engin., Worcester Polytechnic Inst., Worcester, MA

Abstract: Mental health disorders affect one in six adults in the U.S. and altered neural activity is believed to be an underlying symptom, sometimes with known genetic causes. Most prescribed therapeutics that aim to treat these disorders are not effective and have severe side effects, likely due to indirect and off-target compound interactions. Therefore, the identification of therapeutics that act with high specificity to restore function *in vivo* should yield improved treatments for neural activity-dependent diseases. Automated functional screening technologies are particularly useful for identifying compounds that modulate neural activity. However, these methods are currently limited to *in vitro* assays which do not consider multicellular interactions, and therefore lead to treatments that have substantial systemic effects *in vivo*.
To identify more effective therapeutics, we developed an automated high-content functional screening technology to assess long-term compound effects *in vivo* using the model organism *C. elegans*. The nematode *C. elegans* is transparent, small, and genetically tractable, allowing for both stimulation and recording of neural activity in large isogenic populations. Our method enables fast, simple, and cost-effective immobilization of >15,000 animals distributed evenly across 384-well plates, in which ~40 animals per well are exposed to a particular compound condition for over 18 to 24 hours. We screened 640 FDA-approved drugs for changes to stimulated neural responses in >33,000 living animals across two fully-automated experiments in less than one week. Of the several primary hits, we found that felodipine, a voltage-gated calcium channel (VGCC) blocker, suppresses neural activity in *C. elegans* over 6-18 hours of exposure. Interestingly, this compound does not cause severe developmental effects in the worm, unlike other VGCC antagonists, suggesting that it may have greater specificity for the nervous system. Using this method, we also systematically characterized the time course and bioavailability of various compounds in *C. elegans*, such as All-*Trans* Retinal that is required for

optogenetic experiments in nematodes.
Taken together, we expect that our method will accelerate the identification of more effective therapeutics for activity-dependent disorders by directly identifying compounds that modulate cellular activity *in vivo*. In the future, we also plan to screen for modulators of intercellular communication in *C. elegans* and further characterize our primary hits for use in secondary screens and translational studies involving mammalian systems and disease models.

Title: Auditory steady state responses (ASSRs) in awake-behaving primates: A translatable biomarker for drug-discovery in schizophrenia

Authors: *B. J. HANSEN[1], S. J. TYE[1], A. MANOHAR[2], M. J. MARINO[2], J. M. USLANER[2], D. A. HENZE[1]
[1]In Vivo Pharmacol., [2]Neurosci., Merck Res. Labs., West Point, PA

Abstract: A robust pathophysiological finding related to schizophrenia is dysfunction of parvalbumin positive (PV+) interneurons. Numerous post mortem studies have identified a loss of GABAergic markers related to a decrease in PV+ cell function. PV+ cells also referred to as "Fast-spiking interneurons" are characterized by sustained high-frequency spiking activity in response to strong inputs and their ability to respond to such input with minimal delay. It is this unique combination of biophysical properties that suggests PV+ cells underlie gamma band oscillations (GBOs), which have been reported to be deficient in schizophrenic patients. GBOs are hypothesized to play a critical role in cognitive processing, which is supported by studies where disruption in PV+ cell activity decreases GBOs and impairs cognition. Clinically, one of the most consistent biomarkers used in the assessment of schizophrenia is Auditory Steady State Responses (ASSRs). During this procedure amplitude-modulated tones are presented at a rhythm in the gamma range (e.g. 40Hz) while cortical electroencephalograms (EEGs) are measured to analyze gamma power and phase synchronization. It is has recently been suggested that the stimulus-driven changes in GBOs during ASSRs are the result of an increase in PV+ cell activity. Surprisingly, there has been little if any preclinical work exploring ASSRs and GBOs in

awake-behaving primates, which are an ideal animal model that can provide objective and quantifiable results while taking advantage of more complex behavioral testing. We have developed a novel and highly translatable paradigm to record quantitative electroencephalography (qEEG) activity in primates during periodic auditory stimulation. Briefly, 10 male rhesus macaques (Macaca mulatta) were trained to sit quietly in a study chair in a custom sound-attenuated chamber and exposed to a series of 500ms white-noise tones presented at 30 or 40Hz. We assessed spectral power using the continuous wavelet transform and phase synchronization using inter-trial coherence (ITC) analyzed 200ms after stimulus onset to 500ms and ± 5 Hz around the tone frequency. All data were pre-processed and analyzed using custom software coded and complied in Matlab. Gamma power and inter-trial phase coherence of ASSRs were altered following treatments with the NMDA antagonist ketamine at ~10% of the anaesthetic dose. This allows us to explore the mechanisms underlying schizophrenia-like symptoms and assess the role of novel compounds and their influence on cognitive processing in a large animal species in a preclinical setting.

Title: Mitochondrial Translocator Protein (TSPO) binding: A common occurrence in CNS-active plant species used in Peruvian traditional medicine

Authors: *C. GALLO[1], G. POLETTI[2], R. ROJAS[2], A. VAISBERG[2]
[2]Laboratorios de Investigación y Desarrollo, [1]Univ. Peruana Cayetano Heredia, Lima, Peru

Abstract: The mitochondrial translocator protein (TSPO) also known as peripheral-type benzodiazepine receptor is a yet poorly understood protein, which seems to be involved in a

range of functions that span from acting as a housekeeping gene to its participation in the adaptations to stress and the modulation of mood and cognition. At molecular level TSPO promotes the transport of cholesterol across mitochondrial membranes and may play a role in lipid metabolism, although it is apparently not required for steroid hormone biosynthesis. In the CNS, TSPO is expressed both in neurons and in glial cells.
Ethanol extracts (n=477) from plant collections corresponding to 265 species from 87 different plant families were tested for TSPO binding, using [3H]PK11195 as ligand, in the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill (UNC). This repository of ethanol extracts was generated through the collection of information on the traditional use of plants for the treatment of brain disorders in several Peruvian localities and geographical regions.
A total of 176 of the assayed extracts (37%) showed 50% or higher inhibition of [3H]PK11195 binding. Further studies will let us determine the nature of this binding, regarding to an agonist or antagonist action on TSPO function.
The main traditional uses reported for these 176 extracts are: for nerves/madness/schizophrenia (84 mentions), for depression/sadness/ tiredness/cheering up/getting vigorous (50 mentions), for insomnia/ tranquilizer/sedative/anxiety/stress (31 mentions).
Noteworthy, recent studies show that TSPO levels are lower across several brain regions in patients with first-episode psychosis and schizophrenia compared with healthy controls. Also, TSPO ligands have shown to reduce depression and anxiety in rodents.
Our plant extracts are a unique source of novel molecules with TSPO ligand properties which merit additional studies.

Title: The neurosteroid allopregnanolone mediates sensorimotor gating deficits induced by D1 receptor activation

Authors: *F. TRACCIS[1], L. J. MOSHER[2], S. FANNI[1], P. SABA[1], G. GIUA[1], P. DEVOTO[1], M. BORTOLATO[2], R. FRAU[1,3,4,5]

Abstract: Sensorimotor gating, the information-processing function aimed at filtering out irrelevant or superfluous information, is differentially modulated by dopamine. Accordingly, the best-validated operational index of sensorimotor gating, the prepulse inhibition (PPI) of the acoustic startle, is impaired by D_1 receptor agonists in C57BL/6 mice, but not in Sprague-Dawley rats. We previously showed that the dopaminergic regulation of PPI is moderated by 5α-reductase, the enzyme catalyzing the rate-limiting step of neurosteroid synthesis. Here we show that C57BL/6 mice with a nonsense mutation of the enzyme 5α-reductase 1 (5αR1) are insensitive to the PPI-disrupting effects of the selective D_1 receptor agonist SKF82958 (0.3 mg/kg, IP). The sensitivity of 5αR1 KO mice to the PPI-disruptive effects of D_1 receptor activation was reinstated by administration of the neurosteroid allopregnanolone (AP; 3 mg/kg, IP). Conversely, Sprague-Dawley rats were rendered sensitive to the PPI-disrupting effects of SKF82958 (0.05 mg/kg, IP) by administration of AP in the prefrontal cortex (PFC) or sleep deprivation, a manipulation that increases AP levels in the PFC. Taken together, these results show that AP is necessary and sufficient to enable the sensitivity of D_1 dopamine receptor activation with respect to PPI, and may help explain how stress may modulate dopaminergic sensitivity in sensorimotor gating. Future studies will be needed to study whether differences in AP levels in the brain may be responsible for the different sensitivity of PPI to the effects of D_1 receptor agonists.

Title: Plasma levels of metabolites differentiate first episode psychosis in schizophrenia and bipolar disorders patients

Authors: *A. C. COSTA[1], H. P. G. JOAQUIM[3], L. L. TALIB[2], W. F. GATTAZ[2]
[1]Lab. of Neurosci. LIM27 - HCFMUSP, Sao Paulo, Brazil; [2]Psychiatry, Lab. of Neurosci. LIM27 - HCFMUSP, São Paulo, Brazil; [3]Psychiatry, Lab. of Neurosci. LIM-27 - HCFMUSP, São Paulo, Brazil

Abstract: Background: Schizophrenia (SCZ) and bipolar disorder (BD) are serious psychiatric disorders that affect young adults and lead to disability, psychosocial functioning impairment and premature death. These disorders share several characteristics and symptoms and the diagnosis yet is mainly clinical. It is known that the sooner they are identified, diagnosed and treated, the better the clinical prognosis. Therefore, the development of sensitive and accurate biomarkers is highly required. Lipids play an increasingly recognized role in the neuronal function and plasticity of the brain. Glycerophospholipids and molecules-like comprise 60% of the non-aqueous portion of the brain and in an even greater proportion of the dendrites and synapses. Other metabolites directly influence its functioning and remodeling, such as acylcarnitines, sphingolipids, cholesterol and other lipids. Since lipid metabolism is altered differently in neuropsychiatric diseases, alterations in the lipid profile of the membrane can allow a discrimination between subjects in first episode psychosis (FEP). Thus, our aim was to determine plasma levels of metabolites of subjects in first episode psychosis and controls and find cutoff values that differentiate each group. Methods: Plasma samples were analyzed for 55 drug-naïve patients (28 SCZ and 27 BD) and 30 controls in this study. Determining the lipid profile was performed by mass spectrometry - Flow injection analysis, using AbsoluteIDQ p180® kit (Biocrates Life Sciences). Statistical analyzes were performed using a classification method - Classification And Regression Tree. Results: We observed that there the combination of four metabolites are able to differentiate the diagnoses studied: PC aa C26:0, PC aa C38:4, PC aa C34:3 and C16-OH. The accuracy of the method is 87,1%. Discussion: Our results suggest that the levels of some plasma metabolites differentiate subjects in FEP in SCZ, BD and controls. The levels of these metabolites can be a potential biomarker for psychosis, as well as a diagnostic marker for SCZ and BD, aiding clinical practice. The findings from this study require further validation in BD and SCZ subjects, but suggest that the metabolome is a good tool to understand the pathophysiology of these disorders and presents potential diagnostic biomarkers for the diseases studied.

Title: Kynurenine pathway is altered in plasma of schizophrenia patients

Authors: *L. L. TALIB[1], A. C. COSTA[2], H. P. JOAQUIM[3], W. F. GATTAZ[2]
[1]Psychiatry Inst. HCFMUSP, São Paulo, Brazil; [2]Lab. of Neurosci. LIM27 - HCFMUSP, Sao Paulo, Brazil; [3]Psychiatry Intitute HCFMUSP, Lim-27, São Paulo, Brazil

Abstract: The etiology of schizophrenia is still unclear. It is well-known that pro-infammatory cytokines are higher in schizophrenia patients since the frst episode psychosis comparing to healthy controls. Infammatory downstream cascades infuence different cellular pathways, like the displacement of the tryptophan (TRP) metabolism to the production of kynurenine (KYN) instead of serotonin, which results in the generation of several neuro and immunoactive metabolites. The aim of this study was to determine TRP, KYN and IL-1β plasma levels in frst-onset schizophrenia (n = 28) and healthy controls (n = 30). The plasmatic levels of TRP and KYN were decreased in schizophrenic patients (p = 0.004 and p = 0.002, respectively), but there was no diference in the ratio of KYN/TRP (p = 0.554) or either in IL-1β (p = 0.101). Positive correlation was observed between KYN and IL-1β only in the schizophrenia group (r = 0.461, p = 0.021). And, there was also positive correlation between KYN and Positive and Negative Symptoms Scale (PANSS) (r = 0.395, p = 0.037). There is no correlation between the other analytes and other parameters of PANSS. Although our results of KYN have been diferent than expected and there was no diference in the KYN/TRP ratio, we observed a positive correlation between IL-1β and KYN, corroborating fndings that pro-infammatory agents hold up the KYN pathway.

