Abstract: Introduction Organophosphorus compounds such as sarin are known to irreversibly inhibit acetylcholinesterase (AChE). Recent studies have suggested that these compounds can

induce non-cholinergic toxicity *in vivo* and *in vitro* and that this toxicity involves an inflammatory response. However, the precise mechanisms underlying the cytotoxic effect of organophosphorus compounds are not known. In this study, we sought to elucidate these mechanisms. To this end, we cultured human neuroblastoma cells (SK-N-SH cells) with bis(isopropyl methyl)phosphate (BIMP), a sarin-like organophosphate, and examined the cytotoxicity of BIMP as well as the involvement of the inflammatory response in BIMP-induced neuronal death. Methods In Japan, synthesis and use of sarin is regulated by law. Therefore, we synthesized BIMP, which acts as an AChE antagonist, similar to sarin. We examined the non-cholinergic toxicity of BIMP in SK-N-SH cells. SK-N-SH cells were cultured in DMEM supplemented with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin antibiotics at 37°C in a humidified atmosphere with 5% CO2. The cells were exposed to BIMP or vehicle at various concentrations under serum-deprived conditions (0.1% FBS). Cell viability and cytotoxicity were measured using MTT and LDH assay kits, respectively. Cellular morphology was examined by light microscopy, and nuclear morphology was observed by fluorescence microscopy after staining the cells with Hoechst 33342. Prostaglandin E2 (PGE2) content in the medium was measured using an ELISA kit. Total protein was extracted, and western blot analysis was performed to determine cleaved caspase 3, cleaved caspase 9, cleaved PARP, cyclooxygenase 1 (COX-1), and COX-2 expression levels. Results BIMP significantly reduced cell viability and increased cytotoxicity in SK-N-SH cells in a dose-dependent manner. BIMP (500 μM) treatment for 12 or 24 h caused changes in cellular morphology, increased the numbers of floating cells, and resulted in nuclear fragmentation. BIMP significantly increased cleaved caspase 3, caspase 9, and PARP expression in a concentration-dependent manner. Moreover, it induced COX-2 expression and increased PGE2 level. Finally, we examined the effect of a COX-2 inhibitor, ibuprofen, on BIMP-induced cytotoxicity in SK-N-SH cells, and found that ibuprofen pretreatment significantly attenuated BIMP-induced cell death and suppressed COX-2 expression. Conclusion BIMP induces caspase-dependent apoptotic cell death and inflammatory responses in SK-N-SH cells and that the anti-inflammatory drug ibuprofen may protect against BIMP-induced cytotoxicity.

Title: Regulation of the expression of neurodegenerative markers through neuronal energy metabolism

Authors: *M. FLORES LEÓN, C. ARIAS ÁLVAREZ;
Univ. Nacional Autónoma De México, Mexico City, Mexico

Abstract: Introduction: Metabolic conditions associated with the consumption of high fat diets are considered as risk factors for neurodegenerative diseases, for example Alzheimer's Disease, particularly due to the high content of saturated fatty acids such as palmitic acid (PA). It is presumed that PA might be altering the cellular metabolism by modulating the NAD+/NADH relation. Furthermore, a group of Histone Desacetylaces (Class III - Sirtuins) might be modulated by cellular metabolism due to the utilization of NAD+ as a cofactor. Sirtuin 1 (SIRT1) is responsible for the deacetylation of several transcription factors and residues in histone tails, leading to activation or repression of genes. Nevertheless, the mechanisms that relate the intake of high fat diets, the alteration of cellular metabolism and regulation of the expression of neurodegenerative markers, such as the aberrant processing of the amyloid precursor protein (APP) remains to be elucidated. Objective: Analyze the relationship between the inhibition of SIRT1 with the expression of BACE1 and ADAM10 that may lead to an aberrant processing of APP. Metholodogy: Primary hippocampal neuronal cultures in 8 or 12 DIV were exposed to different concentrations of PA or EX527 (SIRT1 inhibitor); 24 hours later protein and RNA were extracted for Western Blot and RT-qPCR analyses. Male Sprague-Dawley rats were intrahippocampally injected with 1 ug/uL of EX527 and 24 hours later they were sacrificed and protein and RNA were extracted for Western Blot and RT-qPCR analyses. Results: Neuronal metabolism was altered by PA resulting in NAD+ depletion and in a reduction of mitochondrial activity. Furthermore, several cytoplasmatic targets of Sirt1 showed changes in their acetylated residues after Sirt1 was inhibited. Conclusions: The alteration of cellular energy metabolism might be implicated in the regulation of the expression of genes implicated in the progression of neurodenerative markers.

Abstract: Alzheimer's disease is most common form of dementia and it is structurally characterized by changes in the brain atrophy and loss of brain volume. The Aβ is one of the most important cause of AD and known to initiate early cascade in AD. Aβ deposition is positively correlated with brain atrophy in AD. Structural brain imaging techniques such as Magnetic Resonance Imaging (MRI) are used to measure neuro-anatomical alterations in Alzheimer's disease brain. Magnetic Resonance Imaging is a non-invasive method to study the brain structure. Objective of the present study is to elucidate the role of Aβ on brain structure of aged rabbit brain. Among 20 aged rabbits, one batch (10) rabbits are injected with Aβ(1-42) and another batch (10) of aged rabbits are injected with saline. The MRI is conducted before Aβ(1-42)/ saline injection and after 45 days of Aβ(1-42)/ saline injection. All the aged rabbits are subjected for MRI and euthanized after 45 days. The MRI results showed a significant reduction in thickness of frontal lobe, hippocampus, midbrain, temporal lobe and increase in the lateral ventricle volume. We also conducted MRI study on 10 AD and 10 normal cases and analyzed for the thicknesses of frontal lobe, hippocampus, midbrain, temporal lobe and lateral ventricle lobe. We found significant reduction in thickness of the frontal lobe and the hippocampus. However, no significant reduction in the thickness of midbrain, temporal lobe and no significant increase in the lateral ventricle volume are observed compared to normal. The results of brain atrophy changes between rabbit brain and human AD brain correlation is established for frontal lobe and hippocampus regions. While, other regions such as midbrain, temporal lobe, lateral ventricle does not show correlation to rabbit brain atrophy changes in the corresponding regions of rabbit brain. The relevance of these changes in AD will be discussed.

Title: Safeguarding effect of protein disulfide isomerase in Aβ intra-hippocampal injected rats; time matters

Authors: *P. SADEGHI[1,2], F. SHAERZADEH[1,2,3], F. KHODAGHOLI[1,2];
[1]Neurosci. Res. Ctr., Tehran, Iran, Islamic Republic of; [2]NeuroBiology Res. Ctr., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of; [3]Dept. of physiology, Fac. of Med., Hormozgan Univ. of Med. Sci., Hormozgan, Iran, Islamic Republic of

Abstract: Introduction Disulfide bonds, covalent cross-link between cysteine residues of proteins, are often formed to stabilize protein structures or join the other proteins. Improper interaction between cysteine residues results in misfolded proteins. To avoid this mismatch, protein folding in endoplasmic reticulum (ER) is assisted by an elaborate system of chaperones and catalysts. Protein disulfide isomerase (PDI), a retained molecule in ER, acts as a molecular chaperone and folding catalyst by introducing disulfide bonds into protein structures and further catalyzing the rearrangement of incorrect disulfide bonds. Also, in spite of the physiological concentrations of nitric oxide (NO) that mediates normal signaling, excessive generation of NO by overactivation of NO synthase results in neurotoxicity and neuronal injury. Methods Adult male Wistar rats were divided into two groups. First group received the intra-hippocampal injection of 3 µl PBS bilaterally and were decapitated immediately after injection. Second group were injected by 3 µl Aβ1-42 (10 ng/µl) in CA1 region of hippocampus and next the animals were killed 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 days after Aβ injection. Reductase activity of PDI was assayed by measuring enzyme-catalyzed reduction of insulin in the presence of dithiothreitol (DTT). To measure nitrites content, homogenates were prepared in Tris-HCl (20 mM, pH 7.3, 1:10) and the absorbance was measured at wavelength of 550 nm. Results We tried to determine the role and trend of ER specific molecules as PDI in neural defense system beside NO determination in intra-hippocampal amyloid beta (Aβ)-injected rats in 10 days running. PDI is considered as a member of the thioredoxin superfamily. Based on the specific reaction that catalyzes, PDI is known as a critical molecule involved in proper folding of protein structures in ER. Two days after injection of Aβ, PDI activity significantly decreased compared to control group. This trend of decline continued till 10th day after Aβ injection. From the other side, one day after Aβ injection, concentration of NO started to increase and reached to the maximum level 6 days after injection of Aβ. Afterward, level of NO decreased but the level of NO in 10th day was still higher than the control group. Correlations and regression between NO level and PDI activity were significant ($P < 0.001$) in Aβ-injected rats. There is a negative correlation between these two factors with a good regression line fit ($R2=0.73$) indicating that increase in NO level was concomitant with decrease in PDI activity.

Title: Radiation induces death of proliferating cells, microglia activation, and blood brain barrier damage in the cerebellum after cranial irradiation in young rats

Authors: ***K. ZHOU**[1], J. EK[1], M. BOSTRÖM[1], T. LI[1], C. XIE[1], Y. XU[1], K. BLOMGREN[2], C. ZHU[1];
[1]Univ. of Goteborg, Goteborg, Sweden; [2]Karolinska Univ. Hosp., Stockholm, Sweden

Abstract: Background: Posterior fossa tumors are the most common childhood intracranial tumors, and radiotherapy is one of the most effective tools for treating children with such tumors. However, radiotherapy has both acute and long-lasting adverse effects, and neurocognitive impairments have significant impacts on the patient's quality of life and are the most important measurements of brain tumor therapy outcomes in clinical trials second only to survival. **Purpose:** The purpose of this study was to characterize the mechanisms of irradiation-induced cerebellum injury. **Methods**: Male Wistar rats were subjected to a single whole-brain dose of 6 Gy irradiation on postnatal day 11. The animals were sacrificed at 6 h or 24 h after irradiation to detect cell death, microglia activation, blood brain barrier permeability, and cell proliferation in the cerebellum or at 16 weeks after irradiation to evaluate cerebellum injury. **Results:** An increasing number of pyknotic cells were detected in the external granular layer (EGL) of the cerebellum at 6 h and at 24 h after irradiation as indicated by H&E staining. This was further confirmed by active caspase-3 staining. The number of replicating cells in the EGL as indicated by BrdU labeling and Ki67 immunostaining was decreased at 6 h after irradiation and much more dramatically at 24 h after irradiation. Microglia invasion and activation in the EGL increased after irradiation as indicated by Iba-1 and CD68 staining. The blood brain barrier permeability increased after irradiation as indicated by albumin staining. The volume of the EGL

increased by about 25% at 6 h and then decreased by about 50% at 24 h after irradiation. Behavior tests showed that irradiated rats spent more time in the open zone area in the open field test and that recognition function was impaired. The total volume of the cerebellum was reduced by almost 50% at 16 weeks after irradiation; however, the total number of Purkinje cells was not significantly different after irradiation compared with controls. **Conclusions:** The cerebellum is more sensitive to irradiation-induced injury, including the death of proliferating cells, microglia activation, and blood brain barrier damage, and it undergoes persistent cerebellar atrophy. All of these factors are probably related to neurocognitive impairment.

Title: Palmitate impairs insulin signaling in hippocampal neurons

Authors: *H. M. DE MELO[1], G. S. SEIXAS DA SILVA[2], S. T. FERREIRA[2], F. G. DE FELICE[2];
[1]Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil; [2]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder that leads to memory loss and cognitive impairment. The causes for development of sporadic AD, which is markedly associated with aging, are still largely unknown. AD brains present Abeta accumulation, tau hyperphosphorylation and impaired insulin signaling, which are thought to mediate synapse and cognitive defects. Indeed, patients with diabetes and obesity have increased risks of developing AD and some studies have supported the emerging idea that AD is a novel brain-specific form of diabetes. Lipotoxicity is a key mechanism in the development of peripheral insulin resistance in obese and type 2 diabetes patients, known to have increased

circulation of saturated fatty acids (SFA). This study aimed to evaluate whether palmitate, the most abundant circulating SFA, inhibits insulin signaling and cause AD markers in cultured hippocampal neurons. Hippocampal neurons were exposed to palmitate and levels of IRS-1 serine phosphorylation (Ser312, Ser307 and Ser636), known to mediate insulin resistance, were analyzed by immunocytochemistry. Results show increased IRS-1 serine phosphorylation and tau phosphorylation in palmitate-exposed neurons as compared to vehicle, similar to what is observed in Abeta-exposed hippocampal neurons. Our findings indicate that palmitate impairs neuronal insulin signaling by inhibiting IRS-1 signaling and causes tau phosphorylation. Thus, common mechanisms accounting for peripheral insulin resistance, including SFA signaling, may be at play across the blood-brain barrier, instigating the initial steps of AD and likely explaining why peripheral metabolism impairments represent a risk factor for AD development.

Title: Manganese loading induces male interspecific predatory aggression in nonaggressive rats

Authors: *L. GELAZONIA, I. LAZRISHVILI, T. BIKASHVILI, N. MITAGVARIA;
I. Beritashvili Ctr. Of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: Generally accepted that aggression and violent behavior may stem from toxic metals due to their excessive accumulation in the body. Despite of numerous studies on the problem of neurotoxicity of manganese, issues concerning its role in aggressive and violent behavior manifestations are almost unknown. The published data concerning this problem are indirect and often - contradictory. The effect of 30 (group I) and 75 (group II) day exposure to different doses of manganese chloride - MnCl2.4H2O (10 and 15 mg/ml in drinking water) on interspecific predatory aggression (IPA) of the initially nonaggressive rats was studied. Prior to the MnCl2.4H2O loading, to eliminate any spontaneously aggressive animals from subsequent experiments, the rats were tested for male interspecific predatory aggression. 30-day exposure to 10mg/ml MnCl2.4H2O does not stimulate aggressive behavior of rats, while after exposure to the higher dose 37,5% of rats manifested IPA and 25% attempted IPA. 75-day exposure to 10mg/ml MnCl2.4H2O 37,5% of rats manifested IPA and 37,5% - IPA attempt. After exposure

to the higher dose 75% of rats manifested IPA attempt and 25% - nonaggressive behavior. The data obtained support the idea that excess of Mn in the body might cause of rats' aggressive behavior. As we see, the 30-days loading by Manganese Chloride (10 mg/ml) is not sufficient for creation of that cumulative dose, which is needed for revealing of aggressive behavior. It is know that long-term high dose Mn-intoxication leads to an abrupt disruption of neurotransmitter systems, especially nigrostriatal dopaminergic system. According to our assumption this violates the motor activity and animals despite repeated attempts are not able provide IPA.

Title: Hexahydrobenzene produces oxidative stress, and glial reactivity in the adult mouse hippocampus

Authors: ***T. V. CAMPOS ORDONEZ**[1], D. ZARATE-LOPEZ[1], V. LOPEZ-VIRGEN[1,2], J. VEGA-RIQUER[1,2], A. GALVEZ-CONTRERAS[3], N. MOY-LOPEZ[1], J. GUZMAN-MUNIZ[1], O. GONZALEZ-PEREZ[1];
[1]Sch. of Psychology/ Lab. of Neurosci., Univ. of Colima, Colima, Mexico; [2]Med. Sci. PhD Program, Sch. of Medicine, Univ. of Colima, Colima, Mexico; [3]Dept. of Neurosci., Ctr. Universitario de Ciencias de la Salud, Univ. of Guadalajara, Guadalajara, Mexico

Abstract: Background: Volatile compounds are the fourth most commonly drug of abuse after alcohol, tobacco, and marijuana. Hexahydrobenzene, also referred as Cyclohexane, is a volatile solvent used as a substitute of dangerous organic solvents in several products, such as: paints, paint thinners, lacquers, gasoline, adhesives, etc. Previous studies have found cellular and behavioral disturbances after inhaling organic solvents. Unfortunately, there is little investigation about the effects of cyclohexane in the Central Nervous System (CNS). Objective: To analyze the effects of cyclohexane inhalation on motor behavior, spatial memory, and reactive gliosis

CA1 and CA3 regions in the hippocampus of adult mice. Method: We use in male Balb/C mice (P60) divided in two groups: controls and the cyclohexane group (exposed to 9,000 ppm cyclohexane daily for 30 days). We evaluated motor skills with a functional observational battery (FOB) and memory performance with the Morris water maze (MWM). We analyzed the expression of AP endonuclease 1 (APE1), astrocytes (GFAP cells +) and microglia (Iba1+ cells) in the hippocampal CA1 and CA3 regions. Statistical analysis was done with the Mann-Whitney ''U'' test. Results: The cyclohexane group showed statistically significant differences in gait, activity function, sensory auditory function, response to two-hand manipulation, forelimb/hindlimb grip strength, salivation and lacrimation as compared to the control group. We did not find statistically significant differences in memory performance in the MWM. Interestingly, we found a significantly increased in the expression of APE1 in the cyclohexane group in the CA1 region (IQR = 1.3-1.6; P = 0.04) and in the CA3 (IQR = 1.7-2.1; P = 0.03) as compared to controls. In the CA1 area the number of astrocytes in the cyclohexane group (IQR = 29.6-35.3) was higher than in the control group (IQR = 25.5-32.6). In the CA3 area, cyclohexane increases significantly in the number of astrocytes (IQR = 37-45.4) as compared to the control group (IQR = 22.9-29.8). The number of microglial cells was increased in the CA1 region of the cyclohexane group (IQR = 11.8-12.3) as compared to controls (IQR = 8.5-9.2). In the CA3 region, the cyclohexane group also showed an increase (IQR = 5-7.9) in the number of microglia cells as compared to the control group (IQR = 2.7-2.9). Conclusion: Cyclohexane produces functional deficit without changing learning and spatial memory. Furthermore, cyclohexane induces oxidative stress, astrogliosis and microglial reactivity in the hippocampal CA1 and CA3.

Title: Intranasal brain delivery of obidoxime prevents mortality and cns damage from organophosphate poisoning

Authors: *J. KRISHNAN[1], P. ARUN[1], A. APPU[1], N. VIJAYAKUMAR[1], T. FIGUEIREDO[1], M. BRAGA[1], S. BASKOTA[1], 1. FREY, II[2], J. MOFFETT[1], A. NAMBOODIRI[1];

Abstract: Intranasal delivery is an emerging method for bypassing the blood brain barrier (BBB) and targeting therapeutics to the central nervous system (CNS). This method has been shown in numerous studies to bypass the BBB and rapidly deliver drugs to the CNS via extracellular and paracellular routes along the olfactory and trigeminal neural pathways. This approach is particularly advantageous because charged molecules and high molecular weight compounds, which cannot penetrate the BBB, can be rapidly delivered to the CNS in therapeutic doses. Oximes are used to counteract the effects of organophosphate poisoning, but they do not readily cross the BBB. Therefore, they cannot effectively counteract the central neuropathologies caused by cholinergic over-activation when administered peripherally. For these reasons we examined intranasal administration of oximes in an animal model of organophosphate poisoning to determine their effectiveness in reducing mortality and seizure-induced neuronal degeneration. Intranasal application of obidoxime (OBD) was effective in partially reversing paraoxon-induced acetylcholinesterase inhibition in the brain and also reduced seizure severity and duration. Further, intranasal OBD completely prevented mortality and nerve cell loss. Fluoro-Jade-B staining revealed extensive neuronal degeneration in the surviving saline-treated animals 24 hours after paraoxon administration, whereas no detectable degenerating neurons were observed in animals given intranasal OBD 30 min before or 5 min after paraoxon administration. Intranasal administration is an effective method for rapidly bypassing the BBB and noninvasively delivering oximes such as OBD to the CNS to counteract the central neuropathologies caused by organophosphate poisoning. Now that this method has been found effective, other neuroprotective modalities, including organophosphate scavenging enzymes, are potentially promising candidates for use via the intranasal route. Title: The zombie apocalypse: neurodegeneration in Alzheimer's disease includes the apoptosis of healthy bystanders near "undead" senescent neurons

Authors: *H. CHOW[1,2], K.-H. TSE[1], K. HERRUP[1];
[1]Div. of Life Sci., The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [2]Inst. for Advanced Study, The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Age is by far the greatest risk factor for Alzheimer's disease (AD) and cellular senescence, a factor strongly correlated with aging, would this be expected to play a role in the AD neurodegenerative process? During neuronal stress, elevated intracellular calcium leads to activation of calpain and cleavage of the Cdk5 activator, p35, to p25. Subsequently, p25 binds to GSK3β, blocking Axin binding and inhibiting access of GSK3β to its β-catenin substrate. This results in elevated levels and enhanced nuclear presence of β-catenin. The increased nuclear localization of β-catenin favors its binding to CBP, a transcriptional cofactor, over its alternate partner, p300. CBP/β-catenin association leads to a switch in downstream targets, from p300-related neuronal maintenance genes to CBP-related genes with pro-proliferation properties. Thus, overexpression of p25 in neurons leads to enhanced β-catenin activity and increased expression of target genes such as cyclin D and c-Myc. This correlates with neuronal cell cycle re-entry, but in p25 expressing cells cell cycle activity results not in neoplastic transformation, but in cellular senescence. β-catenin-positive cells express senescence markers such as β-galactosidase and release senescence related cytokines. These secreted factors trigger apoptosis in nearby untransfected bystander neurons. This bystander effect is also seen in mouse models of AD. Although the levels of total β-catenin are reduced, we find patches of neurons in hippocampus and cortex with strong nuclear β-catenin signals and markers of cellular senescence. The soluble Wnt antagonists, DKK1 and sFRP2, are targets of β-catenin and both are released from both p25- and β-catenin-expressing neurons. They are the likely agents of the bystander effect as DKK1 and sFRP function-blocking antibodies prevent it, despite the persistence of senescence markers in the p25-expressing cells. Thus, induction of senescence occurs in neurons that appear to be cycling. The resulting bystander effect suggests that these abortive attempts at cell division mark zombie-like cells in neuronal populations at risk for death in AD; and in AD, as in Hollywood, the victims of this conversion are innocent bystander neurons in the region.

Title: Facilitation of neurotransmission in bont/a-paralyzed nerve terminals by 3,4-diaminopyridine does not act through the incorporation of cleaved snap25 in vesicle release

Authors: *A. B. BRADFORD[1], T. M. RUSSO[2], E. J. GLOTFELTY[2], K. M. HOFFMAN[1], P. H. BESKE[1], P. M. MCNUTT[1];

Abstract: Botulinum neurotoxins (BoNTs) are highly lethal Tier-1 Biothreat toxins that cause muscle paralysis by targeting and enzymatically cleaving SNARE proteins in motor neurons, thus preventing synaptic vesicle release. In particular, BoNT serotype A (BoNT/A) is a potent and persistent toxin that remains enzymatically active in motor nerve terminals for months, resulting in a sustained paralysis. There are currently no countermeasures to reverse BoNT-intoxication. 3,4-diaminopyridine (3,4-DAP) is a small molecule that has been found to improve neuromuscular transmission for various myasthenic diseases. Clinical evidence suggests that administration of 3,4-DAP transiently improves skeletal and respiratory muscle response in some cases of BoNT/A poisoning. 3,4-DAP specifically blocks voltage-gated potassium channels in neurons, thereby prolonging action potential duration. It has been hypothesized that prolonged AP firing renders cleaved SNAP-25 (cSNAP-25) capable of supporting acetylcholine (ACh) release from BoNT/A-intoxicated motor nerve terminals, but the specific mechanism by which this occurs is unclear. We tested the validity of this hypothesis in isolated mouse phrenic nerve-hemidiaphragm preparations. Application of 10 μM 3,4-DAP to control preparations increased twitch tension strengths by 200-300% within 15 min. Bath application of 6.7, 67 or 670 pM BoNT/A eliminated nerve-elicited muscle contractions with times-to-paralysis that were dose-dependent. At all BoNT/A doses, increasing degrees of partial paralysis reduced the capacity for 3,4-DAP to increase twitch tensions. Importantly, 3,4-DAP did not restore nerve-elicited contractions when applied to fully paralyzed muscles. These results suggest that 3,4-DAP does not enable neurotransmission via incorporation of cSNAP-25 into the vesicle release machinery. We are continuing to explore the conditions and mechanisms by which 3,4-DAP may be able to restore suprathreshold ACh release. Additional approaches, such as the use of tetanic stimulation and muscle endplate potential recording, are underway to allow more sensitive measurements of the 3,4-DAP effect. Mechanistic understanding of how 3,4-DAP potentiates neurotransmission in BoNT/A-impaired neuromuscular junctions will assist in clinical decision-making as well as development of therapeutic approaches to treat BoNT intoxication.

Title: High-density cobalt induces axonal degeneration and inhibits the motility of axonal motile mitochondria

Authors: *S. KIKUCHI[1], T. NINOMIYA[1], T. KOHNO[2], T. KOJIMA[2], H. TATSUMI[1]; [1]Dept. of Anat. 1, Sapporo Med. Univ. Sch. of Med., Sapporo, Japan; [2]Dept. of Cell Sci., Res. Inst. for Frontier Medicine, Sapporo Med. Univ., Sapporo, Japan

Abstract: A recent report has demonstrated that some patients with a metal-on-metal (MoM) hip implant suffer from peripheral or optic nerve neuropathies. Cobalt is one of the main components of the implant and the blood cobalt concentration in patients with a MoM hip implant is higher than normal. However, the mechanisms of neuropathy induced by high cobalt have yet to be elucidated. In the present study, we investigated how cobalt may affect the mitochondrial dynamics in primary cultures of rat dorsal root ganglia (DRG). We assessed (1) changes in the number of motile mitochondria before and after cobalt exposure and (2) the number of swellings per 100 μm axonal length. To observe the axonal mitochondria dynamics, mitochondria in the axons were visualized by the transfection of Lentivirus vectors containing mitochondria-targeted DsRed2 sequences. DRG cultures were produced from 19-day-old embryo of Sprague-Dawley rats. At 4 weeks, the cultures were transfected with Mito-DsRed2 and incubated another 2-3 weeks. Time-lapse imaging was used to assess the motile mitochondria in the axons. Both before and after the cobalt treatment, time-lapse imaging was used to assess the motile mitochondria in the axons. Images were taken every 6 seconds in each axon with a total of 200 images produced pre- and post-treatment. The duration of exposure to the cobalt chloride was 24 hours. The cobalt chloride concentrations of the replacement medium were 0, 200, 400, 600 or 800 μM. After taking the time-lapse images, the cultures were fixed with 4% paraformaldehyde and immunohistochemically stained with a neurofilament protein antibody to count the number of the axonal swellings. The rate of the motile mitochondria in the 600 and 800 μM cobalt concentrations significantly decreased to 27.3% and 0%, respectively. Of particular note, the 800 μM cobalt density suppressed the axonal mitochondria transport completely. The number of

swellings totaled 0.2±0.41, 0.1±0.31, 0.55±0.76, 2.1±1.65 and 5.05±1.85 (average ± standard deviation, n=20) in 0, 200, 400, 600 and 800 μM cobalt concentrations, respectively. Significant differences were recognized between the high densities of cobalt (600 and 800 μM) and the low (0, 200 and 400 μM). Since axonal swelling is thought to occur before axonal degeneration, we concluded from our results that the high-density cobalt caused axonal degeneration in the DRG cultures. Although the molecular mechanisms of neurotoxicity induced by cobalt are not clear, our results showed that high cobalt concentrations induced peripheral neural degeneration by inhibiting axonal motile mitochondria and axonal swelling in the peripheral nerves.

Title: Oxidative stress effect on purinergic receptors and Glycogen synthase kinase 3 beta in hippocampus of rats exposed lo ozone

Authors: ***R. V. PEREZ**, E. CARMONA-MONTESINOS, E. RODRIGUEZ-MARTINEZ, S. L. RIVAS-ARANCIBIA;
UNAM, Mexico D.F., Mexico

Abstract: Ozone exposure at low dosis causes oxidative stress and induces a progressive neurodegeneration in hippocampus of rats when they are chronically exposed to this gas. Adenosine 5´ triphosphate (ATP) can act as a mediator in intercellular communication between neurons and glial cells. The increase of extracellular ATP is associated with inflammation and celular death processes. On the other hand activation of purinergic receptors induces activation of intracellular signaling cascades in which synthase kinase 3 beta (GSK3 β) could be involved. The objective of this work was to study the effect of chronic low ozone dosis on the P2X7 and P2Y2 receptor expression as well as the activity of GSK3β in rat hippocampus. For this purpose there were used 36 Wistar male rats with free acces to food and water, that were housed individually, and randomly divided in 6 groups, each group received one of the following treatments: group 1: control exposed to air ozone free environment, group 2, 3, 4, 5 and 6

exposed to ozone for 7, 15, 30, 60 and 90 days respectively. The ozone exposure was for 4 hours daily at 0.025 ppm.Two hours after the end of treatment, rats were then deeply anesthetized, and processed for western blot and immunohistochemistry techniques using specific antibodies against P2X7,P2Y2 and GSK3β.Results showed an P2X7 receptor increase expression at 60 days of ozone exposition in comparison to the control group, and also we found an increase in the immunoreactivity. Moreover results showed an P2Y2 increase at 15, 30, 60 and 90 days of ozone exposure with respect to the control, as well as, an increase in the P2Y2 immunoreactivity. Results also showed an GSK3β phosphorylation increase at serine 9 which started from 15 to 90 days of ozone exposure. This results indicate that oxidative stress caused by ozone can alter the purinergic receptors expression, mainly the P2Y2 receptor, and lead to the GSK3β phosphorylation, which has an important biological role in inflammation and celular death during neurodegenerative process. We thank Gabino Borgonio Perez for his technical assistance. This work was supported by CONACYT 219703

Abstract: Endoplasmic reticulum stress caused protein misfolding and the release of calcium, which lead to caspase 12 activation, which contributes to progressive neurodegeneration process. The aim of this work was to study the effect of oxidative stress on the endoplasmic reticulum (ER) and its relation to cell death in the hippocampus of rats exposed to ozone. For this purpose

we carried out the following experiments. Seventy-two male Wistar strain rats were randomly divided into 6 experimental groups, each group received one of the following treatments: Group 1) control was exposed to air without ozone; Group 2, 3, 4, 5 and 6 were exposed to ozone (0.25 ppm) for 7, 15, 30, 60 and 90 days respectively. Two hours after the last exposure to ozone, the animals were deeply anesthetized, the brains were removed and the hippocampi were processed for the following techniques: TUNEL, western blot, and immunohistochemistry, with the following antibodies: ATF6 and GRP78 for studying stress of endoplasmic reticulum, we used caspase 12 and TUNEL to study apoptotic cell death and electronic microscopy for the study of ultraestructural changes of endoplasmic reticulum. The results showed that TUNEL-label cells increased in groups exposed to ozone from 30 until 90 days. An increase was also observed in the immunoreactivity of ATF6 and RP78 from 30 days. In addition the ATF6 and GRP78 expression was significantly increase in groups exposed to ozone for 60 days ($p< 0.05$) and 90 days ($p<0.05$) compared with the control group. However, there was also an increase of caspase 12 at 90 days ($p<0.05$) of exposure to ozone compared to control group. Moreover, we observed dilatation and loss of continuity of the membranes of the endoplasmic reticulum from 30 to 90 days of exposure to ozone. In conclusion, the ozone exposure produces endoplasmic reticulum stress; this condition leads to apoptotic cell death through the caspase 12 activation, like what might occur in Alzheimer's disease.

Title: Characterization of chronic methamphetamine neurotoxicity in Parkin knockout rats

Authors: *A. SHARMA, A. FLACK, A. MOSZCZYNSKA;
Pharmaceut. Sci., Wayne State Univ., Detroit, MI

Abstract: Methamphetamine (METH) is one of the most widely used addictive substances. METH is a potent sympathomimetic amine, which affects both central and peripheral nervous system. Both binge and chronic METH is highly toxic to dopaminergic (DAergic) and

serotonergic (5HTergic) nerve terminals in the striatum. Neurotoxicity of METH occurs by multiple mechanisms, primarily via DA-mediated oxidative stress and is manifested by persistent decreases in DAergic and 5HTergic markers, including DA, 5-HT, and their metabolites as well as by astrogliosis. We have previously shown that binge METH oxidatively damages Parkin and decreases its levels in rat striatal synaptosomes shortly after the last dose of the drug. We have also shown that overexpression of Parkin protects against neurotoxicity of binge METH. The objective of the present study was to characterize neurotoxicity of chronic METH in wild type (wt) and Parkin knockout (KO) Long Evans rats. We hypothesized that Parkin-deficient rats would be more sensitive to METH toxic effects. To test this hypothesis, adult male Long Evans rats were treated with chronic doses of METH (wt: 20 mg/kg; KO: 10 mg/kg, for 10 days, once a day, i.p) or saline and sacrificed 5 or 10 days after the last injection. High performance liquid chromatography (HPLC) analysis of striata revealed no statistically significant decreases in 5HTergic or DAergic markers after drug administration. When striatal sections from saline- and METH-treated rats were immunolabeled for tyrosine hydroxylase (TH), a DAergic marker, and glial fibrillary acidic protein (GFAP), an astrocyte marker, TH immunofluorescence was decreased (-25%) while GFAP immunofluorescence was increased (5d: 4 fold; 10d: 3 fold) in METH-treated wt rats as compared to wt saline controls. Parkin KO rats showed no statistically significant decreases in striatal DAergic and 5HTergic markers and similar changes in TH and GFAP as wt rats, a 25% decrease and 3 fold increase, respectively, at 10 days after chronic METH. As Parkin KO rats were treated with two times lower doses of METH (due to high mortality rate), our findings suggest that Parkin KO rats are more sensitive to METH toxic effects than wt Long Evans rats. Moreover, our data also suggest that wt Long Evans rats are more resistant to METH neurotoxicity than Sprague Dawley rats. In summary, our study demonstrates reactive astrogliosis in chronic METH-treated Long Evans rats and suggests that loss of parkin protein results in higher response of astrocytes to METH neurotoxicity. Further studies are warranted to establish the factors responsible for species differences in response to chronic METH and role of parkin in METH-induced astrogliosis.

Title: Colonic neurotoxicity in rats that self-administer methamphetamine

Authors: A. FLACK[1], A. L. PERSONS[2], S. KOUSIK[3], *J. M. GEMECHU[1], T. NAPIER[3], A. MOSCZCYNSKA[1];
[1]Postdoctoral fellow, Wayne State Univ., Detroit, MI; [3]Ctr. for Compulsive Behavior and Addiction, [2]Rush Univ., Chicago, IL

Abstract: Methamphetamine (METH) is a highly abused psychostimulant that is associated with an increased risk for developing Parkinson's disease (PD) (Callaghan et al. Drug Alcohol Depend. 120:35, 2012; Curtin et al. Drug Alcohol Depend. 146:30, 2015). This enhanced vulnerability may relate to the known neurotoxic effects of METH that are also observed in PD pathology. High-dose METH (Butler et al. J Addict Prev 2004) increases α-synuclein levels and decreases the E3 ligase parkin in the striatum of rats, and in PD, α-synuclein is increased in the substantia nigra (Recasens and Dehay Neuroanat 2014). Peripheral factors may contribute to CNS pathology. α-Synuclein levels in the enteric nervous system are increased in PD patients (Shannon et al. Mov Disord. 27:709,2012), as well as in rats that self-administered (SA) METH prior to tyrosine hydroxylase (TH) deficits in the striatum (Napier et al. SfN Abstr #240.12, 2013; Kousik et al. Eur J Neurosci.40:2707, 2014). As in PD patients and rats that SA meth, gut α-synuclein pathology precedes brain monoamine pathology, and we hypothesized that a similar pattern would occur with gut monoamines (i.e., dopamine and norepinephrine). Thus, the aim of the present study was to measure the levels of α-synuclein, TH and dopamine-β hydroxylase (DβH), a noradrenergic marker, at different times following withdrawal from self-administered METH in the distal colon of rats. Male Sprague-Dawley rats were allowed to self-administer METH for 3h per day for 14 days (d) while yoked controls received saline. Colon tissue was harvested at 24h, 14d, and 56d after cessation of the operant task. As compared to their saline-yoked counterparts, METH exposed rats showed a trend for an increase in α-synuclein immunoreactivity at 24h that returned to baseline levels by 14d. At 24h, significant deficits in both TH and DβH immunoreactivity were observed; the deficit in DβH persisted at least up to 14d. The monaminergic markers co-localized with neurofilaments. Our results, coupled with those from our previous studies, indicate that the colon demonstrates an early onset neurotoxicity that may predispose human METH users to develop PD. Supported by DA034783, DA024923 and the Center for Compulsive Behavior and Addiction.

Title: Alterations in phospho-ser129-α-synuclein in the striatum in rats after binge METH may provide clues to understanding the link between METH abuse and PD

Authors: J. M. GEMECHU, *A. FLACK, A. ALBRECHT, A. MOSZCZYNSKA;
Wayne State Univ., Detroit, MI

Abstract: Methamphetamine (METH) is a psychostimulant drug which widely abused in the US and worldwide. At high doses, it causes neurotoxicity in rats, non-human primates, and humans. Previous studies have shown that exposure to METH in earlier stages of life increases the likelihood of developing Parkinson's disease (PD) later on. PD and METH neurotoxicity share several hallmarks of neurodegeneration. For example, in both conditions, tyrosine hydroxylase (TH), a dopamanergic (DAergic) marker, is decreased while α-synuclein is increased in the striatum. The most frequent modification of α-synuclein in PD patients is its aggregation and phosphorylation at Ser129. Phospho-Ser129-α-synuclein is predominantly localized to striosomes in the striatum with lower levels in the matrix. Differential losses in DAergic markers between striosomes and matrix were observed in rodents. It is not known how neurotoxic doses of METH change the levels of phospho-Ser129-α-synuclein in striatal compartments. The matrix contains higher DAergic inervation than the striosomes. We have hypothesized that METH binge will increase the immunoreactivity of phospho-Ser129-α-synuclein in striatal matrix compared to saline (SAL) treated controls. To test our hypothesis rats were treated with 4x7.5mg/kg METH-HCl, euthanized at 7 d after the binge, and examined for changes in immunoreactivity of phospho-Ser129-α-synuclein in the striatum. Co-immunostaining for TH and phospho-Ser129-α-synuclein revealed an increase in phospho-Ser129-α-synuclein immunoreactivity in TH+ axons in the matrix and striosomes. Phosphorylated α-synuclein appeared aggregated in TH+ axons of the matrix. Previous studies have found that approximately 90% of α-synuclein deposits found in Lewy bodies have been phosphorylated at Ser129. Consequently, our findings suggest that aggregated phospho-Ser129-α-synuclein mediates METH neurotoxicity and potentially also susceptibility of human METH users to develop PD later in life. Further examination of this biomarker in METH neurotoxicity is warranted to provide better understanding of the link between METH abuse and PD. Supported by by NIH/NIDA R01 DA034783. Title: Acute d-amphetamine unmasks the effects of adolescent methylmercury exposure on delay discounting in mice

Authors: ***S. BOOMHOWER**, M. NEWLAND;
Auburn Univ., Auburn, AL

Abstract: The developing fetus is particularly vulnerable to the neurobehavioral effects of exposure to methylmercury (MeHg), an environmental neurotoxicant that bioaccumulates in fish, but the consequences of exposure during the adolescent period remain virtually unknown. The current experiments were designed to assess the effects of adolescent MeHg exposure on delay discounting (i.e., preference for small, immediate reinforcers over large, delayed ones) and sensitivity to amphetamine (a dopamine agonist) using a mouse model. Thirty-six male C57BL/6n mice were exposed to 0, 0.3, or 3.0 ppm mercury (as MeHg) via drinking water from postnatal day 21 to 59, the murine adolescent period. As adults, mice lever-pressed for a .01-cc droplet of milk delivered immediately and four .01-cc droplets delivered after a series of delays for 35 sessions. Then a dose-response determination of d-amphetamine (i.p.; 0.1 - 1.7 mg/kg) followed. Adolescent MeHg exposure impaired the acquisition of delay discounting relative to controls. d-Amphetamine increased preference for the larger-later reinforcer to a lesser extent in MeHg-exposed subjects compared to control mice. The current study is the first to demonstrate that adolescence is a period in which MeHg exposure may have long-lasting neurobehavioral consequences.

Title: Neuroaids on methamphetamine and cART: depletion of neuronal energy supplies

Authors: *A. B. SANCHEZ[1], G. P. VARANO[1], M. KINOMOTO[1], C. M. DE ROZIERES[1], R. MAUNG[1], I. C. CATALAN[1], C. C. DOWLING[1], N. E. SEJBUK[1], M. M. HOEFER[1], M. KAUL[1,2];
[1]Sanford-Burnham Med. Res. Inst., La Jolla, CA; [2]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: HIV-1 infection can cause neurological damage and lead to the development of HIV-associated neurocognitive disorders (HAND) despite advanced antiretroviral therapy (ART). In fact, accumulating evidence suggests that ART can itself exert neurotoxic effects. In addition, the use of recreational drugs, in particular methamphetamine (METH), in combination with HIV-1 infection seems to aggravate cognitive impairments and may compromise the efficacy of antiretroviral (ARV) drugs. The combined effect of recreational and therapeutic drugs and virus on the brain is poorly understood. In the present study, we exposed mixed neuronal-glial cerebrocortical cells to several ARVs and METH in the presence or absence of HIV-1 gp120 protein for 24 h and 7 days. First, we assessed neuronal injury and death in fixed cells using specific markers for neuronal dendrites (MAP-2) and pre-synaptic terminal (synaptophysin) in combination with nuclear DNA staining and fluorescence microscopy. When we analyzed the effect of cART compounds representing four different pharmacological categories (AZT, NVP, SQV and 118-D-24) in the presence or absence of gp120, none caused a significant neuronal injury in 24 h. However, after 7 days in the presence of gp120, only neuronal synapses were compromised, while MAP-2 positive dendrites were spared. We also analyzed potential cellular and neuronal toxicity using an ATPlite assay, a well established method used in large-scale drug screening for evaluation of cytotoxicity. The ATP assay similarly indicated that the occurrence

of cytotoxicity was context-specific for each of the drugs or combinations thereof. To recover from energetic stress, autophagy is generally activated in order to preserve the vital cellular functions. To address this hypothesis activation of AMPK, and processing of LC3 and p62 were assessed. Our results indicated that autophagy is induced during exposure of cerebrocortical cells to METH, ARVs and gp120 but fails to restore normal levels of cellular ATP. Altogether, our findings indicate that the overall positive effect of cART in HIV infection is accompanied by some neurotoxicity which is aggravated in the presence of abused drugs.

Title: Brain iron loading impairs dopaminergic function and promotes ADHD-like behavior

Authors: ***Q. YE**[1], J. CHANG[1], M. HAN[1], Y. LI[1], H. ALSULIMANI[1], A. V. MENON[1], R. DETH[2], J. KIM[1];
[1]Northeastern Univ., Boston, MA; [2]Nova Southeastern Univ., Fort Lauderdale-Davie, FL

Abstract: Mounting evidence has indicated that elevated levels of heavy metals, such as lead and mercury, alter epigenetic regulation and dopaminergic function and predispose to the development of mental illnesses, including attention deficit hyperactivity disorder (ADHD), schizophrenia and autism. While iron overload is associated with the progression of neurodegenerative diseases, the role of brain iron loading in psychiatric disorders is largely unexplored. To investigate the influence of brain iron loading on emotional behavior and redox-methylation status, the H67D HFE-mutant mice, a mouse model of brain iron loading, and their control wild-type mice (mixed background; 8-10 wk old) were tested in an open field for overall activity and elevated plus maze for anxiety/impulsivity behavior. Following behavioral testing, brain metal levels were determined by inductively coupled plasma mass spectrometry. Brain levels of thiol species, including glutathione (GSH and GSSG) and S-adenosylmethionine (SAM) and -homocysteine (SAH), were quantified by HPLC. Expression levels of dopamine-

associated proteins were determined by western blot analysis. H67D mutant mice displayed elevated brain iron levels by 20% ($p=0.001$) with normal levels of copper and zinc. H67D mice exhibited hyperactivity (67% increase, $p=0.007$), stereotypy (80%, $p<0.001$) and impulsivity-like behavior (70%, $p<0.001$) compared with age-matched wild-type mice. This ADHD-like behavior was unique to brain iron loading because animals with systemic iron overload, but with normal brain iron, did not show abnormal behaviors. H67D mice also down-regulated tyrosine hydroxylase by 26% ($p=0.008$) and dopamine D1 receptors by 22% ($p=0.043$) and up-regulated dopamine D2 receptors by 262% ($p=0.021$) in the brain. Brain dopamine levels were reduced by 24% ($p=0.025$). Moreover, in the H67D brain the levels of isoprostane, a marker of oxidative stress, were increased by 53% ($p=0.017$) and activity of mitochondrial superoxide dismutase, an essential anti-oxidant enzyme, was down-regulated by 15% ($p=0.026$). In addition, GSH/GSSG ratios were decreased by 38% ($p<0.001$) and SAH levels were increased by 13% ($p=0.015$). These results demonstrate decreased anti-oxidant reserves and reduced methylation capacity in brain iron loading and further suggest that iron accumulation in the brain could promote ADHD-related neurochemical and behavioral changes. Our findings also provide a molecular basis for treatment of metal-related psychiatric and affective disorders.

Title: Phenotype comparisons of ALDH1L1 BAC-TRAP mice under control and neurotoxic (MPTP) conditions

Authors: ***K. A. KELLY**, A. R. LOCKER, L. T. MICHALOVICZ, D. B. MILLER, J. P. O'CALLAGHAN;
CDC-NIOSH, Morgantown, WV

Abstract: A central problem in neurotoxicology is detecting selective and unpredictable damage to specific cells produced by toxic agents/mixtures. With few biomarkers of damage known, evaluating astrogliosis by measuring GFAP overcomes this problem as reactive astrocytes show

the location of toxicant-induced damage occurring anywhere in the CNS. Thus, determining specific *in vivo* transcriptomic profiles of astrocytes under control and reactive conditions will identify additional astrogliosis biomarkers. Heintz and Greengard (2008) introduced BAC-TRAP (translating ribosome affinity purification) technology that allows the characterization of the actively translating transcriptome of a particular cell type. Using multiple models of neurotoxicity we confirmed that ALDH1L1 is an astrocyte specific "housekeeping" gene/protein. Thus, ALDH1L1 BAC-TRAP (ALB-T) mice can be used to characterize the transcriptome of astrocytes under various conditions. Here, we characterize the phenotype of the 0, 1, and 2 copy ALB-T mouse (18 - 26 weeks old) and C57BL6/J (WT) mice, in both sexes, under control conditions and in response to neurotoxic damage using the well characterized dopaminergic neurotoxicant MPTP (12.5 mg/kg, s.c.) at 72 hrs post dosing. Brain, thymus, spleen, liver, kidney, adrenal gland, testes, uterus and ovaries were removed and weights recorded. Additionally, the olfactory bulbs, cerebellum, hypothalamus, hippocampus, striatum, cortex, midbrain, brain stem and pituitary brain regions were dissected and weights recorded. Striatum was analyzed for astrogliosis (GFAP), nerve terminal damage (tyrosine hydroxylase (TH) and dopamine (DA) and results indicate no basal differences in GFAP, TH, or DA in control 0, 1, or 2 copy ALB-T when compared to WT mice. Although ALB-T mice showed greater increases in GFAP protein after MPTP exposure when compared to WT the TH and DA decreases were less than those of WT mice. Striatal tissue obtained at 48 hrs post MPTP was subjected to TRAP to isolate actively translating RNA in astrocytes and changes in the transcriptome determined by microarray (Illumina) and the dataset interrogated with Ingenuity Pathway Analysis. MPTP induced robust transcriptome changes revealing genes both expected to change with astrogliosis and not previously attributed to astrocytes. Our data indicate that BAC-TRAP technology can be used to identify additional biomarkers of astrogliosis and will aid in characterizing various astrocyte phenotypes.

Title: Histopathological indices of rotenone-evoked dopaminergic toxicity: neuroprotective effects of acetyl-L-carnitine

Authors: *Z. K. BINIENDA, B. GOUGH, S. SARKAR;
Natl. Ctr. Toxicological Res/Food and Drug Adm., Jefferson, AR

Abstract: Exposure to the natural pesticide, rotenone, a potent mitochondrial toxin, leads to degeneration in striatal nerve terminals and nigral neurons. Rotenone-induced behavioral, neurochemical and neuropathological changes in rats mimic those observed in Parkinson's disease. Here, the protective effects of acetyl-L-carnitine (ALC) against dopaminergic toxicity after repeated exposures to rotenone were evaluated using immunolabeling methods. Adult male Sprague-Dawley rats were injected i.p. with rotenone alone (1 mg/kg) or rotenone with ALC either 10 or 100 mg/kg(ALC10, ALC100, respectively) once daily on days 1,3,5,8,10,12,15,17,19,22,24, 26,29,31,33, and 37. Control rats received either ALC at 100 mg/kg or vehicle (30% Solutol HS 15 in 0. 9% saline) injections. Animals were weighed on injection days and monitored daily. Rats were perfused after treatment with 4% paraformaldehyde and immunohistochemical analyses of tyrosine hydroxylase (TH) and the dopamine transporter (DAT) were performed in the caudate-putamen (CPu) and the substantia nigra pars compacta (SNc) in order to estimate loss of TH and transporter damage. Additionally, the effect of ALC on rotenone-induced microglial or astrocytic hypertrophy was also evaluated. It was found that ALC at 10 and 100 mg/kg prevented the loss of DAT and TH in the midbrain and also prevented the activation of both microglia and astroglia after rotenone treatment, thus, demonstrating the neuroprotective effects of ALC in rotenone-evoked dopaminergic neurotoxicity.

Title: Rotenone affects the nigral dopaminergic system more readily when the exposure occurs at prenatal and early postnatal life than when it occurs at gestation, lactation or adulthood

Authors: *M. GÓMEZ-CHAVARÍN[1,2], J. RAMIREZ SANTOS[3], P. PADILLA[4], G. PERERA-MARIN[6], G. GUTIERREZ-OSPINA[5];

Abstract: Parkinson´s disease (PD) may ensue following the exposure to herbicides, such as rotenone, throughout life. It is yet unclear whether rotenone affects equally/differently the developing and adult brain's dopaminergic system. Hence, in this work we compare the effects of rotenone upon the adult nigral dopaminergic neurons following gestational and/or early postnatal and adult exposure. Methods: The experiments were conducted in two and twelve months old male Wistar rats that were exposed to rotenone during gestation, lactation or both. Also, rotenone exposure occurred in twelve months old male rats. Serum samples were withdrawn to corroborate the presence of rotenone through high performance liquid chromatography. Dopaminergic neuron damaging was verified using tyrosine hydroxylase immunocytochemistry. The presence of Parkinsonian motor symptoms was evaluated through the use of the inclined beam before animal sacrifice. Results: In our experimental series rotenone exposure decreased the number of dopaminergic neurons regardless of the animal age when the exposure occurs. Nonetheless, the magnitude of the dopaminergic neuron loss was greater in rat groups exposed during gestation and lactation and directly correlated with rotenone serum concentrations. Motor impairment was always more evident in rats exposed to rotenone during gestation and lactation. Conclusion: Our results support that rotenone exposure during prenatal and early postnatal development is much more harmful for the nigral dopaminergic system than the exposure occurring at gestation, lactation or adulthood alone.

Title: Mitophagy alleviated CPF induced neurotoxicity in SH-SY5Y cells by PINK1/Parkin pathway

Authors: *J. ZHANG[1], H. DAI[2], L. ZHAO[2];
[1]Dept. of Neurol., Hunan, China; [2]Paediatrics, Third Xiangya Hosp., Changsha, China

Abstract: A growth body of evidence suggests that the pesticides are associated with the neurological disorders. Organophosphate chlorpyrifos (CPF) is the widely used pesticide throughout the world. Mitochondrial damage was reported to play a key role in CPF-induced neurotoxicity. Mitophagy, the selective autophagic elimination of mitochondria, is an important mitochondrial quality control mechanism. In order to explore the CPF-caused mitochondrial damage and the effect of mitophagy on CPF-induced neuroapoptosis, we examined the PTEN-induced putative kinase 1 (PINK1)/Parkin-mediated mitophagy and the casepase-3 related apoptosis by using dopaminergic SH-SY5Y cells. SH-SY5Y cells were treated with five different concentrations (12.5μM, 25μM, 50μM, 100μM, 200μM) of CPF for 6, 12, 24 or 48 h. Microscopic observations and cell counting kit-8 (CCK-8) assay were used to evaluate the morphological changes and cell viability respectively. Mitochondrial morphology was determined by immunofluorescence staining with an antibody against mitochondrial protein TIM23. The conversion of non-fluorescent chloromethyl-DCFDA to fluorescent DCF was used to monitor intracellular reactive oxygen species (ROS) production according to the instruction. Fluorescent microscopy was used to examine the colocalization between mitochondria and autophagosome. microtubule-associated protein1 light chain 3 (LC3)-GFP and mito-Dsred were used to label autophagosome and mitochondria, respectively. SH-SY5Y cells were transfected with Parkin-GFP plasmids and mito-DsRed plasmids to determine whether CPF treatment caused the accumulation of Parkin on mitochondria in SH-SY5Y cells. The effects of Parkin-knock down and overexpression on CPF-induced apoptosis were both examined. We found that CPF treatment caused mitochondrial fragmentation, excessive ROS generation and mitochondrial depolarization; these further inhibited cell viability and increased casepase-3 related apoptosis. CPF treatment also dramatically induced colocalizaton of mitochondria and LC3, decreased the level of mitochondrial protein, and promoted Parkin accumulation and PINK1 stabilization, these indicate PINK1/Parkin-mediated mitophagy. Furthermore, Parkin knock down dramatically increased CPF-induced neuroapoptosis. Instead, overexpression of Parkin markedly alleviated CPF-induced neuroapoptosis. Our study demonstrated for the first time, that PINK1/Parkin-mediated mitophagy may play a protective role against CPF-induced neuroapoptosis and enhancing mitophagy may be a useful therapeutic strategy for treating CPF-induced neurological disorders.