Title: An efficient, data-driven, trans-diagnostic screen for neurobehavioral health

Authors: *Y. LIU, M. S. MELLEM, H. GONZALEZ, W. J. MARTIN, P. AHAMMAD
Blackthorn Therapeut., San Francisco, CA

Abstract: Mental health screening and diagnosis requires a time-consuming interview between patients and highly-trained specialists within a clinic. Currently available remotely-administered self-assessments tend to be based on discrete diagnostic categories that may fail to reveal trans-diagnostic behavioral changes that warrant intervention. We developed a quick, trans-diagnostic, self-administered neurobehavioral health screen, which is automatically scored by computer, to

overcome some of these barriers. Using the publicly-available Consortium for Neuropsychiatric Phenomics (CNP) dataset, we applied machine learning to build statistical models comprised of trans-diagnostic item-level questions to create a screen to classify groups of subjects as healthy or possibly having a neurobehavioral disorder. CNP consists of individuals diagnosed as healthy (n=130) or as having schizophrenia (n=50), bipolar disorder (n=49) or attention deficit and hyperactivity disorder (n=43) following administration of the Structured Clinical Interview for DSM Disorders by mental health professionals. All participants provided item-level responses to multiple self-administered mental health questionnaires. We used 10-fold cross-validation with logistic regression to classify healthy control (HC) from patients based on scores of these individual items. Using all individual items (578 total), we were able to classify subjects as "HC" or "Patient" with a mean accuracy of 79%. The ROC curve, another performance evaluation metric, had a mean area-under-the-curve (AUC) of 0.88. This model also returned a measure of feature importance from the model coefficients. Thus, in order to examine if shortening the list of questions could provide comparable classification ability, we also constructed a series of models by sequentially adding in features in order of importance (starting with the most important). We found classifier performance across different subsets of questions (1 through 578) varied on AUC from 0.8 to 0.97, and it turns out that only about 5% of the items are needed for an accuracy of 91% and 0.95 AUC. This indicates that a robust classifier can be built from a compact set of questionnaire items and more features are not necessarily better in a classifier-based screen. Notably, the top features included a disproportionate number of questions regarding personality and temperament with additional questions on impulsivity, mood, and mania. Thus, the classifier with the top 5% features could be used to rapidly screen subjects across multiple neurobehavioral disorders without rater involvement, potentially remotely and repeatedly.

Title: T-448 is a specific inhibitor of LSD1 enzyme activity that has minimal impact on LSD1-GFI1B complex through the generation of a compact formyl-FAD adduct

Authors: *R. BABA[1], S. MATSUDA[1], H. OKI[2], S. MORIMOTO[1], M. TOYOFUKU[1], S. IGAKI[2], Y. KAMADA[2], K. MATSUMIYA[2], K. TSUCHIDA[3], R. HARA[1], M. ITO[1], H. KIMURA[1]
[1]Neurosci. Drug Discovery Unit, Res., [2]Biomolecular Res. Laboratories, Res., [3]Extra Value Generation Drug Discovery Unit, Res., Takeda Pharmaceut. Co. Limited, Fujisawa, Kanagawa, Japan

Abstract: Lysine-specific demethylase 1 (LSD1) is a flavin adenine dinucleotide (FAD)-dependent amine oxidase that demethylates histone H3 lysine 4 (H3K4). H3K4 methylation is a critical regulator of gene transcription, and its dysregulation has been implicated in the pathogenesis of several neurodevelopmental diseases. Therefore, treatments which restore normal levels of H3K4 methylation may be a promising approach to treat disorders associated with epigenetic dysfunction.
LSD1 forms a complex with multiple cofactors including growth factor independent 1B transcriptional repressor (GFI1B), a critical regulator of hematopoietic differentiation, in the vicinity of FAD. Known LSD1 inhibitors that target FAD have shown *in vivo* hematological toxicities, such as thrombocytopenia, probably through disruption of the interaction between LSD1 and GFI1B and the transcriptional derepression of its target genes, including *growth factor independent 1* (*GFI1*). We have identified a novel LSD1 inhibitor, T-448, 3-((1*S*,2*R*)-2-(cyclobutylamino)cyclopropyl)-*N*-(5-methyl-1,3,4-thiadiazol-2-yl)benzamide fumarate, which induced H3K4 methylation in primary cultured rat neurons but did not induce *GFI1* mRNA in TF-1a erythroblast cell line. As expected from the *in vitro* profile, T-448 induced H3K4 methylation in mouse brains and restored learning function in NMDA receptor-hypofunction mice, showing superior hematological safety profile.
Here, we describe the mechanisms of action underlying the lack of *GFI1* mRNA induction by T-448 through the comparative analysis of T-711, a representative LSD1 inhibitor which induces *GFI1* mRNA expression. T-711 dissociated the LSD1-GFI1B complex in TF-1a cells. In contrast, T-448 had minimal impact on the complex. In addition, T-448 pre-treatment significantly weakened the T-711-induced dissociation of LSD1-GFI1B complex, suggesting that T-711 and T-448 may share the same binding site on LSD1.
Co-crystal analysis and LC/MS analysis of LSD1 and FAD suggested that FAD-adduct generated by T-711 is bulky and has a steric hindrance with GFI1B in the binding pocket of LSD1. Interestingly, T-448 produced a reduced form of FAD with a formyl group, indicating that T-448 inactivates LSD1 enzyme activity through generating a compact formyl-FAD adduct, and the formyl-FAD adduct has minimal
impact on the interaction between LSD1 and GFI1B. These results suggest that T-448 is a specific inhibitor of LSD1 enzyme activity, and the discovery of T-448 enables the *in vivo* characterization of therapeutic effects evoked by the specific inhibition of LSD1 enzyme activity.

Abstract: Epigenetic control of gene transcription by histone H3 lysine 4 (H3K4) methylation is involved in various neural functions such as learning and memory through the regulation of synaptic plasticity. Dysregulation of H3K4 has been implicated in the pathogenesis of several psychiatric and neurological disorders. H3K4 methylation levels are regulated by lysine-specific demethylase 1 (LSD1), a flavin adenine dinucleotide (FAD)-dependent amine oxidase that demethylates H3K4. Thus, treatments which restore normal levels of H3K4 methylation by the inhibition of LSD1 activity in the brain may be a promising approach to treat central nervous system (CNS) diseases associated with epigenetic dysregulation.
Targeting FAD in the active site of LSD1 is a very promising approach to design novel LSD1 inhibitors. However, in the vicinity of FAD, LSD1 forms a complex with multiple cofactors such as growth factor independent 1B (GFI1B), a critical regulator of hematopoietic differentiation. Known LSD1 inhibitors that bind to FAD have shown hematological toxicities such as thrombocytopenia, probably through the disruption of the LSD1-GFI1B complex and the transcriptional derepression of its target genes, including *growth factor independent 1* (*GFI1*). Hematological toxicity may pose a major hurdle in the development of LSD1 inhibitors as therapeutic agents.
Here, we describe our screening strategy to discover novel LSD1 inhibitors with potent epigenetic modulation and lower risks of hematological toxicity. We set the following three criteria for the selection of lead compounds: 1) selective inhibition of the enzyme activity of

purified human recombinant LSD1, 2) increase in H3K4 methylation levels and the consequent induction of gene transcription in primary cultured rat neurons, and 3) minimal impact on the transcription of *GFI1* gene in human TF-1a erythroblast cell line. As a result, T-448, 3-((1*S*,2*R*)-2-(cyclobutylamino)cyclopropyl)-*N*-(5-methyl-1,3,4-thiadiazol-2-yl)benzamide fumarate was identified. T-448 selectively inhibited recombinant LSD1 activity, and increased H3K4 methylation and mRNA expression levels in primary cultured rat neurons. In contrast, T-448 did not increase *GFI1* mRNA expression levels in TF-1a cells. As expected from the *in vitro* profile, T-448 induced H3K4 methylation and mRNA expression levels in mouse brains, showing improved hematological safety profile. In addition, T-448 restored learning function in NMDA receptor-hypofunction mice. T-448-type LSD1 inhibitors with an improved safety profile may provide unique therapeutic opportunities for CNS disorders associated with epigenetic dysregulation.

Abstract: There are 70k+ papers mentioning PKC proteins family across the literature. Success and reproducibility of the new experiment involving PKC(x) strongly tied to correct interpretation which isoform was meant in prior scientific reports.
Based on our upstream literature-based research of PKCs' role in pain mediating, we conclude that, in spite of the close first-sight similarity, even "small" differences between isoforms PKCγ and PKCε are linked to different and unique functional roles in similar chronic and acute

perceptions of pain.
We utilize machine reasoning methods to discover possible models of biological processes and report clear feasibility to distinguish functional roles of particular PKC isoforms based on machine parsing, interlinking, and clustering of the related interactions.

Title: Imaging mass spectrometry revealed the alteration of amine neurotransmitters in Scrapper-knockout mice brain

Authors: F. ETO[1,2], T. MATSUDA[1], M. SETOU[3,4], *I. YAO[1,4]
[1]Dept. of Optical Imaging, Inst. for Med. Photonics Res., [2]Dept. of Cell. and Mol. Anat, [3]Dept. of Cell. and Mol. Anat., [4]Intl. Mass Imaging Ctr., Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan

Abstract: The detection of low-molecular weight components such as amino neurotransmitters by imaging mass spectrometry (IMS) has been tried and developed by some groups [1, 2]. Recently, several chemical derivatization methods have been made it possible to detect them in tissues. Neurotransmitters play important parts in the brain functions and regulate a variety of biological activities. Abnormal concentrations of neurotransmitters and consequent dysfunction are connected to various central nervous system disorders. Especially, glutamate has pivotal roles in central nervous system and is closely related to neurodegenerative disease such as Alzheimer's disease. Visualization of the amino acid and monoamine of neurotransmitters is suspected to be fundamental understanding their role in various neurophysiological phenomena in different regions of the brain. Here, we applied this technique to investigate *Scrapper*-knockout (SCR-KO) mice. SCRAPPER is a synaptic protein which we have identified as an ubiquitin E3 ligase. SCRAPPER is involved in the ubiquitination of RIM (Rab3-interacting molecule) 1, an important regulator of synaptic plasticity, and thus regulates synaptic transmissions. SCR-KO has the defect in neurotransmission via excessive secretion of neurotransmitters due to the upregulation of the release probability. IMS with on tissue

derivatization revealed that the alteration of not only glutamate but also some other amino acid neurotransmitters abundances and localization in the SCR-KO mouse brain. Intriguingly, our results indicated that the rate of changes of amino acid neurotransmitters were different depending on the region of the brain. The alteration visualized by IMS analysis would reflect the local changes of neurotransmitters caused by defects in neurotransmission in the SCR-KO mouse brain. Title: Electrochemical recording of striatal dopamine in non-human primates performing reward-biased tasks

Authors: *H. N. SCHWERDT, L. STANWICKS, K.-I. AMEMORI, H. SHIMAZU, T. YOSHIDA, S. AMEMORI, R. LANGER, M. J. CIMA, A. M. GRAYBIEL
MIT, Cambridge, MA

Abstract: Dopamine neurochemicals govern a wide range of behaviors including those related to movement, motivation, and learning. Dysregulation of striatal dopamine causes many debilitating disorders such as Parkinson's disease and major mood disorders. Understanding the role of dopamine in the specific behaviors compromised in these disorders is critical to improve diagnostics and treatment. The objective of the present study was to investigate dopamine signaling as it relates to motivational bias and motor performance. Carbon fiber microelectrode (CFM) sensors were implanted in the striatum of two rhesus macaques (*Macaca mulatta*) to selectively measure subsecond dopamine fluctuations with fast-scan cyclic voltammetry. Methods were previously established to probe multiple sites in the striatum from chronically implanted and moveable CFM sensors over several months. We recorded dopamine

concentration changes as the monkeys performed a reward-biased visual saccade task in which saccades to targets appearing on the left or right were rewarded with a small or large amount of liquid food. Physiological parameters including pupil diameter, lick movements, and pulse were synchronously recorded in the second monkey to discriminate better cryptic behavioral states. Preliminary measurements in the first monkey showed that dopamine concentration in the ventromedial striatum increased in response to unexpected food delivery, and that dopamine concentration was higher during large reward trials in comparison to small reward trials. These results agree with previous studies that have demonstrated a correlation between dopamine in the ventral striatum and reward value. Results from multi-site recording indicated diverse dopamine activity across the dorsal striatum. Early analysis suggests changes in dopamine concentration correlate with many task events including error (i.e., premature saccadic break from target), fixation cue, target appearance, and reward delivery. Trial-to-trial fluctuations of the temporal characteristics of dopamine were also observed, the dynamics of which is under investigation. This early work described here suggests heterogeneous functions of dopamine in mediating various goal-directed behaviors. These findings have the possibility to strengthen the rationale for focal pharmacological and therapeutic strategies that can be implemented for a number of disorders in which dopamine is dysregulated in a spatially variable manner. Further investigations are needed to understand the site specific functions of dopamine in motor and mood behaviors, which could help identify new therapeutic targets.