Title: Investigating *in vitro* neurotoxicity of antiretroviral agents

Authors: *V. T. CIAVATTA[1,4], C. CRON[5], S. TENG[6], W. R. TYOR[2,7], P. GARCIA[3,5]; [2]Neurol., [3]Anesthesiol., [1]Dept. of Veteran Affairs, Decatur, GA; [4]Ophthalmology, [5]Anesthesiol., [7]Neurol., [6]Emory Univ., Atlanta, GA

Abstract: Introduction: HIV neurocognitive disorders (HAND) affect approximately 50% of HIV patients that receive antiretroviral agents (ARVs). Studies of HIV patients taking ARVs showed measurable neurocognitive improvements when ARVs were temporarily discontinued. Such studies suggest ARVs may contribute to HAND. Additionally, studies of the effects of ARVs on mixed neuron/glia cultures showed most agents tested decrease neuron density at concentrations lower than therapeutic plasma concentrations as judged by the neuron-specific microtubule associated protein 2 (MAP2). Methods: Here we refine and extend the *in vitro* analysis of ARV effects on neurons by using mature (DIV 16), glia-reduced, primary rat cortical neuron cultures. We assessed the effects of increasing concentrations of commonly prescribed ARVs (amprenavir, AZT, dideoxyinosine, efavirenz, indinavir, lamivudine, stavudine, tenofovir) on neuron viability in high density (188K cells/cm^2) and morphology (dendrite length and extent of branching) in low density (6.4K cells/cm^2). Low density cells were suspended above a glia feeder layer. Viability (via Cell-Titer Blue, Promega, USA) and morphology (via MAP2 immunofluorescence) were assessed 24 hours after agent addition. Results: Cell viability assays showed efavirenz caused significant toxicity. Viability of 50% was reached at about 50 μM, and 0% viability occurred at 100 μM. Immunofluorescence imaging showed significantly lower total dendritic length compared to vehicle-treated cells for efavirenz (≥20 μM), dideoxyinosine (≥200 μM), and tenofovir (≥10 μM) ($p<0.05$, post-hoc Dunn's test). Conclusions: Total dendritic length was a more sensitive measure than cell viability for revealing differences between vehicle- and ARV-treated neurons. Whereas most ARVs tested did not alter neuron viability or morphology, some agents (efavirenz and tenofovir) significantly reduced dendritic length at concentrations within an order of magnitude of the therapeutic plasma concentration in HIV patients taking these agents. Additional studies of neurotoxic mechanisms of ARVs may be useful to optimally treat HIV patients with cognitive disorders.

Abstract: Ocimum gratissimum is an herbaceous perennial shrub which is widely distributed in many regions. It is consumed in food as seasoning locally in Nigeria. In the present study, the effect of the acute administration of the aqueous leaf extract of Ocimum gratissimum (AeOG) on prefrontal cortical neurons was checked to assess its neurotoxicity potential. Thirty adult male Wistar rats weighing between 190-210 g were divided into 5 groups (n=6). Group A (control) received 1 ml of normal saline (p.o), groups B-E received 100, 200, 300 and 400 mg/kg AeOG (p.o) respectively. Treatment lasted for fourteen days. Twenty-four hours after treatment, animals were sacrificed and their brains were removed. The prefrontal cortices neuronal morphology was studied using haematoxylin and eosin (H&E) stain; while activities of acid phosphatase (ACP) and alkaline phosphatase (ALP) were assayed in the cerebral homogenate. AeOG administration at doses 300 and 400 mg/kg cause neuronal fragmentation with significant ($P<0.05$) increases in the activities of cerebral ACP and ALP. Our findings show that the acute use of AeOG caused neuronal fragmentation which may leads to onset of neurodegenerative diseases and affect cognitive and executive functions of the prefrontal cortex.

Abstract: Xanthurenic acid (XA), a metabolite of tryptophan degradation is synthesized through 3-hydroxykynurenine transamination by kynurenines aminotransferases on both cytoplasm and mitochondria. The formation of XA is thought to be the main route to prevent the accumulation of the potential toxin 3-HK. However, some studies have shown that XA induces cell death and produces free radicals as a result of its interaction with metals. On the contrary, some reports show that XA acts as a scavenger and it is able to prevent the lipid peroxidation induced by iron. Dual action of this metabolite is important if we consider that can cross the blood brain barrier and that alteration of XA levels are related with some pathologies. The aim of this study was to investigate the effect of a single intrastriatal injection of XA on mitochondrial function, mitochondrial membrane potential, ROS production, circling behavior and cell death. First, we evaluated the effect of intrastriatal administration of XA (5-50 nmol) in rats, on cellular function, ROS production and mitochondrial membrane potential. Our results showed that after 5 days of XA administration, the mitochondrial membrane potential and MTT reduction were decreased while ROS production was not increased. Interestingly, circling behavior and cell death were increased on a concentration dependent- manner after five days of XA administration. Together, these data suggest that this kynurenine exerts toxic effects through different mechanisms including impairing cellular energetic metabolism, which can leads to cellular degeneration; this mechanism seems to be independent of its pro-oxidant ability.

Title: Acute and subchronic neuropharmacological, genotoxic, and mutagenic profiles of a Brazilian fruit compound, garcinielliptone FC, in mice

Authors: *J. N. PICADA, SR[1], V. R. COELHO[2], L. S. PRADO[1], C. G. VIEIRA[2], L. P. SOUZA[2], G. C. GONÇALVES[1], P. PFLUGER[2], M. T. C. VALLE[2], M. B. LEAL[2], E. DALLEGRAVE[3], A. B. F. FERRAZ[1], P. PEREIRA[2];
[1]Lutheran Univ. of Brazil, Canoas, Brazil; [2]Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil; [3]Univ. Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, Brazil

Abstract: The Amazon region is known to possess a great diversity of natural species, including fruit rich in vitamins and minerals. However, little is known about the biological properties of these species. Garcinielliptone FC (GFC) is a compound isolated from a fruit widely consumed as food in the North and Northeast of Brazil. This study evaluated pharmacological and toxicological effects of GFC, a polyisoprenylated benzophenone isolated from Platonia insignis Mart. fruits, by using behavioral models and genotoxic/mutagenic assays. The effects of GFC were evaluated in mice after acute and subchronic intraperitoneal (i.p.) treatments. The behavioral tests conducted were the motor activity, open field, tail suspension, and rotarod tests. The genotoxic effects were assessed using the comet assay and micronucleus test. The acute toxicity evaluation suggested an LD50 between 50 and 300 mg/kg. No impairment was observed in the rotarod test after subchronic treatment with GFC at all tested doses (2, 10, and 20 mg/kg). GFC did not affect locomotion in mice after acute treatment, and the latency to start locomotion, rearings, or crossings did not change compared to that in the control group, even after 28-day administration of the same doses. GFC did not affect the immobility time in the tail suspension task after both treatments protocols used, and did not show genotoxic effects on the blood and cerebral cortex. However, there was a significant increase in index and frequency of damage in the liver at 20 mg/kg. GFC did not increase the micronucleus frequency in bone marrow assessed using the micronucleus test. These results suggest that GFC had no effect on motivation, exploration, or locomotion at the doses tested, as well as antidepressant-like activity. DNA damage to liver tissue was observed at only the highest dose of GFC (20 mg/kg), suggesting hepatotoxicity at this dose but no mutagenic potential was observed.

Title: Potential adverse effects of sevoflurane on developing monkey brain: from abnormal lipid metabolism to neuronal damage

Authors: ***C. WANG**[1], F. LIU[1], S. W. RAINOSEK[2], J. L. FRISCH-DAIELLO[3], T. A. PATTERSON[1], M. G. PAULE[1], W. SLIKKER, Jr.[1], X. HAN[3];

Abstract: Sevoflurane is a volatile anesthetic that has been widely used in general anesthesia, yet its safety in pediatric use is of public concern. The present study sought to evaluate whether prolonged exposure of infant monkeys to a clinically-relevant concentration of sevoflurane is associated with any adverse effects on the developing brain. Infant monkeys were exposed to 2.5% sevoflurane for 9 hours, and frontal cortical tissues were harvested for DNA microarray, lipidomics, Luminex protein and histological assays. DNA microarray analysis showed that sevoflurane exposure resulted in 576 differentially expressed genes (DEGs) in the monkey brain. In general, these genes were associated with nervous system development, function, and neural cell viability. Notably, a number of DEGs were closely related to lipid metabolism. Lipidomic analysis demonstrated that critical lipid components, [e.g., phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylglycerol (PG)] were significantly down-regulated. Luminex protein analysis indicated abnormal levels of cytokines in sevoflurane-exposed brains. Consistently, Fluoro-Jade C staining revealed more degenerating neurons after sevoflurane exposure. These data demonstrate that a clinically-relevant exposure to sevoflurane is capable of inducing and maintaining an effective surgical plan of anesthesia in the developing nonhuman primate and that a prolonged exposure of 9 hours resulted in profound changes in gene expression, cytokine levels, lipid metabolism, and subsequently, neuronal damage. Generally,

sevoflurane-induced neuronal damage was also associated with changes in lipid content, composition, or both; and specific lipid changes could provide insights into the molecular mechanism(s) underlying anesthetic-induced neurotoxicity and be sensitive biomarkers for the early detection of anesthetic-induced neuronal damage.

Ctr. for Toxicological Res., Jefferson, AR; [5]Office of Translational Res., FDA's Ctr. for Drug Evaluation and Res., Silver Spring, MD

Abstract: To maximize the relevance of data generated in preclinical studies of general anesthetic-induced developmental neurotoxicity, the physiological status of the animal models employed must be maintained within normal ranges during experimental procedures. Depth of anesthesia should also be monitored when potential neuroprotective agents are used to insure that they do not diminish anesthetic efficacy. In addition, the identification of blood borne markers associated with anesthetic-induced neurotoxicity could prove valuable in providing easily obtainable metrics of adverse outcome(s). Physiological parameters were closely monitored during an 8-hour bout of sevoflurane- (2.5%) induced general anesthesia in postnatal day (PND) 5 or 6 rhesus monkeys. The depth of anesthesia was monitored using quantitative

electroencephalography (QEEG), and plasma samples collected during the exposure were analyzed for levels of several pro-inflammatory mediators. In addition, micro positron emission tomography (microPET) using the radiolabeled ligand [^{18}F]FEPPA, which binds to activated glial cells in the central nervous system (CNS), was performed one day following the exposure. Important physiological metrics (e.g., 02 saturation, blood glucose and pH, pCO2) observed in anesthetized monkeys (n = 8) were not significantly altered in comparison with those of control animals (n = 6). The co-administration of acetyl-L-carnitine (n = 7), which is postulated to be neuroprotective by stabilizing mitochondria, did not result in any significant change in the depth of anesthesia as indicated by QEEG. Increased production of two pro-inflammatory mediators (IL-6 and CCL-2) was detected in plasma near the end of the 8-hour sevoflurane exposure and enhanced uptake of [^{18}F]FEPPA was observed in the frontal cortical region the day following anesthesia, indicating reactive gliosis associated with presumed neurotoxic injury. The coincident presence of pro-inflammatory mediators in blood suggests that these markers may be used as indicators of anesthetic-induced developmental neurotoxicity. The data obtained here serve to demonstrate the usefulness of the nonhuman primate model in the evaluation of anesthetic-induced developmental neurotoxicity.

Title: Effects of manganese exposure on the dopaminergic system and antioxidant enzymes in Caenorhabditis elegans with mutations in AKT signaling pathway

Authors: *T. V. PERES[1], M. R. MIAH[1], L. ARANTES[2,1], R. B. LEAL[3], M. ASCHNER[1]; [1]Mol. Pharmacol., Albert Einstein Col. of Med., Bronx, NY; [2]Dept. de Bioquimica e Biologia Mol., Univ. Federal de Santa Maria, Santa Maria, Brazil; [3]Dept. de Bioquimica, Univ. Federal de Santa Catarina, Florianopolis, Brazil

Abstract: Environmental contamination by metals is a risk factor for public health and the central nervous system (CNS) is one of the targets of these toxic agents. Manganese (Mn) is an essential metal, but in excess it may cause a syndrome analogous to Parkinson's disease, called manganism. Mn accumulates preferentially in basal ganglia and may induce oxidative stress and interfere with signaling pathways. In the nematode worm *Caenorhabditis elegans,* the kinases AKT-1, AKT-2 and Serum- and glucocorticoid-inducible kinase (SGK-1) participate in the insulin/insulin-like growth factor signaling pathway (IIS). This signaling pathway regulates worm longevity, metabolism and the action of transcription factors SKN-1 (the worm homologue of Nrf-2) and DAF-16 (homologue of FOXO). To investigate signaling pathways involved in Mn toxicity, wild type (N2) and loss-of-function mutant (for proteins of the AKT signaling pathway) *C. elegans* were used. The worms were exposed to Mn for 1 h at the L1 larval stage using concentrations of 2.5 to 100 mM Mn. Strains with loss of function in *akt-1*, *akt-2* or *sgk-1* had higher resistance to Mn compared to N2 in a survival test. This resistance may be related to the antioxidant response. The N2 worms had decreased levels of glutathione (GSH) after exposure to Mn, which did not occur in AKT mutants. qRT-PCR studies showed that Mn exposure induced an increase in the expression of the gene encoding the SKN-1 transcription factor in *akt-2* mutants, and γ-glutamine cysteine synthetase (GCS-1) antioxidant enzyme in *akt-1* mutants. Notably, the expression of *sod-3* (homologue of superoxide dismutase, SOD) was increased in the *akt-1* mutant worms independent of Mn treatment. Dopaminergic function was evaluated with the basal slowing response behavioral test. Dopaminergic neurons integrity was evaluated using worms expressing green fluorescent protein (GFP) under the dopamine transporter (DAT1) promoter. However dopaminergic neurons showed analogous degeneration in N2 and mutant worms. These results suggest that AKT signaling pathway participates in Mn-induced toxicity in *C. elegans* due to its role in antagonizing the transcription factors SKN-1 and DAF-16, which are important for the production of antioxidant enzymes in the worms. However, this effect is not present in the dopaminergic neurons. This study demonstrates the importance of intracellular signaling pathways to the antioxidant response induced by Mn and establishes AKT as an important research focus for further understanding of the mechanisms of Mn-induced toxicity.

Title: Oxidative stress as a key event in malaoxon-induced neurotoxicity in primary cell cultures of cortical neurons

Authors: *D. K. VENSKE[1], A. A. DOS SANTOS[1], C. SUÑOL[2], M. FARINA[1];
[1]Biochem., Univ. Federal De Santa Catarina, Florianopolis, Brazil; [2]. Inst. d'Investigacions Biomèdiques de Barcelona, Consejo Superior de Investigaciones Científicas (IIBB-CSIC), IDIBAPS, CIBER Epidemiología y Salud Pública (CIBERESP),, Barcelona, Spain

Abstract: Aim: Organophosphates (OPs) comprise many of the most common agricultural and commercial pesticides used worldwide. The acute toxicity of OPs is primarily caused by the inhibition of acetylcholinesterase (AChE). However, there is now substantial evidence that exposure to levels that produce no explicit signs of acute toxicity has been associated with neurobehavioral and cognitive deficits. Nevertheless, molecular mechanisms related to this non-cholinergic neurotoxicity are not yet fully understood. This study aimed to investigate the molecular mechanisms of non-cholinergic neurotoxicity induced by exposure to malaoxon (Mx), the active metabolite of the pesticide Malathion, in an *in vitro* model of primary cell cultures of cortical neurons. Methods: Primary culture of cortical neurons were incubated with different concentrations of Mx (0.01 - 100 μM) and cell viability was determined at 24 and 48h or 6 days *in vitro* (DIV) by the MTT method. AChE enzyme activity was determined by the production of thiocholine from the hydrolysis of acetylthiocholine. General reactive oxygen species (ROS) were measured using the fluorescent probe 2', 7' diclorodiidrofluoresceína acetate (DCFH-DA). Superoxide anion production was determined by using fluorescent dye dihydroethidium (DHE) and mitochondrial membrane potential (MMP) by using the cell permeable fluorescent dyes rhodamine 123. Results: A significant decrease in cell viability was observed at 48 h after Mx treatment (concentrations of 1, 10 and 100 μM). However, a significant increase in pro-oxidative stress-related parameters was already observed in earlier times (1h). Pretreatment of the cells with the antioxidant ascorbic acid (200 μM) prevented the oxidative damage, likewise exhibited partial neuroprotective effects by preventing cell death induced by Mx. Mx treatment significantly decreased AChE activity after 24h of treatment. The incubation with Pralidoxime (600 μM), the oxime most used in the clinical, reversed this inhibition (at the Mx concentrations of 0.01 to 1 μM), but did not reverse the cell death induced by Mx. Conclusion: These results indicate the occurrence of oxidative stress in neuronal cortical cells soon after Mx exposure,

which seems to be critical for Mx-induced neurotoxicity. The present results also disconnect Mx-induced neurotoxicity from its classical anticholinesterasic effects.

Title: Potential neuroprotective effect of docosahexaenoic acid in rotenone-treated rats

Authors: ***N. SERRANO**[1], V. PÉREZ DE LA CRUZ[1], A. JIMÉNEZ-ANGUIANO[2], J. PEDRAZA-CHAVERRI[3];
[1]Natl. Inst. of Neurol. and Neurosurg., Mexico, City, Mexico; [2]Autonomous Metropolitan Univ., Mexico, City, Mexico; [3]Natl. Autonomous Univ. of Mexico, Mexico, City, Mexico

Abstract: Background: The causes of neuronal death in neurodegenerative diseases are currently unknown. However, it has been suggested that mitochondrial dysfunction can promote neuronal death and the symptoms of neurodegenerative diseases. Among the experimental models used, rotenone is one of the most widely used to inhibit respiratory chain's complex l. leading dopaminergic neuronal death resulting in a Parkinson disease-like. Furthermore, it has been reported that the essential polyunsaturated fatty acids (EPUFA) have important effects on the nervous system. In this regard, it has been shown that docosahexaenoic acid (DHA) has a neuroprotective effect on dopaminergic neurons. Also, in recent years, it has been shown that the EPUFA has an effect on mitochondrial biogenesis. Aim: The aim of this study was to evaluate the potential neuroprotective effect of DHA on mitochondrial dysfunction induced by rotenone in rat striatum and midbrain. Methods: Eighty male Wistar rats were assigned under the following conditions: pretreatment of DHA (35 mg/kg/day) for 7 days + rotenone for 8 and 14 days to analyze the exploratory activity, tyrosine hydroxylase (TH) enzyme and, in isolated mitochondria, complex l activity, respiratory control index, transmembrane potential and ATP synthesis capacity. Results: DHA did not attenuate the damage in the exploratory activity at 14 days of treatment with rotenone. In addition, at 8 days, DHA prevented damage of rotenone in the exploratory activity (40%), and attenuated both the histological damage and the decreased in the TH protein content induced by rotenone in striatum and midbrain. On the other hand, DHA was unable to attenuate the rotenone-induced mitochondrial dysfunction in striatum and midbrain Conclusion: DHA administration has a neuroprotective effect after 8 days of rotenone

treatment but this effect was not related to the attenuation of rotenone-induced mitochondrial alterations.

Title: Pathophysiology and experimental therapeutics of tetramethylenedisulfotetramine (tetramine) poisoning

Authors: *D. L. SPRIGGS, S. DEBUS, R. KREMPEL, J. SKOVIRA;
USAMRICD, Gunpowder, MD

Abstract: Tetramethylenedisulfotetramine (TETS) is a highly toxic cage-convulsant that has been banned from use as a pesticide worldwide. Despite this ban, accidental poisonings as well as intentional mass poisonings have been reported. The neurotoxic effects of TETS result from irreversible binding to GABAA receptors which blocks chloride ion influx and facilitate neuronal activation leading to seizures and convulsions. The mechanisms of TETS toxicity remain poorly understood and there is currently no adequate medical countermeasure to mitigate its effects. This study was designed to characterize cardiorespiratory and cortical changes throughout the course of TETS poisoning and evaluate potential therapeutic countermeasures. One week prior to experimentation guinea pigs were instrumented to monitor lead II electrocardiogram, electroencephalogram, and body temperature. A plethysmography chamber was used to measure respiratory rate, tidal volume and minute volume. Survival was assessed 24 hours post exposure. Following a 15 minute control recording, each animal received a single intraperitoneal 2LD50 dose of TETS. The first sign of poisoning was a drop in heart rate (from 281.9 ± 9.1 to 211.8 ± 10 beats per minute) within minutes of intoxication. All animals exhibited an initial brief period of cortical seizure activity and convulsions starting 5.2 ± 1.4 min post exposure which subsided spontaneously (1.2 ± 0.2 min duration). In control animals several periods of seizure activity or progression to status epilepticus occurred. The average time to death in control animals was 67.8 ± 23.6 min post TETS. In the treatment groups therapies were administered following the end of the initial seizure. Phenobarbital (PHB) therapy was compared to the commonly used benzodiazepine, Diazepam. A 37.5% survival rate at 24 hours was

observed following a single dose of PHB (100 mg/kg, ip). Diazepam (5 mg/kg, ip) produced marginally better results, with 50% survival at 24 hours. Neither therapy was completely effective in blocking seizure activity. In addition, both groups had periods of bradycardia, bradypnea and motor dysfunction, including dystonia, ataxia and convulsions. The addition of a muscarinic antagonist to PHB treatment increased 24 hour survival. Administration of the peripherally acting Atropine methyl nitrate (2 mg/kg, im) with PHB improved the 24 hour survival rate to 50%. Co-administration of centrally acting Atropine Sulfate (2 mg/kg, im) with PHB increased the 24 hour survival rate to 75% suggesting central antagonism of muscarinic receptor signaling is important to increasing survival following TETS poisoning.

Title: Dose and gender effects of chronic arsenic exposure in locomotor activity and lipid peroxidation in the dopaminergic system of C57BL/6 mice

Authors: R. CONTRERAS-LÓPEZ[1], M. DÍAZ-MUÑOZ[2], M. GIORDANO[1], *V. RODRIGUEZ CORDOVA[3];
[1]Dept. de Neurobiología Conductual y Congnitiva, [2]Dept. de Neurobiología Celular y Mol., [3]Inst. de Neurobiologia UNAM, Juriquilla, Mexico

Abstract: Arsenic is a highly toxic metalloid, chronic exposure through drinking water (DW) is associated with cancer of internal organs and nervous system dysfunctions. In animal models, As exposure causes alterations of dopaminergic markers and antioxidant response in the brain. Here, we assessed the effects of As exposure on spontaneous locomotor activity and lipid peroxidation in the nigrostriatal and mesolimbic dopaminergic systems in female and male mice. In order to answer our question, two-month old C57BL/6 male and female mice were daily exposed to 0.05, 0.5 or 50 mg As/L DW during for 6 months. Spontaneous locomotor activity was evaluated

monthly, and at the end of the treatment period thiobarbituric acid reactive species, and conjugated dienes were determined in striatum, nucleus accumbens and midbrain. We found that after four and six months of As exposure horizontal activity, and stereotypy number increased only in female mice exposed to 50 mg As/L. On the other hand, levels of conjugated dienes were higher in the nucleus accumbens and midbrain of male mice, and in nucleus accumbens of female mice exposed to 0.5 and 50 mg As/L in comparison to control animals; no alterations in TBARS levels were found. In conclusion, chronic arsenic exposure disrupts spontaneous locomotor activity and alters lipid peroxidation in a gender dependent manner in dopaminergic areas of the brain. We thank Soledad Mendoza, Hector and Dr. Olivia Vázquez Martínez for their technical assistance.

Title: Negative effects of a mixture of lead and aluminum on neurodevelopmental behavior in rats

Authors: *F. CHIGR[1], K. EL MANJA[2], H. MALQUI[2], N. OUASMI[2], M. NAJIMI[2];
[1]Biol., Sultan Moulay Slimane University, Fac. of Scien, Beni Mellal, Morocco; [2]Fac. of Sci. and Techniques, Beni Mellal, Morocco

Abstract: The developing central nervous system is particularly vulnerable to environmental toxicants such as heavy metals (HM). While acute and chronic poisoning of each metal has been extensively studied, the effects of joint exposures to these metals are poorly understood, even though this exposure scenario more accurately reflects the real world situation. HM exposure is not only a health concern for adults but has also been shown to exert deleterious effects on the health of the fetus, newborn and child. In this study, we have examined the effect of a mixture of low doses of lead (Pb): 0.05% and aluminum (Al): 0.12% diluted in drinking water on the growth and development in the rat. At postnatal day (PN) 0, all offspring were counted; weighed, and examined for external malformations. The following physical developments were noted: hair

appearance, incisor eruption, and bilateral eye opening. These parameters are useful indicators of rat fetal development. First of all, prenatal and postnatal exposure to Pb-Al significantly increased the body weights of pups compared to normal pups. Concerning behavioural tests, when Cliff avoidance is applied, latency to win the test was significantly higher in treated rats compared to control rats during all recordings, on postnatal days (PN) 7 and 9. Furthermore, latency to jumping in cage appeared higher in treated rats compared to control rats, but was not statistically significant. Similarly, choice cage test is not different between treated and controls. In conclusion, administration of HM to dams during the entire gestation period affects behavior and development in pups. The observed effects were a delay in opening eyes and incisor eruption as well as behavioral developments and an alteration in the rate of success behavior. The results suggest that HM even given in low doses have a significant effect on the development of behavioral patterns, orientation and motor coordination and function. They also suggest significant growth retardation. These results indicate clearly that the developing brain is especially vulnerable to HM and that vulnerability could have consequences that extend into adulthood.

Title: The effects of methyl parathion on the nigrostriatal system

Authors: J. BEAN[1], *K. R. SHEPHERD[2];
[1]Biol., Morehouse Col., Atlanta, GA; [2]Pharmacology/Toxicology, Morehouse Sch. of Med., Atlanta, GA

Abstract: Organophosphate pesticides (OPs) such as methyl parathion (MeP) are the most widely used insecticides in the world. Due to their widespread use, a large number of poisonings occur every year in occupationally-exposed human populations and in the general population through the consumption of contaminated food and drinking water. The oxon is the mediator of acute OPs toxicity due to its ability to inhibit acetylcholinesterase activity in the nervous system and neuromuscular junctions. Recent studies have revealed several other targets of Ops, such as MeP, that disturb noncholinergic biological systems. The current study was undertaken to determine the effects of MeP on the nigrostriatal system. In the first study, we prepared primary neuron-glia co-cultures from striatum (ST), and the substantia nigra (SN) of C57BL6 mouse pups to determine MeP induced neurotoxicity, MeP significantly induced reactive oxygen species (ROS) in SN and ST cultures at concentrations ranging from 0.1 μM-10 μM. The findings suggest that the MeP is a potent inducer of ROS. In the MTT assay (a determination of mitochondrial activity in living cells); there was no significant change after 72 hours under serum supplemented conditions. However, there was a significant decrease in MTT absorbance after 72 hours under serum-free conditions. Glutathione peroxidase (GPx) activity was significantly decreased only in SN cultures. As a result, the SN may have reduced capacity to remove ROS as demonstrated by the reduction in GPx activity and increased ROS in these cultures after MeP exposure. In the second study, 6 month old C57BL6 mice were treated with i.p. injections of MeP. There was a decrease in tyrosine hydroxylase immunoreactive neurons in the SN. In addition, there was a significant decrease in striatal dopamine by30.1%, dihydroxyphenyl acetic acid (DOPAC) by 28%, and homvanillic acid (HVA) by 44.5%. Collectively, the findings from these studies demonstrate that the SN and ST regions are vulnerable to the effects of MeP. This may have implications for MeP to alter nigrostriatal dopaminergic functioning similar to that observed in neurodegenerative diseases such as Parkinson's.

Title: Ultrastuctural changes in fetal mouse retina induced by two different doses of diazepam

Authors: *M. MARQUEZ-OROZCO, G. DE LA FUENTE-JUAREZ, A. MARQUEZ-OROZCO;
Univ. of Mexico (UNAM), Mexico, Mexico

Abstract: Our purpose was investigated if fetal retinal ultrastructure alterations of mice, are similar in a group (DZ1) which mothers (CD-1 strain mice) were injected with diazepam (DZ) (days 6 to 17) with daily doses of DZ (2.7 mg/kg/bw/sc), other (DZ 2) treated during same period with doses of DZ (1.0 mg/kg/bw/sc) that the DZ1 group. The control group received saline solution (S). A fourth group was not treated (NT). All females were euthanized with CO2 atmosphere the 16th day of gestation and the fetuses removed and perfused intracardiac with 1% paraformaldehyde their eye globes, were fixed with 2.5% glutaraldehido, were post fixed in OsO4 and embedded in epóxica resin. The semi fine sections were stained with toluidine blue and observed under comparative light microscope. The fine sections were contrasted with uranyl acetate and lead citrate and observed under a transmission microscope. In both DZ1 and DZ2 groups the neuroblastic layers and the photoreceptors show delay cellular differentiation. A greater nuclear density of the retinal cells was observed ($p<0.05$). The cells showing nuclei with heterochromatin atypically distributed. The outer nuclear layer presents rounded undifferentiated nuclei and numerous mitotic cells. The photoreceptors layer was very thin. The mitochondrion, the polyribosomes, the Golgi complex and the rough endoplasmic reticulum were more abundant in the photoreceptors from the DZ1 and DZ2 fetuses than in S an NT fetuses. The pigmentary epithelium of DZ1 and DZ2 was thickening, show disorganized microvilli and mitochondrion, abnormal accumulation of glycogen grains, vacuoles and abnormal phagosomes. S and NT groups exhibited neither ultrastructural difference in the outer nuclear layer of the retina and photoreceptors structure the appearance was normal. Such alterations could be attributed DZ inhibiting mitosis, actin and myosin synthesis and the modification of the metabolic pathways by central and peripheral type benzodiazepine receptors. Results show that the DZ administration from doses of 2.7 mg/kg/bw/sc or 1.0 mg/kg/bw/sc during gestation produces the seam type of ultrastructural changes in the fetal retina.

Title: Permanent histological and ultrastructural alterations of the mesencephalic structures in mice prenatally exposed to diazepam

Authors: *A. MARQUEZ-OROZCO, G. DE LA FUENTE-JUAREZ, M. C. MARQUEZ-OROZCO;
Univ. of Mexico (UNAM), Mexico 04510 DF, Mexico

Abstract: The present work was aimed at determining if prenatal exposition to diazepam (DZ) produces histological and ultrastructural alterations in the mesencephalic structure of adult mice. Two gestating CD-1 strain mice groups were injected daily sc from day 6 to 17. The first group (DZ) was treated with single daily DZ doses (2.7 mg/kg/bw) and the second group with saline solution (S). A third group was non-treated (NT). The offspring's were wet nursed by non-treated mice weaned and kept for 240 days. Animals of DZ, S and NT groups were deeply anesthetized, perfused with 10% formalin, the brain were removed, fixed, and embedded in paraffin. The histological sections were stained with Kluver-Barrrera stain for myelin and Bodian techniques. The histological sections were observed under comparative light photonic microscope. Other animals of DZ, S and NT groups were deeply anesthetized and perfused intra cardiac with 1% paraformaldehyde and mesencephalon fixed in 2.5% glutaraldehido, post-fixed in OsO4, and embedded in epoxy resin. The fine sections were contrasted with uranyl acetate and lead citrate and observed under a transmission microscope. In the red nucleus, the superior and inferior colliculi of DZ group was demonstrated the presence of small-sized neurons poor densely packed. The nuclei of the neurons were retracted and showed clumps of heterochromatin. The nucleoli were voluminous. The rough endoplasmic reticulum was frequently dilated and disorganized. The polyribosomes and Golgi complex were abundant. The neuropile were poorly differentiated, and were observed coarse, disoriented and few fibers with irregular myelin sheath. Non histological or ultrastructural differences were found between the S and NT groups. The alterations could be attributed to DZ induces modifications of metabolic pathways mediated by central and peripheral type benzodiazepine receptors. The permanent alterations also may be an epigenetic effect of the DZ because alter the RNA expression. The results show permanent histological and ultrastructural effects of prenatal exposure of DZ in the mesencephalon structures of mouse.

Title: Morphoquantitative evaluation of fibroelastic components in basilar and middle cerebral arteries of rats exposed to passive smoking

Authors: *R. N. ISAYAMA[1], E. ROBELLO[2], N. L. FROIO[2], C. A. FABREGA-CARVALHO[2]; [1]UNICASTELO, Fernandopolis, Brazil; [2]Morphology and Basic Pathology, Faculdade de Medicina de Jundiaí (FMJ), Jundiai, Brazil

Abstract: Basilar and middle cerebral arteries represent a significant bloodstream to the brain. Preview studies have shown that smoking habit can affect vascular wall components. Hence, smokers have more risk for cerebrovascular diseases, such as stroke, with stenosis or aneurysm of cerebral blood vessels. Even minor alterations in cerebral arteries may affect brain metabolism and function. Inflammatory response of the vascular wall is a vulnerable point of smoking, with increased cytokines, leucocytes and metalloproteinases that affect collagen synthesis in the adventitious layers of cerebral arteries. Nevertheless, these correlations have not been completely understood in models of passive smoke yet. This study analyzed fibroelastic components of the basilar and the middle cerebral arteries through stereology in a model of passive smoking in rats. The study was approved by the institutional committee of ethics. Male wistar rats with 6 weeks old each, were assigned to form a control group (CG; n=10) and a smoke group (SG; n=10). The latter was exposed to smoke of 20 cigarettes, distributed in 90 days of exposure, equivalent to 10mg tar, 0.8mg nicotine and 10mg carbon monoxide. Animal handling was standardized for both groups. Acrylic chambers were used to create a circulating cigarette smoke environment to the smokers, but no smoke to CG group. The specimens were anaesthetized, sacrificed, and the brains were dissected, frozen and sectioned in a cryostat. Picrossirius-red and hematoxylin-eosin were used for tissue staining, followed by quantification using Motic Images Plus® 2.0 and statistics. The results showed a significant decrease in collagen density in the adventitial tunic of rats exposed to passive smoke as compared to the control for the basilar (CG=59.54%±11.45 and SG=27.89%±7.91; $P<0.05$) and the middle cerebral (CG=55%±9.12 and SG=32.25%±8.35; $P<0.05$) arteries. The thickness of internal elastic lamella of basilar (GC=0.03±0.01/SG=0.01±0.00; $P<0.05$) and middle cerebral (CG= 0.021±0.004 and SG=0.010±0.002; $P<0.05$) arteries indicated a significant decrease in SG as compared to CG. It may be concluded that passive smoking can affect internal elastic lamella and the collagen of the adventitia in both the basilar and the middle cerebral arteries. These alterations corroborate the

effects of nicotine on cerebrovascular weakening associated with inflammatory conditions and degradation of metalloproteinases.

Title: Loss of DMT1 function is associated with elevated brain copper levels and ADHD-like behavior

Authors: ***M. HAN**, J. CHANG, J. KIM;
Northeastern Univ., Boston, MA

Abstract: Divalent metal transporter 1 (DMT1) is a major iron transporter required for intestinal iron absorption and erythropoiesis. Homozygous Belgrade (b/b) rats display microcytic anemia due to DMT1 mutation. While DMT1 can transport several other divalent metal nutrients, including manganese and zinc, hippocampus-specific DMT1 deficient mice demonstrated impaired prepulse inhibition and cognition, suggesting a novel role of DMT1 in brain metal metabolism and behavioral organizations. To characterize neurobehavioral and neurochemical phenotypes of DMT1 deficiency, b/b rats (12-wk old) and their littermate heterozygous (+/b) rats as controls were subject to elevated plus maze task. After euthanasia, brain tissues were collected to quantify metal levels by inductively coupled plasma mass spectrometry and to determine monoamine-associated protein levels by western blot analysis. In the elevated plus maze test, b/b rats spent more time in open arms (196% increase; $p<0.001$) and less time in closed arms (49% decrease; $p<0.001$) compared with controls, indicating reduced anxiety-like behavior in DMT1 deficiency. In addition, b/b rats entered open arms more frequently (93% increase; $p<0.001$) and traveled more distance in the maze (41% increase; $p=0.017$) than +/b controls. These results suggest increased impulsivity and hyperactivity. The ADHD-like behavior in b/b rats likely results from loss of DMT1 function rather than anemic effect because dietary iron-deficient rats

with normal DMT1 function demonstrated increased anxiety and hypoactivity. Western blot analysis showed up-regulation of dopamine D1 receptors (905% increase; p=0.012) and down-regulation of norepinephrine transporter (28% decrease; p=0.030), vesicular monoamine transporter (35% decrease; p=0.001) and catechol-O-methyl transferase (59% decrease; p=0.044), indicating altered monoaminergic function associated with DMT1 deficiency. Furthermore, metal analysis revealed that b/b rats display reduced brain iron levels, but elevated copper levels in most brain regions, including striatum, cortex and hippocampus. Quantitative PCR data showed that both copper importer Ctr1 (34%; p=0.019) and exporter Atp7a (38%; p=0.022) were up-regulated in the cortex from b/b rats, indicating that brain copper transport is enhanced in DMT1 deficiency. Since brain copper overload is associated with neurological and psychiatric symptoms, our results suggest that copper loading in DMT1 deficiency could impair dopamine metabolism and signaling and promote ADHD-like behavior.

Title: Consumption of fluoridated water leads to damage on the prefrontal cortex III layer of the rat

Authors: *P.-V. MARIA ISABEL;
Univ. De Guadalajara, Lagos De Moreno, Mexico

Abstract: Fluoride is a highly toxic substance. Dysfunction of the central nervous system has been considerate as a result of chronic fluorosis. It has been proposed that excessive accumulation of fluoride can exert toxic effects on many tissues and organs, resulting in serious damage and pathological changes. The prefrontal cortex (PFC) is vital region of the brain regulates thought in terms of both short-term and long-term decision making. It allows humans to plan ahead and create strategies, and also to adjust actions or reactions in changing situations. Additionally, the PFC helps to focus thoughts, which enables people to pay attention, learn, and concentrate on goals. This area is also the part of the brain that allows humans to consider several different yet related lines of thinking when learning or evaluating complex concepts or tasks. The effect of fluoridated water consumption on neuronal density and cell damage of III layer of rat PFC was evaluated. Three groups were formed: control (T), Experimental I (EI) and

Experimental II (EII). T and EII groups ingested water jug during pregnancy and lactation of pups until weaning (day 21 of postnatal age), the control group consumed water jug to 130 days, while the pups EII ingested fluoridated water to 4 ppm, from weaning to 130 days. The EI group was exposed to fluoridated water consumption to 4 ppm during the period of pregnancy, lactation and up to 130 days old. After which sacrificed, the brain was removed and PFC were dissected for analysis and counting III neuronal layer. In the case of animals administered fluoride in their drinking water, the increased levels of fluoride were detected in the plasma, in addition, less density and alterations in the forms of neurons were observated like a dark and picnotic cell. The exposure to F can disrupt the synthesis of neurotransmitters and receptors such as acetylcholine (ACh), Cholinergic neurotransmitter are necesary for learning and memory in animals and human. Cholinesterase activity have specific roles in the development of the nervous system such as regulation of neurite outgrowth, proliferation and differentiation of nerve cells. Another way, the exposure to F also produces neural dysplasia and other damage on the synthesis of proteins in the brain, leading to degenerative changes in neurons.

Abstract: Microtubule targeting agents (MTAs) are widely used as cancer chemotherapies. They prevent spindle formation and induce cell cycle arrest and apoptosis in rapidly dividing tumor cells. Systemic delivery of MTAs often leads to serious side effects, including chemotherapy-induced peripheral neuropathy (CIPN). CIPN symptoms range from numbness/tingling to severe

pain that can be treatment limiting and life threatening. The frequency, severity and reversibility of CIPN vary among different MTAs. As MTAs also vary in their mechanisms of microtubule binding and resulting mechanisms of action, we hypothesize that these different mechanisms underlie the variability seen in CIPN symptoms. To begin testing this hypothesis, we examined biochemical changes in microtubule composition, tubulin post-translational modifications and the levels of select microtubule associated proteins, all of which affect microtubule dynamics and microtubule action. We compared sciatic nerve tissue from mice treated with a Q2Dx3 schedule for 2 weeks at the maximum tolerated doses of paclitaxel or eribulin. Sciatic nerves were fixed, sectioned and immunostained with antibodies directed against α-tubulin, acetylated-tubulin and the microtubule (+) end binding proteins EB1 and EB3. Images were acquired by confocal microscopy and analyzed with Imaris software to quantitate drug-induced changes. Tissue from paclitaxel treated mice exhibited an ~1.9 fold increase in axonal α-tubulin signal, and an ~5 fold increase in acetylated tubulin signal, whereas eribulin treated mice surprisingly exhibited an ~2.5 fold increase in α-tubulin signal, an ~11.7 fold increase in acetylated tubulin signal and an ~2.2 fold increase in EB1 signal. The stronger molecular changes observed with eribulin treatment correlate with less severe axon degeneration in mice and fewer reported instances of severe peripheral neuropathy in humans. We conclude that the increased tubulin, acetylated tubulin and EB1 levels likely indicate increased levels of stable and growing microtubules that could be neuro-protective from toxic drug-induced effects. Subsequent biochemical characterizations in sciatic nerve DRG will provide additional insights into underlying mechanisms of CIPN.

Title: Selective regional targets of hydrogen sulfide poisoning in a mouse model

Authors: *W. RUMBEIHA[1], P. ANANTHARAM[2], B. MAHAMA[2], E. WHITLEY[3], A. KANTHASAMY[2];
[1]VDPAM, [2]Iowa State Univ., Ames, IA; [3]Pathogenesis LLC, Gainesville, FL

Abstract: Hydrogen sulfide (H_2S) is an interesting molecule because in physiologic concentrations it is a gasotransmitter and in toxic concentrations it is neurotoxic. It is endogenously present in the brain playing such essential roles as a neuromodulator, or as an antioxidant, among others. Although its neuronal physiologic mechanisms are not well known, H_2S is believed to effect its function partly through the NMDA type of glutamate receptor. In toxic concentrations, H_2S is believed to increase glutamate release leading to excitotoxicity and neuronal cell death. Currently, there is considerable interest in pharmacological donors of H_2S for therapeutic applications in human brain diseases. This potential therapeutic application of H_2S opens the possibility of H_2S-induced iatrogenic poisoning. The neurotoxicity of H_2S is not well defined, particularly at the molecular level. We have developed an inhalation mouse model of H_2S-induced neurotoxicity. Using this animal model we have demonstrated that H_2S

selectively induces neurodegeneration in the central inferior colliculus (CIC). Acute exposure to 310 ppm H_2S by inhalation for 15-40 minutes significantly increased the glutamate/GABA ratio in the central inferior colliculus. We have also established that H_2S significantly impairs ATP synthesis in the hippocampus. We postulate that the vulnerability of the CIC and the hippocampus are causal to behavioral changes such as motor incoordination and impaired learning and memory we observed following H_2S poisoning in our mouse model. Current ongoing work in our laboratory includes deciphering the molecular pathogenesis of the H_2S-induced neurodegeneration in the CIC. Broadly, this work will improve our understanding of the neurotoxic mechanisms of H_2S which are currently unknown. This knowledge has relevance in clinical settings. Understanding the toxic molecular mechanisms of H_2S-induced neurotoxicity will lead to identification of translational therapeutic targets of H_2S poisoning.

Title: LPA-induced peripheral itch sensation and cellular signaling involving LPA_5 receptor, phospholipase D and TRPA1/TRPV1

Authors: *H. KITTAKA[1], K. UCHIDA[1,2], N. FUKUTA[1], M. TOMINAGA[1,2];
[1]Div. of Cell Signaling, Okazaki Inst. for Integrative Biosci., Okazaki, Japan; [2]Physiological Sci., SOKENDAI (The Grad. Univ. for Advanced Studies), Okazaki, Japan

Abstract: The sensation of itch, called pruritus is defined as "an unpleasant cutaneous sensation provoking a desire to scratch". Many pruritogens that are itch-inducing substances have been revealed to activate receptors expressed in dorsal root ganglion (DRG) neurons that initiate itch signaling in the periphery to the central nervous system. Among them, lysophosphatidic acid (LPA) was found as a pruriogen involved in cholestatic itch. On the other hand, LPA was reported to induce acute pain. Therefore these reports have made it unclear whether LPA induces itch, pain or both in the periphery. We first observed behaviors of mice by a cheek injection method and it revealed that LPA caused itch-related scratching behaviors without increasing

pain-related wiping behaviors. In addition to the ambiguity of the LPA-induced mouse behaviors, not only the receptors expressed in DRG neurons involved in LPA action, but also the underlying molecular signaling induced by LPA in DRG neurons have been largely unknown. Therefore, we further examined those mechanisms caused by LPA using a Ca^{2+}-imaging method, a patch-clamp technique and a cheek injection method. LPA induced increases of cytosolic Ca^{2+} concentration in mouse DRG neurons. Itch-related scratching behaviors and Ca^{2+} responses caused by LPA were revealed to be mediated via activation of transient receptor potential ankyrin 1 (TRPA1) and vanilloid 1 (TRPV1) which are critically important for itch sensation. In addition, pharmacological approaches focusing on LPA receptors and intracellular phospholipases which are expressed in DRG neurons showed that LPA_5 receptor and downstream phospholipases D (PLD) play a crucial role in the LPA-induced Ca^{2+} signaling. We also found that LPA directly induces TRPA1 current from an intracellular side, but not an extracellular side and identified the interaction sites located close to transmembrane domains of TRPA1. This LPA action proposes a cell biological concept that *de novo* intracellular LPA production caused by extracellular LPA leads to activation of TRPA1. Moreover, the itch-related scratching behaviors induced by LPA were decreased by PLD inhibitor treatment, indicating that not only TRPA1 and TRPV1, but also PLD are involved in the LPA signaling *in vivo*. From these results, we concluded that LPA is a pruritogen to induce peripheral itch sensation through the signaling of LPA_5, PLD, TRPA1 and TRPV1 in DRG neurons. Our results provide the detailed LPA-induced itch signaling with the promising mechanism to comprehend cholestatic itch.

Title: Increased resurgent sodium currents in Nav1.8 contribute to nociceptive sensory neuron hyperexcitability in small fiber neuropathy

Authors: *Y. XIAO, C. BARBOSA, T. CUMMINS, R.;
Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: Small fiber neuropathy (SFN) frequently associated with neuropathic pain is a significant public health challenge. The underlying mechanisms remain poorly understood. Painful SFN may be caused by gain-of-function mutations in Nav1.8, a sodium channel subtype predominantly expressed in peripheral nociceptive neurons. We studied two mutations in Nav1.8 that impair fast inactivation; G1662S reported in painful SFN and T790A reported to cause sensory neuron hyperexcitability in the Possum mutant mouse line. Here we show that in dorsal root ganglion (DRG) neurons, these mutations significantly increase TTX-resistant resurgent sodium currents mediated by Nav1.8, which are atypical sodium currents evoked during the repolarization phase of action potentials. While the G1662S mutation exhibits a one-fold increase compared to wild type Nav1.8, the T790A mutation increases resurgent currents five-fold. We also show that the T790A mutant channels greatly enhance DRG neurons excitability by reducing current threshold and increasing firing frequency. Interestingly, the mutant channels endow DRG neurons with multiple early afterdepolarizations (EADs) at membrane potentials of -20 to -10 mV, leading to almost 20-fold prolongation of action potential duration. In L4-L5 DRG neurons, siRNA knockdown of sodium channel β4 subunits fails to significantly alter T790A current density, but reduces TTX-resistant resurgent currents by 56%. Accordingly, DRG neurons expressing T790A mutant channels exhibit reduced excitability with fewer EADs and shortened action potentials. These results suggest that increased TTX-resistant resurgent sodium currents mediated by Nav1.8 play important roles in EAD generation and action potential prolongation. We propose that increased TTX-resistant resurgent currents by gain-of-function mutations in Nav1.8 may underlie the hyperexcitability of nociceptive sensory neurons that contributes to altered sensory phenotypes, including neuropathic pain in SFN.

Title: A model for herpes zoster opthalmicus

Authors: *C. P. STINSON;
Texas A&M Baylor Col. of Dentistry-Biomedical S, Dallas, TX

Abstract Background: Herpes Zoster leads to post-herpetic neuralgia in twenty percent of patients causing chronic pain. In models where varicella is injected into the paw, the virus can induce a nociceptive response for over fifty days. Herpes zoster ophthalmicus occurs when the varicella-zoster virus is reactivated in the ophthalmic division of the trigeminal nerve and occurs in ten to twenty five percent of patients with herpes zoster. Currently, there are no orofacial models for herpes zoster although the disease commonly affects the facial region. Methods: In this study, MeWo cells infected with varicella virus (Poka strain) was injected into the whisker pad of adult male Sprague Dawley rats. The virus was left to incubate and the nociceptive response tested weekly for 8 weeks. The nociceptive response was tested using a thermal contact assay at 45 degrees and von Frey filament orofacial filament test (modified Ugo Basile test chamber). A place escape avoidance paradigm testing the facial region innervated by V2 was also utilized with these animals. Controls included injections of non-infected MeWo or vehicle. Results: A significant increase in mechanical hyperalgesia was observed with the von-Frey filaments and in the place escape avoidance paradigm after injection of virus versus controls. No significant increase in thermal hyperalgesia was measured in the virus injected animals. Conclusion: We conclude that injection of varicella leads to a significant increase in sensory and affective responses in the orofacial region. These results suggest that this varicella injection method can be used as an animal model for orofacial herpes zoster and herpes zoster opthalmicus.

Abstract: Migraine has been linked to cortical hyperexcitability. The aura of migraine is likely caused by cortical spreading depression (CSD), a slowly spreading wave of neuronal and glial depolarization. Familial hemiplegic migraine 1 (FHM1) mutant mice display enhanced glutamatergic neuronal excitability, as evidenced from cellular recordings, and increased CSD susceptibility in the visual cortex in anesthetized mice. It is unknown whether neuronal hyperexcitability is observed also at the cortical network level. Furthermore, it is not clear whether the enhanced CSD susceptibility in FHM1 mice is dependent on cortical location or time-of-day. In the present study, we performed continuous day-night DC-EEG and multi-unit activity recordings in visual and motor cortex from freely behaving FHM1 R192Q and wild-type (WT) mice. Parallel DC-recordings were performed under anesthesia to compare CSD susceptibility between the start of the light and dark period, as well as between visual and motor cortex. Under freely behaving conditions FHM1 mice displayed enhanced gamma (30-45 Hz) EEG power in both visual and the motor cortex throughout vigilance states, while delta (0.75-5 Hz) power was reduced in motor cortex during REM and non-REM sleep. In 4 out of 10 FHM1 mice, spontaneous CSD events occurred that were never observed in WT mice. CSD events occurred both during light and dark periods. For 9 out of 13 events, the start of CSD was observed first at the visual cortex while for 4 events CSD appeared simultaneously in visual and motor cortex. Under anesthesia, CSD frequency did not show a relation with time-of-day and was enhanced in FHM1 mice compared to WT in both visual and motor cortex. Taken together, the changes in EEG power and occurrence of spontaneous CSD events in FHM1 mutants is in line with increased cortical network excitability. This finding is consistent with enhanced CSD susceptibility in both visual and motor cortex. Cortical network changes and occurrence of spontaneous CSD events in FHM1 mice provide a unique opportunity to study the episodic nature of migraine attacks.

Kyushu Univ., Fukuoka, Japan; [4]Physiol., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Chronic itch is an intractable symptom of inflammatory skin diseases, such as atopic and contact dermatitis. Recent studies have revealed neuronal pathways selective for itch, but the mechanisms by which itch turns into a pathological chronic state are poorly understood. Using mouse models of atopic and contact dermatitis, we found that astrocytes are markedly activated in the dorsal horn of the spinal segments corresponding to the itchy skin, and remained reactive over a long period. We further found that STAT3 was selectively activated in dorsal astrocytes and that conditional disruption of astrocytic STAT3 activation prevented reactive astrocytes and chronic itch without affecting acute physiological itch. Pharmacological inhibition of spinal STAT3 alleviated fully developed chronic itch. Moreover, atopic dermatitis mice exhibited a striking enhancement of scratching evoked by intrathecal GRP, an itch-inducing neuropeptide, and this phenotype was normalized by suppressing astrocytic STAT3. Therefore, STAT3-mediated reactive astrocytes in the dorsal horn are necessary for chronic itch by inducing spinal sensitization of itch and thus may be a previously unrecognized target for treating chronic itch.

Title: Interleukin-1β decreases potassium conductance but does not alter the phenotype of medium sized dorsal root ganglion neurons

Authors: *M.-C. NOH[1,2], P. L. STEMKOWSKI[3], P. A. SMITH[2];
[2]Dept. of Pharmacol., [1]Univ. of Alberta, Edmonton, AB, Canada; [3]Dept. of Physiol. and Pharmacology, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: There is growing evidence that inflammatory cytokines play an important role in the onset of neuropathic pain. Interleukin 1β has been proposed as one of the important inflammatory cytokines that contributes to the onset of neuropathic pain as IL-1β knockout mice lack neuropathic pain phenotype following a nerve injury. The levels of IL-1β in primary afferents peak at 7d after the nerve injury, and this has been proposed to trigger an enduring alteration in neuronal phenotype that underlies chronic hyper-excitability in sensory nerves to initiate and maintain chronic neuropathic pain. We have shown previously that 5-6 d exposure of rat dorsal root ganglia (DRG) to 100pM IL-1β increases the excitability of medium-sized neurons. We have now found using whole-cell recording that this increased excitability reverts to control levels within 3-4d of cytokine removal. The effects of IL-1β were dominated by changes in K+ currents. Thus, the amplitudes of A-current, delayed rectifier and Ca2+ sensitive K+ currents were reduced by ~68%, ~64% and ~36% respectively. Effects of IL-1β on other cation currents were modest by comparison. Since the changes in cell excitability in the presence of IL-1β is reversible, it is unlikely that direct interaction of IL-1β with DRG neurons initiates an enduring phenotypic shift in their electrophysiological properties following nerve injury. Persistent increases in primary afferent excitability following nerve injury may instead depend on altered K+ channel function and on the continued presence of slightly elevated levels IL-1β and other cytokines.

Title: Small-animal neuroimaging analysis of the pain matrix in acute and chronic pain model rats

Authors: *Y. L. CUI[1], H. TOYODA[1,2], E. HAYASHINAKA[1], Y. WADA[1], Y. WATANABE[1]; [1]Imaging Application Group, RIKEN Ctr. for Life Sci. Technologies, Kobe, Japan; [2]Brain Function Imaging, Ctr. for Information and Neural Networks, Osaka, Japan

Abstract: Pain is an unpleasant subjective sensory and emotional experience associated with actual or potential tissue damage, and is usually modified by personal memories, emotion, and cognition. Increasing numbers of non-invasive neuroimaging studies in humans demonstrated that the nociceptive processing involves widely-distributed brain regions, including the somatosensory, insular, cingulate, and prefrontal cortices, and the thalamus. Recently, we have developed a small-animal neuroimaging method combining 2-deoxy-2-[18F]fluoro-D-glucose ([18F]FDG) PET imaging with statistical parametric mapping (SPM) analysis to evaluate regional brain activity in the rodent central nervous system. In order to investigate whether the nociceptive pathways in chronic pain overlap with physiological "pain matrix" or not, we analyzed the regional brain activity in a neuropathic pain model of rats produced by ligation of the L5/L6 spinal nerves and then compared with those in an acute noxious mechanical stimulus. In the chronic neuropathic pain model, the regional brain activity was significantly increased in the primary somatosensory cortex hind limb area, primary motor cortex, centrolateral thalamic nucleus, and posterior thalamic nucleus in response to mechanical stimuli to the affected hind paw. In contrast, the highest regional brain activity was observed in the posterior cingulate cortex in response to acute noxious mechanical stimuli, whereas no significant brain activity in the corresponding region was observed under chronic neuropathic pain condition. These results indicate that the nociceptive pathways in chronic neuropathic pain may be different from the physiological "pain matrix" associated with acute mechanical pain.