Abstract: Human-scale whole-brain simulations are expected to become possible using the next generation supercomputer with a theoretical performance of exaflops, which enable to study interactions among all neurons in the brain for brain function and disease.
However, there are still difficulties in realizing the simulation in load balancing of the heterogeneous architecture of the brain and communication of increasing spike information in parallel computing.
In the current study, we investigated an efficient parallelization way that can realize human-scale whole-brain simulations on the next generation supercomputer.
We focused on layered sheet neural network because 99 % of neurons and most of the volume in the brain are included in the cortex and cerebellum that form layered sheets.
Tile partitioning algorithm is one of the candidates for layered sheet model. In the current study, we introduced a new communication method to the tile partitioning method, where spike information is communicated between tiles at intervals of the minimum signal transmission delay between the tiles. The method can reduce the frequency of communication for distant tiles.
To test the performance, we applied the method to a layered cortical sheet model developed based on experimental data of the mouse primary motor cortex. The model had five layers and 18 neuron types. The numbers of neurons and synapses per square millimeter of the cortical surface were about 23000 and 220 million, respectively. The neurons were connected using Gaussian-shape connection probability function. The model consists of 4 small regular squares of different cortical sheets that were partially connected through long-range connections.
We investigated weak scaling performance of the parallelization method using 1024-16384 compute nodes of supercomputer K. With the increase in the size of the network, the frequency of communication between distant tiles decreased drastically. The computational time did not almost increase with the increase in the size of the network, which means the parallelization method achieved excellent scaling performance.
These results suggest hat proposed parallelization method may work for human-scale whole-brain simulation on the next generation supercomputer.

Title: Examination of the roles of basal ganglia afferents in action selection and learning by spiking neuron models

Authors: J. LIÉNARD[1], B. GIRARD[3], *K. DOYA[2]
[1]Neural Computation Unit, [2]Okinawa Inst. of Sci. and Technol., Onna, Okinawa, Japan; [3]ISIR, CNRS / Sorbonne Univ., Paris Cedex, France

Abstract: We use an integrate-and-fire neuron model of the whole basal ganglia to analyze action selection and learning mechanisms. This spiking model was derived from a mean-field model parameterized in a previous work (Liénard and Girard, 2014), which was developed as a theory-agnostic model matching to a large body of anatomical and electrophysiological constraints from the macaque monkey.
We first show that the spiking version of this model exhibits selection properties in the context of an arm-reaching task, as was the case in the previous mean-field model. A comparison to neural activity recorded in the basal ganglia of monkeys performing this task further shows that the amplitude and time courses of the modeled firing rates match the experimental data.
We then carry out a systematic assessment of the functional roles of excitatory inputs to the basal ganglia, namely, the cortico-striatal pathway (CSN), the pyramidal tract (PTN), and the thalamic inputs from centromedian/parafascicular nuclei (CM/Pf). Varying the relative strength of these inputs in a selection task shows that (a) the CSN and PTN, acting alone or together, can affect which action is selected, and (b) CM/Pf inputs can prevent selection of multiple actions by narrowing selection to the most prominent one even in the case of ambiguous cortical inputs. In this model, the cortical pathways are thus compatible to the often hypothesized role of feeding action saliences to the basal ganglia, while the thalamic pathway modulates the selection under ambiguous inputs.
We finally study reinforcement learning at the cortico-striatal synapses using dopamine-modulated spike-timing dependent plasticity (DA-STDP). The exact effect of dopamine in modulating STDP, which depends on tonic and phasic DA concentration and on the dopaminergic receptors expressed by striatal medium spiny neurons, is still uncertain. We thus test different models of DA-STDP and compare the resulting learning performance. The model allows us to test different overlap of D1 and D2 receptors in striatal medium spiny neurons and to identify the range of parameters that are functionally consistent with reinforcement learning.

Title: Implementation and simulation of a cerebellar model on a tile-based general spiking neural network simulator for K supercomputer

Authors: *T. YAMAZAKI[1], H. YAMAURA[1], J. IGARASHI[2]
[1]The Univ. of Electro-Communications, Tokyo, Japan; [2]RIKEN, Saitama, Japan

Abstract: Human-scale brain network simulation is an ultimate goal of computational neuroscience. In Japan, the national flagship supercomputer K has been used for this purpose, and its successor Post-K is expected to achieve the goal. In our project entitled Post-K exploratory challenge #4, we develop a high-performance general spiking neural network simulator for Post-K. The simulator decomposes a simulated network arranged on a two-dimensional grid into a set of subnetworks on two-dimensional smaller subgrids like tiling, and performs numerical simulation of the subnetworks in parallel. Spatially nearby subnetworks or tiles communicate and exchange spikes to make the set of subnewtork simulations consistent with the entire network simulation. In this study, we implemented a spiking network model of the cerebellum that we proposed previously. Using 1,024 cores on K computer, we implemented a corticonuclear microcomplex, which is considered as a functional unit of the cerebellum. Our microcomplex model is composed of 1 billion granule cells, 1 million Golgi cells, 32,000 Purkinje cells, 32,000 molecular layer interneurons, 1,024 cerebellar nuclei, and 1,024 inferior olives. These neurons were connected based on the cerebellar anatomical data, and cell parameters were estimated from electrophysiological data. Neurons were modeled as conductance-based integrate-and-fire units. In the current version, a 6-second simulation of the spontaneous activity of the cerebellum with temporal resolution of 1 millisecond completes within 2532 seconds, indicating 422 times slower than realtime. Moreover, thanks to the tile-based decomposition of the network by the simulator, we obtained good weak-scaling property, which means that the network size can be extended as large as computational cores are available on a computer. This result suggests that when an exascale-class supercomputer is built, we could perform a simulation of a human-scale cerebellar model on the supercomputer. Currently, we are working on connecting the cerebellar model with a cerebral cortical model via a thamalus model, comprising a cerebrocerebellar communication loop model. Our preliminary results demonstrate that the cerebellar model and cerebral cortical model synchronize within the theta frequency range.

Title: The predictive neuron, how active dendrites enable spatiotemporal computation in the neocortex

Authors: *S. AHMAD, J. HAWKINS
Numenta, Redwood City, CA

Abstract: Pyramidal neurons receive input from thousands of synapses spread throughout dendritic branches with diverse integration properties. The majority of these synapses have negligible impact on the soma. It is therefore a mystery how pyramidal neurons integrate the input from all these synapses, and what kind of network behavior this enables in cortical tissue. It has been previously proposed that active dendrites enable neurons to recognize multiple independent patterns. In this paper we extend this idea. We propose a model where patterns detected on active basal dendrites act as predictions by slightly depolarizing the soma without generating an action potential. A single neuron can then predict its activation in hundreds of independent contexts. We show how a network of pyramidal neurons combined with fast local inhibition and branch specific plasticity mechanisms can learn complex time-based sequences and form precise predictive codes. The algorithm scales well, learns continuously and demonstrates excellent performance on real-world data. We then extend the idea to handle sensorimotor sequences. Sensory inputs can change due to external factors or they can change due to our own behavior. Interpreting behavior-generated changes requires knowledge of how the body is moving, whereas interpreting externally-generated changes relies solely on the temporal sequence of input patterns. We show that our predictive network mechanism can learn both pure external temporal sequences as well as sensorimotor sequences. When the contextual input includes information derived from efference motor copies, the cells learn sensorimotor sequences. If the contextual input consists of nearby cellular activity, the cells learn temporal sequences. Through simulation we show that a network containing both types of contextual input can automatically separate and learn sensory sequences containing a blended mixture of both types of input patterns. We discuss the relationship to experimental data and testable predictions made by the model. Given the prevalence of pyramidal neurons throughout the neocortex and the importance of prediction in inference and behavior, we propose that this form of sequence memory may be a universal property of neocortical tissue.

Title: A mechanism for sensorimotor object recognition using cortical grid cells

Authors: *M. LEWIS, S. PURDY, S. AHMAD, J. HAWKINS
Numenta, Redwood City, CA

Abstract: The neocortex is capable of modeling complex objects through sensorimotor interaction but the neural mechanisms are poorly understood. Previously we have proposed that grid cell-like neurons exist in every cortical column. In this paper, we expand on this idea and describe a two-layer network model that uses cortical grid cells and path integration to learn and recognize objects through movement. Grid cells exhibit regular tiling over environments and are organized into modules, each with a common scale and orientation. A single module encodes position within the spatial scale of the module but is ambiguous over larger spaces. A set of modules can uniquely encode many large spaces. In our model, one layer contains several grid cell-like modules. This layer provides a location signal for each learned object such that features can be associated with a specific location in the reference frame of that object. A second layer, a sensory input layer, receives the location representation as context, and uses it to encode the sensory input in the context of a location in the object's reference frame. Projections from the input layer to the location layer invoke possible locations that are consistent with the current input. Movement of the sensor updates the locations via path integration. Projections from the location layer back to the input layer predict the next input. A series of sensations followed by movements quickly results in the unique object identity that is consistent with the series of sensations and movements. Simulations show that the model can learn thousands of objects with high noise tolerance. We characterize the convergence time for object recognition, which is dependent on the number of unique features, the number of unique locations, and the total number of objects stored in the network. We compare our model to experimental data and propose testable predictions made by the model. We discuss the relationship to cortical circuitry and suggest that the reciprocal connections between layers 4 and 6 fit the requirements of the model.

Title: Grid cells in the neocortex, a framework for cortical computation

Authors: *J. HAWKINS, S. AHMAD, M. LEWIS, S. PURDY
Numenta, Inc., Redwood City, CA

Abstract: Recent evidence suggests that grid cell-like mechanisms may be present in the neocortex. In this paper we propose that cells that behave similar to grid cells exist in every cortical column and play an essential role in all cortical function. We present a theoretical framework for understanding how the neocortex operates based on cortical grid cells. Grid cells in the medial entorhinal cortex represent the location of an animal in various environments. We propose that cortical grid cells, in the lower layers of the neocortex, also represent a location. Whereas grid cells in the entorhinal cortex represent the location of one thing, the body, grid cells in the cortex simultaneously represent the location of hundreds of things. Cortical columns that receive input from different parts of the body track the location of each body part relative to external reference frames. Similarly, cortical columns that receive input from the retina track the location of visual features relative to external reference frames. Including a representation of location in each column provides a framework for understanding how the cortex learns the structure and behavior of objects ("what" regions) and how the cortex maps the space around our bodies ("where" regions). The similarity of circuitry observed in all cortical regions suggests that even high-level concepts are learned and represented in a location-based framework. Cortical grid cells suggest a new way of thinking about cortical function, one that is based on the interplay of sensory input and location processing. In this paper we describe this idea and explore some of its implications.

Title: Stability and dynamics in finite-size stochastic neuronal spiking networks

Authors: *D. TODOROV, W. TRUCCOLO
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: In recent years, nonlinear Hawkes processes implemented as point process generalized linear models (PPGLMs) have been proven to be a useful tool for analyzing microelectrode array recordings of neuronal ensemble spiking activity. They are also related to classical models of neuronal dynamics, but unlike ODE-based neuron models, PPGLMs can be fitted directly to the spike-time data, using standard optimization tools.
An ongoing research problem is to further the understanding of the stability and neural dynamics in both univariate and multivariate (network) data-driven PPGLMs. Our previous work in

Gerhard et al. (2017, PLoS Comp Biol), showed that often simulation of these models can be unstable, leading to non-physiologically high firing rates. Thus to make nonlinear Hawkes PPGLMs useful for long-term prediction of neuronal activity and simulation studies, it is important to understand which model features cause the firing rates to become excessively large ("runaway excitation" phenomena). Despite several existing approaches based on statistical physics-inspired methods developed for the analysis of similar systems, their performance when dealing with data-driven PPGLMs, in particular multivariate models, has not been assessed yet. Here, we compare the accuracy of several theoretical approaches for predicting the occurrence of runaway excitation in multivariate Hawkes processes. The approaches are based on the following theoretical approaches: mean field approximation, 1-loop fluctuation expansion based on stochastic path integral formulations, quasi-renewal approximation (Gerhard et al., 2017) and the regular spiking limit test (Gerhard et al., 2017). These approaches are quite different conceptually, having been introduced in different settings and having limitations in different aspects.
Based on simulation studies, we identify model features that make some approaches work much better than others. In addition, we show that, in some cases, the different approaches can complement each other. Furthermore, we demonstrate how these theoretical approaches work when applied to multivariate PPGLMs fitted to nonhuman primate cortex data. Finally, we also illustrate an algorithm for efficient simulation of arbitrary nonlinear Hawkes process networks.

Title: Self-organized swarm control using neural principles of spatial phase coding

Authors: *G. M. HWANG[1], K. SCHULTZ[1], J. D. MONACO[2], R. W. CHALMERS[1], C. W. LAU[1], B. Y. YEH[1], K. ZHANG[2]

Abstract: Background: Recently, Monaco *et al.*[1] discovered a new class of neuronal cells, coined “phasers,” revealing an internal timing code that can localize a rodent based on activation relative to the hippocampal theta oscillation (6—10 Hz) that occurs during locomotion.

Swarmalators[2](sw), a recently formulated mathematical model consisting of distributed agents that 'sync and swarm,' augment the spatial states of agents in the swarm with auxiliary phase states that themselves are coupled to each other in the vein of the Kuramoto oscillator model.[3] This coupling of spatial and phase states introduces novel swarming behaviors due to mobilization controlled by phase-dependent attraction/repulsion and distance-dependent synchronization. We hypothesize that bottom-up control based on neural algorithms allows flexible and adaptive execution of spatial tasks not achievable with state-of-the-art top-down decentralized control mechanisms. **Objective**: We explored mathematical analysis of phase-organized swarming behavior via the sw class of space-phase[2] dynamics coupled with inputs from phaser cell. We demonstrate how sw agents can be used to model spatial navigation tasks in simple and real-world complex environments. Our neuro-inspired algorithms were benchmarked against conventional algorithms.[4] **Methods**: We exploited the auxiliary phase states in the sw formalism to provide an interface to neural coding mechanisms based on spatial patterns of temporal coordination using phaser cell dynamics. **Results**: We demonstrated that emergent behavior of agents persisted when local kernels (linear, exponential, Gaussian) were used to disable global communication in discrete-time simulations for swarms of varying sizes (10-1,000). We demonstrated that a phase-based control field can spatially guide the evolution of a swarm and simulate bump-like control similar to hippocampal place fields. Moreover, we demonstrated swarms of agents avoiding an obstacle in a computational task similar to mammalian navigation. Finally, we developed a novel metacontroller that relinquishes sw agents from a local minimum.

Title: Swimming and synchrony in a reduced model of the xenopus tadpole central pattern generator: Bifurcations of limit cycles

Authors: *R. BORISYUK[1], A. FERRARIO[1], R. MERRISON-HORT[1,2], S. SOFFE[2,3], W. LI[3]
[1]Plymouth Univ., Plymouth, United Kingdom; [2]Univ. of Bristol, Bristol, United Kingdom; [3]Univ. of St Andrews, St Andrews, United Kingdom

Abstract: We study a minimal microcircuit controlling locomotion in two-day-old *Xenopus* tadpoles. During swimming, neurons in the spinal central pattern generator (CPG) generate antiphase oscillations between left and right half-centres. Experimental recordings show that the same CPG neurons can also generate transient bouts of in-phase oscillations between left-right centres [1].
Our aim is to understand how swimming (anti-phase) and synchrony (in-phase) oscillations can be generated by CPG neurons, find conditions for existence of these two dynamical modes, and for the existence of bi-stability. We combine a highly reduced neuronal circuit of two pairs of neurons that are known to be essential for the tadpole CPG function [2] with a detailed model of spike generation. Consideration of a small network allows us to use the bifurcation analysis for studying the dynamical modes. A biologically plausible model of spike generation allows us to mimic specific features of experimental recordings and compare the results of model simulations with experimental data.
The model produces the various outputs and for each dynamical mode the bifurcation analysis reveals the critical boundaries that separate a region of stability in the parameter space. We find a region of bi-stability where swimming and synchrony co-exit. We show that swimming is stable in a significantly larger range of parameters, and can be initiated more robustly, than synchrony. Our results can explain the appearance of synchrony bouts seen in experiments at the start of a swimming episode.
We found one more stable mode - double-period synchrony which can be observed experimentally, for example, by injecting depolarising current into a descending interneuron (dIN), or this regime can spontaneously occur during swimming. Remarkably, the spiking pattern of the double-synchrony in the reduced model perfectly reproduces this experimental finding and the shape of dIN voltages is very similar to experimental recordings (see figure). Title: Rhythmic control of neural network sequential dynamics

Authors: R. LATORRE[1], *P. VARONA[1], M. I. RABINOVICH[2]
[1]Univ. Autonoma de Madrid, Madrid, Spain; [2]Univ. of California, San Diego, CA

Abstract: A large variety of experiments in neuroscience and also clinical rehabilitation protocols use rhythmic brain stimulation. In most cases the effects of this type of stimulation are only assessed in terms of global neural activations or behavioral changes. In this work we emphasize the importance of analyzing the effects of rhythmic stimulation on shaping robust sequential activity in the brain and its associated coordination. For this task, we have built a heteroclinic network of oscillatory nodes using a rate-phase model. The model is used to study

how an endogenous or external periodic frequency can control the switching among different subprocesses in a winnerless competion dynamics that shapes coherence and coordination of the network sequential activity. The analysis of this model shows that a periodic input signal in a heteroclinic motif network can effectively produce a large variety of coordinated sequential activations with key computational properties such as spectrum control, dynamical filtering and encoding enhancement. The results suggest that the analysis of sequential dynamics in protocols that use rhythmic stimulation can be used to relate neural network activity to cognitive functions, and their associated pathologies. The modeling work presented here provides insight for the design and interpretation of novel experimental paradigms with rhythmic transcranial or sensory stimulation.

Title: Coherent chaos and self-tuned criticality in a recurrent neural network

Authors: *I. D. LANDAU[1], H. SOMPOLINSKY[1,2]
[1]The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: We present a minimal model for coherent, macroscopic chaos in a recurrent neural network. We construct the model by adding a structured component to the otherwise random connectivity matrix. The structured component embeds an effectively feedforward structure via unidirectional coupling between a pair of orthogonal modes. Chaotic fluctuations propagate through the random component of the connectivity, and drive coherent activity via the structured component. The orthogonal design of the structured component ensures that feedback is not generated by the coherent activity thus allowing chaos to persevere. In a regime of small structure we apply a perturbative approach in order to solve the dynamic mean-field equations showing how coherent fluctuations initially emerge passively, driven by the chaos of independent residual local-fields. We furthermore show that this model can be generalized to yield coherent fluctuations along multiple modes of activity simultaneously. Strikingly, when we introduce a detailed balance constraint to the random component, the coupling strength of a single mode can be increased by an order of magnitude without subduing the chaotic dynamics. In this strong-structure regime the system displays fluctuations almost entirely constrained to a single coherent mode of activity with switching-like behavior reminiscent of “Up-Down” states in cortical circuits. We describe how in this regime the model achieves intermittent self-

organized criticality in which the coherent component of the dynamics self-adjusts to yield periods of slow chaos in the local fields. Furthermore we show how the dynamics depend qualitatively on the particular realization of the connectivity matrix: a complex leading eigenvalue yields coherent oscillatory behavior, while a real leading eigenvalue yields broken symmetry. Finally we examine how these phenomena scale with network-size.

Title: Simulating source localized power spectra with structural connectivity and neural mass model

Authors: *X. XIE[1], A. KUCEYESKI[2], N. D. SCHIFF[2], S. A. SHAH[2], A. RAJ[3]
[1]Dept. of Neurosci., Weill Cornell Grad. Sch. of Med. Sci., Forest Hills, NY; [2]Weill Cornell Med. Col., New York, NY; [3]Bioengineering, Univ. of California, San Francisco, San Francisco, CA

Abstract: We employ a non-linear neural mass model to simulate both locally interacting coupled neuronal populations as well as a global connectivity network to model the relationship between measureable far field electrical or magnetic potentials and the contribution of underlying neuronal connections. Using EEG and MEG recordings and their corresponding source localized functional time courses, we obtained empirical power spectra for each of the 86 gray matter regions. An optimization procedure was implemented to infer both local and global parameters of the neural mass model to reproduce the source localized spectra. We also investigated on which spatial scale does the neural mass model most accurately recapitulate the spatial distribution of power in the brain. Our simulations demonstrate that structural connectivity networks work in concert with global coupling parameters to produce modeled network brain dynamics through coupled neural masses.

Title: Combination and stability properties of echo-state recurrent neural networks

Authors: *L. KOZACHKOV[1], E. K. MILLER[2], J.-J. SLOTINE[3]
[1]MIT, Cambridge, MA, [2]Brain and Cognitive Sci., [3]Mechanical Engineering; Brain & Cognitive Sci.

Abstract: Understanding how cognitive computations are realized in massively recurrent brain circuits is a primary aim of neuroscience. In the last few years, Reservoir Computing has emerged as a promising framework for addressing this problem. Within this framework, Echo-State Networks (ESNs) have been particularly useful for capturing puzzling features of neural data in higher cortical areas, such as mixed selectivity and persistent activity. ESNs are recurrent neural networks with random—typically sparse—synaptic weight matrices and nonlinear activation functions. The dynamical richness of the RNN ensures that a linear readout from the network can be easily trained to produce desired input-output pairs.
For a network to be an ESN it must satisfy the so-called Echo-State Property (ESP), which is a mathematical condition on the synaptic weights ensuring that the system will be robust to perturbations in initial conditions. This mathematical guarantee is a useful feature of ESNs, and is not shared by other reservoir-computing approaches. However, one difficulty with ESNs is that it is not trivial to verify the ESP when multiple networks that individually satisfy this condition are connected. However, since a key feature of cortical anatomy is dense connectivity

across multiple areas, it is important to understand precisely under which connection schemes the ESP is preserved.
We show that the ESP is a special case of what is known in the dynamical systems and control literature as *contraction*. Recognizing this equivalence has several immediate consequences. Firstly, contraction analysis provides *necessary and sufficient* conditions for the verification of the ESP. Secondly, contraction analysis provides simple sufficient conditions on general, scalable connectivity schemes which preserve contraction. These guarantees pave the way for future brain modeling studies which seek to understand how information is processed not just within individual neural circuits but across *multiple* circuits, in a distributed and parallel fashion.