Title: Disrupted functional connectivity of the sensorimotor cortex in complex regional pain syndrome

Authors: *J. HOTTA[1,2,3], J. SAARI[1,2], N. FORSS[1,3], R. HARI[1];
[1]Brain Res. Unit, Dept. of Neurosci. and Biomed. Engin., [2]Aalto NeuroImaging, Aalto Univ., Espoo, Finland; [3]Clin. Neurosciences, Neurol., Univ. of Helsinki and Helsinki Univ. Hosp., Helsinki, Finland

Abstract: Objective Complex regional pain syndrome (CRPS) causes severe limb pain that movements increase. The sensorimotor skills are impaired not only in the painful limb, but CRPS also tends to affect the functions of the contralateral non-painful limb. Sensorimotor cortex of CRPS patients functions abnormally during movements and somatosensory stimulation, but less is known of its functions during rest. In resting state, healthy brains display multiple networks that are characterized by synchronized low-frequency activity in functional magnetic resonance imaging (fMRI). One such network covers the sensorimotor cortices of both hemispheres. In healthy subjects, experimentally-induced sustained pain disconnects the sensorimotor cortex of the painful body part from the resting-state sensorimotor network and engages it with anterior insula. We thus explored the disruptions in the functional connectivity of sensorimotor cortex in CRPS. **Methods** We recorded 3-T fMRI from 12 female CRPS patients who had suffered from right upper-limb pain for 1.4−15.5 years and from 18 healthy female control subjects. Subjects were instructed to rest still and keep their eyes open. Those showing signs of somnolence in online eye-camera monitoring were excluded from the analysis. For the alert subjects (eight patients and fifteen control subjects) we computed seed-based functional connectivity of left- and right-hemisphere hand sensorimotor areas on the basis of fMRI data. **Results** In healthy subjects, the functional connectivity map of each hand area included the whole rolandic sensorimotor cortex of both hemispheres. In patients, the connectivity of the left-hemisphere hand area (corresponding to the painful hand) was statistically significantly decreased, in both hemispheres, with the rolandic cortex medial to the hand areas but increased with the ipsilateral inferior parietal lobule. The right-hemisphere hand area (corresponding to the non-painful hand) displayed similar abnormalities, but its connectivity was strengthened−the more the longer the disease had lasted−with the left and right anterior insulae and the right secondary somatosensory

cortex. **Conclusions** In CRPS patients, suffering from unilateral pain, the resting-state sensorimotor network was altered in both hemispheres, likely reflecting the influence of the continuous pain on brain connectivity.

Title: The comparison and new findings of invasive and non-invasive neuromodulation methods

Authors: *R. ROKYTA[1], J. FRICOVA[2];
[1]3rd Fac Med. Charles Univ. Prague, Prague 120 00, Czech Republic; [2]Pain Mgmt., Charles Univ. in Prague, First Fac. of Med., Prague, Czech Republic

Abstract: We are comparing the invasive and non-invasive neuromodulation methods which are used for the treatment of chronic pain.As concern of invasive method we shall compare the peripheral nerve stimulation (PNS), spinal cord stimulation (SCS), deep brain stimulation (DBS) and motor cortex stimulation (MSC).From non-invasive methods we are focused on TENS (trancutaneous nerve stimulation),tDCS (transcranial direct current stimulation),TES (trancranial electric stimulation) and rTMS (repetitive transcranial magnetic stimulation). About novel approaches of transcranial electric stimulation (TACS, TRNS, TRNS) is not known too much. In transcranial alternating current stimulation (TACS) an oscillatory electric current is delivered to the cortical tissue with oscillation frequency between 0.1-5000 Hz. Repetitive TMS (rTMS) has been developed as a diagnostic tool as well. It was observed that the magnetic pulses have a long term neuromodulation effect. This lead to a development of more powerful TMS generators capable of delivery of multiple pulses within short time _ the rTMS. rTMS as a clinical tool is a very gentle, non-invasive method and the demonstration of the success of this treatment is a major step to non-invasive methods of pain therapy. According to recent studies (Rokyta and Fricova 2014), this method is able to induce changes in the central nervous system at the cellular level including changes at ionic and metabolic level. Therapeutic effects rTMS was confirmed in the literature of psychiatric disorders such as depression, acute mania, bipolar disorder, panic attacks, hallucinations, obsessive states, schizophrenia, catatonia or post-traumatic stress disorder

(Rokyta and Fricova, 2012). In patients with Parkinson's disease, dystonia neurological stimulation was neurological stimulation was used as well as in patients with tics, stuttering, tinnitus, seizures or epilepsy, or functional disorders of aphasia after a stroke. rTMS showed prolonged therapeutic effect by reduction or elimination of chronic pain. More recent studies suggest (Fricova et al. 2013) the involvement of the peripheral and central nervous system as a possible mechanism in the pathophysiology of atypical odontalgia. Besides, the pain became a test for the application of electrical stimulation of the brain's motor cortex (MCS) and subsequently it was shown in some cases rTMS had prolonged therapeutic effect including reduction and sometimes even complete elimination of chronic pain. As a rTMS the similar comparison is used also for other above mentioned invasive and non-invasive neuromodulation methods.

Title: Differential modulation of default mode network (DMN) connectivity by self-administered acupressure in fatigued breast cancer survivors

Authors: ***J. HAMPSON**[1], E. ICHESCO[2], V. VERMA[2], B. D. WRIGHT[2], T. KHABIR[2], S. ZICK[2], R. E. HARRIS[2];
[1]Anesthesiol., UNIVERSITY OF MICHIGAN, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Introduction: Breast cancer (BC) survivors often present with a cluster of symptoms including persistent fatigue, pain, and depression. While the factors generating the cluster are currently unknown, central neurobiological dysfunction is thought to be involved. Recently we demonstrated that fatigued breast cancer survivors displayed increased functional connectivity of the Default Mode Network (DMN) to the frontal gyrus when compared to non-fatigued cancer controls. We also have shown that self-administered acupressure can alleviate symptoms of fatigue in breast cancer survivors. Here we sought to explore the neurobiological underpinnings of self-administered acupressure techniques on resting state network (RSN) connectivity in

breast cancer survivors. Methods: Nineteen BC survivors with persistent fatigue were randomized to receive either relaxation (RA: n=9) or stimulation (SA: n=10) acupressure over the course of 6 weeks. All participants underwent resting state fMRI at baseline and following treatment. Group independent component analysis was done using GIFT and validated using ICASSO software. SPM group level analysis was performed to compare change in RSN connectivity across each treatment group using a two-sample t-test. Change in clinical pain (BPI), depression (HADS) and fatigue (BFI) were individually correlated to change in RSN connectivity using within group covariate of interest analyses. A two-way ANOVA analysis was also performed to study interaction between brain connectivity between groups and clinical symptoms. Significant clusters were identified at thresholds $P<0.05$ FDR/FWE cluster correction. Results: Following treatment the DMN showed greater connectivity to the bilateral thalamus ($P=0.02$) in the SA group and increased connectivity to the periaqueductal gray ($P=0.005$ SVC) in the RA group. Within the RA group change in pain severity was positively correlated to change in connectivity between DMN and posterior cingulate ($P=0.01$) and mid-temporal gyrus ($P=0.05$). In contrast, a negative correlation was found between change in depression and DMN to perigenual cingulate connectivity ($P=0.05$) in the SA group. Two-way ANOVA analysis showed differential relationships between treatment groups: DMN to mid-temporal gyrus showed positive correlation to pain (r=0.87) for RA and negative relationship (r=-0.30) for SA ($P=0.04$). Conclusion: Our findings suggest that self-administered acupressure formulas have differential effects on symptoms in in BC survivors. These effects were associated with modulation in connectivity to the DMN. It is unclear if similar findings would also be observed in other cancer conditions.

Title: Human sensory neurons derived from iPS as a human *in vitro* model of peripheral pain

Authors: *E. GRAS LAVIGNE[1], D. BUTTIGIEG[2], L. L'HOMME[2], C. BADJA[3], M. OUAMER[2], R. STEINSCHNEIDER[2], F. MAGDINIER[3];

Abstract: Somatosensory disorders due to pathological causes (peripheral neuropathies), to spinal impairment or to injured peripheral nerves can generate a wide range of symptoms. Peripheral pain, one of the most prevalent symptoms, can be unbearable for patients. As the sensitivity of a specific receptor varies between species, a model based on human sensory neurons seems to be of interest. First, we aimed to influence/improve peripheral pain by the enhancement of peripheral nerves regeneration capacity. Some compounds by their positive trophic effect could positively influence the growth of sensory neurons and re-innervate skin by wound healing or injured nerves restoration. To discriminate compounds according to their trophic effect, we developed a relevant *in vitro* cellular model of peripheral pain based on human sensory neurons derived from human iPS cells. We first formed spheroids of neuron precursors to incubate them in the presence of compounds, previously trapped to each pole of the culture well. We validated our cellular model by using NGF as reference compound and demonstrated a preferential growth of neurites network toward NGF. We finally developed a monolayer culture of neuron precursors differentiated in sensory neurons in a 96 well plate model in order to screen compounds according to their trophic actions on the neurite length. The second studied parameter of peripheral pain was the resulting activation of mechanoreceptors and nociceptors. To separately study each sensory receptor, we used human sensory neurons cultured in 96 well cell plates. We characterized several sensory receptors by immunostaining. This model allowed us to carry out/implement several functional studies based on the ability of sensory neurons to release neurotransmitters after specific stimulations in order to screen compounds according to their capacity to decrease nociceptors activation. The technology of human fibroblast differentiation into human sensory neuron enabled to build in-vitro models of compounds screening with predictable results comparable to human in-vivo studies results and is of great interest for further studies.

Title: Function and dysfunction of Kv3.4 channels in DRG neurons: implications in pain signaling and peripheral pain sensitization induced by SCI

Authors: *T. MUQEEM[1], V. PINTO[2], M. COVARRUBIAS[1];
[1]Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]ICVS/3Bs, Univ. of Minho, Braga, Portugal

Abstract: Kv3.4 channels underlie a majority of the high-voltage activating K+ current in dorsal root ganglion (DRG) nociceptors, and are involved in the modulation of action potentials and spiking in the DRG. Additionally, Kv3.4 channel downregulation is implicated in neuropathic pain induced by spinal cord injury (SCI). It remains to be seen whether specific Kv3.4 channel manipulations can influence nociceptor excitability and pain signaling. Previous work also demonstrated that phosphorylation of the Kv3.4 N-terminal inactivation domain at multiple sites slows inactivation kinetics, and that mutations at these sites dramatically alter the Kv3.4 current profile. To investigate more directly the impact of the Kv3.4 channel on pain signaling, we have tested the functional expression of recombinant mutants in acutely dissociated DRG neurons. We introduced the mutants by nucleofection and used cell-attached patch-clamp electrophysiology to examine their functional expression. The results show that Kv3.4-S(8,9,15,21)A (phosphorylation-resistant) and Kv3.4-S(8,9,15,21)D (phospho-mimetic) induce robust currents larger than the endogenous currents from mock nucleofected neurons (5-fold and 6-fold, respectively). Whereas S(8,9,15,21)A currents exhibit a fast inactivating profile, the S(8,9,15,21)D mainly show slow or no inactivation. Therefore, these mutants will be useful tools to test the role of Kv3.4 channels in different "phosphorylation states" on the excitability of DRG neurons (*in vitro*) and pain signaling (*in vivo*). We are currently 1) creating AAV viruses to knock-down Kv3.4 and express mutants *in vivo*, and 2) implementing methodology to examine synaptic transmission in the dorsal horn.

Title: Intravenous injection of mesenchymal stem cells reversed morphine tolerance in mice

Authors: *J. CHENG, L. LIU, Z. HUA, H. WU;
Pain Mgmt. and Neurosciences, Cleveland Clin., Cleveland, OH

Abstract: Backgrounds: Opioid therapy is commonly used for the relief of moderate to severe pain, including cancer pain and various chronic pain conditions. However, chronic or repeated administration of opioids often results in the development of opioid tolerance and thus limits its efficacy and safety. **M**esenchymal **S**tem **C**ells (MSCs) are multipotent cells that possess powerful anti-inflammatory effects. One of the proposed mechanisms for opioid tolerance is that opioids such as morphine can directly activate microglia and cause release of proinflammatory cytokines. We have demonstrated that intrathecal transplantation of MSCs significantly attenuated opioid tolerance induced by daily morphine injections. In this study, we tested if intravenous administration of MSCs can reduce opioid tolerance induced by daily morphine injections in mice. **Methods:** With IACUC approval, mice were treated with morphine (10mg/kg, s.c.) or normal saline once a day for 14 days. A single intravenous injection of MSCs derived from rat bone marrow was administered on day 15. Opioid tolerance was assessed by the difference in latencies of tail flick measured before and 30 minutes after morphine injections for 13 days. A large difference indicates low tolerance and a small difference indicates high tolerance. **Results**: Consistent reduction of tail flick latency was observed with repeated morphine injections, compared to the pre-injection control. This is consistent with the concept of opioid-induced hyperalgesia. Opioid tolerance developed in Day 8 of daily morphine injections in both male and female mice in control group, as reflected by the reduced differences in tail flick latencies measured before and after the morphine injection. Intravenous injection of MSCs significantly reversed this effect of repeated morphine injections in both male and female mice. Opioid-induced hyperalgesia was also attenuated, but only in male mice. There was no difference in body weight between the transplantation and control groups. **Conclusions**: Our observations suggest that intravenous injection of MSCs is a promising therapy to treat morphine-induced opioid tolerance. There may be a gender difference in responsiveness to MSCs therapy, which need to be further investigated. The cellular and molecular basis of MSC therapy is being actively studied in our lab.

Title: The effect of visual information produced by modified mirror therapy in patients with phantom limb pain

Authors: *A. SAKAMOTO, D. SUGIYAMA, M. KAWAMATA;
Anesthesiol. and resuscitology, Shinshu Univ. /school of Med., Matsumoto, Japan

Abstract: Introduction We administered mirror therapy to patients with phantom limb pain. Although the therapeutic principle of this therapy remains to be elucidated, it is hypothesized that mirror therapy enables patients to obtain the sensation of being able to move their phantom limb voluntarily and reduces their pain. To help patients better image the mirror limb, we established a new method “modified mirror therapy (mMT)”, wherein, we recorded a video of the movement of the patient's unaffected limb and reversed the image and corresponded it to the phantom limb. In this study, we evaluated the effect of mMT in healthy volunteers and patients with phantom limb pain by investigating the function of primary motor cortex using functional near-infrared spectroscopy (fNIRS). Method All experimental protocols were approved by the ethics committee. Study 1: Three healthy volunteers were enrolled. We recorded videos of their right hand movement (grasped and opened) and evaluated the activity of the brain cortex during this movement by analyzing changes in oxygenated hemoglobin (oxyHb) levels by using fNIRS (FOIRE3000: Shimadzu). The channels covered the left and right primary motor cortex across the central zone. For fNIRS examination, movements were recorded for 10 s. The volunteers performed the following movements: 1. Movement of the right hand 2. Imaginary movement while watching the video Study 2: Six patients with phantom limb pain were enrolled. The patients performed the following movements: 1. Imaginary movement of the phantom limb 2. The mMT: Imaginary movement of the phantom limb while watching the reversed video of their unaffected limb 3. Imaginary movement of the phantom limb without the video after mMT for 10 min Result Study 1: A marked increase in oxyHb was mainly confined to primary motor cortex corresponding to the right arm during movement. While watching the video of right hand movement, a marked increase in oxyHb was also mainly confined to the primary motor cortex. Study 2: Imaginary movement of the phantom limb increased oxyHb over a wide area, including the primary motor cortex. mMT increased oxyHb in the primary motor cortex region corresponding to the phantom limb. An increase in oxyHb became confined to the primary motor cortex during imaginary movement of the phantom limb without the video after performing mMT for 10 min. The phantom limb pain reduced or disappeared within 1 month of repeated mirror therapy in all patients. Conclusion We were able to evaluate the influence of visual information in the primary motor area by using fNIRS. mMT may lead to functional reorganization of the primary motor cortex in patients with phantom limb pain.

Title: Phosphodiesterases as targets for the treatment of neuropathic pain

Authors: ***I. YALCIN-CHRISTMANN**, S. MEGAT, V. LELIEVRE, A. LACAUD, E. WALTISPERGER, R. SCHLICHTER, M.-J. FREUND MERCIER, S. HUGEL, M. BARROT; CNRS-DR10 INCI UPR3212, Strasbourg cedex, France

Abstract: Antidepressants are a first-line treatment against neuropathic pain. Noradrenaline recruited by their action on reuptake transporters has been proposed to act through beta2-adrenoceptors (beta2-ARs) to lead to the antiallodynic effect. However, the precise downstream mechanism remains to be identified. It is well known that beta2-AR stimulation increases cyclic adenosine-monophosphate production, which is controlled by phosphodiesterase (PDEs). The aim of the present study was to study therapeutic potential of PDE inhibitors (PDEi) and further identify underlying mechanisms by using a neuropathic pain model in mice. Neuropathy was induced by implanting a unilateral cuff around the main branch of the sciatic nerve of C57BL/6J mice. This procedure induces unilateral sustained mechanical allodynia, measured with von Frey filaments. By using pharmacological approaches, we showed that the PDE4i could alleviate mechanical allodynia after chronic treatment. Indeed, PDE4 inhibition decreased expression of Tumor necrosis factor (TNF)alpha in dorsal root ganglia of neuropathic animals and this antiallodynic mechanism also depends on the recruitment of delta opioid receptors. We also showed that the action of a PDE4i is dose dependent since these drugs activate glial cells at low doses and neurons at high doses. In conclusion, our results show the therapeutic potential of PDE inhibitors in the treatment of neuropathic pain.

Title: Bortezomib-induced peripheral neuropathy: clinical data and nerve fiber density measurements in skin biopsies

Authors: M. BECHAKRA, *J. L. JONGEN;
Erasmus MC, Rotterdam, Netherlands

Abstract: Bortezomib-induced peripheral neuropathy (BiPN) is a frequent and disabling complication in patients treated for hematological malignancies. Early recognition is of utmost importance, to prevent irreversible neurological damage and persistent pain. This is the first study that systematically evaluates clinical data and nerve fiber densities in lower leg skin biopsies of 22 patients. Symptoms and signs from the neurological examination, Sensory Sum-Score (SSS), Common Toxicity Criteria of Adverse Events (CTCAE), orthostatic hypotension, Numerical Rating Scale (NRS) of pain intensity, McGill Pain Questionnaire (MPQ) and Neuropathic Pain Scale (NPS) were recorded in these patients. Also, intraepidermal nerve fiber densities (IENFD) of PGP9.5-labeled nerve fibers were determined and compared with age-matched healthy controls. Finally, correlations between pain scores and IENFD were studied. Mean±SD SSS and CTCAE for sensory neuropathy and/or pain in our patients were 6.8±3.2 and 1.18±1.0 respectively, indicating light-moderate sensory neuropathy. Orthostatic hypotension and pain intensity >4 were present in 62% and 77% of the patients, indicating small nerve fiber involvement in the majority of cases. Mean±SD pain intensity NRS and overall MPQ were 5.4±0.7 and 21.0±9.7 respectively, indicating moderate neuropathic pain. IENFDs however, were not statistically significantly different from healthy volunteers (5.5±2.0/mm and 5.7±2.3/mm respectively). Although a statistically significant correlation between the worst pain ($r=0.46$; $p<0.05$) and deep pain ($r=0.44$; $p<0.05$) items of the MPQ and NPS respectively was found, the correlation between the other MPQ and NPS items, pain intensity NRS, overall MPQ and IENFD was not statistically significant. We conclude that BiPN is a sensory neuropathy with substantial small nerve fiber involvement. The finding that IENFDs in BiPN patients were not statistically significantly different from healthy volunteers may indicate relatively mild BiPN in

our cohort. The finding that no correlation between pain intensity NRS, overall MPQ and IENFD was found may also reflect relatively mild BiPN in our cohort or that neuropathic pain is driven by selective degeneration of only a subset of intraepidermal nerve fibers.

Title: 5β- reduced neurosteroid enhances recovery and reduces hyperalgesia in a rodent model of postoperative pain

Authors: *S. JOKSIMOVIC[1], D. F. COVEY[2], K. KRISHNAN[2], V. JEVTOVIC-TODOROVIC[1], S. M. TODOROVIC[1];
[1]Anesthesiol., Univ. of Virginia/Old Med. Sch., Charlottesville, VA; [2]Washington Univ. Sch. Med., St.Louis, MO

Abstract: **Introduction** Neuroactive steroids are potent modulators of neuronal activity in the peripheral and central nervous system causing anesthetic, analgesic and anticonvulsant effects. It has been shown that synthetic 5β-reduced steroid analogues exhibit a potent local analgesic effect *in vivo*. The aim of our study was to investigate spinal and local analgesic potency of 3β-OH ((3β,5β,17β)-3-hydroxyandrostane-17-carbonitrile), a 5β-reduced steroid, in a model of acute postoperative pain in rats. **Methods** To assess antinociceptive efficacy in an acute postoperative pain model using deep tissue incision, thermal stimulation of the plantar surface of Sprague Dawley rat hind paws was performed and paw withdrawal latency (PWL) was measured. ***Results*** We have found that intrathecal injection of 3β- OH induced dose- dependent thermal antinociception in naïve rats in comparison to the vehicle- injected group with maximal effect 60 minutes after injection (maximal dose 16 μg per 50 μl, n=8- 11). Single intrathecal application of the highest effective dose from previous experiments (16 μg) injected after incision produced significant acute antihyperalgesic effect 24 and 48 h post- surgery comparing to vehicle group

(n=6- 13, measured during 180 minutes). Similarly, repeated i.t. application of the same dose in the same timeframes in a time- dependent manner increased PWLs of incised paw 24 and 48 h post- surgery, but not 2 h post- surgery (n=6- 13, measured during 180 minutes). Single intraplantar application (16 or 48 μg per paw) of 3β- OH in incised paw did not exert acute antihyperalgesia in thermal nociception (measured 60 minutes post-injection). However it had a long- lasting antihyperalgesic effect as evidenced by increased baseline PWLs measured daily during post- operative days 1, 2 and 3, in comparison to the vehicle group (n=6). Repeated intraplantar application 2, 24 and 48 h after surgery significantly increased baseline PWLs of the incised paw during 1- 5 days of post- incision follow up, in comparison to vehicle- injected group (dose 16 μg per paw, n=6-8). ***Conclusion*** These results suggest that 3β- OH could be used spinally to reduce thermal nociception in healthy rats. Similarly, post-surgical single or repeated spinal application could alleviate thermal nociception after surgery. Furthermore, even though single intraplantar application did not produce acute antinociceptive effect in incised animals, it did increase the baseline PWL during follow up period of 3 days. As a similar effect was noticed after repeated intraplantar application, these data indicate that local peripheral application of 3β-OH could decrease recovery time after surgery in rats.

Title: Activation of protein kinase B mediates pain related responses induced by the bone metastases of breast cancer cells

Authors: *F. JIANG[1], G. DING[2];
[1]Xinhua Hosp. Affiliated To Shanghai Jiao Tong U, Shanghai, China; [2]Translational Inst. for Cancer Pain, Xinhua Hosp. Affiliated To Shanghai Jiao Tong Univ., Shanghai, China

Abstract: The Protein kinase B, also called Akt, is known to regulate cell proliferation and growth by controlling protein translation. Recently, it has been shown that Akt signaling pathway is involved in long-term synaptic plasticity. However, the role of Akt under different pain conditions, especially in cancer pain, is less clear. In this study, the dynamic activation of Akt in dorsal root ganglia (DRG) which contributes to pain responses induced by bone metastases of breast-cancer cell was investigated. In this study, the left tibia metastases of breast-cancer cell line Wlker-256 was found to induce time-dependent thermal and mechanical hyperalgesia. Simultaneously, the activation of Akt, as well as its downstream molecule mammalian target of rapamycin (mTOR), was found in rat ipsilateral L5-L6 DRG neurons, which started from day 7 and peaked at day 21 after the cancer cell implanted. In addition, intrathecal (i.t.) injection of GSK690693, a pan inhibitor of Akt, was observed to reduce pain related behavioral responses. Thus, these results indicate that Akt signaling pathway is involved in the hypersensitivity induced by bone metastases of breast-cancer.

Title: Altered resting state connectivity in individuals with fibromyalgia following an acute pain stimulus

Authors: *E. ICHESCO[1], T. PUIU[2], J. P. HAMPSON[2], A. E. KAIRYS[3], D. J. CLAUW[2], S. E. HARTE[2], S. J. PELTIER[2], R. E. HARRIS[2], T. SCHMIDT-WILCKE[4];
[1]Chronic Pain and Fatigue Res. Ctr. - Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI; [3]Univ. of Colorado, Denver, CO; [4]Bergmannsheil Ruhr Univ., Bochum, Germany

Abstract: INTRODUCTION: Fibromyalgia (FM) is a chronic widespread pain condition, with patients commonly reporting other symptoms such as sleep difficulties, memory complaints, and fatigue. The use of magnetic resonance imaging (MRI) in FM has allowed for the detection of neural abnormalities in this condition, with augmented brain activation elicited by experimental pain and alterations in resting state connectivity related to clinical pain. Here, we sought to

monitor state changes in resting brain connectivity following experimental pressure pain inFM patients and healthy controls (HC). METHODS: 12 female FM patients and 15 age-matched HC were studied by applying individually adjusted pressure stimuli (equal pain intensity) to the left thumbnail bed during MRI. Resting state functional MRI scanning was performed before and immediately following experimental pressure pain. We investigated changes in functional connectivity to the thalamus and the insular cortex with a seed based region of interest analysis using the Functional Connectivity Toolbox (www.nitric.org/projects/conn) ¬ in SPM8. Subject-specific connectivity maps for each seed were entered into a second-level repeated measures ANOVA (two-factorial design) with group and time point as factors. Analyses included a 1) main effect of group at baseline and post pain, 2) main effect of time within each group, and 3) a group by time interaction. Results were deemed significant with a family wise error (FWE) cluster-level corrected P value < 0.05 derived from a voxel-wise uncorrected P value < 0.001. Connectivity maps from significant results were correlated with clinical symptoms in SPSS v.21. RESULTS: Acute pressure pain increased insula connectivity (analysis 1) to the anterior cingulate ($z = 4.71$, ¬P¬ = 0.015) and the hippocampus ($z = 4.01$, $P = 0.036$) moreso in FM patients than HC. We observed increased thalamic connectivity to the precuneus/posterior cingulate cortex ($z = 4.81$, $P = 0.019$), a known part of the Default Mode Network, in FM but not HC (analysis 3). Increased thalamic connectivity to the cingulate/precuneus was also associated with increased clinical pain ($r = 0.610$, $P = 0.046$). CONCLUSION: These data suggest that an acute painful stimulus may alter the neural signature of chronic pain. It is unknown if these findings are generalizable to other chronic pain conditions.

Hosp., Aarhus, Denmark; [7]Kessler Fndn., West Orange, NJ

Abstract: Fibromyalgia (FM) is a chronic pain disease without cure, where patients can present moderate to intense generalized (and sometimes incapacitating) pain (Wolfe, 2013). Pleasant and relaxing music reduces pain importantly in FM by unknown mechanisms. To study the fMRI representation of analgesia with music, we performed an analysis technique that measures the amplitude of low frequency fluctuations (0.01 - 0.08 Hz or DMN) in rsfMRI called fALFF. We hypothesized that music-induced analgesia would elicit activity in areas of the pain modulation system. Twenty fibromyalgia female patients participated in the study. Inclusion criteria included diagnosis of FM of > 1 year, right handedness and moderate to intense spontaneous pain. During the study, their spontaneous pain was measured using a Verbal Rating Scale (0 - 10). We scanned the patients using a GE Discovery MR750 3T scanner using resting state BOLD gradient echo sequences (TR = 3000 ms, TE = 40 ms, flip angle = 90, matrix = 128 x 128, FOV = 256 mm, slice thickness = 3 mm). The patients listened to experimenter chosen noise and self-chosen music (high valence, low arousal). Before and after each auditory stimulus we performed pain ratings and rsfMRI. The data were preprocessed using the fALFF technique with the AFNI software and we performed statistical analysis using FSL software (paired t-test, FWE correction). Finally, we extracted the time series data from the resulting fALFF cluster to perform correlations with the pain ratings using the Δ (delta) values (Cpos - Mpos). The FM patients reported significantly less pain after listening to music. In the fMRI contrast Music > Noise, we found a significant cluster of higher amplitude in the left angulary gyrus (x=-38, y=-68, z=36, $p < .001$, mean-T = 5.05, size = 64 voxels). We also found a significant negative

correlation between the Δ fALFF Z-score and Δ pain intensity Z-score (r = -.56, p = .03), meaning the report of analgesia was correlated to an increased amplitude of low frequency fluctuations in the left angular gyrus. In this study we found that listening to self-chosen pleasant and relaxing music reduced pain in fibromyalgia patients, and the analgesic effect was correlated to high amplitude of low-frequency fluctuations in the left angular gyrus, an important brain region of the default-mode network also found in pain modulation. In this study, the mechanism behind music-induced analgesia in FM patients seems to be top-down, elicited probably by distraction, emotion and reappraisal. This is the first study of its kind and should be replicated with other forms of cognitive analgesia in fibromyalgia.

Title: Cortical spreading depression induced by targeted optogenetic activation of cortical pyramidal neurons

Authors: *Z. KILLEEN, A. PARGA, J. NICHOLS, C. WU, T. ANDERSON;
Univ. of Arizona-College of Med. Phoenix, Phoenix, AZ

Abstract: Migraine is one of the most common neurological disorders characterized by the recurrence of severe debilitating headaches. While the underlying cause of migraine remains unknown many patients report an “aura” that precedes their migraine pain and is often perceived as sensory disturbances. Cortical spreading depression (CSD) is a slow moving wave of depolarization that propagates across the cortex and is the pathophysiological mechanism behind migraine aura. Intrinsic optical signal (IOS) imaging has proven a powerful technique to monitor and track the development of CSD. Experimental CSD induction paradigms have traditionally used mechanical stimulation (“pin-prick”), high potassium solutions or osmotic disruption. While successful in their induction of CSD these methods are often invasive and have provided limited ability to target activation of specific neuronal populations. To overcome this we herein describe a novel method of combining IOS imaging with simultaneous photostimulation of

channelrhodopsin (hChR2). Cortical pyramidal neurons were selectively targeted by restricting hChR2 expression using stereotaxic injection of adeno-associated virus (AAV) expressing the hChR2 gene under the CAMKIIa promoter or transgenically expressed using cre-lox technology. Activation of hChR2 expressing neurons in cortical brain slices with blue light (470nM) reliably induced CSD that was of similar in phenotype to more traditional high potassium methods. Overall, these data suggest that targeted activation of cortical pyramidal neurons is sufficient to induce CSD. Furthermore, that optogenetic approaches are compliant with traditional imaging methods and provide a valuable approach to study CSD and migraine pathophysiology.

Title: Study of the nociceptive response in female high yawning rats with an anxious trait

Authors: *S. L. RUGERIO[1], J. R. EGUIBAR[1,2], C. CORTES[1];
[1]Inst. de Fisiología, [2]Res. Office-VIEP, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: The high- and low- yawning (HY and LY, respectively) differ one order of magnitude in their spontaneous yawning frequency. The HY and LY rats also differ in the number of grooming bouts in a novel environment or after wetting the fur and in the open-field arena suggesting that HY rats are more anxious. Chronic pain, stress, and anxiety have been considered a public health problem, since 20% of the population suffers them and these illnesses affect in greater proportion to women with 3 to 1 female/male ratio. The aim of this study is to evaluate pain threshold responses along estrous cycle in HY and LY female rats using the tail-flick latency apparatus, as well as the effects of ovariectomy (OVX) and estrogen administration We

studied 32 adult female rats. We measured tail-flick latencies in five control sessions, three additional measurements after OVX and three after subcutaneous 20 μg estradiol benzoate (EB) during 15 days. Our results showed that pain threshold were higher in the LY subline (4.325 s latency), after OVX both sublines showed similar tail-flick latencies and EB administration induced higher effects in LY than HY rats. We concluded that HY and LY sublines differ in analgesic responses and are suitable model for the study of the relationship between sex steroid hormones and pain threshold and probably chronic pain.

Title: Nociceptive reflex stimulus intensity threshold or reflex amplitude? A painful choice in the objective quantification of central sensitization

Authors: *L. D. LINDE[1], L. R. BENT[1], J. P. DICKEY[2], J. Z. SRBELY[1];
[1]Human Hlth. and Nutritional Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Dept. of Kinesiology, Western Univ., London, ON, Canada

Abstract: Central Sensitization (CS) is a maladaptive response of neurons within the central nervous system to persistent peripheral nociceptive input. While CS has been linked to an increasing number of clinical conditions, there is currently no reliable clinical technique for quantifying changes in CS. The nociceptive reflex is commonly employed to assess changes in spinal excitability (CS). The stimulus intensity threshold (SIT) required to elicit a reflex response and the nociceptive reflex amplitude are two common outcome measures used interchangeably to assess spinal excitability; however, the responsiveness of these two outcomes to changes in spinal excitability has yet to be directly compared. The purpose of this study was to compare the effect of experimentally induced CS on the nociceptive reflex SIT to the nociceptive reflex amplitude in young healthy adults. We tested the primary hypothesis that the nociceptive reflex amplitude will increase and nociceptive reflex SIT will decrease following experimentally induced CS. Our secondary hypothesis states that a strong inverse correlation ($r>0.7$) exists between changes in the nociceptive reflex SIT and nociceptive reflex amplitude after the experimental induction of CS. Twelve (12) young healthy adults (23.1±2.74) participated in this crossover-design study. Electrical noxious stimuli (five, 1ms square wave pulses) were delivered

every 10 to 15 seconds to the right index finger at 2mA increments from detection threshold while reflex responses were recorded from upper limb muscles (deltoid, biceps brachii, lateral triceps, flexor carpi ulnaris, extensor carpi radialis) via surface electromyography. Baseline nociceptive reflex responses were recorded prior to the induction of CS. CS was evoked in the C5 neuromere by the topical application of capsaicin cream (Zostrix 0.075%) along the lateral forearm (50cm^2) compared to placebo cream applied on a different session separated by 1 week. Nociceptive reflex responses were recorded at 10, 20, 30, and 40 minutes post-sensitization. The reflex SIT was significantly reduced following experimentally induced CS ($p<0.05$) while the reflex amplitude showed no significant increase following experimentally induced CS ($p>0.05$). The relationship between reflex amplitude and reflex SIT demonstrated a strong inverse relationship in the placebo condition ($r=-0.901$); however, this relationship was significantly weaker following the induction of CS ($r=0.507$). These observations suggest that reflex amplitude and reflex SIT may represent different underlying physiologic mechanisms and may not be interchangeably used to assess changes in central sensitization.

Abstract: Most putative new analgesic treatments developed from targets identified in pre-clinical studies have failed in phase 2 trials, possibly because of species differences. To increase to chances of translational success we selected a pathway with clinical validation, identified by genome-wide association studies. GTP Cyclohydrolase 1 (GCH1) polymorphisms which decrease tetrahydrobiopterin (BH4) levels are associated with reduced pain in patients in various chronic pain conditions. In this study we tested if the BH4 production pathway was relevant in chronic pain sensitivity and if targeting this pathway could be viable therapeutic approach. Using mice that express eGFP under the GCH1 promoter we show that excessive BH4 is produced by both axotomized sensory neurons and macrophages infiltrating damaged nerves and inflamed tissue. We find that constitutive BH4 overproduction in sensory neurons is sufficient to increase pain sensitivity, whereas blocking BH4 production only in these cells using tissue-specific inducible GCH1 KO mice prevents or reduces nerve injury-induced hypersensitivity without affecting nociceptive pain. To minimize risk of precipitating side effects by substantially decreasing global BH4 levels we targeted sepiapterin reductase (SPR), whose blockade allows low level BH4 production through sepiapterin processing in the BH4 salvage pathway. We used a structure-based design to develop a potent SPR inhibitor that allows systemic administration with no adverse effects and characterized sepiapterin accumulation as a sensitive biomarker for SPR inhibition *in vivo*. SPR inhibition significantly reduced pain hypersensitivity in two models of peripheral nerve injury (spared nerve injury and chronic constriction injury) with a concomitant decrease in BH4 levels in injured sciatic nerve and dorsal root ganglia, with no development of tolerance. This treatment was also effective to reduce hyperalgesia in two models of chronic inflammatory pain (intraplantar or knee injection of Complete Freund's Adjuvant), most likely by inhibiting macrophages' function. Altogether our results show that SPR represents a good target for developing novel analgesic treatments for neuropathic and inflammatory pain.

Title: Suppression of oral cancer and chemotherapy-induced chronic pain symptoms by a synthetic peripherally-restricted cannabinoid receptor agonist

Authors: Y. MULPURI[1], D. DANG[2], B. L. SCHMIDT[2], H. H. SELTZMAN[3], *I. SPIGELMAN[1];

[1]Div. of Oral Biol. & Medicine, Sch. of Dent., UCLA, Los Angeles, CA; [2]Dept. of Oral & Maxillofacial Surgery and Bluestone Ctr. for Clin. Res., New York Univ. Col. of Dent., New York, NY; [3]Res. Triangle Inst., Research Triangle Park, NC

Abstract: Oral cancer pain and chemotherapy induced peripheral neuropathy (CIPN) are significant public health problems. Current medications for pain alleviation of these diseases often lack efficacy and exhibit undesirable side effects. Preclinical studies have demonstrated the analgesic effectiveness of brain-penetrant cannabinoids (CB) in the treatment of cancer and CIPN pain symptoms, but their use may be limited by the psychotropic side effects of central CB1 receptor (CB1R) activation. We recently succeeded in the development of several novel CB1R agonists that do not appreciably cross the blood-brain barrier and which suppressed pain symptoms induced by sciatic nerve injury without central side effects (Mulpuri et al, SFN Abstr. Vol. 37:173.21, 2012). Here we examined one of these compounds (4-{2-[-(1E)-1[(4-propylnaphthalen-1-yl)methylidene]-1H-inden-3-yl]ethyl}morpholine, PrNMI) for effectiveness in alleviating pain symptoms in mouse oral cancer models and in a rat model of CIPN. Oral cancer-induced mechanical allodynia was suppressed after systemic PrNMI administration. In these mice, we also observed a >40% reduction in tumor volume. Paw cancer (inoculated with human oral carcinoma cells) mechanical allodynia was also dose-dependently suppressed by systemic PrNMI. Oral administration of PrNMI dose-dependently suppressed cisplatin (3 mg/kg, 1/week for 4 wks)-induced mechanical and cold allodynia with complete symptom suppression at 3 mg/kg. Daily oral administration at 1 mg/kg consecutively for two weeks resulted in similar daily suppression of mechanical and cold allodynia implicating little, if any, tolerance development. Intraplantar PrNMI (0.25 mg/kg) injection completely suppressed CIPN symptoms, suggesting peripheral sensory nerve terminals as the main sites of PrNMI's anti-allodynic action. PrNMI co-administration with selective CB1R or CB2R blockers revealed mainly CB1R contribution to its analgesic effects. In the central side effects assays, brain-penetrant HU-210 exhibited potent side effects at systemic doses that relieve neuropathy symptoms, whereas PrNMI and its analogs showed a complete lack of side effects in tests for catalepsy, hypothermia and motor incoordination. Similar results were obtained with female rats. The potency, peripheral selectivity, *in vivo* efficacy, and absence of CNS side effects of this novel class of CBR agonists point to their potential as a viable treatment for cancer and CIPN pain symptoms.

Title: Neuropathic pain promotes gene expression adaptations in stress and depression related brain regions

Authors: *G. DESCALZI, S. GASPARI, I. PURUSHOTHAMAN, L. SHEN, V. ZACHARIOU;
Fishberg Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Neuropathic pain is a complex condition characterized by sensory symptoms such as allodynia, hyperalgesia and dysesthesia. Around 65% of neuropathic pain patients also develop depression. A growing amount of clinical and preclinical studies reveal that neuropathic pain conditions lead to changes in neuronal activity in several brain networks involved in mood and motivation, including the Nucleus Accumbens (NAc) and the medial prefrontal cortex (mPFC). In this study, we employed the spared nerve injury model (SNI) of neuropathic pain (or control sham surgery) in adult C57Bl\6 mice and performed RNA-sequencing, in order to monitor changes in gene expression in three brain regions known to be implicated in the pathophysiology of depression as well as in the modulation of neuropathic pain symptoms: the NAc, the mPFC, and the periaqueductal grey (PAG). Two months post-surgery, SNI mice displayed mechanical allodynia as well as increased depression-like behaviors. Mice were sacrificed two and a half months post-injury, and RNA samples were extracted and assessed through Illumina based next generation deep RNA-sequencing. Although some common gene expression changes were observed, unique transcriptional profiles were identified across the three brain regions. Real-time PCR and western blot analyses were used to validate gene expression patterns and to further characterize the pathways involved in neuropathic pain symptoms. This is the first unbiased characterization of neuropathic pain induced long-term gene expression changes in three distinct brain regions composed of predominantly different neuronal populations (glutamatergic, GABAergic, and serotonergic).

Title: The therapeutic potential of neurokinin 1 receptor antagonist for arthritic pain and cartilage destruction in rat model of osteoarthritis

Authors: T. KIM[1,2], H. JEON[1,2], Y. KIM[3], E. SONG[1,2], Y. YOON[3], *J. KIM[1,2];
[1]Korea Univ. Coll Hlth. Sci., Seoul, Korea, Republic of; [2]Dept. of Publ. Hlth. Sci., Rehabil. Sci. Program, Korea Univ., Grad. Sch., Seoul, Korea, Republic of; [3]Korea Univ. Col. Med., Seoul, Korea, Republic of

Abstract: Osteoarthritis (OA) is the most common progressively degenerative disease occurring in the elderly. The factors related to the mechanism of the osteoarthritis are neuropeptides, cytokine, growth factors, and protease. Among these, Substance P (SP) is the neuropeptides, which released from the nociceptive primary afferent fiber and is responsible for neurogenic inflammation and pain transmission through neurokinin 1 (NK1) receptor activation. Thus, this study investigated the therapeutic potential of local injected an NK1 receptor antagonist on neurogenic inflammation in OA. Under anesthesia with 2% isoflurane, 4 mg of monosodium iodoacetate (MIA) was intra-articularly injected into the right knee in male Spraque-Dawley rats (200-220 gram). GR 82334 (10 uM), NK1 antagonist, was intra-articular administrated 30 min before (pre-treatment group) or 1 day after MIA injection (post-treatment group). After drug injection in MIA induced OA rats, knee joint diameter, knee bending test, paw withdrawal threshold to mechanical stimuli (Up down method using von Frey filaments) and weight bearing were assessed. Joint structures and SP immunoreactivity were also analyzed in the knee joint. In both pre and post treatment of GR82334 group, the knee joint diameter was decreased at 2 days, and paw withdrawal threshold to mechanical stimuli was elevated at 10 days after MIA injection. However, weight bearing and the knee bending test was no different. Histological degenerative change of knee joint structures and synovial SP and CGRP immunoreactivity were less presented. Thus, NK1 antagonist may regulate the inflammation and degeneration of knee joint structures that holds the possibility of secondary hyperalgesia alleviation in osteoarthritis.

Title: Peripheral nerve injury alters synaptic input and intrinsic connectivity in lamina II excitatory dorsal horn neurons in neuropathic pain states

Authors: *N. GONG[1], T. IKRAR[2], G. HAGOPIAN[1], Z. LUO[1], X. XU[2];
[1]Anesthesiol. & Perioperative Care, [2]Anat. & Neurobio., Univ. of California, Irvine, Irvine, CA

Abstract: The spinal dorsal horn is the first central relay area for pain transmission and modulation. While previous anatomical and electrophysiological studies examined spinal dorsal horn circuitries, functional studies of circuit connections and network activity are required to further understand spinal cord sensory information processing in acute and chronic pain states. Our previous studies suggested that peripheral nerve injury enhanced presynaptic excitatory input onto spinal superficial dorsal neurons, which contributed to nociception development. However, the detailed local postsynaptic circuits underlying heightened behavioral sensitivity in the dorsal horn remain largely unexplored. We combined whole cell electrophysiological recordings with laser scanning photostimulation (LSPS) to test whether spinal nerve ligation (SNL) led to enhanced excitatory synaptic input and/or reduced inhibitory input to lamina II excitatory dorsal horn neurons. Td-tomato-fluorescence labeled, vesicular glutamate transporter 2 (Vglut2)-expressing excitatory neurons were recorded from dorsal horn lamina II in living slice preparations of mouse L4 lumbar slices. High-resolution LSPS was applied to map glutamate-evoked excitability of and local synaptic connectivity to the recorded lamina II excitatory neurons. We analyzed and compared the data recorded from ipsilateral (injured) versus contralateral (control) sides of the lumbar slices 1-2 weeks after the nerve injury when injured mice showed pain hypersensitivity. We found that SNL did not significantly affect intrinsic membrane excitability of superficial dorsal horn excitatory neurons. However, SNL (1-2 weeks) increased glutamate-evoked excitability, shown as increased photostimulation-evoked spiking sites as well as total evoked spikes from recorded dorsal horn neurons in the injury side, averaged 2.1 and 3.7 times of the control side, respectively. Concurrently, SNL enhanced local excitatory synaptic circuit connections to superficial dorsal horn excitatory neurons. The average

total excitatory synaptic inputs of recorded neurons in the injury side were about 5.7 times that of the control side. Local inhibitory synaptic circuit connections to the recorded superficial dorsal horn neurons were decreased 1-2 weeks after SNL. The average total inhibitory synaptic inputs were 17.0% of the control. Together, these data support that SNL-induced maladaptive changes in synaptic input/connectivity to superficial dorsal horn excitatory neurons, which provides new insight in neural circuit basis of pain hypersensitivity.

Title: Lateralization of pain-related neural oscillations in the central nucleus of the amygdala

Authors: ***M. KAJUMBA**, A. L. HARRIS, J. N. STRAND, Y. PENG;
Psychology Dept., Univ. of Texas At Arlington, Arlington, TX

Abstract: The evidence for lateralization of pain-related changes in the CeA has mainly emerged from *in vitro*, and a few *in vivo* studies using anesthetized animals. These procedures eliminate the perceptual component as well as the emotional dimension of pain, and thus the results may not be a complete reflection of the pain experience. Both the left and right CeA receive, and are activated by nociceptive input, but the changes in synaptic plasticity and sensitization have been found to be lateralized in the right CeA. The main goal of this study was to use freely moving animals to determine the differential responses in the left and right CeA activity during the progression of inflammatory pain. Adult Sprague-Dowley rats with: 1) right CeA lesions; 2) left CeA lesions; and 3) no lesions (control), had a bipolar electrode chronically implanted into either the left or right CeA. Inflammatory pain was induced by subcutaneous injection of 2 mg of carrageenan (100µl of 2% (w/v) in saline) into either the left or right hind paw. Local field potential (LFP) oscillations were recorded at 6 time points; that is, baseline, immediately, 1, 3, 5, and 48 -72 hours after the carrageenan injection. The results revealed that: 1) the overall changes in the left CeA oscillations were mainly due to contralateral, while the right CeA oscillations changed in response to both contralateral and ipsilateral injury; 2) there

was initial increase in the delta oscillations (1-4 Hz) of both CeA, but the effect remained in the right, but not left CeA by 48 - 72 hours; 3) alpha oscillations (8-13 Hz) significantly decreased in the right, but not left CeA; 4) the beta oscillations (14-30 Hz) initially decreased in both CeA, but the effect remained significant in the left, but not right CeA by 48 - 72 hours after the carrageenan injection; 5) the left CeA gamma oscillations (30-100 Hz) significantly increased immediately, and at 48 - 72 hours after the ipsilateral injection, and persistently decreased in response to the contralateral injury, while the right CeA oscillations only decreased at 5 hours after the contralateral injection. This is the first *in vivo* study to demonstrate lateralization of pain-related changes in the neural oscillations of the CeA, and provides numerous implications, and insight into directions for future research.

Title: Trait vulnerability to anxiety and chronic stress interact to affect acoustic startle amplitude

Authors: ***M. L. JACOBSON**, P. PEDULLA, D. J. KIM, B. J. ANDERSON;
Psychology and Integrative Neurosci., Stony Brook Univ., Stony Brook, NY

Abstract: Pre-existing individual differences, such as trait anxiety, may make some individuals more susceptible to develop psychopathology than others. To understand the interaction between individual differences and experience, we designed a rodent living environment that allows manipulation of threat stress. Animals were tested on the elevated plus maze (EPM) and then classified as low anxiety (LA) or high anxiety (HA) based on median split of the anxiety index. Animals were then assigned to the control or threat groups with equal numbers of LA and HA in each group. Rats were housed in cages with food and water separated by a tunnel for 3 weeks. When the threat group reached the center of the tunnel, simultaneous presentations of predator odor, abrupt light and sound were presented randomly with a probability of 0.25. The control group crossed without threat presentations. After the 3 week treatment conditions, animals were tested on a battery of behavioral tests. Repeated threat affected acoustic startle response, spatial memory, anxiety index in the EPM (only when tested in aversive test conditions), but not sucrose preference. Individual differences prior to the treatment manipulation did not predict sucrose preference, enhanced spatial memory tested in aversive test conditions, or the anxiety index in an

aversive EPM. However, individual differences were related to acoustic startle. Startle was measured across 2 days, with 2 sessions per day. Individual differences were apparent in the first startle session of each day, but less evident by the second session of each day, when previous threat exposure led to sensitization, whereas the control group habituated. Threat exposed HA animals sensitized to the startle stimuli, whereas control HA animals tended to habituate. A region of the brain implicated in EPM behaviors and startle modulation is the lateral septum (LS). Threat exposure increases metabolic capacity in the LS, hypothalamus and PAG, an axis that supports contextual modulation of innate responses. It is possible that individual differences in LS explain the predictive power of EPM behavior for startle amplitude in session 1. We are currently assessing whether individual differences interact with threat experience to influence metabolic capacity in the LS. In summary, pre-existing individual differences in anxiety measured in the EPM predicted hyperarousal in the first startle session, whereas threat experience had a greater effect on adaptation of the startle response. These studies may aid in identifying the neural substrates that underlie individual differences in susceptibility to stress-related disorders and hyperarousal in PTSD.

Title: Impacts of maternal separation on an animal model of posttraumatic stress disorder using a shuttle box in rats

Authors: ***M. TANICHI**, H. TODA, S. ENOMOTO, K. SHIMIZU, M. UENOYAMA, Y. MASUDA, R. NAKAGAWA, M. NIBUYA, A. YOSHINO;
Natl. Def. Med. Col., Saitama, Japan

Abstract: OBJECTIVES: We have previously reported posttraumatic stress disorder (PTSD) model of rat using a shuttle box, in which rats exposed to inescapable footshocks (IS) corresponding to trauma 2 weeks before had the persistent behavioral alterations characterized by ‘bi-directional changes’. Past clinical studies have shown that exposure to stress during the postnatal development periods is associated with an increased risk for PTSD. In this study, we examined the influence of maternal separation (MS), which is one of the most commonly used procedures for inducing the early life stress in rodents, on our PTSD model. METHODS: Timed

pregnant Wistar rats were delivered on gestation day 14. On postnatal day (PND) 2, litter was assigned to MS or typical animal facility rearing (AFR) groups. MS took place for 3 hours per day for 2 weeks from PND 2 and only male pups were used for the subsequent experiment. On 7 weeks old, the IS session corresponding to trauma was performed, and 2 weeks after the IS session, the avoidance/escape task trials were done. Detailed experimental procedures were described as previously (Sawamura et al, 2004). RESULTS: In the avoidance/escape task trial, the number of the behavior counted as an error, which did not move to the other chamber during the footshock was significantly increased in MS/IS(+) group (13.00 ± 5,45), compared with the other three groups: AFR/IS(-) group (1.00 ± 1.00), AFR/IS(+) group (1.29 ± 0.97), MS/IS(-) group (1.25 ± 0.59). However, MS did not significantly affect the behavioral alterations characterized by 'bi-directional changes', which is related to the symptoms of PTSD. CONCLUSIONS: While the error behavior in the shuttle box system indicate learned helplessness as a depression model of rats, this study may suggests that IS in adolescence subsequent to MS induced the depressive behaviors, not but affect the PTSD symptoms. Title: The pain of others: empathy's influence on anxiety- and depression-like behaviour in female mice

Authors: *S. MALDONADO BOUCHARD, A. KLEIN, J. S. MOGIL;
McGill Univ., Montreal, QC, Canada

Abstract: The aim of this study is to identify the behavioural and physiological effects of long-term exposure to a familiar conspecific experiencing chronic pain. The anxiety- and depression-like behaviour and pain behaviour of mice housed in dyads in which either both, one, or neither have undergone spared nerve injury (SNI) were compared. Adult CD-1 mice (7-13 weeks old), female and male, were used. Experimental housing conditions included both female and male

same-sex pairs: SNI + SNI, sham + SNI, and sham + sham. At arrival, the mice were housed two per cage. No earlier than one week following arrival, baseline behavioural measures were collected. Two weeks following arrival, subjects underwent SNI or sham surgery. Standard tests of anxiety- and depression-like behaviour were conducted with all subjects 2 weeks following surgery, and then at 3-week intervals until the end of the experiment, 6 months post-surgery. Anxiety-like behaviour was assessed by examining center time in an open field, and time spent in the open arms of an elevated-plus maze. To assess depression-like behaviour, sucrose preference, and immobility in the forced swim test were used. In addition, tactile allodynia and spontaneous pain were assessed with von Frey filaments (up-down method) and the Mouse Grimace Scale, respectively. Female (but not male) shams housed with an SNI conspecific showed decreased center time in an open field up to 22 weeks after surgery relative to baseline, whereas shams housed with a sham conspecific did not. No differences were found on measures of sucrose preference or tactile sensitivity across housing conditions. Forced swim test performance and physiological correlates of anxiety and depression-like behaviour will be collected at the end of the experiment. Serum will be collected to examine levels of corticosterone as well as cytokines and chemokine via ELISAs. The current data suggest long-term exposure to a conspecific experiencing chronic pain differentially affects females, resulting in increased anxiety-like signs. In humans, providing long-term care for a relative suffering from a chronic illness, including chronic pain, is associated with depression and anxiety. Beyond the consciously perceived burden and psychological stress experienced by caregivers, the chronic exposure to a relative in pain may contribute to decreased well-being by pre-cognitive mechanisms. The next step will be to identify the mechanism via which exposure to a conspecific experiencing chronic pain modulates behaviour.

Title: Examining associative and non-associative fear memories in the rat exposure test

Authors: *K. FALLON, P. MACCALLUM, J. WHITEMAN, T. KENNY, D. SKINNER, G. MARTIN, J. BLUNDELL;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: A single exposure to a traumatic psychological event may result in the onset of stress-related disorders such as post-traumatic stress disorder (PTSD). PTSD is characterized by four core symptoms including re-experiencing the traumatic event, avoiding trauma-associated stimuli, hyperarousal, and negative cognition or mood. PTSD can be characterized as a disorder involving disturbed emotional learning and memory processes resulting in enhanced fear acquisition and maintenance. Fear memories can occur in response to environments that were previously associated with the stressor (associative fear memories) or can be apparent in environments different from the stressor, which suggests that these changes are not conditioned, but rather are measures of non-associative fear. Associative memory is often assessed using the classical fear conditioning paradigm whereby an animal learns to associate a novel context (or cue) with an aversive stimulus (i.e., mild foot shock). Upon re-exposure to the context or cue associated with the aversive stimulus, rodents will show species-typical fear behaviors, typically measured as freezing. In contrast, stress-induced changes in hyperarousal (as measured as response to acoustic startle) and anxiety-like behaviors (as measured in the elevated plus maze (EPM), open field (OF) and dark/light box (DL)) are measures of non-associative fear. While many studies have examined the neurobiology of associative fear memories using classical fear conditioning paradigms, few have examined non-associative fear. Thus, the aim of the current study was to develop an animal model of PTSD that produced both associative and non-associative fear. We found that a brief exposure of a mouse to a rat produces both associative and non-associative fear memories. Specifically, a single 5-minute protected exposure of a mouse to a rat causes increased freezing to the predator stress context, increased startle response, and increased anxiety-like behavior in the EPM, OF, and DL box. In contrast, exposure to an acute foot shock produces associative fear, but does not alter non-associative fear memories. These data suggest the mechanism underlying shock-induced and predator stress-induced fear memories are different. Current studies in the lab are examining extinction of predator stress-induced associative and non-associative fear memories. Identification of the neural mechanisms underlying associative and non-associative fear memories processes may aid in understanding the development and/or treatment of PTSD.

Title: Aging-related changes in the neural circuits underlying fear memories

Authors: *M. SEHGAL, T. S. BULA, B. HUMMER, B. K. FULLEYLOVE-KRAUSE, K. L. FELDMANN, J. R. MOYER, Jr.;
Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Aging leads to gradual changes in neuronal functioning that can be detected as early as middle age. These changes are also evident as impairments in various forms of learning. The current experiments were designed to address two salient aspects of aging related cognitive decline. First, most behaviors impaired with aging require successful interaction between a distributed network of brain structures. Second, although impaired, aging animals can often acquire these tasks albeit more slowly. In order to assess how the brain adapts in the face of these gradual changes to display successful learning is unknown. Specifically, what are the precise changes in the neural circuitry that allow successful learning during aging? Few, if any, studies have investigated how normal aging alters learning-related changes within a neural circuit. To address these issues, we used trace fear conditioning and extinction as a model. Our lab, as well as other labs, previously demonstrated that acquisition of trace fear conditioning, and its extinction, is impaired during normal aging. To investigate circuit-level changes, we quantified immediate early gene (IEG) expression in various brain regions implicated in fear learning. Briefly, young, middle aged, and aged rats were randomly divided into four groups: naïve, unpaired, trace fear conditioned (TRACE) or extinction (EXT). On day 1, TRACE and EXT groups received 10 CS-US trials. The unpaired group received explicitly unpaired CS and US presentations. On days 2 and 3, EXT and unpaired rats received 10 CS-alone trials. On day 3, fear memory was tested in TRACE, EXT, and unpaired rats using 2 CS-alone presentations after which their brains were removed and processed for immunohistochemistry to quantify the expression of Zif-268 and c-Fos. Results from adult rats demonstrate that conditioning as well as extinction increased the number of Zif-268 and c-Fos labeled neurons within retrosplenial cortex as well as the infralimbic and prelimbic subregions of medial prefrontal cortex (mPFC). Interestingly, these robust learning-related changes in adult rats were either absent or reduced in aging rats (both middle aged as well as aged). Moreover, despite differences in IEG expression, the aging rats were able to acquire trace fear conditioning and extinction. Therefore, fear learning engages mPFC and retrosplenial cortex in the adult but not the older rats. These data suggest that the neural circuitry underlying retrieval of fear memories is altered during normal aging. This is

likely to have profound implications in development and targeting of neurotherapeutic strategies for improving cognitive function in aged animals, including humans.

Title: Maternal inhibition of vicarious blood-injection-injury phobic syncope: a case report

Authors: ***M. ONEILL**[1], A. R. HIRSCH[2];
[1]Caribbean Med. Univ., Lake Forest, IL; [2]Mercy Hosp., Chicago, IL

Abstract: Introduction: Blood injection injury (BII) phobic syncope first described in 1916 effects 15% of the population. While venipuncture is the most common (44%), vicarious stimuli occur in 10%. Familial inhibition of vicarious precipitation has not heretofore been described. Case: Case report: A 42 year-old married female describes, since the age of 18, vasovagal syncope upon the sight of blood. Her first episode of fainting was associated with a venipuncture and occurs whenever exposed to blood. True blood must be present (special effects blood in cinema or theater has no effect). Seeing others bleed, including her husband or siblings, readily induces syncope. However, when confronted with her seven-year-old son's bloody injuries on two separate occasions, she was able to actively participate in his care, without presyncopal symptoms or syncope. General physical, neurologic and psychiatric examinations were abnormal for mildly impaired immediate and remote memory, and poor calculations. Discussion: Possible mechanisms for selective BII phobic syncope include evolutionary advantage to maximize survival of the progeny, predominance of fear/sympathetic response over disgust/parasympathetic discharge, and preferential epinephrine action on α1 over β2 receptors. Conclusion: Selective maternal protection against BII induced syncope suggests that psychological factors can modulate this cardiovascular event. Possibly, artificially inducing fear may act to prevent blood exposure induced syncope. During venipuncture, encouraging a continued fearful state until the disgust dissipates may prevent fainting. Investigation of the therapeutic use of fear in preventing BII phobic syncope is warranted.

Title: The appetitive and aversive context modulates choice behavior, autonomic responses, and the neuronal activity in the primate caudate

Authors: *Y. UEDA, K. NAKAMURA;
Kansai Med. Univ., Osaka, Japan

Abstract: Decision making involves not only the valuation of specific events but also the motivational context such as the net expectation of appetitive and aversive outcomes. The neuronal substrate of the latter process, however, has not been well studied partly due to the lack of objective measures of emotional context. Here we designed a behavioral paradigm in which animals made choice under different emotional context, assessed by the fixation behavior and the autonomic responses. In the task, three fractal images were separately associated with a juice (R), a neutral tone (T), or an aversive airpuff (A). After fixating on a central fixation point (FP) for 1000 ms, a pair of two images, R-T, R-A, or T-A, appeared in the left and right of the FP. The monkeys chose one of the images by eye movements to obtain a reward and/or to avoid a punishment. The same image pair was repeated up to 30 trials as a block while the side of the images changed randomly, which allowed the animal to predict the specific pair before its presentation. In all three monkeys tested (two Macaca fascicularis and one Macaca mulatta), suboptimum choices and fixation variability increased for the pairs that included 'A': R-A (even though another counterpart was 'R') and T-A, than that without 'A': R-T. In two animals whose autonomic responses were measured, the heart rate was significantly higher and pupil size was larger for the pairs that included 'A' than that without 'A'. The changes in the heart rate and pupil size partly predicted the following choice behavior. These findings suggest that the emotional context affects autonomic responses in parallel with the decision making process. We next examined neuronal activity of the caudate, an input channel of the basal ganglia in two monkeys during the performance of the task. Among 207 task-related neurons, 47% (n=97) exhibited

differential modulation in the activity during the fixation period depending on the block type, suggesting that the neurons encoded different value context. Among them, 37 neurons showed stronger activity for the pairs with 'R' (R-T, R-A) than the pair without 'R' (T-A), consistent with the hypothesis that the striatum is involved in reward-based decision making. However, we also found that 53 neurons showed stronger activity for the pairs with 'A' (R-A, T-A) than the pair without 'A' (R-T), indicating the striatum's involvement in encoding aversive context. The results suggest that different subsets of primate caudate neurons encode information about appetitive or aversive context, which may be the neuronal substrate of decision making in different emotional context.

Title: Quantitative analysis of monkey emotional gestures by a markerless 3D motion capture

Authors: R. V. BRETAS, T. NAKAMURA, *J. MATSUMOTO, Y. TAKAMURA, E. HORI, T. ONO, H. NISHIJO;
Univ. of Toyama, Toyama, Japan

Abstract: Monkeys have similar kinematics to those of humans, enabling skillful forelimb control and standing on hind legs. Motion of body parts and gestures in animals reflect various emotions and intentions as well as ongoing goals. Thus, motion capture in monkeys is an important tool to investigate neural mechanisms of socio-emotional behaviors as well as motor control, which may be inherited by humans. For motion capture, many previous studies used markers attached to various parts of the body. However, those markers could disturb normal behaviors and induce stressful behaviors such as biting, scratching or smelling the markers. In this study, we developed a markerless motion capture system for monkeys (Fig. A) and analyzed behaviors of freely moving monkeys. The 3D positions of the body parts estimated by the 3D system were compared with those estimated by experimenters, using the sample data when a monkey was performing a shuttling behavior to get over an obstacle (Fig. B). The averaged errors of the estimated positions of the body parts were less than 10 cm, suggesting the present

system is useful for analyzing arbitrary monkey movements. Then, we analyzed monkey behavioral responses to a fake snake and a neutral object using this system. The results revealed that a significant increase in clinging behavior duration during presentation of the fake snake (56 ± 6 %) compared with the neutral object (34 ± 5 %; $p < 0.05$), indicating that the monkey avoided the snake. Second, we analyzed behaviors after methamphetamine (MTP) administration (1.0 mg/kg, i.m.) in four monkeys. MTP significantly increased head movements (MTP: 5.7±0.2 m/min; saline: 4.6±0.4 m/min; $p < 0.05$), and decreased locomotion speed (MTP: 8.8±2.0 cm/sec; saline: 17.1±2.8 cm/sec; $p < 0.1$). The results are consistent with a previous study reporting that humans feel jittery after MTP administration. Taken together, these results demonstrate that the present system allows analyses of monkey's emotional motion and gestures in a highly reproducible way.

Title: Intracerebroventricular infusion of neuropeptide Y reduces the behavioral effects of social defeat stress and promotes anxiolytic-like behaviors in Syrian hamsters

Authors: *C. M. MARKHAM[1], T. LACEY[3], K. KENNIEL[3], R. KINGSTON[2], M. EDWARDS[1];
[1]Psychology, [2]Biol., Morehouse Col., Atlanta, GA; [3]Psychology, Spelman Col., Atlanta, GA

Abstract: Our lab utilizes an ethologically relevant model of social stress whereby defeated Syrian hamsters exhibit long lasting changes in behaviors, including increased submissiveness and a complete lack of territorial aggression, even when paired with a smaller, non-aggressive intruder (NAI). A small subset of hamsters, however, appears to be resilient to the effects of social defeat stress. Recent studies have suggested that neuropeptide Y, a widely distributed, 36-amino acid peptide may function to reduce the effects of traumatic stress in a variety of animal models. The aim of this study was two-fold: to determine if intracerebroventricular (icv) infusion of NPY can reduce the behavioral response to social defeat stress in Syrian hamsters and to examine whether NPY has anxiolytic-like properties in the elevated plus maze. The data indicate that icv infusion of NPY prior to social defeat significantly reduced submissive behaviors during testing with a NAI 24-hours later (duration of submission in vehicle group: 94.4 secs +39.5; 400pmol NPY group: 8.9 secs +3.9). In addition, hamsters that were infused with NPY 5 minutes prior to testing in the elevated plus maze showed a significant increase in open arm time (duration in vehicle group: 37.1 secs +12.1; 400pmol NPY group: 165.7 secs + 18.7). These results provide further support for the hypothesis that NPY functions as a resilience factor and is also among the first studies to demonstrate an anxiolytic-like effect of NPY in Syrian hamsters. Studies are currently underway to determine the receptor subtype involved in these effects.

Title: Norepinephrine transmission between locus coeruleus and central amygdala regulates aversive Pavlovian-to-instrumental transfer

Authors: *V. CAMPESE[1], J. SOROETA[3], E. VAZEY[4], G. ASTON-JONES[4], J. LEDOUX[2], R. SEARS[5];
[1]Ctr. For Neural Sci., [2]New York Univ., New York, NY; [3]Univ. of Arkansas, Fayettville, AR; [4]Rutgers, New Brunswick, NJ; [5]Nathan Kline Inst., Orangeburg, NY

Abstract: Three experiments provide evidence that norepinephrine (NE) transmission in the central amygdala (CeA) modulates Pavlovian-to-instrumental transfer (PIT). Specifically, experiment 1 demonstrated that, compared to vehicle infusions, muscimol infusions into the CeA significantly impaired PIT, confirming the role of CeA in this phenomenon. Experiment 2 found that systemic NE agonism with procaterol eliminated PIT and NE blockade with propranolol increased PIT. Using excitatory designer receptors exclusively activated by designer drugs (DREADDs) experiment 3 found that excitation of neurons in the locus coeruleus (LC) significantly impaired PIT. Generally less responding and weaker transfer were seen in these rats following treatment with clozapine-n-oxide (CNO) compared to vehicle treatment. This was also true when targeting the terminals of DREADD expressing LC neurons in the CeA with intracranial CNO infusions. Ongoing studies are evaluating the effects of LC inhibition with DREADDs on PIT. These studies provide strong evidence that NE transmission in CeA constrains PIT, which is in agreement with findings that implicate NE processes in the CeA as critical to the expression of aversive Pavlovian threat conditioning.

Title: Selectively-bred anxious rat phenotype is characterized by an early emergence of classical fear conditioning

Authors: *D.-J. CHANG[1], J. HIDER[1], P. BLANDINO[1], R. M. SULLIVAN[2], H. AKIL[1], J. DEBIEC[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Emotional Brain Inst., NewYork, NY

Abstract: Anxiety disorders are the most prevalent psychiatric disorders in childhood affecting around 10% of youth (Kessler et al., 2005). Maladaptive anxiety emerges early in life and disturbs child's psychosocial functioning and development. It is generally accepted that anxiety disorders are caused by a combination of inborn/hereditary and environmental factors. One of the best studied inborn risk factors for anxiety disorders in youth is anxious temperament whereas one of the best known environmental risk factors for anxiety disorders is a history of emotional trauma in childhood. Fear conditioning (FC) is the most commonly used experimental model of emotional trauma. In FC a neutral stimulus (conditioned stimulus, CS), such as neutral sound or odor is paired with an aversive unconditioned stimulus (US), typically a mild electric shock. As a result, upon subsequent exposures to the CS, an organism expresses threat behaviors, such as freezing. Previous rodent studies show that fear conditioning is naturally attenuated until postnatal day (PN) 10 (Landers & Sullivan, 2014). However, the ontogeny of fear learning in phenotypically anxious organisms is mostly unknown. To address this issue, we used a selectively-bred anxiety-prone rat model, in which spontaneous anxiety-like behaviors emerge as early as at PN 11 (Maras et al., SFN Abstracts, 2014). Sprague-Dawley (SD) PN 4 rat pups selectively-bred for anxiety received 11 US electric shocks (0.4 mA, 1 s) to the tail, either paired with a CS peppermint odor (30 s) (Paired), or unpaired (Unpaired). Another group included pups that received 11 CS presentations (CS Only). Additional controls included wild-type SD pups matched for age and experimental conditions. At PN 11, all pups were re-exposed to 3 CSs and their behavior was videorecorded and scored for freezing. Analysis of variance (ANOVA) revealed no significant differences in freezing among the wild type animals ($p>0.05$), a finding consistent with previous studies using similar training parameters. However, the anxiety-prone Paired pups showed significantly higher levels of freezing as compared to the control groups (Unpaired and CS Only pups expressed comparable levels of freezing) (ANOVA: $F(3,46)=16.51$; $p<0.0001$; post hoc: $p<0.05$). This pattern of results demonstrates that fear conditioning in phenotypically anxious pups occurs very early in life, before they spontaneously express anxious behaviors at PN 11, and before the emergence of adult-like fear conditioning in wild-type rats at PN 10. In subsequent experiments we characterized the neuroendocrine mechanisms of infant fear learning in phenotypically anxious rats.

Title: Differential gene expression after contextual fear conditioning in a novel fearful DxH recombinant inbred mouse strain

Authors: R. WICKRAMASEKARA[1], J. BOUMA[1], K. BEISEL[2], *D. M. YILMAZER-HANKE[2];
[2]Biomed. Sci. Dept., [1]Creighton Univ., Omaha, NE

Abstract: Emotions in response to anticipated threats are evolutionarily conserved to ensure the survival of species. However, pathological forms of fear and anxiety can lead to negative emotional and social consequences, causing high individual and socioeconomic burden. Current anxiolytic medications and exposure psychotherapy have variable outcomes in the individuals affected suggesting a role of genetic differences in biological mechanisms that drive fear and anxiety. In an attempt to understand potential genetic mechanisms of anxiety and fear, we have produced a congenic-like C3H-like recombinant inbred (C3HLRI) mouse strain with a high fear phenotype on a DBA/2J genetic background. This was achieved by backcrossing C3H/HeJ mice selected for a high fear sensitized acoustic startle response (FSS) onto DBA/2J mice with a low FSS with the goal of identifying genes related to high fear in the genetic background of low fear mice. In the present study, contextual fear conditioning was studied in fearful C3HLRI and control DBA/2J mice. Gene expression was analyzed in the hippocampus (HIP) six hours after fear training using microarrays. Mice from the contextual fear training group were presented footshocks and control animals exposed to the same context in the absence of shocks. Results obtained with Affymetrix Expression Console and Transcriptome Analysis Console indicated a limited number of differentially expressed genes. A subsequent two-way ANOVA differentiated between strain- and fear training-induced gene effects, which were further investigated with pathways analysis software. Among others, the genes identified included transcription factors, members of the cytoskeleton, synaptic proteins, genes regulating the cell cycle and cell death, ion channels, ion binding proteins, transporters, and enzymes. In summary, the results from bioinformatics analysis of our microarray expression data including analyses of potential molecular pathways involved suggest distinct mechanisms regulating strain effects and contextual fear learning in our congenic-like mouse strains. Further elaboration of these genes and molecular pathways will give us insights into genetic mechanisms of contextual fear and its extinction and may help to understand differential responses of patients to the treatment of anxiety disorders and related conditions.

Title: Galanin administration in the medial prefrontal cortex suppresses expression of conditioned fear memory and modulates plasticity during fear extinction

Authors: D. BHATTI, J. M. SMITH, *P. V. HOLMES;
Univ. Georgia, Athens, GA

Abstract: Posttraumatic Stress Disorder (PTSD) is characterized by a significant impairment in inhibiting learned fear. The goal of exposure therapy is to reduce conditioned fear responses by repeated presentation of a non-reinforced conditioned stimulus. Although exposure therapy is effective for many people with anxiety disorders, it is important to develop strategies to facilitate extinction of the fear response and enhance retention of this learning to improve clinical outcome. The neuropeptide galanin has anxiolytic and neurotrophic potential, but despite its known role in modulating anxiety-like behavior, galanin's potential for facilitating the extinction of aversive memories has not yet been explored. We investigated the effects of galanin administration in the mPFC of male Sprague-Dawley rats on facilitating extinction in a contextual fear-conditioning paradigm. Galanin (acute: .6 nmol in .5 ul/side; chronic: 3 nmol/day) or aCSF was either injected immediately before the first extinction trial or continuously infused (.25 ul/hr) into the bilateral mPFC for 3 weeks via an Alzet osmotic mini pump. For conditioning, rats were placed in an open field for 7 min and received three footshocks (.8 mA, .5 s) on minutes 4, 5, and 6, or received no footshock. 24 and 48 hours after conditioning, rats were placed back in the open field for 10 min. Freezing behavior, defined as the absence of all movements except those required for respiration or scanning, was scored for all trials. Rats were euthanized on day 4; rats that received chronic galanin were tested on the elevated plus maze (EPM) before euthanasia. The mPFC was dissected and PSD95 protein was measured by ELISA kit. Acute galanin administration reduced freezing during the first extinction trial ($p=.036$), but did not affect retention of extinction learning. This may be due to general inhibition of the prelimbic cortex, which is necessary for the expression of fear, or the anxiolytic effects of galanin, as chronic galanin administration, but not aCSF, increased the percent of time

on the open arm of the EPM (p=.0049). Furthermore, shock-naïve rats and rats that underwent fear conditioning and galanin administration expressed significantly lower PSD95 protein than those administered vehicle (p=.049). Our results suggest that galanin suppresses the expression of fear memory without affecting extinction learning and that galanin may modulate prefrontal cortical plasticity occurring during fear extinction.

Title: Selective ablation of the intercalated neurons of the amygdala increased the anxiety-like behavior in the Elevated Plus Maze

Authors: *E. PALOMARES[1], O. HERNANDEZ PEREZ[2], M. CRESPO RAMÍREZ[2], R. AGUILAR ROBLERO[2], K. FUXE[3], M. PÉREZ DE LA MORA[2];
[2]Cognitive Neurosciences, [1]Inst. de Fisiología Celular, Mexico City, Mexico; [3]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: The intercalated (ITC) islands of the amygdala are clusters of inhibitory neurons that surround the basolateral complex (BLA) and contain a dense population of dopamine D1 and μ-opioid receptors. Lateral ITC (lITC) islands provide feed-forward inhibition to the BLA, whereas medial ITC (mITC) islands form an inhibitory interface between the BLA and central nucleus (CeA), the main output region of the amygdala. Previous studies have shown that ITC neurons play a role in fear extinction. However the functional role of the ITC islands in the un-conditioned anxiety has not been studied. To elucidate the involvement of the ITC islands in the anxiety-like behavior in the Elevated Plus Maze, we bilaterally infused the toxin saporin conjugate with the agonist of the μ-opioid receptors, dermorphine, (SAP-DER; 0.75pmol/0.250μl/lado) in closed proximity to the mITC islands to specifically ablate the neurons of the ITC islands. Behaviorally, SAP-DER injections significantly increased the time

that the rats spent in the open arm of the maze as compared with their lesion control group. No effects on locomotion in the open-field test were found. These results suggest that ablate of the ITC neurons results in anxiogenic effects and support ITC neurons play an important role in mediate anxiolytic responses.

Title: Persistent inflammatory pain reduces sexually motivated hedonic behavior in male rats

Authors: *M. H. PITCHER[1], F. TARUM[2], M. LEHMANN[3], M. BUSHNELL[2];
[2]Natl. Ctr. for Complementary and Integrative Hlth., [3]Natl. Inst. of Mental Hlth., [1]NIH, Bethesda, MD

Abstract: Anhedonia, or the loss of interest in previously rewarding or pleasurable activities such as sexual activity, is a diagnostic criterion for major depressive disorder. In male rodents, scent marking of urine from pro-estrous females is a hedonic behavior that is sensitive to stressors such as social defeat. Considering that depression is often comorbid with chronic pain in humans and depressive-like behavior may also be seen in rodent models of persistent pain, we tested whether or not urine scent marking behavior in rodents is altered in persistent inflammatory pain states. We compared urine scent marking behavior in rats (n=12/group) at baseline and one week after unilateral intra-articular injection of Complete Freund's Adjuvant (CFA) or sham injection. Male rats were allowed to scent mark in a large arena with an absorbent paper floor containing a spot of urine harvested from pro-estrous female rats. Scent marking behavior was assessed by measuring the area of scent marking as well as time spent in a circular zone around the female urine spot as well as in the remaining arena. At baseline (prior to CFA or sham injection), males in both the CFA and sham groups exhibited a robust preference for marking the female marked zone, with 51% and 47% more marking in this zone than in the remaining arena, respectively. While scent-marking behavior was unchanged one week after sham injection, intra-articular CFA significantly reduced marking preference by approximately

35% (33.16±6.02%, *p=0.030*). However, the amount of time spent in the female marked zone increased by 21% following CFA (*p=0.036*). These findings demonstrate that inflammatory pain alters hedonic behavior in rats. In the context of Fields' Motivation-Decision model of pain and pleasure, while persistent pain may reduce the communicative component of hedonic behavior (i.e. reduced urine scent marking) to avoid potential conspecific aggression, there is also a concomitant increase in seeking out hedonic signals (i.e. increased time in the female-marked zone). As such, urine scent marking behavior may represent an ethologically relevant assay supporting translational research of persistent pain-induced depression.

Title: Maternal TNF during gestation programs the balance between risk taking and avoidance

Authors: *B. LIU[1], B. ZUPAN[2], M. TOTH[1];
[1]pharmacology, Weill Cornell Med. Col., New York, NY; [2]Vassar Col., Poughkeepsie, NY

Abstract: TNF is a cytokine with roles not only in coordinating local and systemic immune responses but also regulatingneuronal functions.Our previous research showed that maternal TNFduring early postnatal life programsdorsal hippocampal proliferation and the level of adult spatial memory. Here we report a new neurobiological function forTNF; specifically, the requirement for maternalTNFduring pregnancy to establish "normal" risk-avoidant behaviorin the offspring. We found that the adult offspring exposed to TNF deficient maternal environment during their development exhibit less avoidance and more risk taking behavior in a novel, anxiety-inducing environment. Cross-fostering and conditional knockout experiments indicated that TNF deficit in the maternal brain, rather than in the hematopoietic system, and during the prenatal period was responsible for theoffspring phenotype.Our data show a role for maternal brain TNF in programming offspring emotional response to risk.

Title: Exposure to social defeat stress increases morphine consumption and depression-like behavior mediated by the endogenous kappa opioid system

Authors: *K. A. HYMEL[1,2], J. M. MEDINA[1,2], S. O. EANS[1,2], M. L. GANNO[2], H. M. STACY[2], J. P. MCLAUGHLIN[1,2];
[1]Univ. of Florida, Gainesville, FL; [2]Torrey Pines Inst. for Mol. Studies, Port St. Lucie, FL

Abstract: Post-traumatic stress disorder (PTSD) often presents with comorbid substance abuse. Exposure to social defeat stress (SDS), an animal model of PTSD, is known to potentiate cocaine conditioned place preference through a kappa-opioid receptor (KOR) dependent mechanism. The current study examined the effects of SDS on morphine consumption in a two bottle choice paradigm using C57BL/6J and KOR KO mice. After four days' habituation to quinine (0.25 mg/mL) in each bottle, individually housed mice were allowed free access for four days to both quinine and morphine sulfate, demonstrating consistent consumption of the opioid each day at a dose of 1 μg/mL morphine. Mice demonstrating daily stable preference for the morphine bottle then underwent a 4-day SDS procedure as the intruder in the home cage of a CD-1 male aggressor for 20 min, twice a day (Day 9-12). Control mice instead explored a novel environment. Bottles were weighed daily to quantify consumption, and time spent in socially defeated postures was examined. Depression-like behavior was evaluated the day following the last SDS exposure (Day 13) in a 15 min forced swim test. Consumption continued to be measured 4 days after SDS exposure had concluded (Days 13-16). During exposure to SDS, C57BL/6J mice showed a significant 1.6-fold increase in morphine consumption relative to their non-stressed littermates, but this effect was considerably reduced in KOR KO mice. In addition, SDS-exposed C57BL/6J, but not KOR KO, mice demonstrated significantly greater time spent immobile in the forced swim test compared to their non-stressed counterparts. Notably, following the conclusion of the stress procedure, morphine consumption of SDS-exposed C57BL/6J mice returned over four days to levels equivalent to that of non-stressed controls. In contrast, no change in consumption was observed between the stress-exposed and unstressed KOR KO mice. These preliminary findings suggest that SDS-induced increases in morphine consumption are mediated via the activity of the kappa opioid receptor, further suggesting the

endogenous kappa opioid system as a therapeutic target to treat PTSD and other stress-related disorders with comorbid substance abuse.

Title: Empathy for Pain: Mice undergoing neuropathic pain induce specific effects on pain response in cagemates subjected to various nociceptive tests

Authors: *D. B. SOUZA[1], R. L. NUNES-DE-SOUZA[2], A. L. M. CANTO-DE-SOUZA[1]; [1]Univ. Federal De São Carlos, São Carlos, Brazil; [2]UNESP, Araraquara, Brazil

Abstract: AIM: The ability of an individual to identify emotional signals in conspecifics, a phenomenon called empathy, is directly related to the survival of the species. Although usual in human being, empathy has also been observed in animals. For instance, it has been shown that pain-related behaviors are bidirectionally influenced among animals that are suffering pain. In other words, the sight of a rodent suffering pain enhances the nociceptive response displayed by the observer cagemate. Recently, our research group has shown that mice living with a conspecific suffering with chronic pain [e.g., pain induced by sciatic nerve constriction (SNC)] display increased nociceptive responses assessed with the writhing test. Here we investigated whether this type of empathy is also observed when formalin test and hot plate test are employed to assess pain response in the observer mouse living with a cagemate suffering of chronic pain (SNC). METHODS AND RESULTS: Male Swiss mice (n=6-8 per group) were housed in pairs for 28 consecutive days. On day 14th, pairs of mice were grouped as follow: Cagemate (CNC), in which one animal from each pair was subjected to SNC surgery; Cagemate sham (CS), in which one animal from each pair was subjected to SNC sham surgery. After that, each pair was returned to its homecage to live together for further 14 days. On testing day (day 28th): the

observer cagemate (i.e. of each pair was subjected to one of the following nociceptive tests: Writhing test, Formalin test or Hot plate test. Student t-test revealed that the CNC groups displayed higher number of abdominal writhes ($t(9) = 8.64$, $P<0.05$) and lower time spent licking the formalin injected paw ($t(13) = 1.04$, $P<0.05$) than animals from CS group. No significant differences were observed between CNC and CS groups on the latency to lick the paw in mice exposed to the hot plate test ($t(12) = 5.81$, $P>0.05$). CONCLUSION: These results demonstrated that living with animals subjected to SNC induces hyperalgesia and hypoalgesia in the observer cagemate, as assessed in the writhing test and formalin test, respectively. Taken together, the present results suggest using of the writhing test to study the neurobiology of empathy in mice.

Abstract: AIM: As previously described, conspecific rodents are able to respond pain-related responses in cagemates subjected to nociceptive tests. Therefore, cohabitation with a conspecific animal with chronic pain is potentially capable of promoting a stressful situation, which can

trigger behavioral changes such as anxiety and depression and alter nociceptive responses. In the present study we investigated the effect of cohabitation with a mouse undergoing sciatic nerve constriction (neuropathic pain model). The cagemates were evaluated on nociception (writhing test), anxiety (elevated plus-maze and open field), depression (forced swim, tail suspension and sucrose preference test) and the corticosterone levels. METHODS AND RESULTS: Male Swiss mice (n=6-12 per group) were housed in pairs for 28 consecutive days. On day 14th, pairs of mice were grouped as follow: Cagemate (CNC), in which one animal from each pair was subjected to sciatic nerve constriction (SNC) surgery; Cagemate sham (CS), in which one animal from each pair was subjected to SNC sham surgery. After that, each pair was returned to its homecage to live together for further 14 days. On testing day (day 28th): the observer cagemate (i.e. of each pair) was subjected to one of the following tests: Experiment 1, writhing test; Experiment 2, elevated plus-maze (EPM) and open field tests; Experiment 3, forced swim, tail suspension, sucrose preference test and Experiment 4, corticosterone levels. Our results demonstrated that the social interaction of conspecific undergoing SNC induced hypernociception ($F(2.25)=12.00$, $P<0.05$), increased anxiety-related responses [EPM: percent open arm entries - %OA ($F(2.32)= 11.67$, $P<0.05$), percent of time spent in open arms - %tOA ($F(2.32)= 13.24$, $P<0.05$); Open field: percent of time spent in central area ($F(2.21)= 13.10$, $P<0.05$-Experiment 2]; while no changes in depression tests [Forced swim test: total immobility ($F(2.23)=3.59$, $P<0.05$) or latency ($F(2.23)=6.50$, $P<0.05$); Tail suspension test: immobility ($F(2.39)=3.59$, $P>0.81$) or latency ($F(2.39)=6.50$, $P>0.55$); Sucrose preference test: sucrose preference ($F(2.20)=0.78$, $P>0.05$)- Experiment 3] and the corticosterone levels [($F(2.14)=0.31$, $P>0.05$)- Experiment 4] were found. CONCLUSIONS: These results demonstrated that cohabitation with suffering conspecifics (SNC) induces hypernociception and anxiogenic-like effects in mice cagemates. Together, the present results suggest using of the writhing test and elevated plus-maze to study the neurobiology of empathy in mice.

Title: Blockade of medial prefrontal cortex mineralocorticoid receptors impairs defensive reaction in mice exposed to the olfactory fear conditioning

Authors: *R. R. SOUZA[1], V. F. CAMPOS[2], A. CANTO-DE-SOUZA[2];
[1]Univ. Federal De Sao Carlos, Sao Carlos, Brazil; [2]Dept. of Psychology, Univ. Federal de Sao Carlos, São Carlos, Brazil

Abstract: AIM: Central mineralocorticoid receptors (MR) are nuclear and membrane receptors of primary importance for stress-related response and adaptation towards environmental threats. The MR are highly expressed in the medial prefrontal cortex (mPFC), a key area for memory and coping with stressors. In the present study we investigated de effects of systemic or intra-mPFC MR antagonists on the behavior of mice exposed to an olfactory fear conditioning task (OFC). METHODS AND RESULTS: Male Swiss mice (n=8-10/group) were exposed the OFC protocol using a two-side conditioning chamber (A) and an odor-exposure chamber (B). In the Experiment 1, defensive behaviors were measured in non-shocked, non-paired, or odor-paired mice exposed to the conditioned odor (chamber B) and to the conditioned context (chamber A) at different days (24h interval). In the Experiment 2, different groups of odor-paired mice received systemic injections of vehicle or the MR antagonist spironolactone (SPI, 10-30 mg/kg, i.p.) 30 minutes prior the exposure to the conditioned odor or to the conditioned context. In the Experiment 3, odor-paired mice received intra-mPFC infusions of vehicle or the MR antagonist RU20318 (5-10 ng/0.1µl/side) 5 minutes before the exposure to the conditioned odor. For Experiment 1, we found that shock-paired mice exposed to the conditioned odor (B) presented an increased time in the burrow and tunnel zones, and a reduced time in the open surface, approach zone and climbing the grid wall in comparison to non-shocked, or to non-paired mice. Shock-paired mice also showed significantly higher time in SAP and burying, and a reduced frequency of rearings and transitions. Upon the exposure to the conditioned context (A), all mice that received footshock presented a reduction in rearings and transitions, as well as an increase in freezing and a reduced time in the conditioned compartment. For Experiment 2, systemic injection of SPI (10 or 30 mg/kg) did not change spatiotemporal measurements, but significantly reduced the time in SAP and burying, as well as increased the number of rearings. However, injections of SPI did not change behavioral measurements in the conditioned context. For Experiment 3, intra-mPFC infusion of RU28318 (5 or 10 ng) prior the exposure to the conditioned odor, significantly reduced the time in the burrow, as well as the time in SAP and burying. CONCLUSIONS: Altogether, the present study supports the usefulness of the olfactory fear conditioning and suggests that mPFC mineralocorticoid receptors are critically involved in the coping strategy and orchestration of defense reaction towards olfactory fear cues.

CAPES 2053/2013

Title: Chemical inhibition of the left medial prefrontal cortex facilitates anxiety-related behavior in mice subjected to social defeat (but not to restraint) stress

Authors: *R. L. NUNES-DE-SOUZA[1], N. S. COSTA[2], M. A. VICENTE[2];
[2]Pharmacol., [1]Univ. Estadual Paulista, UNESP, Araraquara, Brazil

Abstract: Recent results from our lab have shown that chemical inhibition (e.g., with cobalt chloride, CoCl2) of the left medial prefrontal cortex (LmPFC) produces anxiogenic-like effect in mice exposed to the elevated plus maze (EPM), a widely used animal model of anxiety. Interestingly, similar effect was obtained with injection of NOC-9, a nitric oxide (NO) donor, injected into the right mPFC (RmPFC), suggesting a functional lateralization of the mPFC in the modulation of anxiety-related behavior (Nunes-de-Souza et al., in Neuroscience 2014). It has been suggested that the LmPFC could play an inhibitory role on the RmPFC, reducing the deleterious effects of stressors on emotional states. Here, we investigated the effects of intra-LmPFC injection of CoCl2 on anxiety-related behavior of mice previously exposed to two different stressors: restraint stress or social defeat stress. Male Swiss mice (n=10-20) received intra-LmPFC injection of saline or CoCl2 (0.1mM/0.2µL) 10 minutes before being subjected to (i) 30-min restraint stress or (ii) social defeat stress. 24h later, each animal was exposed to the EPM for a period of 5 minutes, when the conventional anxiety measures (percentage of open-arm entries and percentage of open-arm time: %OE and %OT) and locomotor activity (frequency of closed-arm entries: CE) were recorded. Control groups received either saline or CoCl2 and were not exposed to stress situation. Results [two-way ANOVA followed by Duncan test; Factor 1: Condition (no stress or stress); Factor 2: Treatment (saline or CoCl2)] revealed an important effect for condition x treatment interaction, showing that intra-LmPFC injection of CoCl2 produced anxiogenic-like effects only in socially defeated mice, reducing the open arm exploration [%OE ($F(2,61)=3.88$; $p<0.05$); %OT ($F(2,61)=4.23$; $p<0.05$)]. Importantly, intra-LmPFC injections of CoCl2 did not change locomotor activity [CE ($F(1,61)=1.89$; $p>0.05$)].

These results suggest that a single exposure to the restraint or social defeat stress does not enhance anxiety in mice exposed to the EPM 24 hours later. However, inhibition of the LmPFC induces anxiogenic-like effects in socially defeated (but not restrained) mice. Together, these results suggest that the LmPFC plays a role in the resilience of mice to the anxiogenic effects provoked by social defeat.

Title: Repeated binge drinking increases perineuronal nets in the insular cortex

Authors: *H. CHEN, D. HE, A. W. LASEK;
Psychiatry, UIC, Chicago, IL

Abstract: Perineuronal nets (PNs) are specialized extracellular matrix structures that enclose subpopulations of neurons in the brain. Intragastric administration of alcohol in adolescent mice induces long-lasting increases of PN components in the orbital cortex in adulthood. However, it has not been determined whether binge alcohol exposure in young adults alters PNs. Here we examined PNs and their core components in the insula and primary motor cortex after repeated binge-like ethanol consumption in adult male mice. We performed the 4 day drinking in the dark (DID) procedure for 1 or 6 weeks to model binge alcohol consumption. The impact of ethanol drinking on PNs was examined by fluorescent staining of brain sections using a marker for PNs, Wisteria floribunda agglutinin (WFA). In another set of experiments, cortex was dissected and Western blots and quantitative real-time PCR (qPCR) were performed to evaluate the expression of PN proteins aggrecan, brevican, and phosphacan. We found that 6 weeks of ethanol DID significantly increased PN intensity in the insula, as measured by WFA binding. Aggrecan, brevican and phosphacan protein expression, and aggrecan mRNA expression, were also elevated in the insula after 6 weeks of ethanol drinking. In contrast, expression of PN components did not change after 1 week of DID. The increase in PNs appears to be specific to

the insula, since alterations were not observed in the primary motor cortex. Our results provide the first evidence that insular PNs increase after long-term binge drinking. The insula mediates compulsive alcohol use. Since PNs influence neuronal firing and plasticity, increased PNs in the insula after multiple binge cycles may contribute to restricted neuronal plasticity and lead to the development of compulsive alcohol use.

Title: Alterations in ethanol taste-elicited neuronal activity in the insular cortex following chronic ethanol exposure

Authors: E. DRIVER, B. FERETIC, J. PENPRASE, J. GODFREY, C. QUINTANILLA, *S. M. BRASSER;
San Diego State Univ., San Diego, CA

Abstract: Chronic exposure to alcohol produces neuroadaptations in the central nervous system that contribute both to the maintenance of ongoing drug use and persistent vulnerability to relapse. Part of this neuroplasticity may involve sensitization to stimulus cues that are repeatedly and reliably associated with drug administration. Due to its oral route of administration, the chemosensory cues accompanying alcohol consumption are among the most intimate and consistent stimuli immediately predictive of the drug's postabsorptive effects. In alcoholics and high risk drinkers, alcohol chemosensory stimuli elicit urges to drink as well as activation of mesocorticolimbic structures implicated in drug seeking and motivation. In animal models of relapse, re-exposure to ethanol taste cues following extinction of ethanol self-administration induces strong reinstatement of ethanol seeking. Recent findings have implicated the insular cortex as a significant brain region of interest involved in the processing of drug-associated stimuli. Human imaging studies have revealed insular activation during the experience of drug-related craving and exposure to drug-associated cues, and inactivation of the insula in rodents disrupts conditioned preference for environments previously paired with nicotine or amphetamine. The present study investigated alterations in the neural processing of ethanol

orosensory signals within the insular cortex following chronic experience with the drug, as measured via neuronal Fos response elicited by ethanol chemosensory stimuli in animals with and without a history of exposure. Outbred Wistar rats were chronically exposed to either a 20% ethanol or 0.5% saccharin intermittent access drinking paradigm or were given access only to water. Following the chronic drinking phase, naive and experienced rats from each stimulus condition were allowed to consume a fixed volume of their respective exposure stimulus (20% ethanol or 0.5% saccharin) and neuronal Fos response within the gustatory insula was measured 90 min post-exposure. Oral administration of 20% ethanol produced robust activation of the gustatory insula in naive rats, which was significantly reduced in alcohol-experienced animals. A trend for a similar reduction in tastant-elicited Fos expression was observed in saccharin-exposed subjects. These data suggest that gustatory regions of the insula may process information relevant to the novelty/familiarity of ethanol taste similar to other appetitive tastants.

Title: Chemogenetic inactivation of the insular cortex increases interoceptive sensitivity to alcohol

Authors: *A. A. JARAMILLO, P. A. RANDALL, Z. A. MCELLIGOTT, J. BESHEER; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Previous work has demonstrated a role for the nucleus accumbens core (AcbC) in regulating the interoceptive/subjective effects of alcohol. In order to investigate potential novel circuits involved in modulating sensitivity to alcohol, male Long-Evans rats (n=12) received a microinjection of the retrograde tracer Fluorogold (FG) directed at the AcbC. Projections to the AcbC were visualized through immunohistochemistry. Dense FG immunoreactivity (IR) was found in the insular cortex (IC). Next, to begin to examine a possible role for IC projections to AcbC (IC→AcbC) in modulating sensitivity to alcohol, we examined neuronal response to alcohol (1 g/kg, IG). Examination of co-localized FG and c-Fos IR revealed an alcohol-induced

increase in c-Fos IR within FG positive cells, demonstrating an IC→AcbC specific response to alcohol. Next, to validate the use of a chemogenetic approach by which to inactivate the IC, rats were microinjected with inhibitory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs; hM4D(Gi)) in the IC. DREADD expression and functional validation were confirmed with IR and electrophysiological recordings. To determine the functional role of the IC in modulating sensitivity to alcohol, male Long-Evans rats (n=6-9) were microinjected with the Gi DREADDs in the IC and trained to discriminate alcohol (1 g/kg, IG) vs. water using standard drug discrimination techniques. Rats received pretreatment with 1 mg/kg clozapine-N-oxide (CNO; IP) to activate the Gi DREADDs, 45 min prior to a cumulative alcohol curve (0.1, 0.3, 1.0, and 1.7 g/kg). Chemogenetic activation of the Gi DREADDs following CNO pretreatment resulted in increased sensitivity to low alcohol doses (0.1 - 0.3 g/kg), demonstrating a role of the IC in regulating the interoceptive effects of alcohol. Further these data demonstrate the feasibility of investigating a striatal-insula circuit in modulating sensitivity to alcohol.

Title: *In vivo* two-photon imaging reveals modulation of synaptic and spiking activity in visual cortex following acute and chronic exposure to alcohol

Authors: P. O'HERRON, M. LEVY, M. F. LOPEZ, J. J. WOODWARD, *P. KARA; Neurosci., MUSC, Charleston, SC

Abstract: The medial and orbital regions of the prefrontal cortex along with their direct projection and recipient zones are a major focus of research on the effects of alcohol in the brain. However, although glutamate receptor-dependent plasticity and reward-related activity are found in the visual cortex, this and other sensory neocortical regions are largely ignored in animal models of alcohol dependence. Here we test the hypothesis that responses of neurons in the visual cortex to sensory stimulation are altered after acute and chronic bouts of alcohol exposure. We used two-photon imaging in the mouse primary visual cortex to measure spiking and

synaptic responses by labeling neurons with synthetic and genetically encoded fluorescent sensors (Fig. panel A). Fluorescent calcium indicators OGB-1 AM and gCaMP6s were used to measure spiking activity while a glutamate sensor iGluSnFr was used to track synaptic activity. We first applied ethanol locally to the visual cortex in order to avoid potential effects on retinal and thalamic neurons that could occur via systemic injections. Acute alcohol produced an overall reduction of visually evoked spiking activity (Fig. panel B) and synaptic responses (not shown). We then tested whether this depression of visual responses persisted in mice exposed to four weekly cycles of chronic intermittent ethanol (CIE) vapor exposure in an inhalation chamber. Imaging was performed 72 hr after withdrawal from the last CIE treatment. Surprisingly, we found that CIE treatment increased the amplitude of sensory-evoked cortical responses. This increased response amplitude across a range of stimulus orientations resulted in a marked decrease in orientation selectivity (Fig. panel C). Thus, with CIE treatment, cortical neurons appear to become more promiscuous to sensory stimuli. In summary, our data suggest that sensory cortex undergoes lasting changes in neural circuitry related to alcohol dependence and that these persistent effects appear to be opposite to those produced by acute ethanol.

Title: Orbitofrontal cortex neurons are activated during alcohol and sucrose self-administration

Authors: ***J. HERNANDEZ**, D. MOORMAN;
Univ. of Massachusetts - Amherst, Amherst, MA

Abstract: The orbitofrontal cortex (OFC) is involved in reward valuation and preference, and OFC disruption has been associated with addiction to drugs of abuse. Recent work has shown that alcohol exposure has pronounced effects on OFC neuron excitability and plasticity.

However, it is unknown how OFC neurons signal alcohol reward and motivation in behaving animals. Characterizing the contributions of OFC networks to alcohol reward has the potential to provide a mechanistic understanding of critical neural systems that drive motivation for alcohol in both addicted and non-addicted states. In a preliminary set of results, we found that a subset of OFC neurons are strongly modulated during a basic cue-reward test of ethanol seeking. However, we and others have also shown that OFC neurons in the rat are robustly activated during sucrose self-administration. It is unclear whether OFC activity changes in each task encode reward seeking in general, or whether neurons exhibit selectivity for alcohol or sucrose rewards. Thus in these studies we recorded OFC activity in a task that combined alcohol and sucrose seeking. Long-Evans rats received intermittent access to 20% ethanol in their home-cage for 4 weeks before being trained on a cue-driven combined alcohol/ sucrose-seeking task. Nosepoke-initiated trials triggered one of two auditory cues. Tone 1 (1 kHz) predicted delivery of 20% ethanol. Tone 2 (5 kHz) predicted delivery of 15% sucrose solution to the same location. Reward was delivered if the animal left the nosepoke in less than 500 ms of the cue and initiated licking the tube within 500 ms of leaving the nosepoke. Upon stable performance, we implanted unilateral 32 microwire arrays in medial and lateral OFC to record activity of OFC neurons during the sucrose/alcohol-seeking task. Both sucrose- and alcohol-predicting tones resulted in activation of OFC neurons. Responses were stronger for sucrose than for alcohol, likely reflecting the well-established OFC encoding of relative reward value (sucrose being preferable to alcohol). We are currently recording from animals with varying degrees of alcohol preference to assess the impact of preference on OFC alcohol vs. sucrose encoding. We are also comparing OFC activity in mixed sucrose/alcohol self-administration tasks (as above) to exclusively sucrose or alcohol tasks to investigate the influence of reward availability on relative encoding of sucrose vs. ethanol value.

Title: Investigating changes in medial prefrontal cortex and basolateral amygdala neuronal morphology following long-term ethanol consumption

Authors: *P. M. KLENOWSKI[1], M. SHARIFF[1], A. BELMER[1], M. FOGARTY[2], M. BELLINGHAM[2], S. BARTLETT[1];
[1]Queensland Univ. of Technol., Brisbane, Australia; [2]Univ. of Queensland, Brisbane, Australia

Abstract: Repeated binge alcohol drinking followed by abstinence are key factors contributing to the development of dependence. Long-term alcohol consumption changes reward pathways in the brain and also alters neuronal circuits that control behavioral responses during abstinence. This causes sensitization to negative emotional states of withdrawal such as anxiety and stress, which contributes to alcohol craving and relapse. The activity of the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA) altered by long-term alcohol use and are thought to contribute to the enhancement of alcohol withdrawal symptoms, however limited data is available regarding modifications in morphology and synaptic connectivity that underpin changes in this neural circuit. Therefore, the aim of this study was to assess the effect of long-term ethanol consumption on the morphological characteristics of mPFC and BLA principal cells. We have filled several mPFC and BLA principal neurons with neurobiotin from rats given intermittent access to 20% ethanol for 10 weeks using a two-bottle choice paradigm and age-matched water controls. We have also recorded spontaneous synaptic currents and performed post-immunolabeling with antibodies against key pre- and post-synaptic components of GABAergic and glutamatergic synapses to determine changes in the activity and localization of inhibitory and excitatory putative synapses of mPFC and BLA principal neurons following repeated cycles of binge ethanol consumption. By determining changes in morphology, spontaneous synaptic activity and synaptic density of neurobiotin-filled mPFC and BLA principal neurons following long-term ethanol consumption, we will be able to uncover how changes in the connectivity of this neural circuit enhance withdrawal symptoms and contribute to the development of alcohol dependence.

Title: mPFC modulates interoceptive sensitivity to a nicotine + alcohol compound cue: functional validation using designer receptors exclusively activated by designer drugs

Authors: *P. A. RANDALL[1], A. A. JARAMILLO[1,2], Z. MCELLIGOTT[1], J. BESHEER[1,2,3]; [1]Ctr. for Alcohol Studies, [2]Curriculum In Neurobio., [3]Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Nicotine and alcohol are two of the most common drugs regularly used in combination. As a result, the interoceptive effects of each drug are frequently experienced together and over time, develop into a unique interoceptive cue associated with other reinforcing events. Considering the substantial health risks of combined nicotine and alcohol use, increasing our understanding of functional brain regional involvement in modulating sensitivity to these interoceptive effects is important in developing better treatments. The medial prefrontal cortex (mPFC; prelimbic region) is known to play a role in different aspects of associative learning and drug taking behavior. As such, the current experiments sought to explore the role of the mPFC in modulating sensitivity to a nicotine+alcohol (N+A) compound interoceptive cue. To do so, these studies utilize designer receptors exclusively activated by designer drugs (DREADDs) to silence mPFC in rats trained to discriminate a N+A compound cue from water. The first set of experiments assessed the functional viability of using Cre-dependent AAV-hSyn-DIO-hM4D(Gi) DREADDs in mPFC using both electrophysiological and immunohistochemical methods (n=8). The second set of experiments assessed the effects of silencing mPFC on sensitivity to the N+A compound cue (n=20). Long-Evans rats received bilateral infusions of Cre-dependent AAV-hSyn-DIO-hM4D(Gi) into mPFC. Following recovery, rats were trained to discriminate a nicotine (0.4 mg/kg) + alcohol (1 g/kg) drug state vs. vehicle. 6 weeks post-DREADD infusion robust DREADD expression in the mPFC was observed as measured by IHC. Additionally, clozapine-N-oxide (CNO, 10 μM) significantly decreased measures of cellular activity as assessed by electrophysiology. In the behavioral studies, activation of the inhibitory DREADDs by CNO (1 mg/kg, IP) significantly decreased N+A related goal-tracking behavior at a dose that did not affect locomotor activity. Together these studies demonstrate the functional involvement of mPFC in modulating interoceptive sensitivity to the N+A compound cue.

Title: Alcohol addiction impairs human hippocampal neurogenesis: Effects on proliferation, neuronal stem cells and immature neurons

Authors: *G. DHANABALAN, T. WARDI LE MAITRE, K. ALKASS, H. DRUID;
Dept. of oncology and pathology, Karolinska Inst., Stockholm, Sweden

Abstract: Alcohol abuse is associated with neurodegeneration in the hippocampus, a region associated with learning, memory and mood regulation in humans. We hypothesized that alcohol may have detrimental effect on the neurogenic pool of stem cells and/or immature neurons in the dentate gyrus (DG) of the human hippocampus. Therefore, we investigated whether alcohol abuse affects the number of neuronal stem/progenitor cells, immature/migrating neurons and proliferating cells in postmortem human hippocampal samples isolated from deceased donors subjected to a forensic autopsy. Classification of subjects was based on amount of alcohol consumed the last 4 weeks before their demise, according to information from relatives, the forensic pathology investigations, police reports and medical records. Hippocampal sections from controls and alcoholics were immunostained for Sox2, a neuronal stem/progenitor cell marker, doublecortin, a marker for immature/migrating neurons, and Ki67, a marker of cell proliferation. Positively stained cells were counted in alcoholics and compared with age-matched controls. Counting was performed in whole DG, including the molecular layer (ML), the granular cell layer (GCL) and the subgranular zone (SGZ). We also counted cells separately in the SGZ. The number of cells immunoreactive for doublecortin, Sox2 and Ki67 was significantly reduced in the whole DG and in the SGZ in alcoholics as compared to controls. No correlation between the cell numbers expressing any of the three markers and subject age was observed. In summary, our data indicate that alcohol impairs neurogenesis in the human hippocampus, and suggest that pharmacological agents that act on the hippocampal stem cell pool may be particularly interesting to study in the search for drugs to treat alcohol addiction.