Title: A mathematical model for the circadian rhythmicity of pain sensitivity in the dorsal horn

Authors: *J. CRODELLE[1], S. PILTZ[2], V. BOOTH[2], M. HASTINGS HAGENAUER[3]
[1]Courant Institute, NYU, New York, NY; [2]Mathematics & Anesthesiol., [3]Univ. of Michigan, Ann Arbor, MI

Abstract: The ability of an organism to detect pain is essential for its survival. Sensitivity to painful stimuli exhibits a 24hr (circadian) rhythm, with a peak in pain sensitivity occurring in the middle of the night and a trough in mid-afternoon. In neuropathic patients, those who experience chronic pain usually accompanied by damaged or injured nerve tissue, the sensitivity of pain follows a circadian rhythm of opposite phase, with a peak in pain sensitivity occurring in mid-afternoon. Circadian rhythms underlie many biological processes, including the regulation of many immune cells that contribute to the processing of pain. Additionally, mechanisms underlying neuropathic pain remain unclear. Thus, understanding the interplay between pain processing and circadian rhythmicity is important for further understanding of pain processing. In this project, we propose possible mechanisms underlying the rhythmicity of pain sensitivity, and suggest changes in these mechanisms under neuropathic conditions that yield a rhythm of pain sensitivity that is in opposite phase. To investigate these mechanisms, we develop a firing-rate model of several populations of neurons in the dorsal horn, the main processing center of pain in the spinal cord. This model includes excitatory and inhibitory interneurons, as well as

wide-dynamic range projection neurons, whose output signals painful levels to the cortex. The input to the dorsal-horn network is modeled by Poisson spike trains generated by three types of afferent fibers, with realistic conductance velocities to reproduce the typical pain-response observed in the firing pattern of projection neurons. We validate this model by reproducing experimentally-observed phenomena such as wind-up, the increased pain response to frequency-dependent stimulation of the nociceptive (C) fibers, and pain inhibition, the decrease in pain response due to repeated stimulation of the mechanoreceptive (Aβ) fibers.
Once this model has been verified to reproduce experimentally-observed phenomena, we propose that circadian rhythmicity is introduced at the level of the afferent fibers and show that our model can capture the correct rhythmicity in pain sensitivity over a 24hr day. We then use this model to propose that the dysregulation of presynaptic inhibition could be a potential mechanism for the shift in rhythmicity of neuropathic pain sensitivity.

Title: Activity patterns in networks of excitatory and inhibitory spiking neurons with synaptic noise

Authors: *A. C. ROQUE[1], R. F. O. PENA[1], M. A. ZAKS[2]
[1]Univ. de Sao Paulo, Ribeirao Preto, Brazil; [2]Humboldt-Universität zu Berlin, Berlin, Germany

Abstract: The dynamics of spontaneous population activity patterns in random networks of excitatory and inhibitory two-dimensional integrate-and-fire neurons with synaptic noise is studied. The observed activity pattern types are localized on the parameter diagram spanned by the relative inhibitory synaptic strength and the magnitude of synaptic noise. In the absence of noise, networks display transient activity, either oscillatory or asynchronous non-oscillatory, and noise generates persistent patterns. For weak noise, activity patterns are asynchronous non-oscillatory independently of synaptic strengths. For stronger noise, patterns have oscillatory and synchrony characteristics which depend on the relative inhibitory synaptic strength. In the

inhibition-dominated region of parameter space and for moderate noise magnitudes, networks disclose intermittent switches between oscillatory and low activity (quiescent) states. In the oscillatory state the neuronal voltages alternate between hyperpolarized and depolarized values in a similar fashion to up-down oscillations observed in cortical networks, and in the quiescent state they fluctuate around the resting state as low activity versions of asynchronous irregular activity modes observed in network models of integrate-and-fire neurons. Increase in noise intensity favors transitions from the quiescent to the oscillatory state and hampers the reverse transitions. The oscillatory and quiescent patterns and transitions between them are explained by using local descriptions of individual neurons in their single-neuron phase spaces combined with a phenomenological global description of the network state.

Abstract: The hippocampus has been widely studied in neuroimaging research because of its critical role in the pathophysiology of psychiatric illnesses. Both automated and manual segmentation techniques are used to measure hippocampal volumes. Manual segmentation is time-consuming, expensive and vulnerable to bias in the absence of methodological controls; automated techniques may offer several advantages but their accuracy and reliability must be determined in longitudinal samples of patients. Here, we evaluated segmentation by a deep

convolutional neural network for hippocampal segmentation, hippodeep. Using a large multisite dataset, we examined the ability of hippodeep to reproduce hippocampal volumes of participants scanned across time. The Canadian Biomarker Integration Network in Depression (CAN-BIND) dataset consists of over 200 patients with major depression and 100 healthy comparison participants recruited from six sites across Canada who completed magnetic resonance imaging at three time-points (weeks 0, 2 and 8). Importantly, there was no overlap between The CAN-BIND dataset and datasets used to train and validate the algorithm. Hippodeep segmented 834 T1w brain scans from participants across all time-points. Segmentation outputs from the algorithm were stable across weeks for both healthy controls and depressed patients; Pearson's correlations were .98 to .99 for the left hippocampus of control participants compared across all weeks and .98 for the right hippocampus across weeks. Correlations were high for patients assessed across time points (.96 to .98). Hippodeep consistently produced larger volumetric measures compared to manual tracings from raters following a harmonized protocol. Visual inspection of anatomical boundaries suggested that hippodeep may have incorporated anatomical regions such as the Choroid Plexus and Fimbria in the segmentation.
These results suggest that the deep convolutional neural network hippodeep has a high test-retest reliability over time in both healthy participants and patients with major depression. Whether the relatively larger anatomic boundaries identified by hippodeep reduce the likelihood of identifying illness-associated changes in hippocampal sub-regions needs to be determined.

Title: Efficient estimation of neuronal couplings from multi-point activity data: How effective is the McCulloch-Pitts model for inference?

Authors: *Y. TERADA[1,2], T. OBUCHI[2], T. ISOMURA[1], Y. KABASHIMA[2]
[1]RIKEN, Saitama, Japan; [2]Tokyo Inst. of Technol., Tokyo, Japan

Abstract: Recent advances in experimental technologies have made it possible to observe the activity levels of multiple neurons simultaneously. This provides us with much richer data than

single-neuron recording, leading to a deeper mechanistic understanding of nervous system function. A representative problem, for which such multi-point data are useful, is to identify neuronal couplings at a microscopic level. This is a very challenging problem requiring significant progress in both technological and theoretical methods.
Due to technical difficulties in treating activity from multiple neurons as continuous variables in continuous time, the standard approach for inferring neuronal couplings is to first convert the original signals to binary signals in discrete time. These binary signals can then be modeled using the McCulloch-Pitts (MP) formal neurons; indeed, numerous analytical methods have been proposed on the basis of these MP models over the course of the last decade.
However, there two unsatisfied points in the earlier studies—namely, the lack of objective criteria to determine the bin size for discretizing the signals in time and to screen significant couplings from the estimation results. The purpose of our study is to resolve these two drawbacks.
To this end, we developed two simple methods based on information theory and computational statistics. Using a property of total mutual information of the binarized data of successive times, which typically exhibits a single peak with respect to the bin size, we defined a measure for objectively determining the optimal size. Then, by comparison of the amplitude of the estimated couplings with those of estimates from randomized (surrogate) data, we established a method of computationally screening statistically significant couplings.
We then applied the proposed methods to neuronal data obtained from both simulations and cultured neuronal networks. We found that our method exhibits a fairly good performance in identifying relevant couplings, including the discrimination of their signs. We also stress that the required computational cost in our methods is sufficiently low, suggesting further applications to larger and more complicated networks. Our results highlight the utility of the MP neuron model in analyzing real nervous system function.

Abstract: Abstract To understand how large scale neuronal networks function, it is important to identify their common dynamical operating points or states. The probabilistic characteristics of these operating states will underlie network functions such as its coding schemes. Here, directly from multi-electrode data from three separate experiments, we quantitatively identify a cortical operating state (the "probability polling" or "p-polling"), common across different species (mouse and monkey) and different behaviors. Regarding this state's functional impact, in the three experiments we confirm that it provides a framework that explains why low-order maximum entropy distribution accurately represents the distribution of neuronal firing patterns. Our simulations show that the "balanced state", common in large networks, is also a p-polling state; and that the p-polling state is closely related to weakly correlated networks. However, the p-polling state is more general than these two concepts. These results provide evidence for the p-polling state's commonality and its potential importance for neuronal coding.

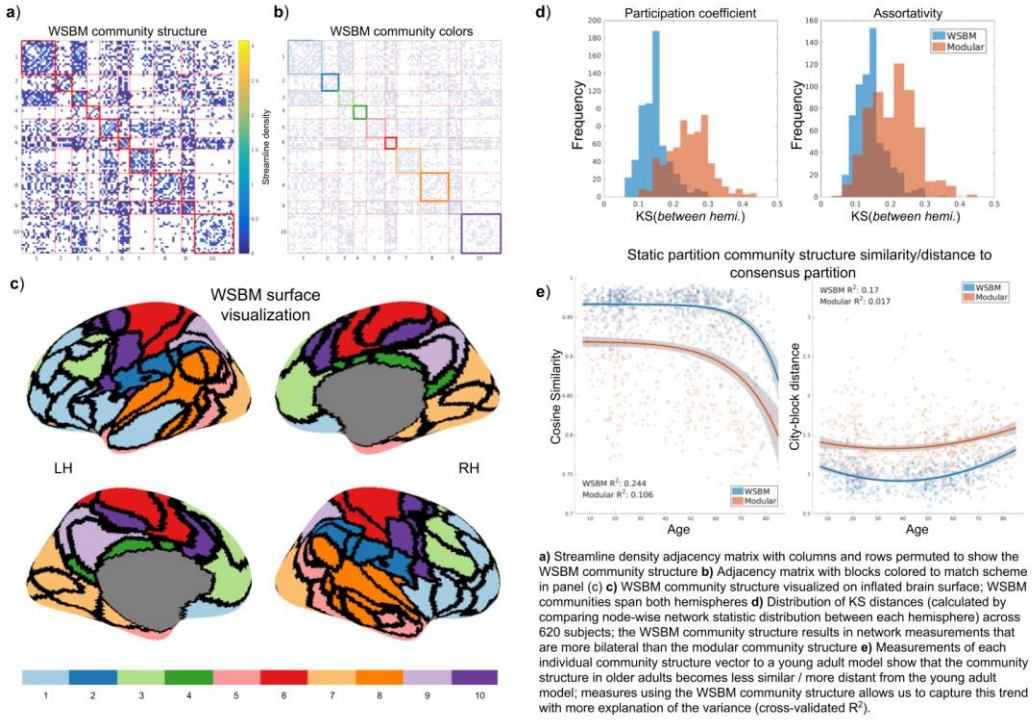
Title: Weighted stochastic blockmodels of the human connectome across the life span

Authors: *J. FASKOWITZ[1], X. YAN[2], X.-N. ZUO[3], O. SPORNS[1]
[1]Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [2]Indiana Univ. Network Sci. Inst., Bloomington, IN; [3]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China

Abstract: The human brain forms a complex network of anatomically interconnected neurons and brain regions, the connectome that can be modeled and analyzed with the tools of network science and graph theory. A hallmark of complex networks, including the human connectome, is the presence of subnetworks, also called communities or modules. However, uncovering network communities is an ill-defined problem with no singular solution. In this study, we employ the weighted stochastic block modeling (WSBM) framework to identify brain network communities that do not have to be exclusively modular. This generative model can identify a wide array of

community topologies, such as core-periphery and disassortative structure. Such flexibility is helpful when applied to brain networks, which might be comprised of a mixture of community structure topologies. In this project we apply the WSBM to analyze, cross-sectionally, how structural brain networks (tractography), and the community structure of these networks, are modulated across the human life span (8-85 years old, +/- 20.88; 63% F). We use the WSBM to identify a non-modular community structure model from young adult data (53 subjects; 25-35 years old; 51% female) and then analyze how the connectivity between communities of this model changes as a function of age. We identify several network blocks that exhibit significant linear and non-linear changes across age, with the most significant changes involving subregions of prefrontal cortex. Additionally, we find that WSBM communities exhibit greater hemispheric symmetry and are spatially less compact than those derived from modularity maximization. Overall, we show that the WSBM generative modeling approach can be an effective tool for describing types of community structure in brain networks that go beyond simple modularity.



a) Streamline density adjacency matrix with columns and rows permuted to show the WSBM community structure **b)** Adjacency matrix with blocks colored to match scheme in panel (c) **c)** WSBM community structure visualized on inflated brain surface; WSBM communities span both hemispheres **d)** Distribution of KS distances (calculated by comparing node-wise network statistic distribution between each hemisphere) across 620 subjects; the WSBM community structure results in network measurements that are more bilateral than the modular community structure **e)** Measurements of each individual community structure vector to a young adult model show that the community structure in older adults becomes less similar / more distant from the young adult model; measures using the WSBM community structure allows us to capture this trend with more explanation of the variance (cross-validated R^2).

Title: Which spike train distance is most suitable for distinguishing rate and temporal coding?