Title: Prolonged abstinence from chronic ethanol exposure impairs hippocampal cognition and plasticity within the hippocampus

Authors: *M. C. STAPLES, M. J. FANNON, C. D. MANDYAM;
Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Alcohol dependence is a condition including repeated cycles of excessive alcohol consumption and periods of abstinence. Impairments in hippocampal (HPC) cognition during alcohol exposure are well characterized, but the long-term effects following cessation of chronic ethanol exposure on HPC-sensitive cognitive function and corresponding measures of structural plasticity and plasticity associated proteins are unknown. A trace fear conditioning (TFC) protocol was used to assess hippocampal cognition during abstinence along with Golgi staining for granule cell structural analysis and western blotting for dentate gyrus (DG) specific glutamatergic receptor expression. Following 7 weeks of chronic intermittent ethanol (EtOH) vapor exposure (CIE, daily 14 hours EtOH and 10 hours air exposure) and 72 hours of withdrawal from EtOH exposure, animals were trained in TFC and tested 24h, 10d, or 21d later. The cortex of each animal was collected and either incubated in Golgi stain or micropunched in the dorsal and ventral DG for western blot analysis. CIE had no impact on acquisition of the task (measured as freezing during the trace periods following the tone presentation on the training day 72 after CIE cessation), or on the contextual recall at any of the three time points. Recall of the trace memory, assessed as freezing during the 1st trace period on the testing day, was significantly impaired by CIE at all three time points of testing demonstrating persistence of impairments in HPC cognition and a lack of recovery during prolonged abstinence. 3D Sholl analysis revealed that the structure of granule cells in the dorsal and ventral hippocampus of CIE animals were significantly altered compared to air controls during abstinence with most effects noted during protracted abstinence. Ongoing studies include biochemical analysis of glutamatergic receptor expression which may be underlying the structural plasticity differences and cognitive deficits observed in CIE animals. It can be concluded that as abstinence from EtOH continues, HPC cognitive performance remains impaired, and this impairment appears to be related to structural abnormalities observed across the time course of abstinence. Further investigations into the neurochemical underpinnings of this perturbed behavior should be conducted to better understand more precisely the deleterious impact of ethanol dependence.

Title: Chronic ethanol self-administration in female macaques disrupts presynaptic dopamine neurotransmission

Authors: ***C. SICILIANO**[1], E. S. CALIPARI[1], J. T. YORGASON[1], D. M. LOVINGER[2], Y. MATEO[2], V. A. JIMENEZ[3], C. M. HELMS[3], K. A. GRANT[3], S. R. JONES[1];

Abstract: Hypofunction of striatal dopamine neurotransmission, or hypodopaminergia, is a consequence of excessive ethanol use, and is hypothesized to be a critical component of alcoholism, driving alcohol intake in an attempt to restore dopamine levels; however, the neurochemical mechanisms involved in producing dopamine signaling deficiencies are unknown. Here we examined the specific dopaminergic adaptations induced by chronic ethanol self-administration that produce hypodopaminergia and may contribute to alcohol use disorders. Female rhesus macaques (3 controls, 5 drinkers) completed one year of daily (22 hr/day) voluntary ethanol self-administration. Animals were given ethanol access until 3.5-6.5 hours before *ex vivo* fast-scan cyclic voltammetry in post-mortem brain slices containing the nucleus

accumbens core was used to determine ethanol-induced alterations in dopamine terminal function including dopamine release and uptake kinetics as well as the ability of quinpirole (D2/D3 dopamine receptor agonist) and U50,488 (kappa-opioid receptor agonist) to inhibit dopamine release. Chronic ethanol drinking increased dopamine uptake rates, and uptake rates were positively correlated with lifetime ethanol intake. Further, the sensitivity of inhibitory D2/D3 dopamine autoreceptors and kappa-opioid receptors were also enhanced following drinking. Together, these factors likely converge to drive a hypodopaminergic state, characterized by an inability to mount an appropriate dopaminergic response to salient stimuli. Additionally, these data suggest that the dynorphin/kappa-opioid receptor system may be an efficacious target for pharmcotherapeutic interventions in the treatment of alcohol use disorders.

Title: Repeated systemic administration of taurine influences the dopamine elevating properties of ethanol in the rat nucleus accumbens

Authors: *L. IVANOFF, L. ADERMARK, B. SÖDERPALM, M. ERICSON;
Inst. of Neurosci. and Physiol., Gothenburg, Sweden

Abstract: When trying to understand the development of addiction, a brain disease known to cause enormous suffering worldwide, much focus has been put on defining the mechanism by which the addictive drug increases dopamine in the mesolimbic dopamine system, which in turn may produce positive reinforcement. Ethanol, an addictive substance with a rich pharmacology, is known to modestly increase dopamine output in the nucleus accumbens (nAc), but the exact mechanism of action has been difficult to determine. We have previously demonstrated that

ethanol increases dopamine via a neuronal circuitry involving glycine receptors in the nAc and nicotinic acetylcholine receptors in the ventral tegmental area. We have also shown that in order for ethanol to increase dopamine in the nAc an initial enhancement of the extracellular levels of the endogenous amino acid taurine is required. Interestingly, intake of taurine has rapidly escalated over the last decade in several parts of the world due to consumption of so called energy drinks. This is interesting since taurine is known to activate both GABAA receptors and glycine receptors but few studies have investigated possible central effects of systemic taurine administration. Thus, by means of *in vivo* microdialysis in adult male Wistar rats we measured extracellular levels of dopamine, taurine, glycine and serine after systemic injections of vehicle, taurine (0.25 g/kg, ip), ethanol (2.5 g/kg, ip) or the combination of ethanol and taurine in rats pretreated with either taurine or saline for 15 days. We found that systemic administration of taurine increased extracellular taurine concentrations in the nAc and that subchronic treatment with taurine enhanced this increase. We also found that subchronic treatment with taurine blunted the ethanol-induced elevation of dopamine. Quantitative PCR analysis of tissue samples from the nAc as well as from other brain regions provided no evidence for altered mRNA expression of the taurine transporter or selected GABAA receptor subunits after subchronic taurine. We conclude that repeated systemic exposure to high amounts of taurine produces subtle alterations of neurochemical events previously suggested to be relevant for the reinforcing properties of ethanol.

Title: Neurosteroids modulate ethanol effects on dopamine release in the nucleus accumbens via actions on GABA(A) receptors on VTA GABA neurons

Authors: ***T. J. WOODWARD**, D. M. HEDGES, A. C. NELSON, H. PARK, N. D. SCHILATY, S. C. STEFFENSEN;
Brigham Young Univ., Provo, UT

Abstract: Dopamine (DA) transmission in the mesolimbic reward system originating in the ventral tegmental area (VTA) and projecting to the nucleus accumbens (NAc) is lowered during withdrawal from chronic ethanol exposure. Levels of neurosteroids with GABA(A) receptor-modulating properties are also lowered in the VTA by chronic ethanol, suggesting that select neurosteroids may be targets for restoring VTA DAergic function. The primary regulation of VTA DA neuron excitability is mediated by GABA(A)-mediated inhibition, presumably from local circuit VTA GABA neurons. We have shown in multiple reports that VTA GABA neurons are inhibited by acute ethanol and become hyperexcitable during withdrawal from chronic ethanol, presumably due to a switch in GABA(A) receptor function on VTA GABA neurons. VTA GABA neurons inhibit DA release either through local circuit inhibition or via projections to DA terminals in the NAc. The goal of this study was to determine the involvement of GABA(A) modulating neurosteroids in VTA GABA neuron excitability and in DA neurotransmission in the mesolimbic pathway. Using fast scan cyclic voltammetry (FSCV), we performed experiments on brain slices in the NAc by superfusing various GABA(A)R-modulating neurosteroids - allopregnanolone, DHEAS, and estrone sulfate. We also tested Trilostane, which enhances the endogenous expression of DHEAS via block of 3β-hydroxysteroid dehydrogenase. DHEAS (20 μM) enhanced DA release in the NAc by 20 %, while allopregnanolone, estrone sulfate, and Trilostane did not significantly alter DA release. Ethanol (20 - 160 mM, IC50 = 80 mM) reduced DA release in wild type (WT) mice. Superfusion of DHEAS (20 μM) significantly attenuated ethanol inhibition of DA release. However, the other neurosteroids did not significantly alter ethanol inhibition of DA release. In electrophysiological single-unit studies *in vivo*, DHEAS markedly enhanced VTA GABA neuron firing rate. Experiments are in progress to further evaluate the effects of the GABA(A) receptor-modulating neurosteroids on VTA and NAc neuron firing rate as well as GABA(A) receptor-mediated synaptic transmission to VTA GABA neurons.

Title: The lateral septum and its involvement in ethanol-induced dopamine elevation

Authors: *M. ERICSON, J. MORUD, S. JONSSON, B. SÖDERPALM;
Neurosci. and Physiol., Gothenburg, Sweden

Abstract: Alcohol and other addictive drugs share the ability to increase extracellular dopamine levels in the nucleus accumbens (nAc), an important node of the brain reward system. Since this specific increase in neurotransmitter levels has been linked to the positive and reinforcing properties of addictive drugs, and dopamine elevation is one of the few common effects produced by these drugs, much focus have been aimed at understanding the mechanism(s) underlying the extracellular increase of dopamine. Ethanol is a small molecule with a wide range of effects in the brain and several hypotheses have been put forward regarding its dopamine elevating properties. We have, in a long series of studies, tried to pinpoint how ethanol increases extracellular dopamine levels in nAc and have suggested that ethanol activates a neuronal circuitry involving glycine receptors in the nAc, and, secondarily, nicotinic acetylcholine receptors in the ventral tegmental area (VTA). The results of the present study include the lateral septum (LS), a brain region previously associated with ethanol-related behaviors, in the neuronal circuitry mediating the dopamine increasing effect of ethanol. By means of qPCR, retrograde tracing and *in vivo* microdialysis in Wistar rats we found that neurons projecting from LS to either VTA or nAc are GABAergic and that they likely express glycine receptors. Administration of tetrodotoxin in the LS slightly but significantly decreased basal dopamine levels in the nAc and completely prevented ethanol but not nicotine from increasing extracellular accumbal dopamine levels. Thus, we suggest that the LS participate in modulating basal dopamine levels in the nAc as well as the ethanol-induced dopamine elevation in the same area. The LS may thus be involved in mediating the reinforcing effects of ethanol, even though its involvement in ethanol intake or alcohol addiction remains to be established.

Title: Key role of dopamine signaling in spine pruning and LTD formation in ethanol dependence

Authors: G. MULAS[1], G. TALANI[3], E. SANNA[1], M. DIANA[4], *S. SPIGA[2];
[1]of Life and Envrn. Sci., [2]Univ. Cagliari, Cagliari, Italy; [3]bInstitute of Neuroscience, Natl. Res. Council,, Natl. Res. Council, Monserrato, 09042 Cagliari,, Italy; [4]Dept. of Chem. and Pharm., Univ. of Sassari, Sassari, Italy

Abstract: Alcoholism involves serious and persistent changes in the brain, including memory impairment and cognitive deficits. Changes in dopaminergic signaling are likely to contribute to synaptic dysfunctions that quickly occur from suddenly ceasing the use of alcohol after chronic ingestion. Here we show the effects of L-Dopa treatment on the reduction of long-thin spines and LTD formation produced by ethanol withdrawal (Spiga et al., 2014) in medium sized neurons of the shell of the nucleus accumbens (NAcc). Confocal microscopy and modified Golgi Cox staining analysis revealed a unique remodeling of the long thin spines selectively after 12 h of ethanol suspension. Reduced, long thin spine density observed during withdrawal promptly returns to control values as a result of a single injection of L-Dopa 1h before sacrifice. Further, whole cell patch clamp recordings of eEPSP from MSNs of NAcc shell revealed that, as previously reported, 12h Wdl from chronic EtOH treatment, are associated with an hampered LTD formation on glutamatergic excitatory synapses. Interestingly, the marked effect induced by Wdl is reverted by L-DOPA injection (6mgKg of body weight) 1h before sacrifice, as well as 10 μM dopamine (DA) perfusion in the slice from Wdl animals, 5 or 30 min before the low frequency stimulation (LFS) protocol given to induce LTD induction. In addition, the effect induced by DA was antagonized by the D1 selective antagonist SCH23390.

Abstract: Alcoholism has a tremendous impact on morphology and functioning of the nervous system. Chronic ethanol intake is a common cause of addiction with multiple interferences. Because alcoholism has its widespread multifactor interference, the present study aimed at analyzing brain morphology, nutritional and behavioral alterations resulting from chronic alcohol exposure in rats. This work occurred under the approval of the ethics committee and all procedures were conducted to minimize suffering of animals. Adult young male wistar rats (n=16) were housed in standard cages and provided with balanced food ad libitum. A control group (CRT, n=8) provided with water and food ad libitum was compared with a group of chronic alcohol drinkers (ALC) for 4 months. ALC received bottles with a traditional and largely consumed alcoholic beverage in Brazil, known as cachaça. Crescent concentrations of cachaça at 5, 10, 15 and 20% were administered for a week each. After this adaptation period, ALC received cachaça, at 25% in drinking water for 4 months. During experimental stages the specimens were submitted to hydric restriction to approximately 80% of their weight ad libitum, aiming the reinforcement effect of water. All animals were submitted to activities that involve prior stimuli of discriminative tasks and sensitivity to their proper behavior. Chambers equipped with a drinking water bar that releases 0.05ml each touch were used for operating conditioning tasks. An additional floor was used to create the open field environment. Animals passed through alcoholism induction period, monitoring of food intake and body weight, behavioral tests and brain analysis. Preliminary results have shown body weight mean initial (401.6 and 407.6g) and final (496.3g and 535.6g) for CRT and CAC, respectively. Histomorphological analysis revealed sings of defragmented and degenerated tissue in ALC brains, with special effect in the cortical layers. Periodic observations and recording for behavioral parameters showed hyperactivity in ALC, compared to CRT. Bearing all this in mind, it may be concluded that chronic condition of cachaça's intake can damage specific areas of the thelencephalon, associated with body weight changes, food consumption and behavioral alterations. These findings were consistent with preview studies on alcoholism but further investigations regarding the use of cachaça are encouraged to elucidate other specific effects of this model.

Title: Genomic signatures of alcohol preference in the HAD1/LAD1 and HAD2/LAD2 replicate rat models

Authors: *C.-L. LO[1], W. M. MUIR[2], A. C. LOSSIE[5], H. J. EDENBERG[3], T. LIANG[2], Y. LIU[4], F. C. ZHOU[1];

Abstract: Familial drinking is a key factor in the alcoholism. However, the genetic contribution is not clear. A number of GWAS studies in human tissue were conducted, but due to limitation and confounding of genetic and environmental factors, these have not provided a clear view on genomic association. To avoid these confounding factors, we use a replicated bi-directionally selected animal model, the high alcohol drinking (HAD) rat and low alcohol drinking (LAD) rat which has been shown to fit every criteria of alcoholism for high resolution sequencing studies. To reduce chance events, replicated line HAD1/LAD1 and HAD2/LAD2 were studied. Spleen DNA of 10 animals from each line, a total of 40 animals were sequenced at 4.8X coverage of sequence. After quality controlling and removal of false positive, over 5.5 millions single nucleotide polymorphisms (SNPs) were screened between HAD and LAD in both replicates. Furthermore, we identified significant SNPs and classified them by gene regions (15KB promoter, intron, exon, exon/intron junction). While most of the regions were partially confounded due to LD, most of the regions were in promoters and intronic areas and few were in the exons. These results suggest that SNPs in regulatory regions contribute greater to drinking behavior than those in the coding region. Many of those SNP involved genes are associated with potential alcohol preference and neuronal function, such as ion channels (Kcnk1, Scn5a, Cacna1h, etc.), and transmitter/synatic receptors (Gria3, Grip1, Chrna10, Syngap1, etc.). In addition, several genes have been previously reported in separate human GWAS studies, including Shank2, Syt1, Tnxb, Adcy3, Ssbp3, and Sh3bp5. IPA pathway analysis reveals canonical pathways controlling neuronal plasticity and LTP in CREB signaling pathway, PPARa/RXRa activation, and Axon guidance signaling may be affected. Overall, we presented unique finding in signature of selection in response to drinking behavior. Our finding implicates potential biomarkers for further analysis of genomic contribution. Better understanding of the genomic-environmental interactions will enhance the understanding of the mechanism and

diversity of alcoholism, for prevention, diagnosis, and treatment. Supported by NIH AA016698 and P50 AA07611.

Title: Alcohol-induced changes in cannabinoid modulation of noradrenergic neurons

Authors: ***R. WYROFSKY**[1], B. A. S. REYES[1], T. RETSON[2], J. HOEK[3], E. J. VAN BOCKSTAELE[1];
[1]Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Neuroscience, Farber Inst. for Neurosciences, [3]Pathology, Anatomy, and Cell Biology, Sidney Kimmel Med. Col., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Alcohol use disorders (AUDs) affect approximately 8.5% of American adults, and while remission is achievable, longitudinal data indicate that 60-90% of alcoholics will relapse within their first four years of abstinence. Moreover, sex differences related to alcohol's negative effects are emerging. For example, chronic alcohol exposure causes increased negative physiological effects on bodily organs and increases feed-forward activation of the hypothalamo-pituitary-adrenal axis in females when compared to males. One major symptom of alcohol withdrawal is increased stress-induced anxiety, which can often lead to relapse in recovering alcoholics. The locus coeruleus (LC) provides the sole source of norepinephrine (NE) to the frontal cortex and high levels of cortical NE have been implicated in the pathophysiology of stress-related psychiatric disorders. Via corticotropin-releasing factor (CRF) neurotransmission, stress exposure activates LC neurons, increasing the release of NE in forebrain targets. Chronic alcohol exposure alters CRF activation of LC-NE neurons and subsequently impacts NE release. The endocannabinoid (ecB) system regulates neurotransmitter release, and emerging studies suggest targeting the eCB system may influence the development of anxiety and stress-induced

psychiatric disorders. Taken together, actions of CRF and eCBs may converge in the LC to modulate stress-induced anxiety responses. However, the effect of alcohol on this interaction remains unknown. Here, we investigated the effect of repeated alcohol administration on cannabinoid type 1 receptor (CB1r) in the LC using Western blot analysis. Male and female Sprague-Dawley rats were match-pair fed a calorically equivalent liquid diet containing 36% of calories as ethanol for 14 days to induce an ethanol-addicted state. Alcohol treated females demonstrated a significant decrease in CB1r levels when compared to control and male counterparts ($p<0.05$). We also expanded on prior results showing co-existence of CB1r and CRF by examining whether CB1r/CRF afferents were excitatory or inhibitory in nature. Triple immunofluorescence microscopy showed that CB1r/CRF afferents expressed either the vesicular glutamate transporter or glutamic acid decarboxylase in the LC. These studies suggest that alcohol causes a greater impact on the eCB system in females compared to males in the stress-integrative LC and that CB1r can regulate CRF release in afferents that express excitatory and inhibitory amino acids.

Title: Neuromodulatory mechanism underlying ethanol-induced behavioral disinhibition

Authors: *G. P. ARANDA[1], K.-A. HAN[2], J. LIM[2], P. SABANDAL[2], P. D. EVANS[3]; [1]Biosci. Building, Univ. of Texas At El Paso, El Paso, TX; [2]Dept. of Biol. Sci., Univ. of Texas at El Paso, El Paso, TX; [3]The Babraham Inst., Cambridge, United Kingdom

Abstract: Alcohol exerts numerous effects on behavior through its interaction with diverse membrane and signaling molecules and effector cells. The effects include lack of motor control, behavioral disinhibition, tolerance, sensitization and addiction. In particular, behavioral

sensitization to alcohol's disinhibiting effects is strongly associated with binge drinking and alcoholism. Dopamine neurotransmitter plays a central role in ethanol-induced behavioral disinhibition and sensitization. However, identifying the neural sites that individual dopamine receptors function and underlying cellular mechanisms needs to be resolved. For this task, we have used *Drosophila* melanogaster as a model organism, which allows us to readily track and manipulate important sites of molecular and neural functions. The focus of this study is the D1-like receptor DopEcR, an insect G-protein coupled receptor that can bind to both dopamine and steroid hormone ecdysone. We found that DopEcR deficient (der) male flies show abnormal disinhibited courtship and decreased synaptic plasticity upon recurrent alcohol exposures. The der mutant's courtship phenotype was fully restored by expressing DopEcR during adulthood. This indicates a physiological, rather than developmental, role of DopEcR in ethanol induced disinhibition and sensitization. We are currently investigating the neural sites that DopEcR functions to regulate behavioral disinhibition and sensitization. We are also conducting experiments to clarify the relative contributions of dopamine and ecdysone to the phenotypes. This study will clarify key *in vivo* functions for a novel insect G-Protein coupled dopamine/steroid receptor and signaling molecules in alcohol-associated behaviors. Title: The impact of chronic alcohol exposure on fear-related memories: a role for mGluR5

Authors: J. MCGONIGAL, H. HAUN, *J. T. GASS;
Neurosciences, Med. Univ. South Carolina, Charleston, SC

Abstract: Despite the high rates of comorbidity between alcohol use disorder (AUD) and post traumatic stress disorder (PTSD) there is a substantial gap in our knowledge concerning how these disorders interact to cause significant deficits in behavior and cognition. For example, how

does chronic alcohol abuse affect PTSD-related fear memories? Also, how does PTSD drive subsequent alcohol abuse? This set of studies examined the impact of chronic intermittent ethanol (CIE) exposure on the extinction of fear behavior and, conversely, how exposure to fear-related cues influences subsequent ethanol consumption. Male Wistar rats were first exposed to a rodent model of PTSD in which a tone (CS) was associated with mild foot shock. After fear conditioning, rats were assigned to either CIE vapor exposure or a control group that received air exposure for two weeks. Prior to the ethanol/air exposures, each rat was briefly placed in the fear environment to activate the fear memory. Rats were then exposed to a daily extinction training regimen (10 tone presentations, but no shocks). A "contextual" recall test followed two days after the final day of extinction. Prior to each extinction session, rats were treated with either the mGluR5 PAM CDPPB (30 mg/kg) or vehicle solution. Compared to air-exposed controls, rats exposed to CIE showed deficits in the extinction learning of fear behavior and in extinction memory consolidation and recall. Treatment with CDPPB, however, attenuated the extinction deficits observed in CIE-exposed rats. In a separate experiment, male Wistar rats were first conditioned to associate a tone with foot shock and then exposed to CIE. All rats were then placed in their home cage and exposed to a two-bottle intermittent access choice paradigm. They received access to a 20% ethanol solution for a period of 24 hours in their home cage three days per week. Water was freely available. After 3 weeks one group was exposed to a single session of fear extinction (10 tone presentations). The control group was not exposed to the CS. All rats were placed back in their home cage and again given access to ethanol and water for 24 hours. The results indicated that a one-time session of repeated exposures (10) to the fear CS lead to a significant increase in ethanol consumption compared to the group not exposed to fear cues. Together, these studies suggest that an interaction of CIE and fear conditioning leads to altered extinction behavior and ethanol consumption while modulation of mGluR5 may serve as a potential treatment mechanism. Studies are currently being conducted using optogenetics to isolate specific neurocircuitry involved in these AUD/PTSD behavioral changes.

Title: Ketamine prevention of alcohol-induced depressive-like behavior is pharmacokinetic-independent

Authors: *L. AKINFIRESOYE, O. KALEJAIYE, Y. TIZABI;
Pharmacol., Howard Univ. Col. of Med., Washington, DC

Abstract: Treating the depression associated with alcoholism is key to improving the success rate of treating alcoholics and preventing relapse. Hence, antidepressants may be of particular therapeutic potential in such cases. However, current antidepressants including serotonin reuptake inhibitors can take several weeks to become effective and are invariably associated with side effects. Ketamine, and NMDA receptor antagonist, commonly uses as a dissociative anesthetic, has been shown to have fast and durable action as an antidepressant in sub-anesthetic doses. We have preliminary data indicating that a very low dose of ketamine given daily prior to alcohol administration can normalize alcohol-induced behavioral impairments reflective of depressive-like behavior in male Wistar rats. Thus, ketamine (2 mg/kg i.p.) blocked the exaggerated immobility in the forced swim test (reflective of helplessness) and decrease in sucrose intake (reflective of anhedonia) induced by daily alcohol administration of 1 g/kg for 7 days. In this study, we sought to determine whether ketamine's effect may also be due to its pharmacokinetic interactions with alcohol, i.e., whether ketamine may reduce the blood alcohol concentration. For this purpose we obtained tail blood from rats 30 min prior to alcohol administration (1 g/kg i.p.) and every 30 min (up to 120 min) after alcohol and alcohol + ketamine (2 mg/kg i.p. 30 min prior to alcohol). Blood alcohol concentrations peaked at 30 min post alcohol administration (approximately 89 mg%) and was back to normal levels at 2 h. Ketamine treatment did not affect blood alcohol levels at any time point. These data suggest that ketamine's antidepressant effects in alcohol-induced depression are independent of its pharmacokinetic interactions with alcohol. Current studies are underway to determine the neurobiological substrates associated with alcohol-induced depression and ketamine's mechanism(s) of action. Supported by: NIH/NIAAA R03AA022479

Title: Alcohol affects vocal learning and activation of underlying basal ganglia of zebra finches

Authors: *C. R. OLSON, D. C. OWEN, A. E. RYABININ, C. V. MELLO;
Dept. of Behavioral Neurosci., OHSU, Portland, OR

Abstract: Speech has long been known to be altered by alcohol, yet studies of the mechanistic role of alcohol on the production or acquisition of learned vocal patterns have languished due to the lack of an appropriate model system. We recently showed that zebra finches, a representative songbird that serves as the primary model to study the neurobiology of vocal learning and production, will self-administer alcohol to high blood ethanol levels (BECs; 50-90 mg/dl), resulting in acute effects on the acoustic features of their learned songs. Song learning resembles human vocal learning in that male finches acquire their songs within a critical juvenile period during which they establish a tutor song auditory memory, present immature vocalizations akin to infant babbling, and learn to imitate the tutor song over a prolonged period of sensorimotor practice. Here we describe the effects of alcohol on song learning. Juveniles were provided free access to 3.5% alcohol during the song learning period (from 45 - 125 days old), while control siblings received only water. Singing was recorded weekly during alcohol-free conditions, until adulthood. To evaluate the effects of alcohol on singing behavior we analyzed song stereotypy and the similarity of songs in experimental and control groups compared to tutors. Alcohol increased stereotypy of undirected and directed song, and these effects were detectable within 10 days after the initial exposure to alcohol. The similarity of juvenile song to tutor song was diminished in the alcohol group, suggesting that these juveniles were impaired either in recalling or imitating the tutor template. We also note increased horizontal vocal learning among alcohol-treated finches, as they were apt to learn some vocalizations from cage mates. In an assessment of the mechanism that underlies these behavioral effects, 70 d male finches were given 6.5% alcohol (or water only for controls) and sacrificed 30 minutes following a period of intense singing. In-situ hybridization revealed that alcohol decreased singing-induced ZENK (egr-1) expression in Area X, a basal ganglia nucleus crucial for song learning. ZENK expression in HVC, a nucleus responsible for the initiation of vocal-motor output, was less affected. We suggest that alcohol affects song development in juveniles by inhibiting activity in a circuit required for vocal motor plasticity, limiting the birds' ability to learn tutor song. The finch offers a powerful model to examine the effects of alcohol on brain development and vocal production, and can aid in the understanding of how alcohol affects cognitive development, particularly as it pertains to the acquisition of speech and language skills.

Title: Ethanol-induced behavioral disinhibition

Authors: *I. MERCADO, P. SABANDAL, J. BURCIAGA, K.-A. HAN;
Univ. of Texas at El Paso, El Paso, TX

Abstract: Dopamine is a major neuromodulator regulating cognition, reward, movement control, learning and memory. Alcohol consumption affects these cognitive and behavioral processes. To elucidate the underlying mechanisms, we used *Drosophila* melanogaster as an animal model since it has dopamine synthesizing enzymes, receptors and transporter homologous to those in humans. Flypub and FlyTracker assays are used to monitor disinhibited sexual and motor behaviors. In this study we investigated the dopamine receptors for ethanol-induced hyperactivity, sedation, tolerance, courtship disinhibition, and sensitization. We found that the flies deficient in or overexpressing D2 receptor (dD2R) showed altered ethanol sensitivity and courtship disinhibition whereas D1 (dDA1) and D5 (DAMB) receptor mutants displayed enhanced courtship disinhibition with normal sensitivity and tolerance. We are currently examining the neural pathways underlying these behavioral changes. This work was supported by the NIH grants: NIMHD 2G12MD007592, NIAAA R15AA020996 and NIAAA R15AA020996-01S1.

Title: Inhibition of the ethanol-induced potentiation of glycine receptors by small molecules that interfere with Gβγ binding

Authors: *L. S. SAN MARTIN[1], F. E. CERDA[2], C. JIN[3], L. G. AGUAYO[2], J. L. GUZMAN[2]; [2]Dept. de Fisiología, [1]Univ. De Concepcion, Concepcion, Chile; [3]Ctr. for Organic and Medicinal Chem., Res. Triangle Inst., North Carolina, NC

Abstract: Ethanol enhances the glycine receptor (GlyR), a ligand-gated ion channel (LGIC) critical for inhibitory neurotransmission in brain stem and spinal cord and possibly associated to reduced motor coordination and respiratory rhythm during acute intoxication. We previously found that peptides interfered with the binding site controlling the interaction between Gβγ and GlyR, and consequently with the ethanol modulation of the receptor. We performed a virtual screening study using a library of small molecules that allowed us to identify a subset of potential pharmacological compounds capable of binding to this binding site. At a concentration of 200 μM, M554 (an indole derivative) inhibited ethanol potentiation from 48 ± 3% in control to 30 ± 2% with 100 mM of ethanol, whereas 200 μM of M890 (a urea derivative) decreased ethanol potentiation to 26 ± 3%. The molecules did not interfere significantly with Gβγ activation of GIRK channels expressed in HEK293 cells. Interestingly, the potentiation of the decay time constant of synaptic GlyR currents in spinal cord neurons produced by ethanol was inhibited by M554 and M890. Thereafter, when we assayed the effect of M554 (200 mg/kg) on the loss of righting reflex (LORR) in presence of 3.5 g/kg of ethanol in C57BL/6J mice, we found that the mice injected with M554 recovered their reflex capacity faster than control mice (45.95 ± 3.6 min for control and 36.35 ± 2.2 min for M554 injected mice). Our results indicate that these small molecules have synaptic effects in an ethanol potentiation model of glycinergic transmission and animal behavior. This data will provide us with information that might help in the design of therapeutic molecules useful in the treatment of acute alcohol intoxication and abuse complications.

Abstract: Harmful alcohol use is among the top five risk factors for disease, disability and death worldwide. Hazardous alcohol consumption is a pattern of alcohol consumption that increases the risk of harmful consequences for the user or others, and has been linked with risky behaviors, accidents and injuries. It is noteworthy that hazardous alcohol consumption does not necessarily implies alcohol dependence. While there is a large body of research on the neurophysiological correlates of alcohol dependence there is little information so far about neurophysiological correlates of hazardous alcohol consumption. It has been reported that subjects with hazardous alcohol consumption but not alcohol dependence present increased beta absolute power at centro-parietal region, and decreased beta mean frequency (MF) in frontal centro-parietal regions. While increased beta absolute power has been already reported in alcohol dependent subjects, no report has addressed beta MF in these subjects, thus it is not yet known whether this decrease in beta MF is a feature correlated specifically with hazardous alcohol consumption or is also related with alcohol dependence. Herein we performed qEEG analysis of beta MF in subjects with alcohol dependence and in subjects with hazardous alcohol consumption but not alcohol dependence. We found decreased Beta MF in subjects with hazardous alcohol consumption but not in subjects with alcohol dependence. Our results suggest that differences exist in the neurophysiological correlates of alcohol dependence and hazardous alcohol consumption, supporting the hypothesis that there are differences in the neurophysiological mechanisms underlying these two conditions

Title: Assessing gender differences in nicotinic acetylcholine receptor contributions to ethanol consumption and reward

Authors: *M. G. DERNER, A. V. SACINO, P. D. GARDNER, A. R. TAPPER;
BNRI Room 144, Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Alcoholism is the third leading cause of preventable mortality in the world highlighting the need for a better understanding of the mechanism underlying the rewarding properties of alcohol. In addition, gender influences alcohol consumption and dependence, with men twice as likely to binge drink compared to women. Previous studies in rodent models indicate that cholinergic signaling via nicotinic acetylcholine receptors (nAChRs) containing the alpha4 subunit (α4* nAChRs) contributes to alcohol binge drinking and reward in C57BL/6J mice. Specifically, we have shown that male alpha4 nAChR subunit knock-out mice (KO) consume less ethanol in the "drinking in the dark" (DID) assay compared to wild-type (WT) littermates and fail to condition a place preference to 2.0 g/kg ethanol in the conditioned place preference (CPP) paradigm. To determine if similar deficits are observed in female α4 KO mice compared to WT, we measured ethanol consumption in the DID assay and ethanol place preference in these animals. During DID, mice were single housed, placed on a reverse light-dark cycle (lights on at 7PM, off at 7AM), and allowed to acclimate for two weeks. Following this period, mice were given a single bottle of ethanol, in place of their water bottle, two hours into the dark cycle for two hours. Bottles were weighed before and after each drinking session and ethanol consumption was calculated. This was done four days a week, and each week the percent ethanol was increased (2, 5, 10, 20%). CPP was done using a three-chamber apparatus with a 30-min habituation on day 1, two training periods (one for saline, one for ethanol) separated by 6 h on days 2-5, and a 30-min test on day 6. Unlike their male counterparts, female α4 KO mice exhibited similar ethanol consumption compared to WT. No differences in control sucrose or saccharin consumption were observed between female WT and α4 KO mice. In the CPP assay, 0.5 g/kg ethanol, but not 2.0 g/kg ethanol, conditioned a place preference in WT females, whereas 2.0 g/kg ethanol conditioned a place preference in α4 KO females, suggesting a shift to the right in the ethanol dose response relationship in KO females. These data suggest

different roles for α4* nAChRs in males and females with respect to ethanol behaviors, and also indicate a potential difference in sensitivity to ethanol between the two genders.

Abstract: The neural circuitry consisting of the dorsal hippocampus and nucleus accumbens contributes to cue-induced learning and ethanol-seeking behaviors in mice. Adenosine plays an essential role in hippocampal and accumbal regulated addictive behaviors. Mice lacking the ethanol-sensitive, adenosine equilibrative nucleoside transporter (ENT1-/-) show increased ethanol drinking, thus we investigated the proteome profile of the dorsal hippocampus and nucleus accumbens of ENT1 -/- and WT mice using label-free quantitative proteomics. We identified 1,196 proteins overlapping between the two regions, 670 mapping exclusively to the dorsal hippocampus, and 2,436 to the nucleus accumbens. Ingenuity Pathway Analysis (IPA) detected region specific significant changes in protein expression that significantly associated with biological processes, including molecular transport, basal ganglia disorders, glutamate degradation, and GABA receptor signaling. Western blot validation of our proteomic analysis confirmed a significant decrease in expression of the SNARE protein VAMP1 and glutamate receptor mGLUR3 in the dHPC of ENT1-/- mice, both of which are associated with molecular transport and presynaptic glutamate release. Similarly we detected a significant decrease in expression of the oxidative phosphorylation Complex-I protein NDUFS2 and a significant increase in the Complex-IV protein COX6c, both of which were significantly associated via IPA with mitochondrial dysfunction. Our findings suggest an important role for adenosine regulation

in the hippocampal-accumbal circuit, which may reveal novel aspects of adenosine signaling in alcohol use disorders.

Title: Intermittent- vs continuous alcohol access in female rats: effects on deprivation phenotype and maternal behavior as a consequence of the drinking pattern

Authors: ***A. BRANCATO**[1,2], C. VITA[1], F. PLESCIA[1], C. CANNIZZARO[1];
[1]Sci. for Hlth. Promotion and Mother and Child Care, [2]BioNeC, Univ. of Palermo, Palermo, Italy

Abstract: In male rats, the intermittent alcohol access paradigm produces relevant and specific consequences on neuronal activity and behavior, with respect to traditional free-access paradigms (Carnicella et al., 2014). In order to explore gender-related effects, this study aimed at assessing the consequences of two different patterns of alcohol self-administration on peculiar feminine behavioral repertoire, such as deprivation phenotype and maternal care. Animals underwent long-term, home cage, two-bottle "alcohol (20% v/v) or water" choice regimen, with continuous (7 days a week) or intermittent (3 days a week) access, and were tested for alcohol intake and preference. During acute deprivation, they were tested for behavioral reactivity in the open field; anxiety-like behavior in the traditional- and fear-potentiated elevated plus maze; novelty-induced exploration and recognition memory in the novel object recognition test; response to natural reward in saccharin preference test; depressive-like behavior in the forced-swim test. Animals were alcohol-deprived during mating and resumed self-administration from late gestation and throughout lactation. Home-cage undisturbed maternal behavior was assessed until weaning. Results show that rats exposed to intermittent access paradigm displayed higher alcohol intake and preference with respect to rats with continuous access ($p<0.001$). During deprivation, rats exposed to intermittent access manifested reduced response to fear, novelty and reward ($p<0.001$), and depressive-like behavior ($p<0.001$), whereas rats exposed to continuous access displayed a prominent anxiety-like behavior ($p<0.001$). Moreover, alcohol drinking

decreased nursing and overall maternal behaviour; the most detrimental consequences were observed in dams with intermittent alcohol access ($p<0.001$). In conclusion, long-term alcohol drinking induces profound alterations in the neuroadaptive systems underlying affectivity and reward, leading to alcohol-deprivation phenotypes and disruption of maternal-care behaviour in a drinking pattern-related manner.

Title: ALDH2 deficiency increases the sensitivity to cannabis as well as ethanol-induced hypothermia and motor impairment in mice

Authors: ***X. LIU**, L. WAN, G. LUO, D. LOVINGER, L. ZHANG;
Natl. Inst. of Hlth., NIAAA/NIH, Bethesda, MD

Abstract: Alcohol and marijuana are among the most widely used and abused substances in the western world. There is strong clinical evidence showing that concurrent use of both drugs can synergistically suppress brain function. In the human body, alcohol is rapidly converted into acetaldehyde by alcohol dehydrogenase (ADH). This toxic aldehyde is mainly metabolized by a key enzyme, aldehyde dehydrogenase 2 (ALDH2). ALDH2 deficiency, caused by a point-mutation, frequently occurs in the human population, with allele frequencies reaching up to around 40%, depending on ethnic background. This deficiency in ALDH2 is associated with the alcohol flushing reaction and cancer. Here, we ask if ALDH2 deficiency can alter motor impairment and hypothermia induced by concurrent treatment with a low dose ethanol and the major psychoactive component of marijuana, delta 9-tetrahydrocannabinol (THC) using rotarod performance and core body temperature measurements in ADH1, ALDH2 knockout mice and their wild type littermates. THC alone at low doses from 0.1 mg/kg to 5 mg/kg, i.p. or 1-5 μg i.c.v. did not significantly alter rotarod performance and body temperature in the mutant and wild type mice. Pretreatment with THC synergistically enhanced EtOH (1g/kg, i.p.)-induced motor impairment and hypothermia in mutant mice and their wildtype (WT) littermates. The impairment in ALDH2 deficient mice was significantly stronger than in WT and ADH1 deficient mice. Moreover, THC when given 30 min after EtOH administration induced synergistic effects on motor deficiency and hypothermia only in ALDH2 deficient mice but not in WT or ADH1

deficient mice. These findings suggest that cannabis may interact with acetaldehyde to produce synergistic behavioral effects *in vivo*. Supported by the NIAAA Division of Intramural Clinical and Biological Research and AA017875.

Title: History of drug intake leads to compulsive appetite via disruption in non-homeostatic control of food intake

Authors: *A. LAQUE[1], N. SUTO[1], Y. HAO[1], A. MATZEU[1], G. DE GUGLIELMO[1], T. KERR[1], R. MARTIN-FARDON[1], T. JHOU[2], R. C. RITTER[3], F. WEISS[1];
[1]Mol. and Cell. Neurosci., The Scripps Res. Institue, LA Jolla, CA; [2]Med. Univ. of South Carolina, Charleston, SC; [3]Washington State Univ., Pullman, WA

Abstract: While the 'food addiction' model of pathological overeating has been popularized, fundamental shortcomings of this nosology still remain to be addressed. Nevertheless, striking similarities in behavioral manifestations and their neurobiological underpinnings exist between substance dependence and eating disorders. We hypothesized that a history of extensive drug or alcohol intake known to result in 1) addiction-like drug motivation and 2) addiction-linked brain changes would result in similar addiction-like motivation for food in rats. Initially, different groups of rats were trained to self-administer cocaine or saccharin (controls). All rats were then given opportunities to self-administer sweetened condensed milk (SCM). The history of cocaine

intake led to addiction-like SCM seeking and taking, marked by heightened resistance to 1) increased workload, 2) extinction, and 3) adverse consequences. However, a history of extensive cocaine intake failed to alter subsequent 1) bodyweight gain, 2) ad libitum chow intake 3) and, interestingly, ad libitum consumption of a highly palatable (high fat/ high sugar) diet. Because the addiction-triggering history of extensive drug intake is insufficient to induce overeating per se, the addiction-like motivation for SCM or 'compulsive appetite' observed in these rats is likely due to dysregulation of non-homeostatic (non-metabolic) rather than homeostatic (metabolic) control of food intake. Consistent with this hypothesis, two additional groups of rats with either a cocaine or alcohol history exhibited heightened resistance to an electric footshock paired with the delivery of a non-caloric saccharin reward. Moreover, a history of cocaine intake induced functional upregulation of group II metabotropic receptors (mGluR2/3) in medial prefrontal cortex (mPFC) and amygdala; brain sites implicated in non-homeostatic control of food intake. These receptors negatively modulate neural excitability via inhibitory Gi proteins and, thus, may contribute to impaired functional connectivity between mPFC and amygdala observed in drug addicts. Together, the nosology of addiction is most applicable to certain phenotypes of eating disorders characterized by compulsive appetite, such as binge-eating disorder and bulimia nervosa, rather than pathological overeating in general. Neurobiological irregularities in the non-homeostatic pathway - abnormalities akin to those observed in drug addicts - are likely to provide the neuroregulatory basis for compulsive appetite.

Title: Embryonic ethanol exposure affects numerical discrimination ability and sex preference of adult zebrafish (Danio rerio)

Authors: ***D. SEGUIN**[1], R. GERLAI[2];
[1]Psychology, Univ. of Toronto, Mississauga, ON, Canada; [2]Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: The zebrafish is a highly social species which live in groups (shoals). Shoal living confers many advantages including protection from predation and increased access to mates and food sources. Past studies have found that early embryonic ethanol (EtOH) exposure in zebrafish leads to deficits in social responding. Based upon these past findings, the current studies have investigated the specificity of these altered social behaviours. Zebrafish embryos were exposed to one of three doses of ethanol (0.00%, 0.50% or 1.00% vol/vol EtOH) at 24h post fertilization for a period of 2 hours. Fish were tested during adulthood on numerical discrimination ability and sex preference. To test numerical discrimination ability, fish were placed in a test tank and exposed to two numerically different animated shoals presented simultaneously on computer monitors placed on opposite sides of the testing tank. Discrimination was measured by quantifying the distance to the numerically larger shoal. Shoal sizes of 4v0, 4v1, 6v2, 6v3, 8v2 and 8v4 were employed, and each experimental fish was tested once in each condition. Control (ethanol unexposed) zebrafish showed significant preference for the larger shoal especially in case of larger ratios. Sex preference was tested by placing zebrafish in a testing tank with a holding section on either side of the tank containing either an all-male shoal, an all-female shoal, or a mixed-sex shoal of live fish. Stimulus fish were separated by a clear, perforated Plexiglas wall, allowing the experimental fish to receive both visual and olfactory cues from the stimulus fish. Fish were tested once in each of the following conditions: all-male vs all-female, all-female vs mixed-sex and all-male vs mixed sex. Preference was measured by the total distance from each shoal the experimental fish swam, and the total amount of time spent near the stimuli shoals. Control female and male zebrafish were found to prefer all-female shoals over all-male and mixed-sex shoals. Results from zebrafish exposed to 0.5% or 1% (vol/vol) ethanol during their embryonic development showed significant impairment. Results will be discussed in the context of how to model cognitive alterations seen in Fetal Alcohol Spectrum Disorder children and in the context of how the employed zebrafish paradigms may be utilized in the analysis of underlying mechanisms.

Title: Individual differences in delay discounting by heterogeneous stock rats

Authors: *J. B. RICHARDS[1], P. J. MEYER[2], S. GRISAFI[1], G. KELLY[1], A. GEORGE[1], A. A. PALMER[3];
[1]Res. Inst. On Addictions, Buffalo, NY; [2]Psychology, Univ. of Buffalo, Buffalo, NY; [3]Univ. of Chicago, Chicago, IL

Abstract: Rats were tested on a sequential choice delay discounting (DD) procedure that simulates contingencies of reinforcement that are intended to be similar to those encountered by animals foraging in patchy environments. Thirsty rats chose between immediate small amounts of water and larger amounts of water that required the animal to travel to a new full patch. Long travel delays make staying in the old depleting patch a better choice, while short travel delays make long stays in the old depleting patch maladaptive. The sequential choice procedure differs from laboratory based "self-control" procedures typically used to study DD in non-human animals because repeated choice of the more immediate alternative can lead to greater consumption rates, whereas in "self-control" procedures choice of the delayed alternative always produces greater consumption due to experimenter imposed inter-trial intervals. It is arguable that the contingencies of reinforcement imposed by laboratory based "self-control" procedures are unlikely to be encountered in the natural environment. Optimal foraging theory predicts that animals will discount by delay to a degree that maximizes the overall rate of consumption. Here we tested a large number of heterogeneous stock rats (n=102) with highly variable genotypes on the sequential choice procedure with delays of 0, 6, 12, 18, 24 s. Rats were sorted according to how much they discounted by delay. Comparison of the twenty of rats that discounted the most (high discounters) with the 20 rats that discounted the least (low discounters) showed that the high DD yielded the greater water consumption rates. We also observed marked differences in switching between the two water feeders at the 0 s delay with some rats switching after every reinforcer while others stayed at the depleting water feeders for much longer periods before switching. Switchers and stayers were not different in the degree to which they discounted by delay. These results demonstrate that a propensity for DD can be advantageous by increasing overall consumption rate. Two behavioral phenotypes, high & low discounters and switchers & stayers were observed. Research is currently underway to identify genotypes that may underlie these patterns. This research may contribute to the identification of genetically determined biases in decision making underlying personality differences related to impulsivity.

Title: Sex-dependent relationships between Pavlovian conditioned approach and cocaine-induced locomotion in heterogeneous stock rats

Authors: C. L. VERSAGGI[1], C. P. KING[1], *J. A. TRIPI[1], L. C. SOLBERG WOODS[2], A. A. PALMER[3], J. B. RICHARDS[4], P. J. MEYER[1];

Abstract: Previous and ongoing research has sought to delineate complex genome-wide associations relating to traits of drug abuse. Heterogeneous stock (HS) rats allow us to investigate individual variability in these traits due to their robust genetic differences. In these experiments, we used two behavioral paradigms to investigate the relationship between these rats' responses to food- and cocaine-associated stimuli ("cues"), and whether this relationship depended on sex. Male (n=61) and female (n=60) heterogeneous stock rats were trained in a Pavlovian conditioned approach procedure, during which an 8-s illuminated lever predicted the delivery of a banana-flavored food pellet into a food cup. Rats received 25 trials daily for 5 days, and then were categorized as sign-trackers (ST; intense approach to the lever-cue), goal-trackers (GT; approach to the food cup), or intermediates (approach to both the cue and food-cup). Subsequently, rats were trained in a conditioned "cue" preference paradigm, during which they were injected with intraperitoneal saline or 10 mg/kg cocaine on alternating days before being placed in chambers with distinct textured floors. Cocaine- and saline-induced locomotion was measured using video tracking software. On the final day of testing, rats were injected with saline and placed in a chamber with both cocaine- and saline-paired floors. Time spent on the cocaine- vs. saline-paired floors was the primary measure of cocaine cue preference. We found no sex or ST/GT differences in preference for the cocaine paired floor. However, females showed more cocaine-induced locomotor activity than males. In addition, female sign-trackers had less cocaine-induced locomotion than female goal-trackers, and sign-tracking behavior was negatively correlated with cocaine-induced locomotion in females but not males. We conclude that the relationship between cocaine-induced locomotion and the responses to food- and cocaine-cues likely involve separable processes across sex. The long-term goal of the presented work is to determine how performance on these tasks can be influenced by genetic variants. As such, we predict that further work will elucidate the genotypic and phenotypic relationships between these tasks. Supported by P50DA037844

Title: Sex-dependent correlations between addiction-related traits in heterogeneous stock rats

Authors: ***P. MEYER**[1], C. P. KING[1], J. F. LUCKE[2], C. L. VERSAGGI[1], J. A. TRIPI[1], L. SOLBERG-WOODS[3], A. A. PALMER[4], J. B. RICHARDS[2];

Abstract: Drug addiction is associated with a number of traits related to behavioral regulation, including the response to novelty, attention, impulsivity, sensation seeking, and incentive salience attribution to cues. Understanding the relationship between these traits may be important for determining common behavioral and genetic processes involved in predisposition to addiction. As a first step in conducting a genome-wide association study of these traits, we tested 100 heterogeneous stock rats in six behavioral tests. We have initially focused on nine behavioral phenotypes, including locomotor activity (distance travelled), sensory reinforcement (responses that produce light onset), delay discounting (value of a delayed reinforcer), choice reaction time (reaction time and false alarms), Pavlovian conditioned approach (sign- and goal-tracking, and conditioned reinforcement), and cocaine-induced conditioned cue preference (preference for CS+, cocaine-induced locomotion). Initial analysis, indicates a subset of correlated measures, while many others appear to be unrelated. For example, sign-tracking and conditioned reinforcement were correlated, which suggests that these measures reflect partially overlapping neurobehavioral constructs. False alarms on the reaction time task were correlated with goal-tracking initially, but this correlation weakened as conditioning progressed. Sex differences were observed in several measures, with females showing more sign-tracking, sensory reinforcement, false-alarms, and conditioned reinforcement compared to males. Finally, several correlations among the measures were sex-specific. For example, locomotor activity was correlated with sensory reinforcement in males only, while it was correlated with indifference point only in

females. In conclusion, this initial analysis indicates that, while some measures are intercorrelated, most are not, and that in some cases the association appear to depend upon sex. Future studies will use genotype data from each rat to construct a genetic relationship matrix which will allow us to determine the extent to which any observed correlations are genetic rather than environmental in origin. We conclude that the genetic underpinning of these behaviors may be dissociable in a sex-dependent fashion. Supported by P50DA037844.

Title: Quantitative trait loci mapping of oxycodone reward and naloxone aversion in c57bl/6 substrains

Authors: *L. R. GOLDBERG[1], S. L. KIRKPATRICK[1], N. YAZDANI[1], W. E. JOHNSON[2], M. K. MULLIGAN[3], C. BRYANT[1];
[1]Lab. of Addiction Genet., [2]Med., Boston Univ. Sch. of Med., Boston, MA; [3]Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Opioid addiction is a heritable substance abuse disorder, whose genetic basis remains poorly understood. Mammalian model organisms are valuable for identifying novel genes that contribute to variation in addiction-relevant intermediate phenotypes associated with various stages of addiction, such as opioid-induced psychomotor stimulation and reward. C57BL/6J (B6J) and C57BL/6NJ (B6NJ) strains show significant strain differences in several addiction-associated traits, including ethanol consumption, psychostimulant behaviors, and naloxone conditioned place aversion (Kirkpatrick and Bryant, 2014). Quantitative Trait Locus (QTL)

mapping in a Reduced Complexity Cross (RCC) between these substrains drastically reduces the number of genetic variants from millions (e.g., B6J vs. DBA/2J) to thousands, accelerating the rate at which the underlying quantitative trait genes (QTGs) can be identified. We conducted QTL mapping for oxycodone conditioned place preference (OXY-CPP; N=76), and naloxone conditioned place aversion (NAL-CPA; N=113), along with saline (SAL; N=83) controls. We utilized a 9 day CPP/CPA protocol; twenty four hours post-assessment of initial preference on Day 1 (D1), mice received drug (1.25 mg/kg OXY, 4 mg/kg NAL, or SAL) on D2 and D4 on the drug-paired side, and SAL on D3 and D5. Mice were assessed for drug-independent CPP/CPA (D8) and state-dependent CPP/CPA on D9 under the influence of drug. QTL mapping was performed in R/qtl using 96 informative markers (1000 permutations). Preliminary analyses identified two OXY-specific QTLs: D8-D1 mean visit on the drug-paired side (LOD=3.55; peak= Ch1 44.33 cM; $p<0.05$) and D9-D8 time on the OXY-paired side (LOD=3.49, peak=Ch11 42.15 cM, $p=0.05$). Additionally, we identified two overlapping NAL-specific QTLs: D9-D1 freezing bouts on the NAL-paired side (LOD=3.18; peak= ch18 31.67 cM; $p<0.10$) and D9-D1 time on the NAL-paired side (LOD= 2.98; peak= ch18 29.22 cM; $p=0.16$). We are currently increasing our sample size to N=150 per drug treatment and will use genome editing and transcriptome analysis to validate novel genetic and neurobiological factors underlying the motivational properties of opioids.

Title: Identifying human striatal gene networks and pathways associated with obesity

Authors: C. WU[1], Z. JIANG[2], S. P. GARAMSZEGI[3], X. XIE[3], N. F. TSINOREMAS[2], *D. C. MASH[3];
[1]Dept. of Mol. and Cell. Pharmacol., [2]Ctr. of Computat. Sci., Univ. Miami Miller Sch. Med., Miami, FL; [3]Dept of Neurology, Univ. Miami Miller Sch. Med., Miami, FL

Abstract: Drug addiction and obesity share common neurobiological mechanisms that regulate the excessive consumption of both addictive drugs and palatable foods. The neurologic influence of insulin and downstream signaling molecules provides a molecular link between feeding behaviors and reward in the mesolimbic and nigrostriatal dopamine (DA) system. We speculate that the obesity phenotype may be associated with dysregulation of coordinated gene networks of the ventral and dorsal striatum that process reward saliency. To test this hypothesis, we used RNA sequencing (RNA-seq) to identify genome-wide expression profiles in brain from non-obese and obese subjects. RNA-seq was used to survey the brain transcriptome of the caudate and nucleus accumbens from young subjects (n=25) over a range of body mass indices (BMI range, 18.7kg/m^2 - 40.7kg/m^2). RNA-seq alignment and splice junctions were determined from TopHat with resulting data fed to Cufflinks (v. 2.1) to assemble aligned RNA-seq reads into transcripts. In the caudate nucleus, we detected 185 transcripts that are associated with increasing BMI by linear regression at a false discovery rate of 0.5 (n=25). We identified 184 BMI-related transcripts by performing group comparison of normal weight (BMI $\leq$ 25 kg/m^2, n=7) and obese subjects (BMI $\geq$ 30 kg/m^2, n=9). Gene set enrichment analysis (GSEA) demonstrated dysregulated neurophysiological processes in the human caudate associated with neurotransmitter release, amine ligand binding receptors and lipid biology. Interestingly, the type 2-diabetes gene set was the top pathway that correlated with BMI (q-value=0.035, NES=-2.088). Preliminary quantification of insulin receptor (InsR) and phospho-Akt (Thr308) proteins in the dopamine nigrostriatal pathway demonstrates dysregulation of insulin-mediated signaling in brain. These findings suggest that overfeeding and increased body weight may be associated with central insulin resistance. Funded by PHS grant DA033684.

Univ., Canberra, Australia

Abstract: Sensitivity to the locomotor stimulant effects of amphetamines is a heritable trait in mice that may aid in our understanding of the genetic and neurobiological basis of neuropsychiatric disorders involving perturbations in dopaminergic transmission. We previously used short-term selected mouse lines derived from a C57BL/6J (B6) x DBA/2J (D2)-F2 cross to identify a quantitative trait locus on chromosome 11 that was causally associated with reduced methamphetamine-induced locomotor activity (D2 < B6). We replicated this QTL in a standard B6 x D2-F2 cross and used phenotypic analysis of interval specific congenic lines containing various D2-derived segments of chromosome 11 on an isogenic B6 background to uncover a 206 Kb critical interval containing only two protein-coding genes, Rufy1 and Hnrnph1, that was necessary for reduced MA sensitivity. Here, we used transcription activator-like effector nucleases (TALENs) to induce small deletions in the first coding exon of Rufy1 or Hnrnph1. Phenotypic analysis of replicate lines heterozygous for the Hnrnph1 deletion (Hnrnph1 hets) recapitulated the congenic phenotype while those heterozygous for the Rufy1 deletion did not, thus identifying Hnrnph1 as the quantitative trait gene. With regard to addiction-like phenotypes, Hnrnph1 hets displayed increased MA-induced conditioned place preference (MA-CPP) relative to WT B6 littermates at the 2 mg/kg dose. Transcriptome analysis via mRNA sequencing of B6.D2 congenic (chr.11: 50-60 Mb) striatal tissue followed by pathway analysis revealed perturbations in “glutamate receptor signaling” and “GalphaQ signaling”, and identified “Cellular development, nervous system development and function, behavior” as the top network. We hypothesize that Hnrnph1 regulates neurodevelopment of the mesocorticolimbic circuitry, thereby affecting both dopaminergic neuron development and glutamate signaling, and hence the stimulant response to amphetamines. These results will likely have widespread implications for understanding the genetic and neurobiological bases of disorders comprising perturbations in dopamine neurotransmission, including addiction, schizophrenia, ADHD, OCD, and Parkinson’s disease.

Title: A polymorphism in the OPRM1 3' untranslated region is associated with methadone efficacy in treating opioid dependence

Authors: *R. CRIST[1], G. A. DOYLE[1], E. C. NELSON[2], W. H. BERRETTINI[1];
[1]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Psychiatry, Washington Univ., St. Louis, MO

Abstract: There is a wide range of outcomes for opioid dependent patients treated with either methadone or Suboxone. A significant percentage of patients do not have successful treatment outcomes and continue to use opioids other than the ones prescribed. Both environmental factors and genetic variation contribute to these differences in treatment efficacy in the patient population. Identification of relevant genetic markers may allow individuals to be prospectively genotyped and then prescribed the medication with the best chance of working. *OPRM1* encodes the mu-opioid receptor (MOR), the primary receptor for opioids of abuse, and single nucleotide polymorphisms (SNPs) in the gene may be important to the pharmacogenetics of opioid addiction treatment. The primary *OPRM1* transcript in neurons is MOR-1, which has a large ~11kb 3' untranslated region (UTR). The MOR-1 3' UTR has five common haplotypes (>10% frequency) in European-Americans and these haplotypes are tagged by 5 SNPs. Since 3' UTRs are often involved in regulating gene expression, we analyzed these 5 SNPs in 566 European-American patients enrolled in the Starting Treatment with Agonist Replacement Therapy (START) clinical trial. The START trial was a 24 week, open-label trial, which randomized opioid dependent patients to either methadone or Suboxone. One *OPRM1* SNP, rs10485058, was

significantly associated with the percentage of weekly opioid positive urine drug screens in patients prescribed methadone ($p = 0.002$). Individuals with the A/A genotype had 33.4% positive urines over the 24 weeks of the trial, while those with either the A/G or G/G genotypes had 48.6% positive urines. No effect was present in the Suboxone population. When analyzed using a generalized estimating equation to account for the effects of time, sex, and age, rs10485058 was again significant in the methadone population ($p = 0.007$). To further study this finding, rs10485048 was analyzed in an independent Australian cohort of opioid addicts undergoing agonist replacement therapy ($n = 1215$). Patients with the A/A genotype were more likely to self-report abstinence during the trial compared to individuals with the A/G or G/G genotypes, supporting the initial association. *In silico* analysis of microRNA binding sites near rs10485058 revealed a miR-95-3p site predicted to be disrupted by the A allele of the SNP, providing a potential mechanism of action for the observed pharmacogenetic effect. We hypothesize that individuals carrying the G allele of rs10485058 express lower levels of MOR-1 protein than those with the A/A genotype, reducing the ability of methadone to prevent illicit opioid use.

Title: Association of GABRA2 polymorphisms and haplotype analysis in Alcohol Dependence

Authors: *B. M. SHANKARAPPA;
psychiatry, Natl. Inst. of Mental Hlth. and Neuroscien, Bangalore, India

Abstract: Aim: 1. To analyze the effects of polymorphisms (rs279836, rs279845 and rs279871) in the GABRA2 gene on the risk of alcoholism. 2. To determine associations between genetic markers basing on haplotype analysis. Background: Alcohol consumption, particularly heavier drinking, is an important risk factor for many health problems and, thus, is a major contributor to the global burden of disease. The major inhibitory neurotransmitter γ-aminobutyric acid (GABA) has been studied extensively in the human CNS. Genetic variation in GABA may be an important source of risk for developing alcohol dependence based on evidence. Evidence suggests that alcohol initially potentiates GABA effects; increases inhibition, and often the brain becomes mildly sedated. But over time, chronic alcohol consumption reduces the number of GABA receptors through the process of down-regulation. When alcohol is eventually withdrawn, the loss of its inhibitory effects, combined with a deficiency of GABA receptors, may contribute to over-excitation through-out the brain. This effect, in turn, can contribute to withdrawal seizures. Methods: In the present study we have analyzed the GABRA2 SNPs among AD cases (N=200) and age matched controls (N=124). Male participants were selected from patients seen at the Centre for Addiction Medicine, NIMHANS. Individuals who met the criteria for alcohol dependence (ICD 10) were recruited into the study after obtaining informed consent. The clinical instruments applied included Semi Structured Assessment for Genetics of Alcoholism-IV, Severity of Alcohol Dependence score, MINI psychiatric interview, scale for family interview and Revised combined clinical & laboratory index for alcoholic liver disease. DNA isolated from the peripheral blood was used for genotyping, done by Polymerase Chain Reaction followed by Restriction Fragment Length polymorphism method for rs279845 and by predesigned TaqMan® SNP genotyping assays in RT-PCR for rs279836 and rs279871 was performed. Haplotype analysis is performed using UNPHASED software. Results: Among the three SNPs analyzed none of them showed significant difference between AD subjects and controls. All three SNPs were in LD (r2= 0.99) and they are in strong association when present together in haplotype , which is significant in cases but not in controls (Likelihood ratio chisq = 29.285 df = 5 p-value = 2.03857e-005) Conclusion: Even though there is a absence of single SNP association with alcoholism. The Haplotype analysis showed there is a strong association of these 3SNPs with alcoholism

Title: Reduced cadherin 13 expression alters dopaminergic fibers and cocaine-related behaviors in mice

Authors: *G. R. UHL[1], J. DRGONOVA[2], L. HARTSTEIN[2], M. BAUMANN[3], B. RANSCHT[4]; [1]Mol. Neurobio., NMVAHCS, BRINM and NIH/NIDA, Albuquerque, NM; [2]Mol. Neurobio., [3]Medication DIscovery, NIH/NIDA, Baltimore, MD; [4]Sanford-Burnham Reserach Inst., LaJolla, CA

Abstract: Proper function of brain circuitry requires accurate expression and regulation of cell adhesion molecules (CAMs), including those of the calcium-dependent cadherin family. Cadherin-13 (*CHD1*3; T-cadherin) is an atypical cadherin in that it lacks an intracellular domain and is localized to the plasma membrane *via* a glycosylphosphatidylinositol anchor. Molecular genetic studies in humans associate variants in *CDH13* with vulnerability to substance dependence, reward from modest amphetamine doses and ability to quit smoking. In mice, Cdh13 mRNA is expressed in cerebral cortex, hippocampus, amygdala, striatum, ventral tegmental area, and other brain regions implicated in addiction circuitry. *CDH13* knockout mice (*CDH13-KO*) provide a good model for possible behavioral and anatomical influences of variation at this gene locus. *CDH13-KO* mice exhibit increased sensitivity to cocaine reward as assessed by conditioned place preference test, and increased densities of dopaminergic fibers in cingulate cortex, consistent with *in vitro* observations that homophilic CDH13 interactions inhibit neuronal growth. The changes in dopaminergic innervation are accompanied by neurochemical evidence for increased dopamine turnover in the cortex but not in other brain areas tested. These behavioral, neurochemical and anatomical observations are consistent with contributions of variants in this gene to human addiction phenotypes. *Support: NIH IRP (NIDA); NIH HD25938 (BR).*

Title: Adolescent cocaine experience differentially augments adult sensitization and alters nucleus accumbens epigenetic profiles in selectively bred rats that differ in addiction liability

Authors: *A. PARSEGIAN[1], J. GARCIA-FUSTER[2], P. BLANDINO[1], S. J. WATSON, Jr[1,3], S. B. FLAGEL[1,3], H. AKIL[1,3];
[1]The Mol. & Behavioral Neurosci. Inst., Ann Arbor, MI; [2]IUNICS, Univ. of the Balearic Islands, Palma de Mallorca, Spain; [3]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: While many people experiment with drugs of abuse, only a small minority go on to become drug addicts. Genetic predisposition is implicated, but early initiation of drug use in adolescence also reliably predicts the likelihood of addiction in adulthood. Thus, adolescence may be a critical period during which drug use can elicit neuroadaptations that might render one more susceptible to addiction in adulthood. There has been growing evidence for an important relationship between chromatin modifications, the genes they modify, and the enduring neurobiological impact of cocaine in promoting addiction. Using a unique genetic rat model that captures individual differences in vulnerability to addiction, we asked whether adolescent drug exposure alters their genetic predisposition via epigenetic chromatin modification. Rats selectively bred based on locomotor response to novelty also differ on a number of addiction-related traits. Specifically, relative to bred low-responder (bLR) rats, bred high-responders (bHR) are more sensitive to the psychomotor-activating effects of cocaine and reinstate drug-seeking more readily following a prolonged period of abstinence. We exposed these bred rats to a sensitizing regimen of cocaine (15 mg/kg) or saline for 7 days during adolescence (PND 33-39) and assessed phenotypic differences in the acute and sensitized response to cocaine during this

period. We also tested some rats, with or without a history of adolescent cocaine exposure, for response to cocaine in adulthood (PND 77-84). We then measured two histone modifications, acetylation (ac) and tri-methylation (me3) on histone 3 lysine 9 (H3K9) in the nucleus accumbens (NAc) core and shell during either adolescence, or adulthood. As expected, bHRs showed greater sensitization than bLRs to repeated cocaine exposure during both adolescence and adulthood. However, adolescent cocaine exposure shifted the bLR phenotype to express greater sensitization in adulthood. Conversely, bHRs with prior adolescent cocaine showed blunted expression of sensitization in adulthood. Adolescent cocaine also induced epigenetic differences in bHRs relative to saline controls, with an increase in both the repressive mark H3K9me3 in the shell and the permissive mark acH3K9 in the core. By comparison, in bLRs, adolescent cocaine reduced both marks in the core, but had no significant change in the shell, relative to their saline controls. Importantly, all of these epigenetic changes were present in adolescence and persisted into adulthood. These results indicate that adolescent drug use might influence inborn genetic addiction liability via epigenetics.

Title: Serum exosomal microRNA-137 is a potential biomarker for repeated psychostimulant exposure

Authors: ***H.-I. IM**, E. NAM, B. KIM, J. KIM, S. LEE, H. KIM, J. WOO;
Korea Inst. of Sci. & Technol., Seoul, Korea, Republic of

Abstract: Current biological assay for detecting psychostimulant exposure is applicable up to few months of abstinence, but determining psychostimulant exposure after several months to years of abstinence and distinguishing acute/repeated psychostimulant exposure are still difficult. A significant amount of exosomal microRNAs (miRNAs) are circulating in remarkably stable

forms within blood serum, and some miRNAs have a high degree of brain specificity. Thus the brain-originated exosomal miRNAs in serum may prove to be suitable for detecting long-term changes in brain caused by repeated psychostimulant exposure. Here we demonstrate on complementary studies using mouse brain tissue and blood, patient blood samples, biochemical assays and transgenic approaches to show that both striatal and serum exosomal miR-137 are concordantly diminished in mice after repeated cocaine exposure, and that the reduction in serum exosomal miR-137 can effectively distinguish the individuals with history of chronic methamphetamine addiction. Additionally, we provide evidences that striatal and serum exosomal miR-137 levels correlate with each other after repeated cocaine exposure, and that striatal biomolecules could be directly delivered by blood-to-brain transport. Overall, our data suggest that the exosomal miR-137 in peripheral bloodstream can potentially serve as a non-invasive, sensitive and reliable biomarker for repeated psychostimulant exposure.

Title: Significant association of rs2240158 in the glutamate receptor subunit gene (GRIN3B) with heroin addiction

Authors: ***X. XIE**[1,2,3], H. LIU[1,2,3], W. ZHOU[1,2,3];
[1]Ningbo Inst. of Microcirculation and Henbane, Zhejiang, China; [2]Lab. of Behavioral Neuroscience, Sch. of Medicine, Ningbo Univ., Ningbo, China; [3]Ningbo Addiction Res. and Treatment Ctr., Ningbo, China

Abstract: Objective Growing evidence suggest that N-methyl-D-aspartate (NMDA) receptor-mediated glutamate neurotransmission may be involved in the pathophysiology of drug addiction. The NMDA receptor is consisting of three subfamilies (NR1, NR2 and NR3). The ability of NR3 to negatively modulate the NMDA receptor function makes it an attractive

candidate gene of heroin addiction. The purpose of this study is to explore the association between two single nucleotide polymorphisms (SNPs) (rs4807399, rs2240158) in the glutamate receptor subunit gene (GRIN3B) and heroin addiction. Methods The genotypes of the two SNPs (rs4807399, rs2240158) in heroin dependent patients and normal control subjects of the male Han Chinese were detected by TaqMan SNP genotyping method, and the association between heroin dependence and the two SNPs were analyzed. Results The frequencies of genotype and allele at rs2240158 were significantly different between the cases and the controls (nominal P were 0.0168, 0.0062, respectively). The distributions of genotype and allele at rs4807399 were not significantly different between in the cases and in the control group ($P > 0.05$). In addition, the C allele frequency of rs2240158 was significantly higher in cases compared with the control group (OR = 1.603, 95% CI 1.142-2.252, P = 0.0062). And the frequency of CC genotype of rs2240158 was significantly higher in cases compared with the control group (OR = 1.599, 95% CI 1.086-2.354, P = 0.0171). Conclusion Our study indicates that the rs2240158 of the glutamate receptor subunit gene (GRIN3B) play a major role in heroin addiction.

Title: Identification of addiction-relevent genes using high-throughput drug naïve behavioral screens in the knock out mouse project (KOMP)

Authors: *P. E. DICKSON[1], T. WILCOX[1], J. NDUKUM[1], J. CLARK[1], J. A. BUBIER[1], S. J. RIZZO[1], J. C. CRABBE[2], J. M. DENEGRE[1], K. L. SVENSON[1], R. E. BRAUN[1], V. KUMAR[1], E. J. CHESLER[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Given the substantial evidence that predisposing behaviors predict subsequent addiction and the prevalence of dual diagnosis of addiction, alcoholism and other disorders, we expect that these behaviors will predict the tendency to self- administer drugs, and therefore enable identification of clinically relevant addiction genes using drug-naïve mice. Behavioral phenotypes were incorporated into The Jackson Laboratory Knockout Mouse Phenotyping

(KOMP) pipeline based on predicted relevance to addiction and mood disorders. To test the predictive validity of these assays for alcohol and drug related phenotypes, strains that exhibited significantly different phenotypes relative to C57BL/6NJ controls on at least one behavioral assay with relevance to anxiety, depression, or response to novelty are being tested on three different addiction-relevant assays: nicotine two bottle choice, methamphetamine two bottle choice, or ethanol two bottle choice. We predicted that anxiety, reactivity and depression mutants will have increased alcohol consumption, anxiety and depression mutants will have increased nicotine consumption, and novelty response/exploratory behavior mutants will have increased methamphetamine consumption. Results support this predictive relationship. For example, Htr3b knockout mice are anxiety/reactivity mutants that also show significant increase in ethanol drinking in the two bottle choice test. These studies provide an indication of the predictive value of the additional behaviors in the JAX KOMP pipeline for addiction research and will inform decisions about future inclusion of related traits.

Title: Tolerance for perceiving a stable world depends on visual and vestibular variability

Authors: *I. GARZORZ[1], P. R. MACNEILAGE[2];
[1]Grad. Sch. of Systemic Neurosciences, Muenchen, Germany; [2]German Ctr. for Vertigo, Univ. Hosp. of Munich, Muenchen, Germany

Abstract: Whenever the brain encounters simultaneous signals from different sensory modalities, it has to judge whether these signals originate from the same external event or object. This process implies comparison of sensory signals leading to integration if signals agree or segregation if they don't. While statistically optimal cue integration has been widely studied, there is less work on probabilistic signal comparison. A straightforward model for sensory cue comparison implies subtraction of sensory signals leading to a difference distribution with mean

equal to the difference of compared signal means, and variance equal to the sum of compared signals variances. When this distribution has mean significantly different from zero, signals are likely to have independent origin. To test this model for visual-vestibular cue comparison we conducted an experiment using a virtual reality set-up allowing for independent control of visual and vestibular stimulation. The stereo visual scene consisted of red spheres (diameter = 0.6 cm; density = 0.004 spheres/cm^3; clipping planes: near = 25 cm, far = 65 cm) and a head-fixed fixation point. Lateral translations had a Gaussian velocity profile of constant duration (0.8 s) and displacement of 5 cm for the reference movement (peak velocity = 0.125 m/s). The variances associated with visual and vestibular estimation of self-motion were measured in two single-cue amplitude discrimination conditions using a 2IFC task and an adaptive staircase procedure. These unimodal measurements of eight participants were used to make subject-specific predictions about response variability in a third condition with simultaneous visual and vestibular stimulation and a visual gain factor that was varied from trial to trail. On each trial, subjects had to indicate whether the visual scene moved with or against them in world coordinates, which required an evaluation of visually-simulated self-motion speed relative to perceived self-motion speed. The visual gain factor that elicited an equal number of "with" versus "against" responses leads to perception of a stable visual environment. Previous studies have reported gains greater than one, but we observed gains less than or equal to one. Previous studies have not explicitly related visual gain variability to single-cue variability measurements. Supporting the difference-distribution model, we observed that variance on visual-gain judgments, which quantifies tolerance for discordance in perceiving a stable visual world, is well-predicted by the sum of measured variances on single-cue estimates.

Abstract: ABBI, the Audio Bracelet for Blind Interaction, is a bracelet that is worn on the wrist and provides an audio feedback about body movements to help visually impaired children to build a sense of space and facilitate the social interactions. This study was designed to assess the effectiveness of ABBI system for improving mobility and spatial cognition in visually impaired children. Eight low vision children (aged 9-16, with residual vision lower than 1/10) took part in this study. The study lasted 12 weeks. Once per week each child participated in a 45-minutes spatial rehabilitation session where he was blindfolded and performed different mobility and spatial cognition exercises. He also had to use it one hour per day at home alone or with one relative. The mobility and spatial cognition abilities were measured before and after the 12-weeks rehabilitation program with three different tests targeting the proprioceptive, audio and motor abilities. Results showed that the use of the Audio Bracelet for Blind Interaction allowed the low vision child to improve their mobility and audio abilities.

Title: Audiovisual integration in areas MT & MST of marmoset monkeys

Authors: *T. A. CHAPLIN[1,2,3], B. J. ALLITT[1], M. A. HAGAN[1], N. S. C. PRICE[1,3], R. RAJAN[1,2], M. G. P. ROSA[1,2,3], L. L. LUI[1,3];
[1]Physiol., [2]ARC Ctr. of Excellence for Integrative Brain Function, [3]Monash Vision Group, Monash Univ., Melbourne, Australia

Abstract: The traditional model of sensory processing states that each modality is processed independently and is only integrated in higher-level multisensory cortical areas. However, recent studies have shown anatomical and physiological evidence for multisensory integration in regions that have historically been attributed to one sense. The middle temporal area (MT) and the medial superior temporal area (MST) of the primate cerebral cortex have well known roles in processing visual motion, but in marmosets they are known to have direct connections with auditory cortex (although these connections are more abundant for MST than MT). Therefore we tested if neurons in these areas are responsive to auditory motion stimuli, and whether these neurons can integrate auditory and visual motion cues. We performed extracellular recordings (n = 29, 24 in MT, 5 in MST) in 3 anaesthetised marmosets and measured the neurometric

thresholds of neurons for visual, auditory, and audiovisual motion stimuli. Visual stimuli were random dot kinematograms moving either left or right. Auditory stimuli were interaural level difference ramps of 6-12kHz bandpass noise presented with headphones which simulated auditory motion. The strength of the visual motion signal was manipulated by decreasing the coherence of the dots, whilst the auditory motion signal was weakened by adding background white noise in both ears. Auditory and visual stimuli were presented at the same spatial location, direction and speed for 1 second with matching noise levels, to maximise the chance of neurons showing multisensory integration and enhancing neurometric thresholds in the audiovisual conditions. None of the neurons from either area was reliably responsive to auditory stimuli alone. While there were some circumstances where auditory stimuli appeared to modulate visual responses in MT, auditory stimuli which complemented visual motion did not reliably improve neurometric thresholds in any of our MT cells in a left-right discrimination paradigm. Only one neuron from area MST showed a statistically significant change in threshold between the visual and audio-visual conditions. These data, while not ruling out minor modulatory influences from the auditory domain, suggest that MT does not integrate auditory cues for motion. It is more likely this occurs in downstream areas such as MST, VIP or beyond.

Title: The relationship between body representation and visuospatial perception

Authors: ***K. NAKATA**, S. NOBUSAKO, S. MORIOKA;
KIO UNIVERSITY, Nara, Japan

Abstract: [Objective] Illusory perceptions of rubber hand ownership that are induced by the rubber hand illusion (RHI) modulate pseudoneglect. That study reported that the subjective midpoint of a line in a bisection task shifts from left to right in response to the left-handed RHI. However, the cause of this shift is unclear. One possibility is that the motor response changes when the line is bisected. This study was conducted to determine if the left-handed RHI affected the gaze behavior of the premotor response in the line bisection task. [Method]The participants were 23 healthy right-handed adults (12 males, 11 females, mean age: 25.0, standard deviation:

3.3). RHI was done with the left hand to change body representation. The rubber hand was placed 20 cm to the right of the actual left hand. Brush stimulation was performed for 3 min in synchronous and asynchronous conditions. The illusion was evaluated with proprioceptive drift and questionnaires. The line bisection task was conducted with 20-cm and 30-cm line segments before and after the RHI and evaluated with an eye tracker (Tobii Studio). The participants were asked to watch the subjective midpoint of each line for 10 s. The area of interest was set from the center of each line segment to the left and right, and the total fixation duration (s) and gaze points (pixels) were compared before and after the RHI. [Results]Proprioceptive drift was larger in synchronous conditions than in asynchronous conditions. Questionnaire items that reflected the sense of ownership and agency, location, and loss of own hand were significantly higher ($p < 0.05$) in synchronous conditions than in asynchronous conditions. Deviation of the gaze point on the left side of the actual midpoint of the 20-cm line was observed before the RHI, and the gaze point shifted significantly to the right after the illusion ($p < 0.05$). The changes in the gaze points and the proprioceptive drift were positively correlated ($r = 0.6000$, $p = 0.0181$). The total fixation duration in the area of interest before the RHI was longer on the left side, and the illusion later showed a tendency to increase the total fixation duration on the right side. [Conclusion]A series of behavioral changes shifted the gaze point to the right due to the right-sided RHI, which has been suggested to be due to the perception of a subjective midpoint of a line segment by a change of body representation. In addition, the questionnaires showed that the consciousness structure of embodiment(sense of ownership and agency, location, and loss of own hand) was an important factor in visuospatial perception. However, these changes were behavioral, and the underlying mechanisms were not clear.

Title: Tactile and crossmodal localization in adults with autism spectrum disorder

Authors: ***M. HENSE**[1], S. BADDE[1], S. KÖHNE[2], J. HABICH[1], I. DZIOBEK[2], B. RÖDER[1]; [1]Univ. of Hamburg, Hamburg, Germany; [2]Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Skin-based, anatomically anchored coordinates of a touch seem to be automatically remapped into external space by taking into account body posture; the final location estimate likely results from a weighted integration of information from multiple reference frames. Remapping of tactile stimuli is a prerequisite for multisensory integration of tactile and visual stimuli, which are initially coded in different, modality-specific reference frames. Prospective studies in children have suggested that multisensory localization follows a protracted developmental time course reaching adult level in early adolescence. There is evidence that children with Autism Spectrum Disorder (ASD) may stronger weight anatomical reference frames when localizing tactile stimuli. However, it might be argued that this finding arose from a developmental delay and would thus have disappeared by reaching adulthood. Finally, possible consequences of altered touch localization for multisensory processing is not yet known. In the present study, 16 high-functioning adults with ASD and 16 typically developed controls performed both a tactile temporal order judgment task (TOJ-task) as well as a visuo-tactile crossmodal congruency task (CC-task) while adapting either an uncrossed or crossed hand posture. In both tasks participants had to localize a tactile target stimulus at one hand in the presence of either a tactile (TOJ-task) or a visual (CC-task) distractor stimulus, respectively. Since with crossed hands anatomical and external coordinates are in conflict, a comparison of touch localization between both postures allows estimating the weights assigned to the anatomical vs. external reference frame. Results for both tasks were indistinguishable between groups. Therefore, we concluded that the automatic remapping of touch into external space and the weighting of reference frames is not affected by ASD provided that developmental delays are taken into account.

Title: Mechanisms of multisensory stochastic resonance in the superior colliculus

Authors: *N. HUIDOBRO[1], I. MENDEZ-BALBUENA[2], B. DE LA TORRE VALDOVINOS[1], E. MANJARREZ[1];
[1]INSTITUTO DE FISIOLOGIA, BENEMERITA UNIVERSIDAD AU, PUEBLA, Mexico;
[2]Maestría en Diagnóstico y Rehabilitacion Neuropsicológica, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: In previous studies we described the occurrence of a phenomenon named multisensory stochastic resonance (SR), which is exhibited in psychophysical experiments in humans (Manjarrez et al., 2007) and electrophysiological experiments in the superior colliculus in cats (Huidobro and Manjarrez, 2014; Abs Soc Neurosci 331.03). Here we extended these studies by means of single unit recordings in several regions of the superior colliculus which are conceivable involved in multisensory integration. Experiments were performed in three precollicular-post mammilary decerebrate cats. Extracellular unitary recordings were obtained by means of quartz-platinum/tungsten microelectrodes from Thomas Recording (5 to 7 MΩ). We recorded 215 neurons distributed in the stratum zonale (45), stratum griseum superficiale (59) and stratum griseum intermediale (111). The input signal consisted of periodic-subthreshold visual stimuli elicited by a pair of LEDs. In addition, we applied continuous auditory noise with a pair of headphones adapted to the cat eardrum. We found that most of the neurons did not exhibit a background activity and they were in subthreshold conditions until an optimum level of auditory noise induced its firing. Furthermore, the total number of spikes measured from the peristimulus histogram exhibited an inverted U-like form as a function of the auditory noise level. We did not observe statistically significant differences in the strength of the SR at optimum noise among the different layers of the superior colliculus. We suggest that the multisensory SR observed in the superior colliculus, under visual stimulation, is mediated by the activation of subthreshold cross-modal neurons which reach the threshold at an optimal level of auditory noise.

Title: Spatial influences on audio-visual interactions in the monkey brain

Authors: *R. S. MUERS[1], M. J. BARTOLO[1], T. D. GRIFFITHS[1,2], A. THIELE[1], C. I. PETKOV[1];

Abstract: Multisensory signals that are in spatial and temporal register modulate a number of cortical areas. Many such regions, including those in caudal auditory cortex, belong to a dorsal, presumably spatial-processing pathway. However, brain imaging studies in nonhuman animals have not directly assessed the impact of spatial influences on audio-visual interactions. Thereby, an epistemic gap exists between human neuroimaging and nonhuman animal electrophysiological studies on spatial multisensory interactions. To advance our understanding, we used spatially moving audio-visual stimuli during functional MRI with two Rhesus macaques. Tonotopic maps for each animal were also obtained to approximate the location of auditory cortical fields. The monkeys were presented with unimodal (auditory or visual) and bimodal (audio-visual) stimuli moving in azimuth. Auditory stimuli were, virtual-acoustic space, moving broadband noises. Visual stimuli were moving black squares on a gray background. Bimodal stimuli either moved congruently or incongruently in spatial relation to each other. We analysed the fMRI data seeking to identify brain regions showing supra-additive multisensory interactions (modelled as: Bimodal (AV) > Unimodal (A+V)). Significant supra-additive interactions were observed in a number of brain areas (cluster corrected, $P < 0.01$) including areas VIP and LIP in the intra-parietal sulcus, area TPO in the superior-temporal sulcus, and visual area MT. Primary auditory and visual cortical areas also showed strong multisensory interactions. Stronger multisensory interactions were observed in posterior auditory cortical fields, including field A1 (RM-ANOVA, $P < 0.01$) and incongruent audio-visual stimuli preferentially modulated postero-medial auditory cortex. The multisensory effects in auditory cortex showed some interesting differences between the left and right hemispheres, although at the whole-brain level the effects were largely bilaterally distributed. In a control experiment with one of the macaques, we evaluated whether interactions were specific to moving stimuli. We observed that moving unimodal stimuli were more effective than stationary stimuli in activating caudal auditory fields and visual area MT. However, moving and stationary supra-additive multisensory interactions were comparable in these regions. Our results identify spatial

influences on audio-visual interactions in the primate brain and serve as a bridge between human neuroimaging studies and those in animal models studying multisensory interactions at the neuronal level.

Title: Neural correlates of multisensory behavior in the auditory cortex

Authors: A. HAMMOND-KENNY[1], V. M. BAJO[1], A. J. KING[1], *F. R. NODAL[2];
[1]Physiology, Anat. and Genet., [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Our perception of everyday events relies on the ability to integrate information obtained from different sensory modalities. Such integration often results in shorter detection times and greater accuracy or discriminability. Recent neural recording studies have shown that multisensory processing occurs even at the level of early sensory cortices. However, to date, these studies have mainly been performed under anesthesia and, therefore, the behavioral relevance of the cross-modal interactions observed remains to be determined. Here, we explore the multisensory nature of the ferret auditory cortex by recording neural activity while animals perform different tasks, thereby enabling correlation of neural and behavioral changes. Ferrets were trained by positive operant conditioning in two audio-visual tasks. Task 1 tested the performance accuracy of animals when localizing multisensory stimuli as compared to component unisensory stimuli, presented from 1 of 7 sites separated by 30° around the frontal hemifield of a circular arena. Task 2 tested the ability of ferrets to categorize multisensory stimuli according to the spatial congruency of their unisensory components. Once behavioural abilities were established and performance was stable, neural activity was recorded during task performance via bilaterally implanted electrode arrays. Behaviorally, animals showed an improvement in localization accuracy for multisensory versus component unisensory stimuli, with greatest gains observed at the shorter stimulus durations (<200 ms) and at more lateral locations. In addition, Race model inequality analysis of approach-to-target response times and

head orienting reaction times showed that different mechanisms, multisensory integration and probability summation, respectively, were responsible for the multisensory facilitation observed in the two response modes. Recordings from cortical neurons showed that approximately 40% of units responded to both stimulus modalities, with the majority (>90%) of bisensory units displaying sub-additive interactions to spatially congruent audio-visual stimuli presentations. In addition, although ferrets can correctly identify spatially congruent multisensory stimuli, bisensory units exhibited higher firing rates to spatially incongruent than to congruent stimuli presentations. Together, our results suggest that multisensory activity is widespread in the auditory cortex and that the magnitude of the interactions between visual and auditory inputs changes when the stimuli are categorized behaviorally according to their relative locations.

Title: Assigning a touch on the hand to a foot: post hoc construction of tactile location

Authors: *T. HEED[1,2], B. RÖDER[2], S. BADDE[2];
[2]Fac. of Psychology & Human Movement Sci., [1]Univ. of Hamburg, Hamburg, Germany

Abstract: Touch activates primary somatosensory cortex (S1), and tactile skin location is reflected in the homuncular organization of this cortical region. However, human participants sometimes confuse tactile locations, for example, when reporting which of two stimuli, one on each hand, occurred first while the hands are crossed [1, 2]. This finding is thought to indicate that tactile location is estimated by integrating skin-based and spatial information, as skin and space indicate opposite sides with crossed hands [3]. Yet, though caused by spatial conflict, such confusions may index errors in choosing between the two stimuli rather than spatial mislocalization of the first stimulus to the location of the second. Here, we show that participants systematically mislocalize touch to body parts that have not been stimulated, and, accordingly, whose associated S1 region has not received peripheral input. Participants sat on the floor, resting their hands on a see-through platform just above their outstretched feet. To dissociate

body side from side of space, hands and feet could each take on uncrossed and crossed postures. In each trial, two of the four limbs were tactually stimulated in short succession. Participants reported which limb had received the first touch, either by moving the respective limb, or by calling out the color of a sleeve worn on it. Independent of response mode, participants made two kinds of errors. First, they often reported the second touch to have occurred first, and more so when the limb receiving the first touch was crossed than when it was uncrossed (15 vs. 20%). Second, they often reported touch on a limb that had not been stimulated at all (10%). Both error types systematically reflected three characteristics: Participants erroneously reported the homologous limb (e.g., left hand response for right hand stimulus); they reported the limb of the same body side (e.g., left foot response for left hand stimulus); and they reported limbs on the same side of space (e.g., response with crossed left foot for stimulus on uncrossed right hand). In a new experiment, participants received only a single touch per trial. Again, they reported touch on non-stimulated limbs, with fewer, but similar, systematic errors as for the two-stimulus paradigm. In sum, tactile localization to a limb can occur without any peripheral tactile input to the respective S1 region, resulting in drastic mislocalization, for example across hands and feet. Accordingly, our results imply that tactile location is constructed post hoc by integrating skin location with three types of body-related and spatial information about the touched limb: limb type (hand vs. foot), body side, and side of space.

Title: The role of auditory cortex in the audiovisual ventriloquist aftereffect

Authors: *B. ZIERUL[1], B. RÖDER[1], C. TEMPELMANN[2], P. BRUNS[1], T. NOESSELT[3,4]; [1]Biol. Psychology and Neuropsychology, Hamburg Univ., Hamburg, Germany; [2]Dept. of Neurol., [3]Inst. of Biol. Psychology, [4]Ctr. for Behavioral Brain Sci., Otto-von-Guericke Univ., Magdeburg, Germany

Abstract: When presented alongside a simultaneous but spatially incongruent visual stimulus, localization of an auditory stimulus is usually biased toward the location of the visual stimulus. This is known as the ventriloquist effect (VE). Exposure to a train of audiovisual stimuli, where the visual stimuli are displaced from the auditory stimuli in a constant direction, can bias later localization of unisensory auditory stimuli in the direction of displacement, which is known as the ventriloquist aftereffect (VAE). Whereas VE most likely indicates an immediate interplay of visual and auditory stimulus processing, VAE most likely reflects a recalibration of spatial auditory representations (i.e. sensory learning). Based on previous ERP-studies, it has been suggested that this recalibration occurs in low-level auditory areas. In the present study, we aimed to identify the neural underpinnings of VAE in humans using fMRI. During fMRI-data acquisition, blocks of unisensory auditory stimuli were presented, separated by blocks of spatially incongruent audiovisual stimuli (A-pretest, AV-recalibration, A-posttest). Sounds were presented from one of three speakers (left, middle, right). During the unisensory auditory pre-/posttests, participants judged where they had perceived each tone via button press. During the audiovisual recalibration blocks, visual stimuli were constantly displaced by 14° to the right of the auditory stimuli and the participants' task was to react to occasional deviant stimuli. The behavioral results revealed that the VAE was successfully induced, i.e. auditory localization judgements were significantly biased to the right in posttests vs. pretests. With regard to the fMRI results, we hypothesized that spatial hearing would be reflected by a difference in neural activity between left- and right-hemispheric auditory areas for lateralized sounds. This difference was expected to be altered by the audiovisual recalibration. Corroborating our hypothesis, we found reduced fMRI-signals in the right auditory cortex (planum temporale, PL) following audiovisual recalibration, replicating previous findings on VE. Importantly, during VAE we additionally observed enhanced fMRI-signals in left auditory cortex (PL), not observed during VE. Moreover, the areas modulated by VAE overlapped with those areas that differentially responded to lateralized sounds in the pretest. Thus, spatially misaligned audiovisual input modulates the differential response in left- and right-hemispheric auditory areas that code for auditory space, and the increase in contralateral neural activity in auditory cortex might be directly related to VAE but not VE.

Title: Interactions between visual capture and front-back confusions in sound localization

Authors: C. MONTAGNE, *Y. ZHOU;
Speech and Hearing Sci., Arizona State Univ., Tempe, AZ

Abstract: Unlike rodents, primates experience frontal vision while hearing in a 3D spatial domain. Modality-specific attraction and avoidance is crucial for minimizing localization errors during 3-D navigation. As a result of ambiguities in interaural time and level cues, which is known as the "cone of confusion", front-back errors are often reported in sound localization tasks. In this study we investigated the extent to which front-back confusion may be modified by visual stimulation in the frontal field. We are particularly interested in whether or not vision influences the perceived location of a sound source that is outside the field of vision. We had human subjects lateralize 15-ms noise bursts in free field conditions. Two pairs of hidden loudspeakers were positioned in front of and behind a subject at lateral positions of ±45º. Apparent sound source locations spanning 360º around a subject were generated by varying the time delay (up to 1 ms) or the intensity ratio between any two loudspeakers. Three high-powered LED lights positioned in front at -45º, 0º and +45º were used as visual stimuli. Listeners reported their perceived spatial locations of a sound by pushing a button on a touch screen in a single-interval forced-choice experiment. Results show that in audio only (AO) trials subjects show a similar extent of front-back confusion for sound sources in the front and rear hemi-field. In audio-visual (AV) trials front-back confusion decreased (7%) for frontal auditory stimuli and increased (19%) for rear auditory stimuli. Left-right hemifield-specific visual capture also occurred in the AV trials, in congruence with previous "ventriloquist effect" studies. Overall, visual capture is not limited to interactions between information from single light and sound sources, but also extend to perceptual dimensions within an internally computed auditory space. These results suggest that the spatial alignment between vision and audition may fundamentally change the way in which visual cues interact with the directional information from multiple sound sources based on whether they are "in-sight" or "out-of-sight" targets. While visual cues help minimize front-back errors for "in-sight" sound sources by pulling perceived sound locations to the frontal field, visual capture may jeopardize detection of rear-approaching targets.

Title: Landmark processing by retrosplenial and postsubicular head direction cells

Authors: *Y. R. LOZANO, P. I. JACOB, M. A. VALENCIA-GARZA, K. J. JEFFERY; Univ. Col. London, London, United Kingdom

Abstract: Spatially modulated neurons in the rat brain such as place, grid and head direction (HD) cells cooperate to form a representation of the local environment that can be used for navigation. A number of studies have examined the role of visual cues in updating the position and directional firing of such cells. However, a question that remains relatively unexplored is how visual information is transformed between primary visual cortex and the spatial system. To investigate this question, extracellular recordings of HD cells were conducted in adult male Lister Hooded rats implanted in the postsubiculum (PoS) and the retrosplenial cortex (RSC). These two interconnected brain regions receive visual and self-motion information from diverse pathways and have been hypothesised to play an important role in the encoding of landmarks. Cue control experiments were conducted as the rats foraged for food inside a light-grey cylindrical arena with two opposing cue cards attached to the inner wall, 180 degrees apart. The cue card pair varied in contrast (black-white), orientation of a bar (vertical-horizontal), height of a bar (top or bottom of the card) and lateral position of a bar (left or right), with control stimuli comprising identical cues. The cues were designed to explore to what extent the cells can process fine details of visual stimuli; if they could not, the cues would be indistinguishable and the cells should either flip randomly between two opposing firing directions within the arena, or else disregard the cues. The cue control protocol consisted of a series of trials where both cue cards were rotated together by a variable magnitude and direction before the rat was placed back in the arena at randomly chosen entry points, and HD cells recorded as it foraged for food. Circular kernel density estimates of preferred firing direction shifts showed that both RSC and PoS HD cells could discriminate the cue cards, as shown by the cells almost always adopting a consistent firing direction within the arena relative to the cue pair. Contrast and orientation features exerted strong landmark control, while height (top-bottom) and symmetry (left-right) were less well discriminated, albeit only slightly. Landmark control for the different cue types did not differ between brain areas suggesting that the activity of HD cells is tightly coupled in the HD cell circuit, consistent with attractor network models. These findings indicate that HD cells can process low-level visual features, and offer a potential model system with which to explore how the signal is transformed from retina through visual cortex to the landmark-processing HD areas.

Title: A potential extrastriate locus for adaptation to composite radial frequency patterns

Authors: *S. J. LAWRENCE[1], B. D. KEEFE[1], R. J. W. VERNON[1], A. D. GOUWS[1], H. D. BROWN[1], A. R. WADE[1], D. J. MCKEEFRY[2], A. B. MORLAND[1,3];
[1]Univ. of York, York, United Kingdom; [2]Bradford Sch. of Optometry and Vision Sci., Bradford, United Kingdom; [3]Ctr. for Neurosci., Hull York Med. Sch., York, United Kingdom

Abstract: Adaptation to radial frequency (RF) patterns has been used extensively to interrogate the properties of early level shape encoding mechanisms. However, the neural locus of these mechanisms is unclear. Extrastriate visual areas, such as V4, have been hypothesised as likely candidates (Wilkinson et al., 1998; Pasupathy & Connor, 2001; Poirier & Wilson, 2006) and recent TMS evidence has shown area LO2 plays a causal role in the detection of amplitude modulations of RF patterns (Silson et al., 2013). We measured shape aftereffects from composite RF patterns where the phase of one RF component was the adapted feature. We explored the size and location tuning of these aftereffects to gain insight to the receptive field properties that underpin this shape adaptation. We had participants adapt to shape comprising a composite of RF2 and RF3 patterns. The phase of the RF3 pattern in the adaptor was rotated so the shape was asymmetric and appeared similar to the outline of a face with a viewpoint rotated away from the observer. Following adaptation we had participants make judgements on the direction of rotation of a test stimulus. The test stimulus was the same RF2+3 pattern where a staircase procedure was used to establish the phase of the RF3 component that was perceived as front-facing or symmetric. Strong aftereffects were observed for test stimuli that were of equal size and location to the adaptor and corresponded to ~70% of the phase rotation used in the adaptor. The tuning functions were relatively broad for size with aftereffects dropping to ~50% of the normal aftereffect when the size of the test stimulus was half or twice the size of the adaptor. For location, tuning appears to be narrower. Test stimuli presented in the same hemifield as the adaptor but in a different, non-overlapping location elicited only small aftereffects (~20% of the normal aftereffect). The results indicate that the illusion is underpinned by mechanisms that are relatively tolerant to size changes, but less tolerant to changes in location. Given the quantitative relationships we have measured we propose that an extrastriate rather than striate locus for this

shape adaptation is likely. References Pasupathy, A., & Connor, C. E. (2001). Journal of Neurophysiology, 86(5), 2505-2519. Poirier, F. J. A. M., & Wilson, H. R. (2006). Title: Adaptation-induced changes in gain, but not correlation, account for perceptual aftereffects

Authors: *N. S. PRICE, E. ZAVITZ, H.-H. YU, M. G. ROSA;
Physiology, Monash Univ., Clayton, Australia

Abstract: Prolonged exposure to a stimulus induces changes in the neuronal responses to subsequent stimuli and changes in the perception of those stimuli. Responsivity and tuning of single sensory neurons have been shown to adapt to reflect stimulus history, and perceptual shifts result when these changes occur across an ensemble of the neural population. We set out to answer two questions: How do neurons, as units and as members of a population, adapt in response to continually changing stimuli; and how does this adaptation produce perceptual phenomena such as the direction aftereffect? We used a multielectrode Utah array to measure the activity of a population of MT neurons in three sufentanil-anaesthetised marmoset monkeys. We presented a continuous motion stimulus consisting of a random sequence of 500 ms periods of coherent motion in one of 12 directions. Each motion period served as both a test and as an adaptor for the subsequent motion periods. As the direction was continuously changing, we defined 144 trial types, representing the sequential pairings of every possible adapt and test direction. This allows us to determine how the adaptation affects both the representation and decoding of the test. With this paradigm, we were able to show for the first time that changes in

neuronal gain and correlation structure outlast the duration of a test stimulus, and can survive intervening visual stimulation (up to three intervening stimuli, or 2 seconds). We used a decoding model to estimate motion direction from 30 ms of neural activity across 20 units. We trained the decoder using neural responses from the adaptation period of 80% of trials and then applied the decoder to the test period (500 ms later) of the remaining 20% of trials. The model gives a continuous (i.e. not categorical) estimate of motion direction. Critically, errors in the predicted test direction depend systematically on the difference between the adaptor and test directions. This systematic dependence was repulsive, as in the classic psychophysical direction aftereffect. For example, an adaptor 60° counterclockwise (positive) from the test produced an error distribution with a mean of 7° clockwise (negative). By training and testing the model on both shuffled and unshuffled data we were able to demonstrate that the changes in responsiveness, not changes in correlation structure were sufficient to produce the direction aftereffect.

Title: Stimulus dependence of receptive field organization in the visual wulst of owls

Authors: J. MACHADO DE SOUSA[1], P. VIEIRA[1], C. MONIER[2], M. PANANCEAU[2], Y. FRÉGNAC[2], *J. BARON[1];
[1]Fisiologia e Biofísica, Univ. Federal De Minas Gerais, Belo Horizonte, Brazil; [2]Unité de Neuroscience, Information et Complexité (CNRS-UNIC), Gif-sur-Yvette, France

Abstract: Accumulating evidence suggests that the receptive field (RF) ON/OFF organization of striate cortex (V1) neurons is not fixed, but varies depending on how sensory input statistics activate different functional topologies of thalamocortical and intracortical connections. This

study was designed to investigate whether such an adaptive feature could also be evidenced in the owl visual wulst, an interesting avian model system to be compared with mammalian V1 since both structures seem to transform incoming signals from the visual thalamus in an analogous manner. Experiments on awake burrowing owls (Athene cunicularia) and lightly sedated barn owls (Tyto alba) were performed using standard single-unit recording techniques. RF subfield preferences for point-light increments (ON) and decrements (OFF) were first measured by reverse correlation with sparse white noise stimuli consisting of pseudorandom sequences of white (112 cd/m2) and black (1 cd/m2) squares (0.3° X 0.3°) presented singly on a grey background (56 cd/m2) for 50 ms. We found that statistically robust spatial activation maps of ON and OFF subfields start approximately 30 ms after stimulus onset and last for about 50 ms. Peak OFF responses (median = 60 ms, interquartile range = 40 - 80 ms) usually occur earlier than their ON counterparts (median = 70 ms, interquartile range = 50 - 90 ms), but no obvious ON/OFF signal strength imbalance was evident across our cell population. The spatiotemporal RF slice exhibiting the largest ON/OFF activity integral was chosen to quantify the degree of overlap between subfields using several indices as in Mata and Ringach (J. Neurophysiol., 93: 919-928, 2005). Strong significant correlations were obtained among all overlap indices, but none of the later could predict the F1/F0 ratio estimated from steady-state responses to optimal sine-wave gratings as in Skottun et al. (Vision Res., 31: 1079-1086, 1991). Sparse-noise RF maps were also found to be clearly distinct to those generated in response to ternary dense noise. The spatiotemporal reorganization of ON/OFF subfields induced by this stimulus statistics modification is compatible with the inverse relationship between RF linearization and noise sparsity found in cat V1 by Fournier et al. (Nature Neuroscience: 14,1053-1062, 2011). Altogether, our results validate the white-noise reverse correlation approach to characterize RF structure dynamics in the owl visual wulst. They further suggest that, like in V1, wulst cells can adapt their linear/non-linear filtering properties to visual context, presumably due, at least in part, to network-regulated mechanisms optimized for natural vision.

Title: Adaptation-induced tuning shifts in excitatory and inhibitory neurons of primary visual cortex

Authors: *D. J. THENGONE, Y. YU, E. I. NITZANY, J. D. VICTOR;
Brain and Mind Res. Inst., Weill Cornell Grad. Sch. of Med. Sci., New York, NY

Abstract: The brain employs a variety of strategies to adjust to changes in the external world. Adaptation is one such strategy, as it modifies responses based on recent inputs. As with other modulatory influences (such as attention) that affect network dynamics, adaptation is likely to involve a broad range of processes at the neuronal level. Here we study how adaptation influences neuronal responses in functionally distinct cortical cell-categories (excitatory vs inhibitory) in two hierarchically-related brain regions, V1 and V2, of the visual pathway. We examined responses of 36 neurons in V1 and V2 of 2 macaques, under propofol/opiate anesthesia and neuromuscular blockade. We performed multi-tetrode single-unit recordings to measure neural responses to drifting sinusoidal gratings before and after 400ms adaptation to preferred and non-preferred stimuli, and we distinguished functionally distinct cell types on the basis of the shape of their extracellular action potentials and a comparison to a much larger laboratory database. We identified a subset of narrow-spiking neurons (putative inhibitory interneurons) that showed narrow orientation tuning curves and small receptive fields, consistent with the properties of parvalbumin-positive interneurons. In both excitatory and inhibitory cell types, we found adaptation-induced changes consisting of gain reduction and tuning shifts. Consistent with previous studies, we found that the shifts could be attractive or repulsive; the wave-shape analysis here reveals that both kinds of shifts are present in both excitatory and inhibitory cell types. These findings have implications for models of orientation selectivity, in which recurrent intracortical connections enhance the orientation bias of incoming thalamic signals. If the tuned recurrent signals are purely excitatory (i.e., in a network in which inhibition is untuned), the model accounts for adaptation-induced reductions in response amplitude and repulsive shifts of the orientation tuning curve. Critically, this type of model does not account for attractive tuning shifts. However, if the recurrent signals also originate from tuned inhibitory neurons - and these inhibitory neurons adapt, as we found -- the model not only predicts the gain reductions and repulsive shifts in the tuning curve, but also accounts for attractive tuning shifts towards the adapted stimulus. More broadly, our findings demonstrate that inhibitory neurons play a key role in the way that sensory representations are recalibrated according to context.

Title: Cross-correlation investigation of neurons in supra and infragranular layers in cat V1 before and following adaptation

Authors: ***N. CHANAURIA**[1], V. BHARMAURIA[1], L. BACHATENE[1], S. CATTAN[1], J. ROUAT[2], S. MOLOTCHNIKOFF[1];
[1]Biol. Sci., Univ. of Montreal, Montreal, QC, Canada; [2]Univ. of Sherbrooke, Sherbrooke, QC, Canada

Abstract: V1 neurons are systematically organised into domains of selectivity known as orientation columns. Each of these columns is divided into supra (upper) and infragranular (lower) layers wherein neurons are highly similar in different properties such as orientation selectivity. V1 neurons are highly plastic as they have an innate property to change their orientation selectivity in response to a non-optimal stimulus called adapter. On adapting, these neurons change their orientation tuning peaks either towards or away from the adapter exhibiting attractive or repulsive shifts (Dragoi et al., 2000; Ghisovan et al., 2009; Bachatene et al., 2012). Recently our lab showed in supra granular layers that following adaptation entire orientation map is re-organised (Bachatene et al., 2015; Cattan et al., 2014) however there are no reports showing how neurons in deeper layers change their orientation selectivity when adapted. Since the cortical column extends down to layer VI we hypothise that neurons not only to a specific layer change, but the whole cortex is reprogramed. To investigate this we simultaneously recorded layer II-III and V-VI neurons in conventionally prepared anaesthetised cats by lowering a multichannel depth electrode in V1. Cross-correlations were computed within and between the spike trains of neuron pairs of layer II-III and layer V to disclose functional connections and observe how adaptation affects this functional connectivity. Our preliminary data shows that adaptation changes the tuning curves of neurons in supra and infragranular layers. The proportion of neuron pairs in supra and infragranular layers exhibiting positive cross-correlations is relatively small. However contrary to that, cells within the same layers show frequent positive cross-correlations. This data may suggest that neurons in supra and infragranular layers shift their orientation tuning in an independent fashion.

Title: Decoding visual stimulus orientation from adapted neural populations

Authors: *T. B. CZUBA, A. KOHN;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Adaptation is a nearly ubiquitous feature of neural circuits. Although much is known about the effects of adaptation on the tuning of visual cortical neurons, a broad gap remains in understanding how adaptation alters population responses and the information they contain. It is also unclear whether the perceptual effects of adaptation can be explained simply by altered encoding, or whether the inappropriate decoding of adapted signals contributes. To address these issues, we measured the responses of populations of neurons in anesthetized macaque primary visual cortex (V1) following adaptation to high-contrast dynamic orientation stimuli. Experiments were designed to address two primary questions: 1) How does adaptation alter the quality of visual information encoded in a neural population? 2) How might a system alter the readout mechanism(s) to accommodate the effects of adaptation? We adapted neurons with a rapidly presented sequence of drifting gratings (~6° diameter, 80 ms/orientation, 2.4 s/trial). We varied the composition of orientations in the adaptation sequence, from a single orientation to a uniform distribution (0-180°). Brief test stimuli were presented after each adapter. These consisted of small drifting gabors (2.5° fwhm, 400 ms) of different orientations, embedded in dynamic pixel noise. We adjusted the pixel noise on the test stimuli to provide both easily discriminable and more challenging cases. Adaptation had a pronounced effect on V1 population responsivity. We quantified the information about stimulus orientation in the population by measuring the performance of a linear classifier (SVM). Across adaptation ensembles, we found a substantial loss of information about stimulus orientation, relative to an unadapted baseline. Decoder performance decreased more after adaptation to a single orientation than to a uniform distribution of orientations. We tested whether the detrimental effects of adaptation could be overcome by re-training the classifier on the adapted responses. Surprisingly, in most cases performance deficits were not mitigated by re-training. Our results suggest that adaptation reduces information about stimulus orientation in V1, and that this loss of information cannot be compensated for by using a decoder aware of the altered V1 responses. Ongoing experiments in

awake primates performing a fine discrimination task will allow us to relate these findings to perceptual decision making, on a trial-by-trial basis.