Authors: *T. KREUZ[1], E. A. SATUVUORI[2,3,4]
[1]Inst. For Complex Systems, Sesto Fiorentino, Italy; [2]Univ. of Florence, Sesto Fiorentino, Italy; [3]Cnr, Inst. for Complex Systems, Sesto Fiorentino, Italy; [4]Vrije Univ. Amsterdam, Amsterdam Movement Sci. (AMS), Inst. for Brain and Behaviour Amsterdam (iBBA), Fac. of Behavioural and Movement Sciences, Dept. of Human Movement Sci., Amsterdam, Netherlands

Abstract: Introduction: During the last decade spike train distances have become an essential means to characterize neural coding in a wide range of neurophysiological contexts. The underlying assumption is that repeated presentations of a stimulus to a coding neuron elicit similar responses. One common way to assess similarity are spike train distances. These can be divided into spike-resolved, such as the Victor-Purpura distance **[1]** and the van Rossum distance **[2]**, and time-resolved, e.g. the ISI-distance **[3]**, the SPIKE-distance **[4]** and the RI-SPIKE-distance **[5]**.
Methods: We use independent steady-rate Poisson processes as surrogates for spike trains with fixed rate and no timing information to address two basic questions: How does the sensitivity of the different spike train distances to temporal coding depend on the rates of the two processes and how do the distances deal with very low rates?
Results: Spike-resolved distances always contain rate information even for parameters indicating time coding. This is an issue for reasonably high rates but beneficial for very low rates. In contrast, the operational range for detecting time coding of time-resolved distances is superior at normal rates, but these measures produce artefacts at very low rates. The RI-SPIKE-distance alone is sensitive to timing information only.
Conclusion: We find that the most appropriate measure depends on the rates of the data being analysed. These results are summarized in one table that allows an easy selection of the preferred measure for any kind of data **[6]**.
Software: ISI-distance **[3]**, SPIKE-distance **[4]** and SPIKE-Synchronization **[7]** as well as the directional measure SPIKE-Order **[8]** are implemented in the Matlab-based graphical user interface SPIKY **[7]**, the Matlab command line library cSPIKE, and the Python library PySpike **[9] [10]**.

Title: DeepBehavior: A deep learning toolbox for automated analysis of animal and human behavior imaging data

Authors: *A. ARAC[1], P. ZHAO[2], S. CARMICHAEL[3], P. GOLSHANI[4]
[1]Neurol., [2]UCLA, Los Angeles, CA; [3]UCLA Sch. Med., Los Angeles, CA; [4]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: A major goal in neuroscience is to understand the relationship between brain and behavior. This can be achieved only if both brain and behavior can be defined in detail. While tremendously exciting tools exist to characterize the structure of, and the functional activity in the brain, the tools to define behavior are scarce, thus making behavior analysis very challenging. The best and the least invasive way to define a behavior is observation which can be achieved by high-speed video recording. However, analyzing these videos can be challenging and has traditionally been done manually. Here, we present a deep learning toolbox to analyze videos for detection and tracking of different body parts in mice and in humans during different behavior tasks. We achieve this by using convolutional neural networks and transfer learning approach. In particular, we present use of four different network architectures, and show examples of four different behavior paradigms. By using this technique, during a skilled food pellet reaching task in mice, paw of the mouse can be detected and 3D trajectories of the paws and the kinematic data can be obtained. Moreover, the shape and position of the paw can be determined by unsupervised learning methods using convolutional neural networks to capture the structure in the images. In social behavior tasks in mice such as three chamber test and resident intruder assay, different body parts can be tracked in multiple animals in the same cage, and their interactions can be defined accordingly. In humans, when the subjects are performing a reaching

task, individual joint movements including the digits can be tracked simultaneously. This provides a very detailed, and rich dataset for behavior analysis. Of note, for any of these videos, there is no need to place a marker or tag the body parts before video recordings, thus allowing a more natural observation and analysis of the behavior. By using automated and unbiased methods based on deep learning techniques, behavior analysis can be performed at an unprecedented detail and speed.

Abstract: Functional two-photon imaging is an essential tool in understanding connectivity and operation of neural networks in the brain. Achieving this goal requires gaining access to deeper layers than the superficial ones. Ideally, functional cortical imaging should gather data from all the cortical layers in the area of interest. Understandably, recording from large population of neurons results in hundreds of thousands traces and calls for automatization of analysis to extract data from recordings.
Here we report results of a fast deep imaging in mouse visual cortex area V1, encompassing all 6 layers in it. The latest generation of our three-dimensional acousto-optical microscope makes it possible to measure up to 1000 cells from an 800 x 800 µm field of view as deep as 1000 µm under the pia, while maintaining 20-40 Hz temporal resolution for functional imaging of neurons. The imaging was performed on transgenic adult mice of either sex. The same population was imaged for multiple number of repetitions over the span of several days, yielding a large amount of data (tens of Gigabytes) for one animal. Due to time consuming preparation for the measurement and the measurement duration itself one has to consider utilizing automated

data analysis methods for an efficient data extraction. In this research different sections of the workflow are performed by separated personnel with manual interception and criteria set between each session. However, one has to be aware of an increased possibility for errors or missed findings due to the overly intense automation.
We have developed a complex, semi-automatic workflow for three-dimensional acousto-optical measurements and analysis, involving preparation of the animals, repeated measurements for multi-day imaging session from the same set of neurons, also involving data analysis and visualization. Our analysis software allows automatic cell detection, background and ΔF over F calculation as well as sorting and visualization of the data, while having multiple check points for human interaction minimizing the room for error.

Title: A manifold learning approach to imaging mass spectrometry analysis in mice brain

Authors: *H. SUETANI[1,2], F. ETO[3,4], I. YAO[3,5]
[1]Oita Univ., Oita, Japan; [2]Riken Ctr. for Brain Science, RIKEN, Wako, Japan; [3]Dept. of Optical Imaging, Inst. for Med. Photonics Res., [4]Dept. of Cell. and Mol. Anat, [5]Intl. Mass Imaging Ctr., Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan

Abstract: Recently, the methods of imaging mass spectrometry (IMS)[1], which is the combinations of mass spectrometry that ionizes chemical species and sorts the ions based on their mass-to-charge ratio with spatial visualizations, are receiving attention in the various fields of science and technology.When the IMS is applied to a sample such as biological tissues, for each spatial point , the information on particles and molecules is obtained as the ion signals as a function of the mass-to-charge ratio called the mass spectrum. Therefore, data in association with IMS is composed of a huge number of mass spectra, which brings difficulty to apply conventional statistical analyses.In this study, we propose an approach based on “manifold learning”[2], which is a framework of unsupervised nonlinear dimensionality reduction for

visualizing high-dimensional data into a low-dimensional space for analyzing the IMS data. To this end, we first introduce a distance measure that is based on the information geometry[3] for measuring the similarity between two mass spectra in an appropriate way. Then, we employ conventional algorithms of manifold learning including the LLE, the ISOMAP, and the t-SNE using the information-geometrical distance measure.We apply our approach to slices of the mouse brains and show that our prosed approach is useful for visualizing a set of the mass spectra as well-separated “islands” of points where each island reflects a specific character of chemical species in the brain.We also discuss how our results can be interpreted in terms of neurophysiology.

Title: Large-scale automated deep neural network training framework for robust inference of neural ensemble dynamics

Authors: *M. R. KESHTKARAN[1], C. PANDARINATH[1,2]
[1]Coulter Dept. of Biomed. Engin., Emory Univ. / Georgia Tech., Atlanta, GA; [2]Dept. of Neurosurg., Emory Univ., Atlanta, GA

Abstract: Over the past decade, the ability to record from large populations of neurons has increased exponentially. These capabilities motivate powerful new tools to understand the computations underlying the activity of large neural ensembles. We recently demonstrated a deep learning tool, Latent Factor Analysis via Dynamical Systems (LFADS), that uses sequential autoencoders (SAEs) to precisely estimate neural ensemble dynamics on a single trial, moment-by-moment basis (Pandarinath et al. 2017, BioRxiv). In the motor cortex (M1), for example, estimating ensemble dynamics led to a dramatic increase in our ability to decode arm movements during reaching. However, like many deep learning methods, SAEs require careful hand-tuning of complex model hyperparameters (HPs) to ensure optimal performance, which is challenging, time-consuming, and critically limits their application. Importantly, current SAEs are susceptible to overfitting if HPs are automatically searched, due to a lack of appropriate cross-validation strategy. We addressed this by developing a new cross-validation strategy that allows the SAE to

be trained on partially-sampled time-series data, and validated on the complementary samples. Further, we developed a novel network optimization scheme to force the SAE to only model structure that is shared across neurons, which helps avoid overfitting. With these modifications in place, we created a large-scale, automated HP tuning framework based on Population Based Training (PBT; Jaderberg et al. 2017, arXiv), which uses distributed computing to train many tens of models simultaneously while using evolutionary algorithms to tune HPs and find optimal models. We tested the modified SAE along with PBT on M1 ensemble activity from two monkeys performing a center-out task, and found that it consistently matched or outperformed the performance of the original LFADS with hand-tuned HPs (arm movement decoding, quantified by R^2). Strikingly, the modified SAE with PBT was more robust to dataset size, achieving ~30% better R^2 than LFADS for limited datasets. Finally, the modified SAE with PBT learned models with better generalization to movement conditions they had not been trained on: when more than half of the conditions were held out during model training, but used in decoding, the modified SAE with PBT led to an ~11% improvement in R^2 over LFADS. Our large-scale, automated training framework for SAEs will provide the neuroscience community with a robust and easy to use tool to estimate neural ensemble dynamics. We aim to make this tool applicable to many different regions of the brain, to further scientific study of how neural ensembles perform computation.

Abstract: Differences in attentional state, biophysical kinetics, and other unobserved latent variables often cause neural firing patterns to be shifted and skewed in time across repeated behavioral trials. In the rodent olfactory bulb, mitral cell activity is highly stochastic when aligned to odor presentation, but aligning to inhalation reveals precise temporal coding [1, 2]. In motor tasks, the onset and duration of movements may vary considerably from trial-to-trial, even for relatively simple behaviors.

To account for variability in timing, studies have manually warped neural activity to align with sensory cues or behavioral events (e.g., [3]). However, even simple experiments are often compatible with multiple alignment strategies, and neural activity measured far from the sensory/motor periphery may not have reliable behavioral or sensory correlates. Ideally, the optimal temporal alignment for each trial could be directly inferred from the neural activity alone. Building off of previous work [4, 5, 6] we propose an unbiased and data-driven method to achieve this aim. We simplify previous approaches by considering piecewise linear time warpings, which are both simpler to interpret and more easily scaled to larger datasets. We apply this method to datasets derived from diverse brain regions (olfactory bulb, motor cortex, and orbitofrontal cortex) and animal models (rodent and primate).

Despite its simplicity, the model can uncover strong effects that transfer to measurable behaviors and held out neural data. In primate hand reaching, applying time warping to hand velocity traces reduces the variance in reaction times by ~80% when the model is fit purely on neural data. In rat motor cortex, we uncover prominent oscillations in firing rate that are imperceptible in single-trial data and are obscured by naive trial-averaging. For this dataset, time warping increases the signal-to-noise ratio by two- to four-fold in neurons that are held out during model fitting. Overall, this method identifies previously hidden but surprisingly precise and behaviorally relevant spike timing patterns, enabling the discovery of new circuit functions and mechanisms.

Abstract: Alzheimer's disease (AD) is the most common type of dementia, which is considered to be important along with the emergence of a population aging society. Despite of recent advances in amyloid PET imaging to measure beta-amyloid (Aβ) deposition in living human brain, which is one of the hallmark of AD pathologies, the use of amyloid PET is still limited due to its high costs and low accessibility. In this context, prediction of individual's cerebral Aβ deposition using magnetic resonance imaging (MRI) can have several strengths including lower expenses, higher accessibility, and no radiation exposure. Recently, the development of deep learning has made it possible to obtain complementary information from images of different modalities. Here, we propose the modified model of the conventional Convolutional Neural Network (CNN) structures to predict Aβ positivity using multi-modal magnetic resonance (MR) image data of old-aged individuals. As a predictor of this model, multi-modal MR image data including T1, T2, and FLAIR of cognitively impaired (CI) older adults consisting of mild cognitive impairment (MCI) and AD dementia groups were obtained from the database of Korean Brain Aging Study of the Early Diagnosis and Prediction of Alzheimer's Disease (KBASE), an ongoing prospective cohort study started in 2014. All participants in the KBASE cohort underwent comprehensive clinical assessment, multi-modal MRI scans, and [^{11}C]PiB PET. As an outcome of this prediction model, amyloid PET positivity for each subject, defined by quantitative measurement of PiB uptake on PET image was used. After pre-processing MR images and quality control, MR images of 476 individuals were used for development and testing of deep learning based prediction model. Accuracy of model was measured by area under the curve (AUC) value.