Abstract: Sensory adaptation is an important physiological phenomenon that results from repeated stimulation of sensory neurons in the brain but whose mechanisms remains poorly understood. Here, we measured the effect of visual adaptation on the spontaneous activity of single neurons in the primary visual cortex of awake behaving primates. We used chronically-implanted ultra-thin electrodes with impedances of 1 to 3 MΩ (Swadlow et al, 2005; Lashgari et al, 2012) in area V1 of awake primates to measure local field potentials (LFPs) and the activity of neighboring single-unit (SU) simultaneously recorded with the same electrode tip. We measured neuronal responses before and after stimulation with a grating drifting at the preferred orientation for 2-3 sec at 2 Hz (usually 4 trials). We analyzed 109 single neurons and found 55 neurons that had a significant reduction in spontaneous activity following stimulation with the preferred stimulus orientation (mean reduction in firing rate: 7.5 SPK/sec; $p<0.001$, Sign rank test). To estimate the cortical depth of the recordings, we measured the polarity of the LFP integrated between 0 and 60 ms following the stimulus onset (Lashgari et al, 2012; Li et al, 2014). We found that reductions in spontaneous firing rate after adaptation could be demonstrated in cortical layers with both positive and negative LFP polarities. To investigate the types of neurons that were most affected by sensory adaptation, we measured the width of spike waveform from the spike onset (initial deflection from baseline) to the maximum amplitude. We found that reductions in the spontaneous firing rate with sensory adaptation could be demonstrated in neurons with different spike widths. We conclude that sensory adaptation can

cause a reduction in the spontaneous firing rate of neurons in the awake primary visual cortex and that this reduction affects different types of neurons located in different cortical layers.

Title: Adaptation to orientation statistics in the visual cortex of awake mice

Authors: ***M. PACHITARIU**, C. STRINGER, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Animals immersed in their natural environments receive a continuous stream of visual inputs, whose temporal statistics depend on context. How do responses in the visual cortex adapt to these temporal statistics? We sought to answer this question in the mouse, where one can most readily dissect circuits and mechanisms underlying computations. We used 2-photon Calcium imaging to monitor neuronal populations in the superficial layers of awake mouse visual cortex, while showing gratings flickering at different temporal rates and modulating the probability of individual orientations. To capture the results we ran simulations of recurrent network models with short-term spike rate adaptation. We obtained good quality receptive fields and orientation tuning curves both for fast and slow stimulus presentation rates, approaching orientation selectivity indices of 1. Responses measured at high presentation rates (10 Hz) were roughly proportional to those measured at 1 Hz, though they were markedly smaller in size. To investigate the effects of bias in the temporal statistics, we increased the probability of presenting one orientation over the remaining orientations. A similar design has been shown to result in cell-specific and stimulus-specific adaptation in the visual cortex of anesthetized cats (Benucci et al, Nat Neurosci, 2013). We found similar results in the awake mouse cortex: stimulus responses were suppressed (contrast adaptation) and tuning curves shifted away from the adapted

orientation (pattern adaptation). The impact of adaptation was broader than the tuning curve of single cells, reducing responses also of cells that did not respond to the adaptor (indirect adaptation). A simple recurrent network of excitatory neurons replicated many of the observed effects. In the model, contrast, pattern and indirect adaptation arise from a combination of specific excitatory connectivity (i.e. enhanced connectivity between neurons of similar preferred orientation) and short-term spike rate adaptation. These results suggest that changes in the temporal statistics of visual stimuli have multiple effects on cortical response. The effects are present in the mouse visual cortex, where they can be studied at the level of microcircuits and cell types. At the level of computation we find that stimulus-specific adaptation - which has beneficial effects for discriminability - could arise from a combination of single cell adaptation and specific recurrent connectivity known to exist in cortex.

Title: Short-term light or pattern but not orientation deprivation alters interocular balance in adult macaque visual cortex

Authors: *D. Y. TS'O, M. BEGUM;
Dept of Neurosurg., SUNY - Upstate Med. Univ., Syracuse, NY

Abstract: Short-term monocular deprivation (STMD, patching one eye for 1-3 hours) disrupts interocular balance in adult humans, as measured psychophysically, and also in our present studies using anesthetized adult macaques, as measured with intrinsic signal optical imaging of the V1 ocular dominance columns. Surprisingly, in all these studies, the relative contribution of the patched eye was elevated for more than an hour after patch removal. V1 imaging studies using pattern deprivation rather than full occlusion STMD also yielded a similar rapid shift in interocular balance in which the contribution of the nondeprived eye showed a steady decrease during the deprivation of the other eye. Once the deprivation period ended, the nondeprived eye dramatically shifted course (increased), despite the stimulus to this eye remaining constant during the entire experiment. To further probe the underlying mechanisms of the STMD effect, we tested "orientation deprivation". As with the pattern deprivation studies, the stimuli were

dichoptically viewed 4 degree gratings of various orientations. However during the 1-3hr deprivation period, one eye was presented with only a single orientation (instead of a mean gray screen). The imaging data collected showed no shift in interocular balance to STMD using orientation deprivation. We also conducted multi-electrode recordings in V1 with the STMD paradigm. Single cell responses to monocular and binocular stimuli were plotted before, during and after STMD. The single-unit recordings revealed several different types of cell responses, including cells that showed unremarkable shifts in responses due to the STMD, other cells that exhibited an apparent strengthening of the non-deprived eye during STMD, and cells where the non-deprived eye showed dramatic drops in responsivity during STMD, consistent with the observed imaging (and psychophysical) results. The weakened response for the non-deprived eye during the deprivation period was striking. It cannot be explained by adaptation or fatigue in the eye or cortex. The apparent lack of orientation tuning of the STMD effect suggests a gain-controlling source that is not orientation-tuned. The electrophysiological results show a corresponding alteration of interocular balance at the single cell level. These results matches the previous psychophysical and imaging studies, and suggests a dynamic mechanism for regulating interocular balance and gain that includes the neurons in V1.

Title: Neural mechanism of reactivation of consolidated visual perceptual learning revealed by the concentration of excitatory and inhibitory neurotransmitters

Authors: *J. BANG, K. SHIBATA, T. WATANABE, Y. SASAKI;
Brown Univ., Providence, RI

Abstract: Visual perceptual learning (VPL) by training on a task is interfered with by another training if it occurs within one hour after the initial training. This indicates that VPL is fragile immediately after training but is stabilized within one hour so that it becomes resilient against

interference. However, already stabilized VPL of a task becomes susceptible to interference by practicing a small number of the task again (Bang et al, 2013, VSS). Although this so-called reactivation has made us reconsider a role of stabilization/consolidation in VPL, the neural mechanism has yet to be clarified. Here, we examined excitatory and inhibitory processing associated with reactivation. There were psychophysical and brain-imaging experiments. The psychophysical experiment lasted 3 day. On Day 1, subjects were trained on a detection task (2IFC) on orientation A with 16 blocks in staircase. On Day 2, subjects were asked to perform 3 blocks on orientation A for reactivation and then were trained on orientation B. On Day 3, performance on orientations A and B was measured. In the bran imaging experiment, using functional magnetic spectroscopy, we measured the concentration of glutamate and GABA in the early visual cortex before, immediately after and 3.5 hours after the reactivation. An E(excitation)/I(inhibition) ratio in the early visual cortex was taken by dividing the concentration of glutamate by that of GABA. Performance on orientation A significantly decreased between Days 2 and 3, indicating that reactivation makes already stabilized/consolidated VPL of orientation A labile to interference again. The E/I ratio increased immediately after reactivation of VPL of orientation A, and then returned to the baseline level 3.5 hours later. This time course changes are similar to those for stabilization after the first training (Shibata et al, 2015, VSS), suggesting that the neural mechanism of reactivation is similar to that of stabilization.

Title: Visual adaptation modulates correlated activity within and between cortical areas

Authors: ***C. A. HENRY**, A. KOHN;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Visual processing involves neuronal populations distributed within and between distinct cortical areas. Correlated responsivity in these populations can provide insight into

circuit architecture and the signaling between networks, and may also limit encoded information. Sensory adaptation can modulate this correlated activity; however, recent work has provided conflicting views of its effect on 'noise' correlations in local populations. In addition, it remains unknown how adaptation affects inter-areal correlations and how change in correlations with adaptation depends on the test stimuli. We examined the effect of adaptation on correlations within and between cortical areas, using simultaneous multielectrode recordings in primary visual cortex (V1) and area V2 of anesthetized macaque monkeys. Drifting sinusoidal gratings were presented at a range of test orientations; stimuli were centered and sized to simultaneously drive all V1 and V2 receptive fields. Adaptation consisted of brief (0.4-1.6s) presentations of high contrast gratings immediately prior to the onset of test stimuli. Control (unadapted) responses were measured to test stimuli following an equal period of mean grey screen. Adapted and unadapted trials were randomly interleaved. We found that correlations were modulated by visual adaptation in a stimulus-specific manner. After adaptation, correlations increased for responses to test stimuli similar to the adapter, and either decreased or showed no change for stimuli different from the adapter. This pattern held for both within-area (V1-V1, V2-V2) and across-area (V1-V2) correlations. In contrast, the effect of adaptation on correlations exhibited little dependence upon the orientation preferences of the neuronal pair. To elucidate the mechanisms that might underlie these effects, we measured how correlations and their modulation by adaptation depended on the normalization signals received by the pair. The recruitment of normalization signals has been shown to affect the strength of correlations, and to influence the effects of adaptation on neuronal tuning. We found that neuronal pairs with strong within-receptive field (RF) normalization (i.e. showing strong masking by an orthogonal stimulus) had lower noise correlations than those with weak normalization, both within area (V1-V1) and across areas (V1-V2). However, it was not these neurons, but instead those with weak within-RF normalization, that showed the largest increase in correlations after adaptation. Our results suggest that adaptation affects correlations in a stimulus-specific, not neuron-specific, manner, altering coupling with downstream networks.

Title: Pulse trains to percepts: The challenge of creating a perceptually intelligible world with sight recovery technologies

Authors: *I. FINE, G. M. BOYNTON;
Dept. of Psychology, Univ. of Washington, Seattle, WA

Abstract: An extraordinary variety of sight recovery therapies are either about to begin clinical trials, have begun clinical trials, or are currently being implanted in patients. However, as yet we have little insight into the perceptual experience likely to be produced by these implants. Here we focus on methodologies such as optogenetics, small molecule photoswitches, and electrical prostheses, which use artificial stimulation of the retina to elicit percepts. For each of these technologies the interplay between the stimulating technology and the underlying neurophysiology is likely to result in distortions of the perceptual experience. Three example models of the potential perceptual experience of sight recovery are shown. (A) Scoreboard model. The luminance of the percept is linearly related to the strength of current on the retina. (B) Simulation of electrical stimulation. This particular simulation is based on a model of simultaneously stimulating ON- and OFF pathways, followed by the model of axonal stimulation (C) Simulation of small molecule photoswitch stimulation. This simulation is based on the model of simulating ON-centre pathways in isolation, followed by the effects of sluggish temporal dynamics. As well as describing some of these potential distortions, we discuss how they might be minimized either through changes in the encoding model or through cortical plasticity.

Title: Braille processing in visual cortex of congenitally blind individuals

Authors: S. KANJLIA, *J. S. KIM, M. BEDNY;
Johns Hopkins Univ., Baltimore, MD

Abstract: Reading print depends in part on a specialized cortical circuit that supports letter and word recognition, the visual word form area (VWFA). This “reading” area responds more to written language than spoken language or other visual images (Cohen & Dehaene, 2004). Blind individuals read using a tactile system called Braille. Does Braille reading similarly depend on specialized cortical mechanisms? Previous work suggests that like print reading, reading Braille recruits the VWFA (Reich et al., 2011). However, there are alternative explanations for Braille responses in the VWFA relating to language and tactile processing. We used fMRI to ask whether there are cortical mechanisms that process Braille orthography as opposed to spoken language or fine-grained tactile discrimination. We compared reading of Braille words and Braille consonant strings to discrimination of tactile shapes made out of Braille dots, listening to words, and listening to noise (backwards speech). Ten congenitally blind participants heard or felt a list of 6 items followed by a probe item and determined whether the probe came from the preceding list. Regions in ventral, lateral and medial occipital cortices were more active when reading Braille words than listening to auditory words or discriminating tactile shapes. ROI analysis revealed that these occipital areas respond most to Braille words, followed by auditory words and Braille consonant strings, and then tactile shapes and noise. This suggests an interaction between input type (tactile/visual) and linguistic content (language/non-language). In summary, 1) processing of Braille orthography is not restricted to the VWFA but is distributed across regions in visual cortex and 2) unlike the VWFA in sighted adults, Braille areas respond similarly to spoken words and written (Braille) consonant strings, suggesting an influence of high-level linguistic information. We conclude that blind individuals recruit visual cortex for orthographic processing, but visual cortex Braille reading mechanisms are qualitatively different from those for reading print.

Title: Can an fMRI signature of reorganization of visual processing in patients with retinal lesions be found in normally sighted individuals?

Authors: ***H. D. BROWN**[1], A. D. GOUWS[1], R. GALE[2], S. J. D. LAWRENCE[1], R. J. W. VERNON[1], H. A. BASELER[1,3], A. B. MORLAND[1,3];
[1]Psychology, Univ. of York, York, United Kingdom; [2]York Teaching Hosp. NHS Fndn. Trust, York, United Kingdom; [3]Ctr. for Neurosci., Hull York Med. Sch., York, United Kingdom

Abstract: Macular degeneration (MD) causes a loss of central vision, removing input to the corresponding representation in primary visual cortex (V1) referred to as the Lesion Projection Zone (LPZ). There is disagreement in the literature as to whether the LPZ can be activated, and under what conditions such activity can be detected. Moreover, it has been debated whether activity in the LPZ can be taken as evidence of reorganization. For example, Baker et al. (2005)

reported activity in the LPZ during a stimulus-related task and interpreted it as a reorganization of visual processing. Masuda et al. (2008) found similar activity in the LPZ, but only during stimulus-related task conditions, and not passive viewing. This was taken to support the view that feedback from extrastriate areas is responsible for activity in the LPZ of V1. Importantly, LPZ activity was only detected in MD patients, but not controls. However, it is challenging to provide an appropriate control condition in normally sighted individuals. In this study we provided a control condition that better mimics the deficit that affects MD patients. To this end we presented a brightly lit (15,000 cdm-2) central 12deg (diameter) disc to participants with normal vision, thereby bleaching central retina to generate a transient 'retinal lesion'. An fMRI block design experiment was performed comparing responses to faces or scrambled faces with responses to a mean gray background. Participants were exposed to the central bleaching stimulus at the beginning of the scan and topped up for 18s between 6s stimulus or gray intervals. Stimuli subtended 5x5deg and were presented in the upper right quadrant adjacent to the bleached area. Scans were repeated in both passive viewing and one-back task conditions. The simulated LPZ and surrounding stimulus representation were localised in each participant in separate scans. Analysis of the BOLD responses to the visual stimuli during passive viewing revealed that activity was elicited at the stimulus representation and did not spread into the representation of the bleached zone. In contrast, activity spread into the representation of the bleached zone when participants performed a stimulus-related task. Our results indicate that one of the response signatures that has been taken as evidence for reorganization can be observed in normally sighted control participants. It is unlikely therefore that mechanisms giving rise to signals in the LPZ are specific to patients, but are more likely a reflection of normal feedback from extrastriate visual areas as proposed by Masuda et al. (2008). Baker et al., J.Neurosci (2005). 25(3):614 - 618. Masuda et al., Cerebral Cortex (2008). 18:2483-2493.

Title: Exploring the preservation of specificity in 'visual' areas of the human congenitally blind brain using the EyeMusic Sensory Substitution Device and fMRI imaging

Authors: S. MAIDENBAUM[1], S. ABBOUD[1], S. DEHAENE[2], *A. AMEDI[1];
[1]Dept. of Develop. Med. Neurobio., Fac. of Medicine, The Hebrew Univ. of Jer, Jerusalem, Israel; [2]Colle`ge de France, Universite´ Paris 11, Inst. Natl. de la Sante´ et de la Recherche Me´dicale, Paris, France

Abstract: Over the past decade a series of 'visual' brain regions with preferred specificity for certain categories of stimuli have been located and researched. For example, the Visual Word Form Area (VWFA) shows preferential selectivity for the shapes of letters and the Visual Number Form Area (VNFA) shows selective preference for the shape of numbers. But what happens to these regions in congenital blindness? How large a part does vision take in driving and creating this preference? what is the contribution of shape biases to its formation and whether visual processing underlies it? These questions are especially intriguing in the case of categories such as those above, which only became relevant very recently on an evolutionary time scale yet still show anatomical consistency across human brains. How do we have regions dedicated specifically to letters or numbers if we only started using these concepts several thousand years ago? Here we use congenital blindness as a model for brain development without visual experience. During fMRI, we present blind subjects with shapes encoded via The EyeMusic, a novel visual-to-auditory Sensory Substitution Device which can convey whole scene visual information such as location, shape and color via audition. We find that greater activation is observed in the rITG when subjects process symbols as numbers compared with control tasks on the same symbols. Using resting-state fMRI in the blind and sighted, we further show that the areas with preference for letters and numerals exhibit distinct patterns of functional connectivity with language-processing and quantity areas, respectively. These findings suggest that specificity in the ventral ‘visual’ stream can emerge independently of sensory modality and visual experience, under the influence of distinct connectivity patterns. Finally, we will then turn to discuss more low-level visual features such as color - will such features also emerge independently of sensory modality and visual experience? And to what extent will they do so?

Title: Examining tactile motion responses within hMT+

Authors: *F. JIANG[1], M. S. BEAUCHAMP[2], I. FINE[3];
[1]Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Univ. of Texas Med. Sch. at Houston, Houston, TX; [3]Univ. of Washington, Seattle, WA

Abstract: Here we examine tactile motion BOLD responses within the human MT+ complex. Although several studies have reported tactile responses overlapping with hMT+, many used group average analyses, leaving it unclear whether these responses were restricted to sub-regions of hMT+. Moreover, previous studies either employed a tactile task or passive stimulation, leaving it unclear whether or not tactile responses in hMT+ are simply the consequence of visual imagery. Here we carried out a replication of one of the classic papers finding tactile responses in hMT+ (Hagen et al. 2002). We mapped MT and MST in individual subjects using visual field localizers. We then examined responses to tactile motion on the arm, either presented passively or in the presence of a visual task performed at fixation designed to minimize visualization of the concurrent tactile stimulation. Without a visual task, we found only weak tactile motion responses in MT (6% of voxels showing tactile responses) and MST (2% of voxels). With an orthogonal visual task, responses in MST reduced to almost nothing (<1% regions). Consistent with previous results, we did observe tactile responses in STS regions superior and anterior to hMT+. The weak nature of tactile responses in hMT+ (and their abolition by withdrawal of attention) suggest that hMT+ may not serve as a general, cross-modality motion processing module.

Title: Parallel processing of center and surround signals in the superficial and deep layers of macaque V1

Authors: *M. BIJANZADEH[1,2], L. NURMINEN[3], A. ANGELUCCI[3];
[1]Ophthalmology, Moran Eye Inst., Univ. of Utah, Salt Lake City, UT; [2]Neurosci. Program, Salt lake city, UT; [3]Moran Eye Institute, Univ. of Utah, Salt lake city, UT

Abstract: The laminar architecture is a fundamental principle of cortical organization. Yet, we still do not know how simple sensory stimuli are processed across cortical layers. Using linear electrode arrays in macaque V1, we have examined the spatiotemporal patterns of laminar activation induced by visual stimuli presented inside and outside the receptive field (RF) of the recorded cells in the column. Small (0.5-1.5°) grating patches were flashed inside the RF, or in the surround at progressively larger distances from the RF. Annular gratings (2° in width) were also flashed in the surround. We recorded both local field potentials (LFPs) and spikes, and applied current source density (CSD) analysis to LFPs. At each cortical depth we measured the onset latency of the first current sink in CSD and of the spiking responses in the PSTHs. CSD in the absence of RF stimulation reflects the net synaptic input caused by connections terminating in a layer. A 0.5° stimulus inside the RF evoked the earliest CSD signals in layer (L) 4C, followed by supragranular (SG) and infragranular (IG) layers almost at the same time. Larger (1-1.5°) gratings inside the RF caused faster onset of CSD signals in L6, almost as fast as in L4C. The earliest spiking activity in response to either stimuli occurred in L4C and IG layers almost at the same time. Small (0.5-1.5°) patch stimuli located up to 2.25° from the RF center (in the near surround) evoked markedly delayed current sinks in L4C. When these stimuli in the surround were collinearly aligned in visual space to the preferred orientation of the recorded cells in the center, current sinks occurred first and almost simultaneously in L6 and SG layers. Instead, non-collinear surround stimuli evoked the earliest CSD signals in L6, but no activation of SG layers. These data suggest that intra-V1 horizontal connections (HC) within SG layers and L6 provide the modulatory signals from the near surround; moreover while these horizontal inputs in the SG layers are specific for orientation and retinotopic axis (consistent with the known functional specificity of HC), horizontal inputs within L6 are not. Surround gratings located ≥3° from the RF center (in the far surround) evoked the earliest CSD signals almost simultaneously in L1 and 6, but markedly delayed current sinks in SG layers. These data are consistent with our previous proposal that inter-areal feedback connections to V1 IG layers and L1 provide the modulatory signals from the far surround. Similar onset latencies of granular and IG activation induced by stimuli in the RF, and of superficial and deep layers activation induced by stimuli in the surround suggest two parallel processing circuits within the cortical column.

Title: Anatomical and functional specificity of V2-to-V1 feedback circuits in the primate visual cortex

Authors: *F. FEDERER, S. MERLIN, A. ANGELUCCI;
Moran Eye Inst., Univ. of Utah, Salt Lake City, UT

Abstract: Corticocortical feedback (FB) connections are a prominent feature of the cerebral cortex whose role remains speculative. In the visual cortex FB may mediate functions such as attention and contextual effects. To understand how FB connections perform such computations, it is crucial to understand how they are anatomically and functionally organized. Previous studies of FB connections have been hampered by the unavailability of efficient anterograde tracers that unambiguously label FB axons, without also labeling the reciprocal V1-to-V2 axons. As a consequence, there have been conflicting reports of both anatomically diffuse and non-orientation specific (Stettler et al. 2002), and patchy and orientation-specific (Shmuel et al. 2005) V2-to-V1 FB connections. Here we have examined the anatomical and functional organization of V2-to-V1 FB connections in macaque and marmoset monkeys, using a GFP-expressing AAV9 viral tracer that allows unambiguous labeling of FB axons. Injections were targeted to specific V2 cytochrome oxidase (CO) stripes and orientation-preference domains identified using intrinsic optical imaging (OI). After 5-7 weeks animals were either perfused and their brain sectioned sagittally to identify cortical layers, or underwent further OI of orientation, retinotopy and ocular dominance maps in V1 and V2. The latter were sectioned parallel to the imaged plane, and labeled FB axons warped to the functional maps using surface vasculature. We found that in both primate species, V2 FB to V1 shows laminar and compartmental specialization. Both thick and thin V2 stripes send FB primarily to V1 layers (L) 1-2 and 5, and sparser projections to L3A and 6; however, only thick stripes send projections to L4B. In all V1 layers of termination, V2 FB axons form columnar patches. The patches arising from cells in the V2 thick stripes lie primarily in the V1 interblobs, and those from thin stripes lie primarily in the CO blobs. In

summary, there exist parallel FB pathways from V2 to V1 that target the same V1 layers and compartments giving rise to parallel feedforward projections to V2. We also found that V2 FB axons arising from thick stripes preferentially contact V1 domains with similar orientation preference, showing no bias for left or right eye columns. Moreover, these FB fields are markedly anisotropic in V1, with their retinotopic axis of elongation being collinear with the orientation preference of the V2 injected site. In contrast, V2 FB axons arising from thin stripes predominantly terminate at/near orientation pinwheel centers in V1. Orientation-specific FB pathways may underlie orientation-tuned far-surround suppression (Angelucci et al. 2002).

Title: Frontal cortex for top-down control: organization of long-range inputs and outputs

Authors: ***S.-Y. ZHANG**[1], M. XU[2], W. CHANG[3], J. DO[3], Y. DAN[2];
[1]HHMI /UC Berkeley, Berkeley, CA; [2]HHMI/UC Berkeley, Berkeley, CA; [3]UC Berkeley, Berkeley, CA

Abstract: Long-range projections from the frontal cortex are known to modulate sensory processing in multiple modalities. Although the mouse has become an increasingly important animal model for studying the circuit basis of behavior, the functional organization of its frontal cortical long-range connectivity remains poorly characterized. Here we used virus-assisted circuit mapping to identify the brain networks for top-down modulation of visual, somatosensory, and auditory processing. The visual cortex is reciprocally connected to the anterior cingulate area, whereas the somatosensory and auditory cortices are connected to the primary and secondary motor cortices. Anterograde and retrograde tracing also identified other cortical and subcortical structures belonging to each network. Furthermore, using novel viral techniques to target subpopulations of frontal neurons projecting to the visual cortex versus the superior colliculus, we identified two distinct subnetworks within the visual network. These findings provide an anatomical foundation for understanding the brain mechanisms underlying top-down control of behavior.

Title: Readout of fine-resolution shape contours from V1 activity via bottom-up reconstruction

Authors: *G. ZURAWEL, I. SHAMIR, H. SLOVIN;
The Leslie and Susan Gonda (goldschmied) Multidisciplinary Brain Res. Ctr., Ramat-Gan, Israel

Abstract: Primates have a remarkable capacity to process visual stimuli under variable conditions. The primary visual cortex (V1) employs multiple mechanisms for encoding the physical stimulus attributes: receptive fields, contrast, non-linearity, etc. In contrast, complex features like invariant categorization and face processing are associated with RF convergence to and processing by higher visual areas. However, the visual experience and perception of objects are rich and detailed, not completely "stripped down" to invariant "labels" only (e.g. invariant category). V1 is a natural candidate facilitator of the "detailed" component of visual representation, yet its actual role remains unclear. To facilitate detailed visual perception, representation of both physical (stimulated) and implied (non-stimulated) stimulus features (e.g. missing contour parts) should be present, and therefore potentially re-constructible from evoked V1 neuronal activity. Reconstructing visual contents directly from cortical data via naïve, bottom-up modeling has had limited success so far. Specifically, extracting object contours in high-resolution has not yet been accomplished. We therefore set out to reconstruct contours of both physical (stimulated) and implied (non-stimulated) parts of stimuli directly from cortical activity and without use of a prior image bank. We presented small monochromatic shapes that varied in shape, size and position, that were either complete or had a missing part of the contour. Using voltage sensitive dye imaging (VSDI) from fixating monkeys, we imaged V1 responses, capturing sub- and supra-threshold membrane potentials of neuronal populations. Reconstruction was carried out by reversal of a simplified, brain-inspired bottom-up encoding model that accounts for retinotopy, receptive fields, contrast and non-linearity. Both physical contours and the "completed" representation of implied contours were reconstructed from the data, including at single-trial level. Overall, we demonstrate physical and implied contour reconstruction directly from V1 cortical activity without the use of an image prior. Our results indicate that V1 serves an important role in facilitating detailed visual representation.

Title: Natural images and redundancy reduction in primate visual cortex

Authors: ***L. O. NURMINEN**, M. BIJANZADEH, A. ANGELUCCI;
Moran Eye Ctr., Univ. of Utah, Salt Lake City, UT

Abstract: Barlow (1961) suggested that early sensory processing should reduce redundancy between neural responses. Theoretical work by Schwartz and Simoncelli (2001) applied this principle to natural images, and found that cortical non-linearities such as surround suppression are well suited for redundancy reduction. Experimentally, natural stimulation of the receptive field (RF) surround reduces pair-wise correlations between the responses of neurons in primary visual cortex (V1; Vinje & Gallant 2000). However, for highly non-Gaussian signals, such as neural responses to natural images, correlations may be only weakly related to redundancy. Thus, it is unknown whether there are mechanisms in primate visual cortex for reducing redundancy between neural responses to natural images. To address this question, we recorded V1 cell responses using Utah electrode arrays in sufentanil anesthetized macaques. The linear RFs of 41 simple-like single- and multiunits were estimated using binary noise and an automatic locality determination algorithm (Park & Pillow 2011). Spike count responses were measured to repeated (20 times) and randomized sets of monocularly displayed 6º x 6º natural image patches randomly sampled from the Van Hateren image database. The dependencies between the measured spike-count responses were compared to predictions made by the linear RF estimates. RF non-linearities and neural noise estimated from the measured neural responses were added to the linear estimates. Moreover, to elucidate how non-linear RF surrounds affect statistical dependencies, the dependencies in spike-count responses to the 6º x 6º image patches were compared to the dependencies in spike-count responses to the same image patches windowed so

that the minimum response field of just few neurons was stimulated. We found that the correlations between the measured spike count responses were lower than the correlations predicted by the linear RF. Correlations were reduced the most between cells with similar RFs. This reduction originated from both the instantaneous spike-rate non-linearity and surround suppression. In addition, we characterized the higher-order dependencies between neural responses by first removing the correlations between the responses, and then computing energy correlation and mutual information between the responses. We found that also the higher-order dependencies between the measured spike-counts were lower than those predicted by the linear RFs. These results demonstrate that non-linearities in primate V1 reduce redundancy between neural responses to natural images.

Title: Effects of naturalistic vision on contrast sensitivity and V1 activity

Authors: *J. NIEMEYER, M. PARADISO;
Brown Univ., Providence, RI

Abstract: Most studies of visual processing and perception are designed to minimize stimulus complexity and eye movements -- both key components of natural vision. Clinical tests are also generally conducted with simple stimuli lacking context. Yet, research in our lab has shown that saccadic eye movements and scene complexity significantly influence neuronal responses in area V1. Here we examine whether more naturalistic vision impacts contrast sensitivity, an important tool for characterizing vision and visual disorders. While recordings were made from V1 neurons, macaques performed a 2AFC contrast discrimination task. Gabor stimuli were presented, either inside or outside a V1 receptive field (RF), on a complex scene background; the stimuli were either flashed on or brought into an RF by a saccadic eye movement. Contrast sensitivity in the more natural saccade condition was reduced by over 30% compared to flashed

stimulation and V1 population responses were reduced by over 25%. Moreover, there was a clear correlation in the neural and perceptual measures: performance was similar in flash and saccade conditions at higher spatial frequencies (> 6 cy/deg) but at lower spatial frequencies performance was significantly worse with saccades. These findings demonstrate that natural vision has important effects on contrast sensitivity and the effects correlate with V1 visual responses. We hypothesized that the cause of the frequency-dependent differences was rapid adaptation to the portion of the natural image that covers the RF prior to the Gabor test stimulus. In the saccade condition, this adaptation might carry across the eye movement and influence the response to the Gabor at the end of the saccade. In the fixation condition adaptation may wane before the Gabor is flashed on. We found that when we covered the RF with uniform gray prior to the saccade, contrast sensitivity and V1 responses were the same in fixation and saccade conditions. This finding suggests a novel form of rapid adaptation that carries across saccades. Thus, contrast sensitivity and V1 responses are reduced with natural images, which are dominated by low SFs. These findings have broader implications for the accurate characterization of V1 responses and clinical assessment in more naturalistic vision.

Title: Conductance-based interactions predict the suppressive effect of interacting propagating waves in awake monkey visual cortex

Authors: *A. DESTEXHE[1], Y. ZERLAUT[1], S. CHEMLA[2], A. REYNAUD[2], F. CHAVANE[2]; [1]CNRS, Gif-sur-Yvette, France; [2]INT, CNRS, Marseille, France

Abstract: Propagating waves can be detected in primary visual cortex of awake monkey, either in spontaneous activity of following visual stimulation, as recently shown by a phase-based analysis (Muller et al., Nat. Comm., 2014). Using voltage-sensitive dye imaging, we show here that two visual stimuli in different positions in space and time evoke two distinct propagating waves, which can collide. The interaction between the two waves is always suppressive (sub-linear). To investigate possible mechanisms for such a suppressive effect, we used a population (mean-field) model of cortical activity, taking into account excitatory and inhibitory conductance-based interactions. This model used "biologically-realistic" transfer functions based on a recent characterization from slice experiments with dynamic-clamp injection of conductance-based synaptic inputs in cortical neurons. In response to an afferent localized excitatory input, this model reproduced propagating waves arising from lateral connectivity. Interestingly, this model also reproduced the experimental observations of the suppressive interactions between propagating waves. In this case, the suppression was caused by the conductance (shunting) effect of recurrent synaptic interactions. The conductance-based model reproduced the speed of the suppression as seen in the experiments. Using transfer functions without this conductance effect, did not reproduce these features and were inconsistent with experiments. We conclude that conductance-based interactions between recurrent synaptic inputs is a possible candidate explanation for the suppressive effect of propagating waves in visual cortex.

Title: Visually-driven behavior at the limits of sensory information

Authors: ***B. SRIRAM**[1], A. CRUZ-MARTÍN[2], L. LI[1], D. BISHOP[1], A. GHOSH[1,3]; [1]Div. of Biol., UCSD Div. of Biol., La Jolla, CA; [2]Boston Univ., Boston, MA; [3]CNS Discovery and Biomarkers, F. Hoffmann-La Roche, Basel, Switzerland

Abstract: One of the most salient features of neural responses in primary visual cortex (V1) is its preference for stimuli oriented at a specific angle. While V1 orientation preferences are largely shaped by the pattern of thalamic inputs, the way in which these neural representations develop over time and how the individual circuits components contribute to this development is unclear. To understand this dynamics, we have developed a visual discrimination behavior task in freely moving rodents. By forcing mice to make visual discrimination decisions after presenting brief stimuli, we find that mice integrate information extremely quickly and are able to perform above chance with very brief stimulus exposures. Reversible V1 Lesion by activating Channel rhodopsin targeted into PV neurons, causes significant reduction in performance indicating that the task is cortex dependent. Electrophysiological recordings indicate that at these very short stimulus durations there is high failure rate (fraction of trials with no spiking) in cortical firing, indicating that the cortex can compute complex discrimination using extremely sparse data. Title: Decoding orientation of contrast edges from evoked and induced oscillatory brain activity

Authors: M. FANG[1], J. LI[1], Q. LI[3], R. CICHY[1], *D. PANTAZIS[2];
[2]McGovern Inst. for Brain Research, MIT, [1]MIT, Cambridge, MA; [3]Massachusetts Gen. Hosp., Boston, MA

Abstract: To yield a coherent perception of the visual world the human brain must bind simple features into complex wholes. A seminal study by Gray et al. (1989) has shown that spatially separate orientation columns in cat V1 lock their gamma oscillations (40-60Hz) to reflect global stimulus properties, suggesting gamma oscillations as a mechanism for simple feature binding. Since then a multitude of studies has revealed the role of gamma frequencies as mediators of bottom-up feature binding. However, the relationship between evoked and induced gamma oscillatory responses in the encoding of simple visual features is still under debate. To

investigate the encoding of simple visual features in both evoked and induced oscillatory responses we systematically investigated the encoding of oriented contrast edges in coherent wholes (gratings). We recorded human MEG data while participants viewed six grating stimuli with different angles (0-150° in 30° steps; 800 ms presentation time; 3 cycles/degree) (Fig 1a), performed time-frequency Morlet wavelet decomposition, and used multivariate pattern classification on MEG sensor levels to decode stimulus orientation. Our findings show that orientation information can be decoded not only from evoked signals (Fig 1b; significant onset 39ms) but also from oscillatory components with two dominant frequency ranges: 25-30Hz and 50-60 Hz (Fig 1c). Comparing representations of orientation across time (train classifier at one time point, test at other time points), we found that evoked components had transient representations (Fig 1d), whereas oscillatory components were sustained for the duration of the stimulus (Fig 1e,f). Together, our results show that both evoked and induced components encode simple visual features, though their different temporal dynamics indicate they may subserve different neuronal processes.

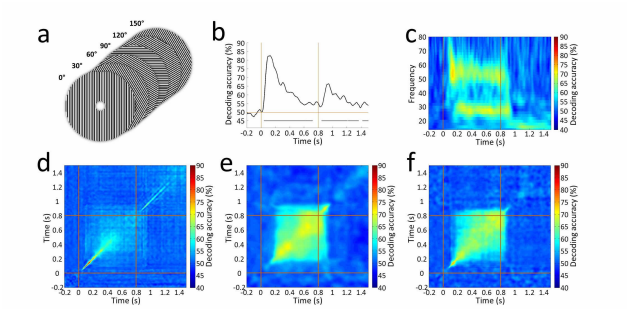

Figure 1. a) The stimulus set consisted of 6 grating patterns with different orientations and randomized phase. We used multivariate pattern classification to decode orientation between pairs of grating patterns. **b)** Orientation information could be decoded from evoked responses both at the onset (0s) and offset (0.8s) of the stimulus. Horizontal line indicates statistical significance. **c)** Orientation information could be decoded from induced responses at two frequency bands (25-30Hz and 50-60Hz). **d-f)** Time-time decoding shows that evoked responses were transient (d) whereas induced components at 25-30Hz (e) and 50-60Hz (f) were sustained.

Abstract: The large size of the human brain imposes computational constraints that are reflected in its structural organization. For example, specialized visual processing of spatial and categorical information is partially segregated in dorsal and ventral regions in the occipital and temporal lobes; these regions are widely separated in cortex. For effective vision and action, the processing performed in these regions must be coordinated. Classical as well as recent studies identify the human Vertical Occipital Fasciculus (VOF), as a likely white matter bundle that includes axons that communicate between the dorsal and ventral regions. In this study, we compare the human vertical occipital pathways with similar tracts in the much smaller macaque brain in order to better understand similarities and differences across species. Methods. We obtained diffusion MRI (dMRI) at several spatial resolutions, and we used fiber tractography to estimate the trajectories of several different occipital pathways. DMRI data were acquired from 4 macaque monkeys and many humans (Takemura et al., 2015). We analyzed the data using constrained spherical deconvolution (CSD) and an ensemble of probabilistic tractography methods. We optimized the tractography results and tested statistical hypotheses using Linear Fascicle Evaluation methods (Pestilli et al., 2014). Results. A substantial bundle of vertical occipital fibers could be found in all the macaque and human datasets. The location of the macaque VOF (mVOF) is consistent with a schematic description in a post-morterm monkey brain described by Wernicke (1881). The mVOF terminates near cortical areas V3d, V3A, V4d and MT dorsally and V4v/TEO ventrally. The pattern of mVOF terminations is similar to those of human VOF, which are principally V3A/B dorsally and hV4 ventrally. In both species, the VOF is lateral to the optic radiation (sagittal stratum). In human, the VOF is also lateral to the Inferior Longitudinal Fasciculus (ILF) and clearly distinguishable from the ILF; but the mVOF intermingles with the vertical component of macaque ILF and does not form a very distinct bundle. The estimates of the position, size and cortical terminations of the mVOF depend on

instrumental parameters, such as dMRI resolution; but in all cases the core of the tract can be identified and the estimates are consistent. These findings suggest that the human and macaque vertical occipital fiber systems diverged from a common ancestor. The human system significantly enlarged and became separated from the ILF. The change in white matter may be part of the general evolution of the size and position of extrastriate maps with the increase in brain size.

Title: Population receptive field changes in hV5/MT+ of healthy subjects with simulated visual field scotomas

Authors: *A. PAPANIKOLAOU[1,2], G. A. KELIRIS[1,3], S. LEE[2], N. K. LOGOTHETIS[1], S. M. SMIRNAKIS[2];
[1]Max-Planck Inst. For Biol. Cybernetics, Tuebingen, Germany; [2]Baylor Col. of Med., Houston, TX; [3]Dept. of Biomed. Sci., Univ. of Antwerp, Antwerp, Belgium

Abstract: An important question is whether the adult visual cortex is able to reorganize in subjects with visual field defects (scotomas) as a result of retinal or cortical lesions. Functional magnetic resonance imaging (fMRI) methods provide a useful tool to study the population receptive field (pRF) properties and assess the capacity of the human visual cortex to reorganize following injury. However, these methods are prone to biases near the boundaries of the scotoma. Retinotopic changes resembling reorganization have been observed in the early visual

cortex of normal subjects when the visual stimulus is masked to simulate retinal or cortical scotomas. It is not known how the receptive fields of higher visual areas, like hV5/MT+, are affected by partial stimulus deprivation. Here, we measured responses in human area V5/MT+ in five healthy subjects under two stimulation conditions. FMRI measurements were obtained under the presentation of a moving bar stimulus spanning the entire visual field while the subjects were fixating. In a second session the stimulus was masked in the left upper quadrant of the visual field to simulate a quadrantanopic scotoma ("artificial scotoma" or AS) occurring often as a result of partial V1 or optic radiation lesions. PRF estimates were obtained using a recent method of pRF topography estimation (Lee et al., A new method for estimating population receptive field topography in visual cortex, NeuroImage, 2013) which is consistent with other pRF methods. Responses obtained under the AS condition were compared with simulations obtained from a linear AS model (or LAS model). The LAS model provides an estimation of the pRF changes expected to occur as a result of the truncated stimulus assuming that the pRF linearly integrates the AS. We found that pRFs in hV5/MT+ are nonlinearly affected by the truncated stimulus presented: pRF centers shifted towards the border of the AS, pRF size decreased and pRF amplitude increased near the AS border. In addition, using the full bar stimulus to estimate the pRF topography (when in fact the stimulus presented included the AS) produced erroneous pRF estimates inside the region of the artificial scotoma. These biases are not the result of a trivial methodological artifact but appear to originate partly from asymmetric BOLD responses occurring when the stimulus moves from seeing to non-seeing locations of the visual field. Distinguishing between pRF changes that occur as the result of true reorganization versus different test-stimulus presentation conditions is an important task that needs to be undertaken when studying visual cortex organization in patients with visual field deficits.

Title: Deriving contrast response functions from fMRI responses to natural images

Authors: *W. ZUIDERBAAN, S. O. DUMOULIN;
Utrecht Univ., Utrecht, Netherlands

Abstract: Introduction Neural responses in early visual cortex are strongly modulated by image contrast. These neural responses do not sum linearly to an increase in contrast, but saturate at high contrast. Contrast response functions (CRFs) are typically measured using synthetic images that are systematically manipulated. Ultimately, these measures are assumed to extrapolate to natural images. Here we measure the fMRI responses in early visual cortex to natural images. We use the inherent variation in contrast in natural images to derive the CRF. Methods We measured fMRI responses elicited by different types of visual stimuli using a 7T MRI scanner. First, we estimated the region of visual space a voxel responds to: the population receptive field (pRF, Dumoulin et al, 2008). The stimuli consisted of conventional bar-shaped population receptive field mapping stimuli with natural image content. We used a 2D Gaussian to represent the pRF. Convolution of the visual field mapping stimulus with the pRF gives a prediction of the fMRI time-series. The pRF parameters were estimated by minimizing the residual errors of the predicted and measured fMRI time-series. Second, we measured the response amplitude elicited by viewing natural images (45 natural images and 1 full-contrast synthetic image). The natural images were taken from the 'Berkeley Segmentation Dataset and Benchmark' database (Martin et al, 2001). Third, we computed the RMS contrast of the natural image within each pRF. We derived the contrast response function by plotting the fMRI response amplitude against the RMS-contrast of all pRFs within a given visual field map. Results The pRF estimates using natural image content were comparable to those previously published with synthetic image content. Typically, we recorded high fMRI response amplitudes to the viewing of natural images. However, these amplitudes varied across the cortex even for single image presentations. When plotting these response amplitudes against RMS contrast, we derived the CRF. This CRF does not sum linearly with increasing contrast, but shows the characteristic non-monotonic increase in response amplitude with RMS contrast. Discussion We show that it is possible to derive the CRF in early visual cortex without systematically varying the contrast. We use the pRF model and contrast variations inherent to natural images. The CRF is comparable to those derived from synthetic image manipulations. These CRFs can be modulated by different mechanisms. This new method provides us with a tool to test hypotheses of effects on the CRF, to give us more understanding of the underlying mechanisms of the contrast response.

Title: Linking attentional modulations of single-voxel population receptive fields and region-level spatial reconstructions

Authors: *V. A. VO, T. C. SPRAGUE, J. T. SERENCES;
Neurosci. Grad. Program, Psychology, UCSD, La Jolla, CA

Abstract: Studies in macaques and humans have documented significant changes in visual receptive field properties with covert attention shifts (Womelsdorf et al., 2006; Klein et al., 2014; Sheremata & Silver, 2015). It is hypothesized that these changes improve the fidelity of visual representations at the attended location (reviewed in Anton-Erxleben & Carrasco, 2013). This is supported by neuroimaging studies which find that the pattern of changes across population receptive fields (pRFs) jointly improves the fidelity of larger-scale neural representations (Kay et al., 2015; Sprague & Serences, 2013). However, unlike macaque electrophysiology studies, subjects did not maintain a static focus of attention, and instead attended to the mapping stimulus. We sought to quantify: 1) how pRF properties change when spatial attention is directed to a fixed location and 2) how changes in pRF response properties jointly impact the quality of region-level representations in retinotopic visual and posterior parietal cortex. Subjects (N = 5) covertly attended to a fixed location in the left or right hemifield (2.1° eccentricity), or to fixation, while small flickering checkerboards (1.4° diam.) mapped voxel spatial selectivity across the visual field (up to 4.5° ecc). We estimated spatial selectivity profiles for each voxel (pRFs) and then used all voxels in a region to estimate a spatial encoding model. We inverted the encoding model to reconstruct images of the stimulus under different attention conditions. We determined pRF changes by comparing responses during attention to fixation with responses during attention to the left or right. We found that pRFs within 1° of the attention locus increased in amplitude. Many pRFs also decreased in size and shifted toward the attention locus. We then compared stimulus reconstructions across attention conditions. Stimulus reconstructions near the attention locus increased in amplitude. Our results support the hypothesis that collective changes in receptive field properties increase the fidelity of visual representations.

Title: The field of view available to cortical reading circuitry

Authors: ***R. LE**, M. BARNETT, B. WANDELL, N. WITTHOFT;
Stanford Univ., Stanford, CA

Abstract: Background. An important part of skilled reading is the ability to quickly and efficiently see words. The proper spatial and temporal resolution, as well as the appropriate field-of-view, are required for rapid word recognition. If only a small part of the field of view is delivered to the reading circuitry, word recognition will necessarily be slowed. Measurements over the last decade have shown that as children learn to read, circuits in ventral and lateral occipito-temporal cortex rapidly recognize word forms (Wandell, 1999). Here, we use population

receptive field (pRF) measurements (Wandell & Winawer, 2015) to characterize the field of view delivered to cortical reading circuitry in skilled readers. **Methods.** We made functional MRI measurements in eight subjects. Using a localizer that compared words with objects, faces, bodies, scenes, and numbers, we identified the visual word form area (VWFA) in ventral occipital cortex of each subject. We then performed pRF mapping with moving bar stimuli (Dumoulin and Wandell, 2008); the contrast pattern within the bar was either words, checkers, or false fonts. The visual stimuli spanned a range of +/- 16 deg of visual angle. For each voxel in the brain, we fit its pRF: a 2D Gaussian (with a peak of 1) in the visual field. The parameters of the pRF are its center location (x,y) and its spread (σ).The pRF can be thought of as the region in visual space that significantly drives responses in the voxel. We visualize visual field coverage by taking the maximum pRF value at each point in the visual field. **Results.** When word stimuli were used within the bars, fitting the pRF model resulted in over 76% of the voxels having variance explained exceeding 10%. Of the voxels exceeding this 10% threshold, the mean variance explained was 32%. (In V1, the mean variance explained of voxels exceeding the 10% threshold is 49%). The visual field coverage of the VWFA extends to about 10 deg. The sizes of the pRF spread are larger in VWFA than at corresponding eccentricities in V1 or V2. While we could not identify a retinotopic map, the visual field coverage was reliable in each subject. **Conclusions.** It is possible to assess the visual field coverage within cortical circuitry essential for skilled reading. In English readers this cortical region responds to stimuli spanning about 10 deg of visual angle, and the region is most responsive to stimuli along the horizontal meridian. **References.** Wandell, B. Title: Different population-level measurements and analysis techniques enable complementary insights into attentional modulation of visual responses

Authors: *T. C. SPRAGUE[1], S. ITTHIPURIPAT[1], J. T. SERENCES[1,2];
[1]Neurosciences Gradaute Program, [2]Dept. Psychology, UCSD, La Jolla, CA

Abstract: Visual attention enables protection of relevant information representations from degradation (Sprague, et al, 2015). When contrast response functions (CRFs) are measured across spatial attention conditions using different measurement tools, several modulation patterns are observed: contrast gain (the CRF shifts leftward), response gain (response increases multiplicatively with attention), and additive shifts (response amplitude increases by a constant amount across all contrasts). When measured using fMRI, attention results in a purely additive increase in CRFs (Buracas & Boynton, 2007; Murray, 2008; Pestilli et al, 2011). However, CRFs based on stimulus-evoked responses measured using EEG exhibit either response gain or contrast gain (Kim et al, 2007; Lauritzen et al, 2010; Itthipuripat et al, 2014a; 2014b). We sought to directly compare attentional modulation of CRFs quantified using several analysis techniques applied to fMRI and EEG data acquired while the same participants performed identical tasks with controlled behavioral performance. Participants (n=7) viewed a display featuring a flickering checkerboard stimulus presented at 1 of 6 contrasts. On half of trials, they attended to the checkerboard; on the other half, they attended to the fixation point. During fMRI scanning, on separate runs participants viewed a spatial mapping stimulus consisting of checkerboards presented at different locations across the screen so we could estimate voxel-level population receptive fields (pRFs) and an inverted encoding model (IEM; Sprague & Serences, 2013) used for stimulus reconstruction. In fMRI measurements, we exclusively observed additive shifts: univariate activation levels, stimulus reconstruction amplitude, and activation levels in voxels sorted by pRF position and size relative to attended position all showed additive shifts (in V1-hV4). However, we found evidence for both response gain and additive shifts in EEG measurements: response gain was observed in early ERP components (P1/N1 complex and late positive deflection, LPD) and steady-state visually-evoked potentials (SSVEPs); while additive shifts were observed in alpha band desynchronization and the late sustained contralateral negative ERP waveform. While there are differences in fMRI measurements and stimulus evoked responses measured by EEG, similar results seen between fMRI measurements and the late negative ERP component and alpha desynchronization suggest a potentially similar source for these modulations. Finally, these data place constraints on mechanisms of attentional modulation, which must account for all simultaneous modulations that are observed.

Title: Changes in the temporal dynamics of BOLD co-fluctuations underlie the variability of cortico-cortical population receptive field maps derived from resting-state data

Authors: *N. GRAVEL[1], B. HARVEY[3], S. DUMOULIN[3], B. CURCIC-BLAKE[2], F. CORNELISSEN[1];
[1]Exptl. Ophthalmology, [2]NeuroImaging center, Groningen Univ., Groningen, Netherlands;
[3]Exptl. Psychology, Helmholtz Inst., Utrecht Univ., Utrecht, Netherlands

Abstract: In previous work, we have shown that population cortico-cortical receptive field maps can be derived from resting state (RS) functional magnetic resonance imaging (fMRI) applying connective field (CF) modeling (Gravel et al., 2014). This model-based analysis estimates the spatial integration between blood-oxygen level dependent (BOLD) signals in distinct cortical visual field maps using fMRI. Just as population receptive field (pRF) mapping predicts the collective neural activity in a voxel as a function of response selectivity to stimulus position in visual space, CF modeling predicts the activity of voxels in one visual area as a function of the aggregate activity in voxels in another visual area. In combination with pRF mapping, CF locations on the cortical surface can be interpreted in visual space, thus enabling reconstruction of visuotopic maps from resting state data. Hence, once we know the layout of V1's visual field map, CF modeling of RS activity allows us to derive extrastriate visual field maps resembling those derived by conventional methods. Remarkably, estimates of CF properties differ slightly when estimated with different RS scans, even in the same scanning session. This indicates that - despite uncertainty from methodological origins and considerable inter-scan variability- blood-oxygen level dependent (BOLD) co-fluctuations in the early visual cortex preserve fine-grained visuotopic organization, even in the absence of visual stimulation. Here, we ask which changes in the BOLD signal affect the variability of RS-CF estimates, and, more generally, how estimates of RS-fMRI connectivity in the early visual cortex change over time. We find that the

resemblance between VFM and RS derived extrastriate CF maps is partly explained by a similar periodic structure in the BOLD activity. In particular, the presence of low frequency (~0.01-0.1 Hz), phase-locked BOLD co-fluctuations within the RS visual system seems to underlie the resemblance between connective field maps obtained from RS and VFM data. During VFM, the BOLD responses are locked to strong position-varying visual stimuli. As during RS scans there are no changes in visual stimulation, we speculate that the VFM-like periodic structure in the BOLD signals may be caused by changes in the endogenous state of the early visual cortex.

Title: Lines of Baillarger *in vivo* and *ex vivo*: myelin contrast across lamina at 7T MRI and histology

Authors: *A. FRACASSO[1], S. J. VAN VELUW[2], F. VISSER[3,4], J. J. M. ZWANENBURG[3], S. O. DUMOULIN[5], N. PETRIDOU[3];
[1]Utrecht Univ., Utrecht, Netherlands; [2]Neurol., Brain Ctr. Rudolf Magnus, Utrecht, Netherlands; [3]Radiology, Univ. Med. Ctr., Utrecht, Netherlands; [4]Philips Med. Systems, Best, Netherlands; [5]Helmholtz institute, Utrecht, Netherlands

Abstract: Introduction Myelin concentrations vary across the cortex and cortical lamina. These variations in myelin concentrations are the basis for the parcellation of human cortex. Recent advances in *in vivo* MRI allow the visualization of myelination contrast and have in particular focused on the stria of Gennari in primary visual cortex. Here we focus on the stria of Gennari as well as laminar contrast outside primary visual cortex and the occipital lobe with the aim to reveal the lines of Baillarger, in-vivo. Methods We extended a 3D T1-weighted MPRAGE (T1-w) sequence to optimize contrast between low and high myelin content within human cortex for

ex-vivo and in-vivo imaging. Images were acquired at 7 Tesla (Philips, NL) with a volume transmit and 32-channel receive head coil (Nova Medical, USA). We measured laminar profiles within the human cortex comparing ex-vivo, histological measurements and in-vivo data. Histology: striate and extra-striate areas were sampled and 4μm-thick sections were stained with Luxol Fast Blue-Periodic Acid Schiff for myelin. Ex-vivo MR imaging parameters: TE: 7.7/3.5ms, flip: 8 deg, resolution 400 μm isotropic, 80 slices, TI:280ms, Time delay (TD): 2s. In-vivo MR imaging parameters (4 adult participants): TD: 6s,TI: 1200ms, TR/TE 8/3ms, flip angle: 8 deg, voxel size = 500 μm isotropic. 60 coronal slices, bandwidth 202Hz/px, turbo factor: 275, and adiabatic inversion. Laminar profiles: MRI samples were manually segmented and laminar profiles were extracted from 0.36mm diameter cylinders, from the gray/white matter border to the gray surface. 100 profiles were extracted for each region. Laminar profiles from each area were derived from 1000 bootstrapped datasets. Results *Ex vivo* T1-w laminar profiles showed a consistent T1-w intensity increase for both calcarine and extra-calcarine areas of the cortex, located in the middle of the cortical thickness. These laminar profiles are comparable to those found on the histological sections. Comparable profiles were also obtained on in-vivo T1-w images in healthy adults on calcarine and extra-calcarine areas. Here the laminar profile identifying a T1-w increase in the middle of the cortical thickness extended into parietal and frontal lobes. Conclusion We reliably identify a distinct myelin variation in the middle of the cortical thickness that extends beyond primary visual cortex in ex-vivo and in-vivo images. We propose that this structure represents the lines of Baillarger. These findings provide the basis to apply the principles of myeloarchitectonics, *in vivo*, in humans, using high field MRI.