Table 1

Performance metrics	AD dementia	MCI	Cognitively impaired
AUC	90.24%	86.08%	87.70%

In Table 1, we provided a quantitative evaluation on our dataset. Our method produces high accuracies and few false negative errors. In this work, we showed the possibility of predicting the positivity of amyloid beta with MRI data only.

Title: Spike-triggered regression (STR) method for neuronal network reconstruction

Authors: *Y. ZHANG[1,2], Y. XIAO[1,2], D. ZHOU[3], D. CAI[2,1,3]
[1]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates; [2]New York Univ., New York, NY; [3]Shanghai Jiao Tong Univ., Shanghai, China

Abstract: Neurons in our brain are connected with one another to process information. The single neuron behavior has been well characterized, however, the connectivity of a large group of neurons is poorly understood. Based on the feasibility of recordings of intracellular membrane potentials and spikes of neuronal network dynamics, we propose the spike-triggered regression (STR) method, which can efficiently recover the underlying network structure even under the conditions that recording time is relatively short (20~100s) or network dynamics is nearly synchronous. In particular, pairwise application of STR can accurately predict the coupling strength between any pairs of neurons in sparse networks. Our work provides a potential means of shedding light on the organization of the neuronal network in the brain.

Title: Supervised dimensionality reduction on spike trains with smooth-constrained autoencoder

Authors: *Y. WU[1], A. A. FAISAL[2]
[1]Imperial Col. London, London, United Kingdom; [2]Imperial Col. London, London, United Kingdom

Abstract: Neural recordings with multiple electrodes enable researchers to study activities of neural populations simultaneously, in order to capture features only appear in population level. Dimensionality reduction methods are commonly applied for feature extraction from multi-dimensional spike trains. We propose here a supervised dimensionality reduction method using a time-convolutional autoencoder, which is capable of finding a latent space best representing task-relevant features. Since spike trains are binary, stochastic and could be extremely sparse, it is not feasible to apply vanilla autoencoder without any constraints or approximations. Thus, we introduce smooth constraints to convolutional kernels to reduce the number of free parameters and at the same time to project spikes to continuous latent space. Smooth parameters are assigned as attributes of individual neurons in the population and are trained together with the autoencoder. The entire structure of our neural network consists of three components: 1. an encoder performing both smoothing and projection; 2. a decoder reconstructing signals from latent space; 3. a predictor providing task-dependent supervised information. The loss function is defined as a combination of both reconstruction loss and prediction loss and the network is trained with back-propagation. Our model is able to implement either supervised (with predictor) or unsupervised (without predictor) dimensionality reduction. It also shows advantage: 1. 1-step optimisation, no need to apply smooth pre-processing procedure compared with conventional 2-step methods; 2. analytical solution, achieving results directly via analytical calculation instead of optimisation (compared with Gaussian process methods); 3. task-relevant features, supervised information can be easily introduced to our model without changing the structure or training algorithm.

Title: Driving fatigue detection by brain activity estimated from electrodermal activity

Authors: *P. SEO, D. YEO, H. KIM, S. HER, S. CHOI, K. KIM
Biomed. Engin., Yonsei Univ., Wonju-Si, Gangwon-Do, Korea, Republic of

Abstract: This study is to develop core technologies for a practical bio signal-based driving assistance system, which exploits the physiological signals from a wrist-type sensor module that can replace the electroencephalogram (EEG) information. We tried to recognize driver's fatigue status based on the EEG biomarkers estimated from electrodermal activity (EDA)Twenty-one healthy, driver license holding university students participated in the experiment. Every participant slept enough the night before driving, and they had routine daytime. Taking Cold medicine, alcohol, and caffeine was inhibited before driving. Multichannel EEGs, EDA, and driver's face video were recorded for 90 minutes monotonous driving on PC based driving simulator, from 8 p.m.Driver's fatigue was descripted by scoring driver's face video by four experimenters in every 1 minute, based on Karolinska Sleepiness Scale (KSS). We decided KSS score over 6 as fatigue state, and under 5 as awaken state. The EEG spectrum power was calculated using short-time Fourier transform (STFT) with a 50% overlapped hamming window of 10 seconds was applied. We selected channel-averaged alpha-band spectrum power in every 1 minute, which is the most correlated with KSS score as a training feature of support vector machine (SVM) classifier. We used support vector regression (SVR) to estimate the input feature of SVM above, from mean EDA amplitude in every 1 minute. Finally, we combined regression model (EDA to EEG) and classifier (EEG to KSS).We calculated intra-subject classification accuracy. The classification accuracy was 59.52 ± 13.06%, maximum 82.60%. Sensitivity and specificity were 62.80 % and 56.25%. Although we did not use the best feature to classification in this paper, with selecting optimal features it could be useful.

Title: Zero shot generative adversarial network for EEG based classification

Authors: *S. HWANG[1], K. HONG[2], H. BYUN[3]
[1]CVPR Lab., [2]Yonsei Univ., Seoul, Korea, Republic of; [3]Yonsei Univ., Seou, Korea, Republic of

Abstract: Introduction: EEG-based classification has researched in several decades. However, lack of dataset for EEG-based classification is a still challenging problem. To overcome the issue, we first propose the method to classify EEG feature without training using Zero-Shot Learning(ZSL) model and Generative Adversarial Network(GAN). Method: The proposed model consists of following two-part: generative network G and discriminative network D. Given the EEG data and semantic vectors, G tries to generate EEG features using semantic vectors with random noise, while D distinguish the EEG features are real (Given) or fake (Generated). Both G and D consist of three Fully Connected (FC) layers followed by Rectified Linear Unit (ReLU) and Dropout. Experiment: We evaluate our model using the Mindbigdata (David 2018), that is recorded with the stimulus of seeing random images from ImageNet ILSVRC2013 (Zeiler et al. 2013). The dataset provides a large amount of EEG signals containing 3 seconds signals with 569 class labels. To generate EEG images by semantic vectors, we use pre-trained word2vec containing ImageNet labels while we have used MFCC for the EEG representation. Among the 569 classes, we selected 70 seen classes for training the proposed network, 30 unseen classes are used to test. We adopt Adam optimization algorithm to learn the proposed model. We found that Zero-shot GAN can recognize the unseen classes. Conclusion: We first introduce Zero-shot GAN to recognize untrained EEG dataset. Furthermore, the proposed ZSL model showed the possibility for classifying untrained EEG features.

Zero-shot Accuracy on Mindbig dataset

Channel	**Spectrum(David et al. 2018)**		**MFCC**	
	Top-1	Top-5	Top-1	Top-5
AF3	4.3	17.13	**5.71**	16.93

AF4	4.72	16.93	4.53	17.13
T7	N/A	N/A	5.51	**17.32**
T8	N/A	N/A	5.12	16.34
Pz	4.72	17.13	4.92	16.14
All Channels	4.92	15.35	5.31	15.16
We trained 70 seen classes, and 30 classes are use to test. We evaluated Zero-shot Accuracy using two types of EEG features.

Title: Unsupervised discovery of neural sequences in large scale recordings

Authors: *A. H. BAHLE[1], E. L. MACKEVICIUS[1], A. H. WILLIAMS[2], N. I. DENISENKO[1], S. GU[1], M. S. GOLDMAN[3], M. S. FEE[1]

Abstract: The ability to identify interpretable, low-dimensional features that capture the dynamics of large-scale neural recordings is a major challenge in the field of neuroscience. Dynamics that include repeated temporal patterns (which we call sequences), are not succinctly captured by traditional dimensionality reduction techniques such as principal components analysis (PCA) and non-negative matrix factorization (NMF). The presence of neural sequences is commonly demonstrated using visual display of trial-averaged firing rates (1-3). However, the field suffers from a lack of task-independent, unsupervised tools for consistently identifying sequences directly from neural data, and cross-validating these sequences on held-out data. We describe an extension to an existing technique, convolutional NMF, that avoids its common failure modes. This extension, which we call seqNMF, provides a framework for extracting sequences from large high-dimensional datasets, and is easily cross-validated to assess the significance of each extracted factor. We apply seqNMF to test the recovery of sequences from ground-truth simulated datasets, and to demonstrate its performance on previously published data from rat hippocampus, as well as a new dataset from the songbird pre-motor area HVC. In the hippocampal data, seqNMF automatically identifies neural sequences that match those calculated manually by reference to behavioral events (1-2). The bird dataset was recorded in animals that never heard a tutor, and therefore sang pathologically variable songs. Despite this variable behavior, seqNMF is able to discover stereotyped neural sequences. These sequences are deployed in an overlapping and disorganized manner, strikingly different from what is seen in tutored birds. Thus, by identifying temporal structure directly from neural data, seqNMF can enable dissection of complex neural circuits with noisy or changing behavioral readouts (4).

Title: Simulation-based evaluation of PCA application to neuronal population activity

Authors: *A. FILIPPOW[1,2], B. DANN[1], H. SCHERBERGER[1,2]
[1]German Primate Ctr., Goettingen, Germany; [2]Dept. of Biol. and Psychology, Univ. of Göttingen, Göttingen, Germany

Abstract: Simultaneous recording from large numbers of neurons has recently become available, and its analysis has revealed low-dimensional representations of task parameters within these high-dimensional neural populations. Principal component analysis (PCA), or one of its variant, is the most commonly used method for extracting the underlying low-dimensional population structure. Although PCA is deterministic, its application on neuronal activity needs to be justified and tested. Neuronal spiking activity has various limitations, e.g., it is a point process, its firing rates cannot be negative, and neural recordings are subsamples of the underlying population. We hypothesize that these properties limit the usability of PCA on neuronal population activity.
Investigating the performance of PCA on real recordings is difficult because we do not know the ground truth of the underlying low-dimensional population structure. Therefore we simulated neuronal population spiking activity with known structure. Firing rates for simulated neurons were sampled from neurons recorded from three macaque cortical grasping networks. To generate the population structure, firing rates were modulated by a set of latent variables. Contributions of single neurons to each latent variable were randomly selected and orthogonalized between latent variables at the population level. As an example, we modeled a center-outreach task by three latent variables, representing the vertical and horizontal components of the motion and a condition-independent component, respectively.
Principal components, despite capturing maximal variance, rarely captured single latent variables. Instead, they consisted of random mixtures of noise and linear combinations of latent variables. Still, PCA performed well in recovering the true number of latent variables. Furthermore, canonical correlation between the latent variables and the principal components revealed that PCA reliably captures the dynamics of the latent variables. For a larger number of latent variables, the distribution of variance captured per principal component tended towards a power law curve, regardless of the true distribution of latent variable weights.
Overall, we found PCA to be a reliable method for estimating the dimensionality of a neuronal dataset, but a different method is necessary for recovering the true latent dimensions. Notably,

the distribution of variance captured by each principal component did not represent the true distribution of latent variable weights and conclusions should therefore be drawn carefully.

Title: Balancing friendship networks while breaking up: Integrative network properties during avalanche homeostasis in nonhuman primates

Authors: *S. R. MILLER[1,2], S. YU[3], S. PAJEVIC[4], D. PLENZ[2]
[1]UMCP, Washington, DC; [2]Sect Critical Brain Dynamics, NIMH, Bethesda, MD; [3]Brainnetome Ctr., Inst. of Automation, Chinese Acad. of Sci., Beijing, China; [4]OIR/CIT, NIH, Bethesda, MD

Abstract: Cortical networks function robustly and reliably even while their internal configurations flexibly adapt to external environmental changes. Across many species, spontaneous and evoked neuronal activity in cortex has been found to be scale-invariant, termed ‘neuronal avalanches’. The scale-invariance dictates that avalanche sizes and durations obey fixed ratios over all spatiotemporal scales as quantified by power laws. Whether and how the cortex reconfigures internal connections while maintaining these fixed avalanche ratios is currently not known. Here, we specifically study 'friendship networks' (characterized by high neighborhood overlap between strongly connected nodes), which have been observed in the functional connectivity of many complex networks as well as cortex (Pajevic and Plenz, 2012). We followed neuronal avalanche dynamics over many days and weeks in premotor and prefrontal cortices of non-human primates (n = 3). The ongoing local field potential (LFP) was recorded with chronically implanted high-density multielectrode arrays for 20-60 min each day over successive weeks. Avalanches were defined as spatiotemporal clusters of negative, threshold-crossing LFP fluctuations on the array. We found that the power law in avalanche size, i.e. the number of threshold crossings within a cluster, was stable in each monkey and cortex area as was the mean pairwise correlation strength between local cortical sites. In contrast, individual pairwise correlations changed significantly over time, with highest changes observed in premotor cortex. Despite these changes, integrative 'friendship' network properties were maintained with regard to (1) robustness to weak-link pruning and (2) a positive correlation between excess clustering and link weights. This demonstrates that changes between two cortical

sites consistently alters their neighborhoods. We are currently exploring these network properties using parametric models with correlation matrices, i.e. functional connectivity derived from the mean and co-variance of experimentally obtained activity. Our results demonstrate avalanche homeostasis over many weeks in nonhuman primates in the face of changing pairwise correlations that preserve integrative network properties.

Title: Generalized linear model approach for predicting neural spiking activity from oscillatory phase

Authors: *T. D. JOHNSON[1], T. P. COLEMAN[2], L. M. RANGEL[1]
[1]Cognitive Sci., [2]Bioengineering, UCSD, LA Jolla, CA

Abstract: The synchronous ionic currents that give rise to neural oscillations have complex influences on neuronal spiking activity that are often challenging to characterize. Here we present an unbiased workflow using a generalized linear model (GLM) that characterizes the conditional probabilistic relationship between neural spiking activity and the instantaneous phase of a neural oscillation. Importantly, this workflow does not require any *a priori* knowledge of the distribution of spikes across the phases of an oscillation. The workflow generates a parametric point process GLM using an overcomplete basis of circular Von Mises functions in order to capture multi-modal aspects of spike-phase relationships that individual Von Mises function models cannot. It performs model-fitting with L1-regularized maximum likelihood, where selection of the regularizer coefficient is performed with model selection procedures (e.g. Akaike Information Criterion) to select the optimal penalty that enables the model to best capture spike-phase relationships without overfitting. We apply the time rescaling theorem to assess goodness of the fitted model and compare actual and theoretical spike distributions through Kolmogorov-Smirnov plots. This workflow is applied to synthetic data where it successfully characterizes spike-phase relationships. When applied to *in vivo* hippocampal data acquired from behaving rodents, the workflow robustly characterized a relationship between CA1 interneuron spiking and the instantaneous phase of the theta rhythm, a phenomenon that has been widely observed.

In addition, the workflow captures spiking relationships to faster rhythms (e.g. high gamma) nested within a slower rhythm (e.g. theta). In summary, the workflow advances the manner in which spike-phase relationships are both visualized and quantified, and can capture multi-modal spike-phase relationships, including coherence with multiple nested rhythms. As such, the workflow shows promise as a general-purpose tool for assessing the role that neural oscillations can have on the generation of spiking activity in neurons.

Title: Interactive data visualization for electrophysiological data

Authors: *E. L. DENOVELLIS[1], E. P. STEPHEN[3], U. EDEN[1], M. A. KRAMER[2]
[1]Mathematics and Statistics, [2]Dept. of Mathematics and Statistics, Boston Univ., Boston, MA; [3]MIT, Cambridge, MA

Abstract: Functional network analysis is a growing area of neuroscience research, driven in part by technological improvements allowing us to record from more sensors simultaneously. However, as researchers record from more sensors, network analyses can become unwieldy and hard to interpret, because the number of possible network connections scales quadratically with the number of sensors (e.g. electrodes). Further, we expect neural processes to form dynamic networks that vary over time, frequency, and spatial scales (e.g. within and between brain regions), adding complexity to network analyses. While careful statistical modeling and strong hypotheses are important for yielding interpretable results, interactive visualizations are a neglected tool for coping with high-dimensional analyses. Visualizations allow us to make multiple simultaneous comparisons, easing the cognitive burden on working memory by efficiently encoding properties of the data into features salient to the visual system. Adding interactivity allows the user to change perspectives and modify analyses on demand, facilitating comprehension and hypothesis generation.
We present an interactive web-based visualization application, SpectraVis, that: (1) displays task-related functional networks over time and frequency, (2) compares individual and associative measures on sensor pairs (e.g. spectra, coherences), (3) compares different measures of association (e.g. correlation vs. coherence, binary vs. weighted networks), and (4) views networks at two spatial scales (sensor- and region-of-interest-level). The different modules of SpectraVis are dynamically linked, highlighting relationships between the metrics in response to user interaction. We demonstrate its capabilities on an electrocorticography dataset collected

during an overt reading task. Additionally, SpectraVis is open-source and free to use by the community. See https://github.com/NeurophysVis/SpectraVis

Abstract: RRIDs have proliferated in the scientific literature in the last three years leading to the need to create additional tools. How does the inclusion of RRIDs help? Readers of the paper with RRIDs are much more likely to find the reagents that authors used, making replication of parts of the paper easier. In 2016, we (Bandrowski et al) showed that being able to find an antibody in the Journal of Neuroscience before RRIDs was about 50% and after RRIDs was close to 90%. However, the use of RRIDs, now that this is more established is also capable of linking papers together based on the reagents they use. In SfN journals, the data about the RRID is also linked to the scicrunch resolver and links are visible that take readers to the information about the reagent, including a section where other papers that also use the reagent are described. The more RRIDs that are used, the richer this data set becomes, making it more likely that readers will be able to more easily find all of the reagents they are looking for and track down any problems with these reagents more easily. RRIDs are currently found in nearly 7000 scientific papers, and have been enforced in the Society for Neuroscience and Cell press journals since mid 2016. As of April 27, 2018, the Journal of Comparative Neurology has published 644 papers with RRIDs, the Journal of Neuroscience 604, Neuron 415, eLife 768, and eNeuro has published 158 papers. Altogether, 480 journals have at least one RRID.In order to keep up with the literature being released, current rate of papers is 13.3 per day, we have built automated tools to detect RRIDs and to make sure that papers that are published are added to the reagent records so that subsequent authors will see all the papers published which used the reagent.

Title: Specifying PKC(x) isoform in different cellular location and anatomical locations of the cns based on the extracted knowledge

Authors: *Y. BUINITSKAYA[1], R. GURINOVICH[2], A. PASHUK[2], V. PUNTUS[1], A. DMITRIEVSKIY[2], A. SCERBACOV[2], Y. PETROVSKIY[2]
[1]sci.AI, Minsk, Belarus; [2]sci.AI, Tallinn, Estonia

Abstract: There are 70k+ papers mentioning PKC proteins family across the literature. Success and reproducibility of the new experiment involving PKC(x) strongly tied to reutilization of the knowledge about particular isoform in prior scientific report. It leads to different functional roles of the similar molecules. (Differentiation of the functions is reported in our adjacent poster "Inferring PKC(x) function in CNS Based on the Extracted Knowledge About Protein's Isoform").
Based on our upstream literature-based research of PKCs' role in pain mediating, we observed exceptional need to match cell and, in general, anatomical locations to identify specific PKCα, PKCγ, PKCε etc. isoforms. Locations hints present in sparse, distributed and, often, indirect, form in the macro context of the publication.
We utilize machine reasoning methods to discover possible models of biological processes and report clear feasibility to extract knowledge about particular PKC isoforms according to researcher's query.

Title: RRIDs reduce the use of contaminated cell lines in scientific papers

Authors: *Z. BABIC[1], A. E. BANDROWSKI[2], M. E. MARTONE[3], J. S. GRETHE[4], T. GILLESPIE[5], B. OZYURT[2]
[1]UCSD, San Diego, CA; [3]Neurosci., [2]UCSD, La Jolla, CA; [4]UCSD, Poway, CA; [5]Neurosci., UCSD, LA Jolla, CA

Abstract: According to Capes-Davis et al (2010), reducing the prevalence of contaminated cell line use in papers requires significant vigilance on the part of journal editorial staff. The inclusion of Research Resource Identifiers, RRIDs, in contrast, requires that the author looks at the data entry for a cell line, which includes the information that the cell line is contaminated. We hypothesize that RRID inclusion impacts the prevalence of contaminated cell line in the absence of specific editorial oversight. The list of contaminated cell lines, their RRIDs and synonyms was obtained from the Cellosaurus database (April 1, 2018). RRIDs were noted by authors for 1,554 cell lines (686 papers), of which 52 in 47 papers were on the list of

contaminated cell lines, which constitutes 3.3% of cell lines in 6.9% of papers. The population of all papers that used cell lines was estimated based on the SciScore tool run across ~2M open access papers' methods sections (data was obtained from PubMed Central). Of these 305,161 unique cell line names (150,459 articles) were identified and contamination was estimated at 26,418 (8.6%), this corresponds to a rate of use of contaminated cell lines in 16.1% of papers, a number somewhat lower than previous estimates of 20% by experts using only PubMed Central and other search tools. To verify that SciScore recognized most cell lines, we tested 1,004 random Scientific Reports articles and manually annotated whether or authors used cell lines, then we compared results and found a concurrence of 95% between SciScore and our curator who was blinded to the SciScore results. Our results show that the rate of use of contaminated cell lines is significantly lower in RRID papers than in the average paper, thus we suspect that inclusion of RRIDs, without the need for direct editorial oversight or a specific workflow reduces the use of contaminated cell lines in papers.

Title: An online platform for reproducible neural data analyses

Authors: *E. M. MEYERS[1], L. RITHICHOO[3], T. ZHANG, 01002[2], P. LU, 01002[2]
[1]Brain & Cognitive Sci., [2]Hampshire Col., Amherst, MA; [3]Mount Holyoke Col., South Hadley, MA

Abstract: As neuroscientists continue to collect larger datasets (Stevenson et al, 2011) new data tools are needed that can efficiently extract insights from this data (Brown et al, 2004). To continue to address this need, we have created an open source R implementation of the Neural Decoding Toolbox (Meyers 2013) that makes it easy to apply decoding analyses to neural data. Because the R programming language is widely used by Statisticians and Data Scientists, we hope that this package will encourage researchers from these communities to become more involved with analyzing neural data. Additionally, we have created an interactive online platform

where neuroscientists with no programming experience can apply decoding and other analyses through a web-based graphical user interface. The platform outputs a reproducible document that contains data analysis code along with the resulting figures, making it easy for researchers to reproduce and extend the results. We also aim to connect the platform to cloud based servers to allow drastic speedups in the time it takes to analyze data. Overall, these tools will make it significantly faster and easier to analyze neural data, which should increase the pace of discovery in neuroscience.

Title: Maximum likelihood and machine learning based methods for automated cell sorting of large-scale neural calcium imaging data

Authors: *B. AHANONU[1,2,3], L. J. KITCH[2], T. H. KIM[2], M. C. LARKIN[2], E. OTTO HAMEL[2], J. LECOQ[5], D. E. ALDARONDO[6], M. J. SCHNITZER[1,2,3,4]

Abstract: Recent advances in large-scale calcium imaging allow neuroscientists to visualize concurrently the dynamics of thousands of individual neurons in live animals, but analysis of these datasets remains a bottleneck. There are several existing algorithms for extracting individual cells and their calcium activity traces from the raw video data, yet no algorithm to date has demonstrated the requisite speed, scalability, accuracy, and versatility to provide a general solution. Here we present CELLMax (Cell Extraction by Log-Likelihood Maximization), a high-fidelity cell extraction method that makes no assumptions about the statistical structure of cell shapes or activity waveforms. CELLMax is highly parallelizable and its runtime scales favorably with dataset size. In validation studies on simulated and real datasets, CELLMax yielded activity traces of higher signal-to-noise ratio than those from other commonly used cell sorting methods. Neural activity traces extracted by CELLMax also enabled superior decoding of

neural ensemble signals. We further combined CELLMax with machine learning based classification approaches to distinguish actual neurons from other non-cellular signal sources in the calcium videos. This combination enabled fast and accurate cell identification when applied to one- and two-photon calcium imaging datasets acquired in multiple brain areas including neocortex, basal ganglia, hippocampus, and amygdala. Overall, our computational pipeline comprising CELLMax and automated signal source classification provides a versatile, reliable, parallelizable and scalable means of extracting cellular dynamics in a wide variety of calcium imaging studies. Thus, we expect its usage will improve the speed and accuracy of experiments relying on large-scale neural imaging.