Title: Columnar segregation of color- and disparity-selective stripes in human areas V2 and V3

Authors: *R. B. TOOTELL[1], J. R. POLIMENI[2], S. NASR[2];
[1]MGH-NMR Ctr., Charlestown, MA; [2]Radiology, Martinos Ctr. for Biomed. Imaging, Boston, MA

Abstract: Background: In non-human primates (NHPs), secondary visual cortex (V2) is made up of repeating columnar 'stripes', labeled with cytochrome oxidase (CO) histology. Among these, the CO-dark 'thin' and 'thick' stripes respond selectively to variations in stimulus color and binocular disparity, respectively. Hypotheses: The NHP data, plus human histology, predict that any homologous color- and disparity-selective stripes in humans should: a) radiate 'outwards' from the V1-V2 border, b) be spaced ~7 mm apart (full cycle), c) be non-overlapping and interdigitated, and d) have segregated functional connections. Additionally, e) stripes for disparity (but not color) should terminate a few mm from the V1-V2 border, and f) similar columns might exist in adjacent area V3. Approach: We used specialized fMRI techniques (7T, 0.8–1 mm iso) to reveal V2 stripes in 6 human subjects. Color-selective stripes were revealed using color- vs. luminance-varying gratings. Disparity-selective stripes were localized using random dot stereograms, presented at near-through-far vs. zero disparity. Areas V2 and V3 were localized retinotopically. A cortical surface analysis enabled extensive signal averaging across multiple scan sessions (thus increasing the contrast/noise), plus selective sampling of activity from the lower cortical layers (minimizing contributions from pial veins). Results: All predictions were confirmed. Color- and disparity-selective stripes radiated perpendicularly to V1/V2 border, spaced 7.2 mm apart. The stripe maps correlated strongly across sessions (e.g. $p < 10^{-30}$). Interdigitation of color- and disparity-selective stripes was confirmed as percent overlap when the maps were topographically aligned, vs. spatially shuffled. An analogous functional segregation was found in V3. This visualization of multiple types of columns is novel in human extrastriate cortex, especially in V3. Next we measured functional connections in the resting state (eyes closed) in both functional types, in V2 and V3. In a double dissociation, activity fluctuations in functionally alike stripes (e.g. color-to-color) correlated more strongly than in unlike stripes (e.g. color-to-disparity), within and between V2 and V3. Conclusions: Prior fMRI results showed differences between specific human visual cortical areas. Here we found a more detailed segregation of feature-selective streams within areas V2 and V3, which extends streams that are known to link V1 and V2 in NHPs. This color- vs. disparity-selective segregation may be a special case of a broader parallel analysis of visual surfaces vs. boundaries, respectively.

Title: Curvature-biased cortical areas in human visual cortex and its functional implications

Authors: *X. YUE[1], A. GANDHI[2], L. G. UNGERLEIDER[2];
[2]Natl. Inst. of Mental Hlth., [1]NIH, Bethesda, MD

Abstract: In a recent fMRI study, we observed a network of cortical areas selective for curvature processing in macaque visual cortex. These curvature-biased areas partially overlapped with the well-studied face-processing areas. Here, we aimed to determine whether human homologues of monkey curvature-biased cortical areas exist and, if so, their anatomical relationship to the face-processing cortical areas in the human brain. FMRI was acquired in a 7T scanner in response to the visual presentation of round vs. rectilinear shapes matched to those used in the monkey fMRI study. Our results revealed significant fMRI biases in the human ventral visual pathway to round vs. rectilinear shapes. Areas biased to round shapes included human V4, OFA, FFA1, and part of V8. A curvature-biased area in human V4 corresponded to the posterior curvature-biased patch in macaques. The curvature-biased areas in OFA and FFA1 appeared to be the homologues of the middle curvature-biased patch in macaques. However, it remains unclear from our data where the human homologue of the monkey anterior curvature-biased patch is, or if it exists. The close proximity of curvature-biased and face-processing areas in both species indicates a functional link between face and curvature processing, which we investigated in two psychophysical experiments using humans. In the first experiment, a sample image (a computer generated face or chair) was presented briefly on each trial, followed immediately by a mask (curved or straight) to interrupt visual processing. The mask was then followed by a 2-choice recognition test. The presentation time of the sample images varied from trial to trial using a staircase method to make performance comparable across conditions. Our results showed that subjects required significantly longer viewing time of the sample images to perform the face recognition task with curved masks compared to straight masks ($t(15) = 3.25$, $p < 0.01$). This pattern was reversed for the chair recognition task ($t(15) = -2.34$, $p < 0.05$). To address the concern that the above pattern of results could be explained by the smooth surfaces in computer generated faces rather than the irregular features found in real faces, we conducted a second experiment using images of natural faces and scenes. As before, these images were presented briefly before and after a curved or straight mask. Subjects categorized faces as male/female, and scenes as forest/non-forest. Thus far, our data suggest that curved masks caused a higher error rate than straight masks in the face task, while the reverse true in the scene task. These findings support the idea that curvature and face processing are functionally related.

Abstract: The perceived continuity of the visual image despite frequent interruptions by eye blinks is a ubiquitous visual illusion. We investigated the neural correlates of this illusion using electrocorticography in patients being evaluated for epilepsy surgery. Patients were presented with blocks of still images while monitored for spontaneous and intentional eye blinks. In control blocks, the retinal impact of these events was mimicked by artificial darkenings of the screen ('gaps'). We found that in V1, the disappearance of the visual stimulus due to either gaps or blinks led to a drop in broadband gamma activity. The reappearance of the stimulus was followed by a rebound of the activity beyond the pre-drop levels. Surprisingly, high-level ventral visual areas such as the Fusiform-Face Area exhibited a post-disappearance drop that was slightly more pronounced for blinks than for gaps, an effect inconsistent with the intuitive account for blink invisibility by perceptual 'filling-in'. In contrast, the rebound elicited by the termination of gaps and blinks indeed reflected the established sensation-perception gradient across the ventral visual stream hierarchy: when moving downstream from the early visual cortex towards high-level ventral visual cortex, the rebound response subsided for blinks more than for gaps. This pattern was observed both within single patients and at the group level (the accompanying figure depicts offset-locked grand averages). In conclusion, broadband gamma

response in ventral visual areas can indeed be viewed as a correlate of the perceptual distinction between blinks and external darkenings. However, the temporal structure of this response does not directly correspond with the apparent continuity of the perceived visual image.

Title: A shift toward dendrite targeting inhibition in extrastriate visual cortex

Authors: *D. MORROW-JONES[1], A. DISNEY[2];
[1]Psychology, [2]Vanderbilt Univ., Nashville, TN

Abstract: The primate neocortex has distinct populations of inhibitory interneurons that have been classified using various anatomical and functional criteria. One such classification scheme is based on immunoreactivity for the calcium-binding proteins parvalbumin (PV), calbindin (CB), and calretinin (CR). The PB-, CB-, and CR-immunoreactive populations are believed to represent non-overlapping classes that together make up ~95% of all inhibitory interneurons in macaque V1. Furthermore, these subpopulations have some correspondence with classically-defined morphological neuron types and with physiological phenotypes. The cell body laminar distribution of these neuron subpopulations has been previously characterized in the primary visual cortex (V1) of macaques. 74% of all inhibitory interneurons in V1 are estimated to be PV-ir. These PV-ir cells are present in all layers except layer I, with a heavy band in layer IVc. CB-ir

neurons, on the other hand, are mainly present in layers II and III (van Brederode et al., 1990), and CR-ir neurons are mainly present in layer II (Meskenaite, 1997). This laminar distribution of cell bodies appears to be conserved in the frontal lobe. The prefrontal cortex (PFC) has PV-ir neurons in all layers besides layer I, especially layers III and IV. Similar to V1, PFC has a strong PV-ir neuron presence in layer IV. In addition, the PFC has CB-ir neurons mostly in layers II and III, and CR-ir neurons mostly in layer II (Condé et al. 1994). However, the PV-ir neuron predominance seen in V1 is not observed in the PFC. Instead, the CR-ir population is estimated to be twice that of CB-ir or PV-ir neurons. In macaque V4, we characterized the distribution of calcium-binding protein expressing neuron subpopulations using triple label immunofluorescence confocal microscopy. Labeled neurons were counted for each layer. Similar to V1 and PFC, V4 PV-ir neurons are present in all layers besides layer I, especially layers II/III and IV. In addition, CB-ir neurons are mostly present in layers II and III, and CR-ir neurons are mostly present in layer II. PV-ir neurons are the predominant subpopulation, similar to V1, but comprise only half the population of calcium-binding protein expressing neurons. There was virtually no dual or triple labeling for any class. PV-ir neurons often target the soma or axon, in contrast with prominent dendritic targeting seen in CB-ir and CR-ir neurons. This allows PV-ir neurons to regulate an integrated response in pyramidal cells. Our findings suggest an increased emphasis of dendritic integration as a method of inhibitory signaling in downstream cortical regions, as a result of a relative decrease in the PV-ir neuron population.

Title: Age-related shift in E-I balance in dorsal visual pathway

Authors: *C. SIU[1], K. M. MURPHY[2];
[1]MiNDS, [2]Psychology, Neurosci. and Behaviour, McMaster Univ., Hamilton, ON, Canada

Abstract: Many aspects of visual perception decline in older adults, but surprisingly they perform better than young adults on motion discrimination that activates surround suppression. An age-related loss of GABA-mediated surround suppression is the main hypothesis to explain that better motion discrimination. However, there is global age-related loss of GABA in the cortex but not global changes in visual tasks that rely on surround suppression. Alternatively, local changes in other neurotransmitters systems might contribute to the loss of surround suppression. For example, in visual cortex feedforward-driven activity is strongly mediated by AMPA receptors, while feedback modulation is mediated by NMDA receptors. Perhaps, expression of these glutamatergic receptors is maintained in the dorsal/motion visual pathway but lost in other visual areas. To address this question we used Western blotting to quantify expression of AMPA (GluA2) and NMDA (GluN1) receptor subunits in V1, V3 (dorsal), and V4 (ventral) of human postmortem tissue samples. We studied 15 cases ranging in age from 5-80 years. We also measured the expression of GAD65, the enzyme that makes the on-demand pool of GABA. First, we compared expression of GAD65 in V1, V3, and V4 of human cortex. We found similar age-related losses of GAD65 in all 3 areas. Next we compared expression of GluA2 and GluN1 among the 3 areas. We found similar losses in V1 and V4, but surprisingly no loss of these glutamatergic receptor subunits in V3. Furthermore, only the dorsal pathway had a change in GAD65 vs GluA2 and GluN1 that could shift the excitatory-inhibitory balance in favor of excitation. These findings provide new information about pathway specific neurobiological changes in the aging human visual system. The maintenance of high levels of glutamate receptors in the dorsal pathway suggests that this excitatory neurotransmitter system is likely to have a greater contribution to motion perception in aging. Finally, the findings point to the E-I balance rather than absolute levels of excitation or inhibition as important for surround suppression in aging visual perception.

Title: Perception of depth sign from motion parallax relies on combining extra-retinal signals regarding eye and body rotation

Authors: *V. KOGAN[1], D. E. ANGELAKI[2], G. C. DEANGELIS[1];
[1]Brain and Cognitive Sciences, Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY; [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Motion Parallax (MP) refers to the relative image motion of objects located at different depths, caused by the translation of the observer. In the absence of pictorial depth cues, MP is ambiguous regarding depth sign (near vs. far). Retinal motion of a near object during a leftward translation could be the same as retinal motion of a far object during rightward translation. Psychophysical studies (e.g., Nawrot & Joyce 2006) have shown that smooth eye movements can disambiguate depth sign from MP. Theoretical work by Nawrot and Stroyan (2009) showed that the critical variable for disambiguating depth sign from MP is the rate of change of eye rotation relative to the scene. Importantly, eye rotation relative to the scene (R_{es}) is determined by the combination of eye rotation relative to the head (R_{eh}), head rotation relative to the body (R_{hb}), and body rotation relative to the world (R_{bw}): $R_{es} = R_{eh} + R_{hb} + R_{bw}$. Thus, the brain should ideally combine the relevant extra-retinal signals and use the resultant (R_{es}) to disambiguate depth sign from MP. Alternatively, the brain might rely on smooth pursuit signals (R_{eh}) as an approximate solution. To explore this issue, we trained macaques to discriminate depth sign from MP, manipulating depth coherence to control task difficulty (Kim et al. 2015). The animal was translated back and forth by a motion platform (to generate MP), and was required to execute smooth eye movements to maintain fixation on a world-fixed target. In addition, the motion platform was used to rotate the body around an axis through the eye. Thus, R_{es} was determined by the combination of passive body rotation (R_{bw}) and active eye pursuit (R_{eh}) - there was no rotation of head on body ($R_{hb} = 0$). By presenting various combinations of R_{bw} and R_{eh} that all produced the same R_{es}, we could examine which variables determine perceived depth sign. If perception relies on R_{es}, then all combinations of $R_{bw} + R_{eh}$ should evoke equivalent performance. If perception relies solely on R_{eh}, performance should decline as R_{bw} increases, reaching chance when $R_{bw} = R_{es}$ ($R_{eh} = 0$). When $R_{bw} > R_{es}$, such that the sign of R_{eh} reverses, perceived depth sign may reverse. Results to date show robust depth discrimination performance for a variety of combinations of R_{eh} and R_{bw} in which $R_{bw} \leq R_{es}$ (including $R_{eh} = 0$), indicating that vestibular rotation signals contribute to disambiguating depth sign. However, performance is erratic when R_{eh} and R_{bw} have opposite signs ($R_{bw} > R_{es}$, $R_{eh} < 0$), suggesting that depth perception may not rely on a true representation of R_{es}. This paradigm will provide an excellent vehicle for exploring how different sources of rotation signals contribute to neural computations of depth from MP.

Title: The role of disparity and viewpoint in the processing of observed actions

Authors: *S. FERRI, G. RIZZOLATTI, G. A. ORBAN;
Univ. of Parma, Parma, Italy

Abstract: The present human fMRI study investigated the role of disparity and the observer's point of view in processing of observed manipulative actions. The actions (grasping, dragging, pushing, displacing) were simultaneously recorded by two camcorders supplied by 3D lenses, one on the left of the actor and the other facing him. 21 right-handed subjects underwent to two fMRI sessions (16 runs), where 2D or 3D action videos were contrasted in a 2x2x2 block design: viewpoint (frontal/lateral), spatial dimensions (2D/3D), video-type (action/control videos: static and dynamic-scramble) with separate runs for the two controls. To control both saccades and vergence, we used a binocular eyetracker confirming steady fixation. In the first level analysis motion in depth was taken as a variable of not interest, because dynamic disparity differed between experimental and scrambled videos. The three-way interaction, computed at the second level and conjoined for the two types of control conditions, positive for frontal view, 3D and actions, produced three sites in the left hemisphere: DIPSM (-22 -56 54 t=5.6; FWE p=0.05), PFop (-54 -28 20 t=5.7; FWE p=0.006) and PreCentral Gyrus (PrCG, -40 -4 48 t= 5.9 FWE p=0.002). Splitting the data according to viewpoint indicated that dimension and video-type interacted only for frontal and not lateral viewpoint. We noticed that the motion in space of three out of four action exemplars was congruent with the frontal viewpoint. Hence the interaction sites were either specific for frontal viewpoint or for action along the Z-axis of the observer. We therefore ran a control experiment with viewpoint and direction in space as factors. ROI analysis on 15 subjects showed the activity in all regions was stronger for actions out of the fronto-parallel plane of the observer (2way ANOVA interaction: DIPSM $p<0.01$; pfOP: $p<0.005$; PrCG: $p<0.005$). However the profiles of the four conditions were different in the three ROIs: 3 (area) x4 (conditions) ANOVA (interaction $p<0.001$). The main effect of view point was significant only in PrCG ($p<0.05$). Thus stereo enhances action processing in parietal and premotor regions, an effect strongest for out of the fronto-parallel plane actions. Viewpoint enhanced the stereo effect only at the premotor level. This study is supported from ERC Grant

Title: Natural binocular fixations in humans and binocular disparity

Authors: *M. S. BANKS[1], W. W. SPRAGUE[2], S. RESSIER[1];
[1]Optometry, [2]Vision Sci. Grad. Program, Univ. of California, Berkeley, CA

Abstract: The two views of the world from forward-facing eyes in humans and other species generate binocular disparities from which precise depth estimates can be derived. There is keen interest in the distributions of disparities that occur naturally in different parts of the visual field. To determine those distributions, one must know the 3D geometries of natural scenes and where viewers look in those scenes. Several investigators have estimated disparity distributions from simulated scenes and eye fixations. Others have measured distance distributions in real scenes and then produced simulated fixations in those scenes. Recently, we measured binocular eye position and 3D scene geometry simultaneously as humans performed natural tasks in a variety of scenes (Sprague et al., 2015). From those measurements, we determined the natural distributions of disparities across the central visual field. The distributions are consistent with disparity preferences among V1 neurons of primate. The distributions of binocular fixation are not consistent with those from previous simulations because viewers are biased toward fixating nearer points among all visible points and are biased toward looking up and down and left and right rather than in all directions equally. We examined how disparity distributions depend on observed binocular fixations. We did this by computing mutual information between vergence eye position (convergent vs divergent) and disparity, and between version eye position (left-right, up-down, etc.) and disparity. Mutual information is a measure of variables' mutual dependence with few assumptions about the type of dependence (unlike the correlation coefficient). We found that mutual information is high between vergence and horizontal disparity in the upper and lower visual field, but not the left and right fields. We also observed that mutual information is very high between vergence and vertical disparity for oblique regions of the visual field. We observed clear dependency between horizontal version and vertical disparity and between version and horizontal disparity. Our results show quite clearly that knowing binocular eye position and 3D scene geometry simultaneously is essential to determine the disparities human normally encounter.

Title: Effects of drift speed and stimulus size on binocular rivalry rate and mixed percept duration in healthy individuals: Implications for endophenotype studies in clinical psychiatric groups

Authors: *S. MILLER[1,2], P. C. F. LAW[1,2], T. T. NGO[1,2,3];
[1]Monash Univ., Melbourne, Australia; [2]Monash Alfred Psychiatry Res. Ctr., Melbourne, Australia; [3]Genet. Epidemiology Laboratory, QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Abstract: Presenting conflicting images, one to each eye, results in perceptual alternations known as binocular rivalry (BR). BR rate (BRR) is slower in the heritable psychiatric condition, bipolar disorder (BD) compared with healthy controls (HC). BRR is also around 50% genetically determined. Thus slow BRR rate has been proposed as an endophenotype for BD. To assess this endophenotype potential, large-scale studies are required with sample sizes in the thousands to tens of thousands. In preparation for such work, we have been examining two issues: the relationship between individuals' eye movements and their BRR (reported in Law, Paton, Riddiford, Gurvich, Ngo, and Miller, in press), and the stimulus parameters that maximize separation between BD and HC. Here we report the effects of stimulus drift speed (a measure of stimulus strength) and size on BRR in HC. We previously reported that gratings drifting at 4 cycles/sec better separated BD and HC than stationary gratings, perhaps due to the different stimulus strengths' effect on HC. In the present study, we varied stimulus drift speed to assess whether BRR can be further increased in HC. We also assessed mixed percept duration (MPD) with each drift speed, aiming to minimize MPD. In addition, we assessed the effect of varying stimulus size on BRR and MPD. We conducted a repeated-measures within-subjects study of HC (N=40, mean age=34.4) viewing BR on a True3DiTM liquid-crystal display monitor through passive linear polarizer 'filters' at a distance of 3 m. Stimuli were green, orthogonally-drifting vertical and horizontal square-wave gratings with spatial frequency 8 cycles/deg (contrast=0.99;

mean luminance=4.8 cd/m2) in a circular aperture on a black background. Drift speed and aperture size varied across four conditions: (i) 4 cycles/sec at 1.5° and (ii) 8 cycles/sec at 0.5°, 1° and 1.5°. BRR was stabilized for 7 minutes, followed by four counterbalanced 7-min test blocks. We found: (i) for 1.5° stimuli, 8 cycles/sec produced faster BRR (median=0.52Hz, s.d.=0.24) than 4 cycles/sec (median=0.47Hz, s.d.=0.22) ($p<0.01$), (ii) BRR was slower for 8 cycles/sec in a 0.5° aperture (median=0.40 Hz, s.d.=0.16) compared with all other stimulus conditions ($p<0.001$), (iii) MPD was shorter for a 1.5° aperture than a 1° aperture at 8 cycles/sec ($p<0.01$), and (iv) MPD was longer for a 0.5° aperture compared with all other stimulus conditions ($p<0.001$). The findings suggest that stimuli drifting at 8 cycles/sec in a 1.5° aperture could maximize group separation in endophenotype studies of BRR, without introducing higher MPD. However, we are currently repeating these experiments with BD subjects before instigating this protocol change.

Title: Loss of binocular depth perception by genetic functional inactivation of ipsilateral retinal projections

Authors: ***T. DOLIQUE**[1], S. SEDIGHI[2], K. CULLEN[2], F. CHARRON[1,3,4,5,6];
[1]Inst. De Recherches Cliniques De Montréal, MONTREAL, QC, Canada; [2]Aerospace Med. Res. Unit, Dept. of Physiology, McGill Univ., MONTREAL, QC, Canada; [3]Dept. of Anat. and Cell Biology, McGill Univ., Montreal, QC, Canada; [4]Dept. of Biology, and Div. of Exptl. Medicine, McGill Univ., Montreal, QC, Canada; [5]Dept. of Medicine, Univ. of Montreal, Montreal, QC, Canada; [6]Integrated Program in Neuroscience, McGill Univ., Montreal, QC, Canada

Abstract: Binocular vision allows depth perception through the convergence of visual information from both eyes in the brain. During development, most retinal ganglion cell (RGC) axons cross the midline at the optic chiasm and project toward the opposite side of the brain (contralateral axons), while a small number of axons remain on the same side (ipsilateral axons). Ipsilateral projections have been suggested - with no formal proof as yet - to be important for depth perception. Here we used a genetic approach to functionally inactivate ipsilateral projections and investigate whether these projections are important for depth perception. Synaptic transmission was suppressed in ipsilateral-projecting RGCs (iRGCs) by conditionally expressing the tetanus toxin light chain subunit (which inhibits neurosecretion) using a Cre-mediated recombination approach. Interestingly, we showed that the functional inactivation of iRGCs did not induce changes in the retinal patterning and did not prevent their axons to maintain their normal trajectory, target to the appropriate brain regions, segregate and consolidate their normal amount of target territory into the late postnatal period. Most importantly, using visual tests, we demonstrated that while these transgenic mice maintain proper visual discrimination, they fail to detect depth in a binocular visual test. Therefore, our data provide for the first time a clear demonstration of the specific requirement of functional ipsilateral retinal projections for binocular depth perception.

Title: A probabilistic approach to multiple object tracking in three-dimensions

Authors: ***J. R. COOKE**[1], R. J. VAN BEERS[2,1], A. C. TER HORST[1], P. MEDENDORP[1]; [1]Donders Ctr. For Cognition, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Fac. of Human Movement Sci., VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Many daily situations require us to track multiple objects and people, from avoiding walking into people in the street to monitoring the traffic around us as we drive. Our multiple

object tracking (MOT) ability has traditionally been investigated in stationary observers tracking objects in a plane. This simplifies the task and does not address how observers track objects when targets move in 3D and when the observers move themselves. Having objects move in depth adds additional complexity to tracking. Depth estimation requires integration of complex cues such as disparity, relative size, shading and motion parallax. These cues also depend on our self-motion, for example motion parallax is a sum of parallax from self-motion and object motion. As such to effectively track in depth the brain must integrate as well as disambiguate cues. Here, we are studying how stationary observers track objects in 3D. A prominent approach to studying how observers solve a task given the available cues is to create a Bayesian ideal observer model and compare its performance to human performance. We have developed a Bayesian multiple object tracking model which performs MOT by estimating the time-varying state (position and velocity) of objects using noisy observations provided from cues such as retinal motion, disparity, relative size and motion parallax. To perform this state estimation it is important that sensory measurements are assigned to the correct object, the data association problem. This is crucial in MOT as objects move close to each other and so generate sensory measurements that could be from either object. Our model treats this data association probabilistically using a particle filter that samples possible associations. Combined this provides a model of how a Bayesian observer tracks objects taking into account sensory uncertainty. Simulations of this model show that adding, removing or altering sensory cues will alter tracking ability. One prediction is that observers tracking objects moving at a given speed will be more accurate when the objects move in depth (with disparity, motion parallax and size as cues) than if objects move at the same speed in a plane. We are currently testing this prediction using a 3-D display which renders moving objects in 3-D using disparity, motion parallax, relative size and shading cues. Our results confirm the prediction that tracking with multiple depth cues improves tracking compared to tracking in a plane.

Title: Disparity selective adaptation to correlated and anticorrelated patterns in V1 neurons requires computation across a broad population of neurons

Authors: *P. L. APARICIO, B. G. CUMMING;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Adaptation is ubiquitous in the visual system. Here we describe the effect of adapting to both correlated (cRDS) and anti-correlated random dot stereograms (aRDS) on 42 disparity selective V1 neurons recorded from two fixating macaque monkeys. The aRDS elicit disparity selective responses in many V1 neurons that are inverted relative to the responses produced by cRDS. As reported in other domains, adaption frequently produced changes in response gain, which we estimated using linear regression of adapted on unadapted responses. The slope defined a response gain ratio produced by adaptation. We also computed a "preferred index" quantifying whether the adapting disparity was closer to the neuron's preferred or null disparities. For disparities close to the preferred disparity, adaptation to cRDS produced response decreases (mean gain ratio 78%, n = 28), while adaptation to aRDS produced response increases (mean gain ratio 113%). Disparities closer to the null disparity produced the opposite pattern (mean ratio 110% for cRDS, 88% for aRDS, n = 36). The slope of the relationship between preferred index and gain ratio had similar magnitudes but opposite signs for cRDS (-0.42) and aRDS (0.37) Thus, cRDS and aRDS had opposite effects on the responsiveness of disparity selective neurons that were approximately equal in magnitude. This is surprising as aRDS typically produce weaker responses. We also observed clear adaptation to aRDS in neurons that showed no disparity selective responses to aRDS. To examine this in the population, we used a median split on the response modulation to aRDS. Adaptation to aRDS produced similar effects in the two groups: the slope relating "preferred index" to response gain was 0.33 in cells strongly modulated by aRDS, and 0.32 in the weakly modulated group. Many neurons also showed stimulus specific adaptation effects, not captured by changes in gain/offset of the whole response curve. Preferred cRDS produced a stimulus-specific response reduction (mean 21%), that declined as a Gaussian function of distance from the adaptor (SD 0.07 degrees). The same disparities in aRDS produced the opposite effect, smaller in magnitude (mean 7%). Thus, adaptation to disparity in cRDS produced effects in V1 neurons that are comparable to the effects previously reported for other stimulus dimensions. Adapting to aRDS produces equivalent, but reversed effects. The magnitude of this effect, however, was not related to the strength of responses to aRDS in individual neurons. This implies that adaptation is not driven simply by the relationship of the responses of a single neuron to the adapting stimulus, but depends on the properties of a broad population of neurons.

Title: Binocular imbalance in macaque MT in strabismic amblyopia

Authors: *T. J. VAN GROOTEL, J. A. MOVSHON, L. KIORPES;
New York University, Ctr. For Neural Sci., New York, NY

Abstract: Cortical area MT plays a central role in processing information about motion and depth. V1 cells and some MT cells sense the motion of image components, while other MT cells signal the motion of integrated patterns - a property known as pattern direction selectivity (PDS). Most MT cells in normally reared animals receive input from both eyes and respond similarly to stimulation through either eye, a key component of their sensitivity to stereoscopic depth. Both of these properties are immature in infant macaques, suggesting that their development might be vulnerable to abnormal postnatal visual experience. Strabismus, a misalignment of the visual axes, often leads to amblyopia, a disorder in which visual acuity is reduced in one eye and stereopsis is often abolished. Some amblyopic observers also have difficulty detecting visual motion with their amblyopic eye, especially for stimuli of slow and moderate speed. To investigate the neural correlates of the motion processing deficits in strabismic amblyopia, we have recorded from neurons in MT of an awake, fixating strabismic amblyopic macaque monkey. We used drifting gratings, plaids, and dot fields to measure direction selectivity, speed tuning, spatiotemporal tuning and eye dominance in amblyopic MT cells. Most MT neurons in this animal were monocular, and only about ¼ were dominated by the amblyopic eye. The tuning properties of cells driven by the amblyopic eye were similar to fellow eye cells. PDS cells were equally prevalent among cells dominated by the two eyes, and, for binocularly driven cells, tuning properties were the same regardless of viewing eye. However, in a small population of cells tested binocularly as well as monocularly, we did not see any change in firing rate during binocular viewing compared to viewing through the fellow eye alone, suggesting that the fellow eye suppressed activity evoked by the amblyopic eye when both were stimulated. Reflecting the overall shift in eye dominance, firing rates were lower when viewing with the amblyopic eye. The receptive field positions of MT neurons were not shifted proportionally to the misalignment of the eyes. We conclude that MT neurons in amblyopic monkeys have similar response properties in the two eyes, but that neurons driven by the amblyopic eye are weakly responsive

and numerically underrepresented. The lack of influence of the amblyopic eye under binocular viewing conditions may reflect an active process that filters out the input from the amblyopic eye.

Title: Radial frequency discrimination is impaired in amblyopic non-human primates

Authors: *S. SHARIAT TORBAGHAN, B. N. BUSHNELL, L. KIORPES;
Neural Sci., New York Univ., New York, NY

Abstract: Radial frequency (RF) stimuli have been used to assess global shape discrimination in human subjects. RF patterns are circular patterns in which the base circle is sinusoidally modulated; they are described by the frequency and amplitude of that modulation. The ability of human subjects to discriminate the modulation is in the hyperacuity range at threshold - finer than 1 arc min. It has been hypothesized that these stimuli modulate the responses of V4 neurons in extrastriate visual cortex, where neurons are thought to encode curvature and global form. Amblyopic human adults and children have previously been shown to perform poorly on RF discriminations, suggesting that there may be a deficit in processing these hyperacuity-range stimuli at the level of V4. Amblyopia is a disorder of spatial vision that results from abnormal visual experience in early life. Amblyopia has been associated with a wide range of spatial visual deficits, including poor performance on Vernier acuity tasks which are also typically performed in the hyperacuity range. To assess whether performance on RF shape discriminations reflects a similar deficit to Vernier acuity, and in preparation for electrophysiological recording studies in V4, we assessed the performance of macaque monkey subjects on RF and Vernier acuity tasks. We trained 7 non-human primates (*Macaca nemestrina*) ranging in age from 33 to 630 weeks, 4 strabismic amblyopic and 3 visually-normal controls, to perform 2AFC discrimination tasks. For the RF task, animals were shown two circular patterns, one with and one without radial deformation. They indicated which stimulus contained the deformations as a function of amplitude and frequency of the modulation. The youngest animal showed higher RF

threshold than older controls and fellow eyes of amblyopes, especially at the higher RF values. Amblyopic animals' performance was impaired with their amblyopic eye compared to both their fellow eye and control animals, especially at the higher RF values. We also tested Vernier acuity (VA) in a subset of amblyopic animals and compared their losses on the two tasks. We found that the RF deficits at high RF values were larger than the VA deficits, suggesting that they do not depend on the same underlying mechanisms. The RF deficits may therefore represent a specific disorder of global shape perception which may reflect disorder of extrastriate visual processing.

Title: Receptive-field center/surround interactions in V2 neurons of amblyopic monkeys

Authors: *B. ZHANG[1], X. TAO[2], E. L. I. SMITH[2], J. WENSVEEN[2], Y. CHINO[2];
[1]Col. of Optometry, Nova Southeastern Univ., Davie, FL; [2]Univ. of Houston, Houston, TX

Abstract: Beyond the well-established loss of contrast sensitivity and acuity, amblyopic primates exhibit a variety of complex spatial vision deficits; in particular, amblyopic children and adults exhibit position uncertainty, image distortion, and poor contour integration. What is common in these perceptual impairments is their inability to accurately encode, weigh, and pool local stimulus feature information over the extended range of space. We previously found that the receptive-field (RF) subunit maps of V2 neurons in amblyopic monkeys show substantial 'disarray' (heterogeneity), which may explain some of the perceptual impairments in behavioral tasks that require orderly integration of visual features over space. In this study we examined the RF center surround interactions of V2 neurons to explore the wider range of spatial interactions covered by individual neurons in amblyopic monkeys. We found that the strength of surround suppression over the center responses was abnormally elevated in V2 neurons of amblyopic

monkeys. Moreover, the strength of surround suppression paralleled the degree of disruptions in RF subunit maps (higher average heterogeneity index values) for individual amblyopic monkeys. When we stimulated the small, restricted regions of RF surround, using grating patches that are placed across the unit's RF center for 4 different positions (i.e., top-bottom, side, oblique 45/225, and oblique 135/315), we observed surround facilitation depending on the locations of surround patches in both normal and amblyopic monkeys. In normal monkeys, the highest surround facilitation occurred for the collinear surround patches (top-bottom) as previously reported. However, in those neurons driven by the amblyopic eye showed the weakest surround facilitation with co-linear surround patches. These results suggest that the long-range intrinsic and/or feedback connections in V2 are abnormal in amblyopic monkeys, and that this neuronal abnormality may be related to their poor performance in contour integration tasks.

Title: Loss of binocular disparity selectivity following monocular deprivation in mouse V1

Authors: *J. PATTADKAL, B. SCHOLL, N. PRIEBE;
Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Experience dependent plasticity during the critical period of development shapes anatomical and functional elements of cortical circuits. In primary visual cortex (V1) of mice, neurons in binocular zone shift preference toward the ipsilateral eye if the contralateral eye is occluded during the critical period. This shift equalizes the relative contribution of input from each eye. Here we tested how this increased ocular input affects binocular disparity selectivity of V1 neurons, a response property arising from the integration of ocular inputs. Using two-photon calcium imaging we measured ocular dominance (OD) and disparity selectivity of neurons in the binocular zone of mice after occluding one eye during the critical period. Surprisingly, a

decrease in disparity sensitivity accompanied increased binocularity in deprived animals. The median ODI changed from -0.36 to -0.03 in monocularly deprived animals while the DSI was 0.2 in normal (n = 878 cells) and 0.14 in monocularly deprived animals (n = 752 cells). Decreased disparity tuning was most pronounced in moderately binocular neurons. The decline in disparity could reflect the formation of disparity selectivity during the critical period or a disruption of disparity selectivity by deprivation. To distinguish between these possibilities, we measured disparity selectivity at the onset of the critical period and found similar ranges of disparity selectivity as in adult animals (median DSI = 0.21, median ODI = -0.38, n = 916 cells). Therefore the decline in disparity selectivity by monocular deprivation reflects a disruption of selectivity by deprivation and not an interruption in the emergence of disparity signals. Our results indicate that changes in ocular dominance by monocular deprivation are not solely due to changes in the synaptic weights of existing connections, but also the emergence of novel synaptic connections, which could not be guided by disparity signals during monocular deprivation. Therapies to improve binocular function often include the occlusion of one eye, which increases the degree to which cortical neurons are sensitive to the open eye, but may also disrupt binocular integration in visual cortex.

Title: Dynamic representation of saccades in mouse frontal cortex

Authors: *R. KIMURA[1], H. OSAKI, M[1], T. K. SATO, M[2], T. R. SATO, M[1,3];
[1]Werner Reichardt Ctr. for Integrative Neurosci., Tuebingen Univ., Tübingen, Germany; [2]UCL Inst. of Ophthalmology, London, United Kingdom; [3]JST, PRESTO, Tuebingen, Germany

Abstract: Saccades brings the eyes toward an object of interests. These voluntary eye movements are essential in information processing, and observed in various species including mice. While the circuit-level questions in mice have been addressed effectively, the cortical circuits underlying saccades has remained unapproachable, due to the lack of behavioral paradigm for mouse saccades. Here using a newly developed behavioral paradigm in mouse saccades, we show the dynamic nature of the mouse cortical circuits that controls the two eyes with narrow overlap of the visual field. The movements of the two eyes were coupled during the

voluntary saccades, and these binocularly coupled saccades were controlled by a small region of the medial prefrontal cortex (mPFCeye). Microstimulation of mPFCeye induced binocularly coupled contraversive saccades. Optogenetic inhibition of mPFCeye suppressed contraversive but not ipsiversive saccades. *In vivo* two-photon calcium imaging revealed greater activity of neurons in this region during contraversive saccades. However, the neural circuitry responsible for the contraversive saccades is not hard-wired but more adaptable. mPFCeye acquired the capacity to control ipsiversive saccades within days of contralateral mPFCeye optogenetic inhibition. Therefore, saccades are dynamically regulated by cortical circuits, allowing mice to adjust their visuo-motor behavior in ever-changing environment through binocularly coupled eye movements.

Title: Decomposing saccade-related potentials using ICA

Authors: ***M. MIYAKOSHI**[1], O. BALKAN[1], C. LEE[1], F. MEDEIROS[2], S. MAKEIG[1]; [1]Swartz Ctr. For Computat. Neuroscience, INC, UCSD, La Jolla, CA; [2]Dept. of Ophthalmology, Univ. of California San Diego, La Jolla, CA

Abstract: We developed a novel active visual search task in which participants saccade freely across an evolving display of Gabor patches. Here we report event-related potentials (ERPs) time-locked to saccade events identified using independent component analysis (ICA). Participants were 20 healthy young adults (10 female, mean 20.9 yrs, SD 3.0, range 18-26). Five Gabor patches were always present on a gray background. A sequence of 1200 patches were pseudo-randomly selected from four patch sizes and five orientations (SOA 2 sec, duration 5 sec). The task was to detect infrequent (15%) instances in which the size and orientation of the newest patch matched those of another patch that was still visible, prompting a button press. Eye-tracking data were obtained from the left eye while 205-channel, 512-Hz scalp EEG data were recorded. Around 350/4000 independent components of EEG were grouped into 19 clusters with the criterion of anatomical locations of ICs. The results confirmed that the total of 80 ICs included in the four occipito-patietal clusters account 96.2 % of variance in the lambda response, a classical occipital ERP component presumably phase-locked to fixation onset, observed in the

scalp channel measurement. In the figure, black traces represent the envelopes, maximal and minimal channel values, of the lambda response time locked to fixation onset; colored traces represent the envelopes of the mean projections of independent component processes in 4 posterior IC clusters. The results suggest that the lambda response has a distributed network over the occipito-parietal regions, and they are activated in different time courses. We conclude that ICA-based ERP analysis on saccade could shed light on the distributed network across the occipito-parietal lobes.

Title: Saccadic preparation at the presentation of visual stimuli to the leading and unleading eye

Authors: *V. MOISEEVA[1,2], M. SLAVUTSKAYA[1], V. SHULGOVSKIY[1];
[1]Lomonosov Moscow State Univ., Moscow, Russian Federation; [2]Ctr. for Cognition and Decision Making, Higher Sch. of Econ., Moscow, Russian Federation

Abstract: When oculomotor system selects a stimulus as a saccadic target there is a simultaneous inhibition of other possible responses, irrelevant for the current behavior. The cognitive processes of attention and decision-making play an active role in the saccade programming. The aim of our research was to analyse spatial-temporal parameters of saccades and presaccadic ERP-potentials at the simultaneous presentation of the target and distracting stimuli to the leading and unleading eye. 15 healthy right-handed volunteers participated in the study. Target and distracting peripheral visual stimuli were presented monocularly on the monitor in various spatial combinations. Eye movements were recorded using the EOG. The LP of correct saccades increased when the target and distracting stimuli were presented in the different visual hemifields at the distance 15-20 dergees and were minimal when the stimuli were presented at the same hemifield at the distance 5 degrees. At the same time the number of erroneous saccades was the biggest. More often error was a saccade to the distracting stimulus the first and to the target one the next. Such incorrect saccades appeared when LP saccades decreased by 50-60 ms compared to the LP of correct saccades ($p < 0.05$). The complex of the positive and negative potentials was revealed in the saccade latent period. Latency of all components was shorter upon presentation of stimuli to the left, unleading eye, that may indicate the earlier saccade preparation. At the same time LP saccades were longer in this conditions ($p<0.05$). The results show that early potentials N1 and P1 were higer in amplitude and dominated in the controlateral parietal-occipital areas. It can be reflection of visual sensory processing. The amplitude of the later negative potential N2 at the stimulation of the right eye increased in the case when target stimulus was at the same location than at the previous realisation. At the backward averaging of EEG from the saccade beginning premotor potentials have been obtained and analyzed. Potential N-1 immediately preceding the beginning of saccade and associated with activation of neurons in the contralateral oculomotor fields in the parietal cortex (LIP and 7a). This study found the fact of changing the localization of N-1 potential. It had a maximum amplitude and dominated in the frontal eye fields contralateral to the hemifield where the distracting stimulus were located. Such localization of N-1 foci may be associated with an active inhibition of leading oculomotor fields of frontal cortex in case of avoid the saccade initiation to irrelevant stimulus.

Title: Power and frequency of human visually induced gamma-band activity reflects retinal but not perceived stimulus speed

Authors: *B. F. HANDEL[1], P. FRIES[2,3];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci. In Cooperation With Max Planck, Frankfurt, Germany; [2]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany; [3]Radboud Univ., Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Human visually induced gamma-band activity is modulated by cognitive factors like attention and by stimulus factors like e.g. contrast and motion speed. Increasing stimulus speed leads to increasing gamma power and frequency. Interestingly, very similar stimulus motion on the retina can also be generated by movements of the eyes, i.e. smooth pursuit. The self-generated retinal motion is however not perceived as external stimulus motion (except for minute illusory effects). This offers the possibility to investigate whether gamma reflects retinal motion or rather the perceived motion. We recorded MEG from 15 human subjects, while they saw visual grating stimuli that were either static or moved at one of two speeds, and while they held their eyes still or moved them at one of two speeds. This allowed us to disentangle whether gamma depended on retinal speed or on perceived speed. We find that gamma power and gamma frequency over visual cortex are positively correlated with retinal speed, irrespective of whether retinal movement was due to stimulus movements or eye movements. Gamma power and frequency were not correlated to perceived speed, when changes in perceived speed did not entail changes in retinal speed, i.e. when the eyes moved with the stimulus, thereby holding the stimulus stable on the retina, but giving the perception of a moving stimulus. We also investigated alpha power and found a different pattern. Alpha power was negatively correlated with pursuit speed, irrespective of whether changes in pursuit speed led to changes in retinal speed or perceived speed. With the current paradigm, it was not possible to exclude that this effect is related to increased attentional demands introduced by pursuing a moving target compared to fixation. Alpha power was not correlated with changes in retinal or perceived speed, if they were not accompanied by changes in pursuit speed. Our results suggest that the dominant alpha and gamma MEG sources are differentially related to retinal and eye speed. This is relevant for the concept of predictive coding, which suggests that top-down predictions are subtracted from sensory evidence and only the resulting prediction error is sent in the bottom-up direction. In our experiment, gamma depended on retinal speed in a similar way, when retinal speed changed due to external factors, or due to internal and thus predictable factors. This

suggests that in this case, gamma reflects the sensory evidence rather than the prediction error. Visually induced gamma in human MEG recordings is likely dominated by primary visual cortex. Further analyses at the source level will determine whether alpha and gamma show differential patterns across cortex.

Title: A coarse-to-fine neural dynamics resulting from eye movements

Authors: *A. CASILE[1], M. RUCCI[2];
[1]Dept. of Neurobio., Inst. Italiano di Tecnologia and Harvard Medica, Boston, MA; [2]Dept. of Psychological and Brain Sci. and Grad. Program in Neurosci., Boston Univ., Boston, MA

Abstract: Multiple studies support the notion that the human visual system follows a coarse-to-fine dynamics, in which the gist of the scene is examined before fine details. The mechanisms responsible for this dynamics remain unclear. On the basis of neurophysiological recordings in cats and monkeys, it has been hypothesized, that neurons in the early visual system undergo similar dynamic changes in their response sensitivity, progressively shifting their receptive field tuning to higher spatial frequencies during the course of a fixation. However, the processes mediating such a fast reshaping of the neurons' receptive fields have never been identified. Here, we provide a novel account that suggests that coarse-to-fine processing of visual input might be a consequence of oculo-motor behavior. Under natural viewing conditions, humans continually alternate large saccades with periods of small fixational movements. These movements yield sequential temporal transients in the visual signals impinging on the retina, which appear compatible with a coarse-to-fine dynamics. To examine the potential contributions of eye

movements, we examined the time-course of neural activity during natural post-saccadic fixation in standard models of retinal ganglion cells. These models enable analytical expressions of the temporal evolution of the neuronal frequency sensitivity. Our theoretical analysis shows that immediately following a saccade, cell responses are dominated by the low spatial frequency components of the visual input. However, shortly after fixation onset, sensitivity starts to gradually shift toward higher spatial frequencies, so that, approximately 150ms after fixation onset, neurons no longer respond to low spatial frequencies. By means of computer simulations, we show that this dynamics of neural activity can be easily mistaken for a change in the cell receptive field during the course of fixation, even though the simulated cell filter does not change. The apparent changes in receptive fields peak frequency and size in our simulations were very similar to those reported in neurophysiological experiments but were caused by the dynamic reorganization of power across spatial frequencies operated by the natural alternation between saccades and fixational eye movements. Our results carry important implications for the encoding of visual information. They suggest a scheme of neural encoding in which eye movement transients play a critical role and visual information is timed to fixation onset. In this scheme, a coarse-to-fine processing of the visual input is not an intrinsic processing strategy of the visual system but a consequence of oculo-motor behavior.

Title: Head centered encoding in monkey area V1 as the basis of a veridical percept of upright despite false torsion of the eyes due to Listing´s law

Authors: ***M. F. KHAZALI**[1], F. BUNJES[2], P. W. DICKE[2], P. THIER[2];
[1]Hertie Inst. For Clin. Brain Res., Tübingen, Germany; [2]Hertie Inst. for Clin. Brain Res., Tübingen, Germany

Abstract: Goal-directed saccades and the fixations that follow are governed by Listing´s law that restricts all rotations necessary to move the eyes from any starting position to new positions to a plane that is specific to that starting position. According to Listing´s law the eyes rotate about the line of sight, a “false” torsion that grows with eccentricity when the eye is at an oblique (or “tertiary”) position. Although false torsion causes considerable image tilt (e.g. 9° for an

oblique eccentricity of 30°/30°), we do not perceive a tilted image. As first shown by Hermann von Helmholtz in his "Handbuch der Physiologischen Optik" (1867) this reinterpretation of the tilted image tilt as being upright requires the consideration of non-visual information on the eye movement. Although known to be necessary for more than 140 years, it has remained completely unclear how the integration of nonvisual information ensuring the maintenance of a veridical percept of upright is implemented in our visual system. We hypothesized that the perceptual compensation of false torsion is an achievement of primary visual cortex (V1) as we had previously shown that a significant subset of neurons in primary visual V1 encodes space relative to the head rather than the eye if body tilt causes ocular counterroll (Daddaoua et al. Nat. Com. 2014). To test this hypothesis we carefully characterized the receptive fields (RFs) of V1 cells of rhesus monkeys during fixation at 3 different gaze positions: straight ahead, 20°/20° upper right and -20°/20° upper left with the visual display always oriented tangentially to the line of sight. Eye position was documented by a combination of 2D-search coil recordings and an analysis of eye rotation about the a-p eye axis using high resolution video images. The latter demonstrated that the difference in false torsion between the two opposite oblique position amounted to around 9° as predicted by Listing´s law. Our preliminary analysis of the receptive fields of 52 neurons mostly recorded from supragranular layers shows that indeed many of them encode spatial positions in a head centered frame of reference, i.e. they shift their position on the retina taking information on the amount of false torsion into account.

Title: Contributions of response magnitude and variability to the presaccadic enhancement of visual representations

Authors: M. SHAMS-AHMAR[1,2], H. KARIMI[1,2], M. PARSA[4], R. EBRAHIMPOUR[1,3], *B. NOUDOOST[4];
[1]Sch. of Cognitive Sci. (SCS), Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]Dept. of Electrical Engin., [3]Dept. of Computer Engin., Shahid Rajaee Teacher Training Univ., Tehran, Iran, Islamic Republic of; [4]Cell Biol. and Neurosci., Montana State Univ., Bozeman, MT

Abstract: Modulation of the presaccadic activity of extrastriate neurons has been suggested to underlie the representational enhancement of saccadic targets. In order to understand how changes in firing rate, correlated activity (noise correlation) and response variability (Fano factor) of extrastriate neurons contribute to presaccadic representational enhancement, we used 16 channel linear array electrodes to simultaneously record the activity of multiple neurons in the middle temporal (MT) cortex of macaque monkey. Two monkeys were trained to maintain fixation while a target stimulus was presented for 1s within the neurons' receptive field (RF). At the end of the trial, animals moved their eyes either toward or away from the stimulus, as instructed by a visual cue. Similar to previous studies of presaccadic responses in V4, we found an increase in firing rate and a reduction in Fano factor in the responses of MT neurons prior to saccades toward a target within their RF. Moreover, we found that the correlation in trial-to-trial variability between pairs of MT neurons drops prior to a saccade into their RF. The increased magnitude and reduced variability of presaccadic responses resulted in an enhanced representation of visual targets, as quantified by the performance of a support vector machine classifier designed to discriminate the orientation of the RF stimulus based on neuronal responses. In order to understand the relative contributions of response magnitude and variability to this representational enhancement, we developed an artificial spike generator to control for the effects of rate as well as correlated and independent variability (noise correlation and Fano factor, respectively). Our results indicate that changes in the response magnitude play a prominent role in driving the presaccadic enhancement of visual representations. These findings contrast with previous reports that changes in correlated variability, rather than firing rate, are the primary drivers of representational enhancement during covert attention, potentially indicating different mechanisms of representational enhancement during covert and overt attentional deployment.

Title: Visual and presaccadic activity in Area 8A of the dorsolateral prefrontal cortex in macaque monkeys

Authors: *K. BULLOCK[1,2], F. PIEPER[3], A. SACHS[4], J. C. MARTINEZ-TRUJILLO[5]; [1]Western Univ., London, ON, Canada; [2]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [3]Univ. Med. Ctr. Hamburg-Eppendorf (UKE), Inst. for Neuro- & Pathophysiology, Hamburg, Germany; [4]Dept. of Surgery, The Ottowa Hosp. Res. Institute, Univ. of Ottowa, Ottowa, ON, Canada; [5]Dept. of Physiol. & Pharmacol., Robarts Res. Institute, Western Univ., London, ON, Canada

Abstract: The prefrontal cortex, particularly the dorsolateral area 8A, is thought to play a role in transforming visual signals into goal-directed behavior. Neurons within this area exhibit visual and saccade-related responses during oculomotor tasks. Several trends in spatial encoding are observed in visual and oculomotor-related areas, including the frontal eye fields, the primary visual area, and the superior colliculus. For example, the receptive fields and movement-related fields in these areas are retinotopically organized, exhibit a gaussian shape, and scale with eccentricity. It is unclear whether receptive fields and movement-related fields in area 8A share these characteristics. Here we recoded the responses of 166 neurons in area 8A of two male Macaca fascicularis monkeys while the animals made visually-guided saccades to a peripheral sine-wave grating stimulus positioned at one of 40 possible locations (8 angles arranged along 5 eccentricities). To characterize the receptive fields and movement-related fields, we fit a bivariate gaussian model to the average firing rate at each location during stimulus presentation (early and late visual epoch) and prior to saccade onset (presaccadic epoch). 40 percent of neurons showed visual and presaccadic responses. Of the spatially-selective neurons, 93 neurons had contralateral-preferring and 25 had ipsilateral-preferring visual receptive fields. We determined that the endpoints of saccades were less accurate at greater target eccentricities ($p<0.05$,ANOVA). Furthermore, we observed that the angular width of visual and movement-related fields scaled positively with increasing eccentricity ($p<0.05$,ANOVA). Finally, we found that most neurons preserve the same directional preference across eccentricity.

Title: Saccadic corollary discharge underlies stable visual perception

Authors: W. M. JOINER[1], *J. CAVANAUGH[2], R. A. BERMAN[3], R. H. WURTZ[2];
[1]George Mason Univ., Fairfax, VA; [2]Lab. of Sensorimotor Res., NEI, NIH, Bethesda, MD;
[3]NIH, NIMH, MD

Abstract: Each saccadic eye movement directs the high-resolution foveae of our retinas towards objects of interest. The retinal input therefore changes substantially with each saccade. Our visual perception, however, remains stable despite the massive disruptions in visual input occurring several times per second. Philosophers and scientists over centuries have proposed that our perceived stability of the visual scene depends upon registering out retinal input to an internal signal representing each eye movement. This signal, referred to as corollary discharge (CD), has recently been identified in the monkey brain, but its contribution to visual perception is still a matter of dispute. We now show that disrupting the CD signal in the medial dorsal thalamus by muscimol inactivation alters visual perception. After saccades, we were able to change the monkey's perception of where its gaze was directed. We conclude that the CD is the most critical component for stable visual perception, rather than proprioception or visual cues. Our results show that the same brain area that generates saccades, which cause displacement of the retinal image, also generates the CD signal that allows us to organize jumbled retinal inputs into a stable visual scene.

Abstract: Despite the nearly constant motion of information on our retina due to eye movements, we perceive the world around us as stable. Many have investigated how the brain accomplishes this spatial reconstruction during horizontal and vertical retinal displacements, but, surprisingly, little focus has been placed on the effects of torsional rotations. Due to the spherical shape of the eyes, retinal input is rotated during oblique eye orientations. Importantly, Listing's law provides that there is no actual torsion of the eyeballs at these orientations, so, to reconstruct a stable perception of space during eye movements, the brain must utilize an eye orientation-based internal model of this oblique gaze-induced effect. To investigate if this is the case, we induced rotations of retinal input using oblique eye orientations, and presented oriented bar stimuli for one frame (8 ms) pre-, peri- and post-saccadically during horizontal saccades (presentation window from 400 ms before saccade onset to 400 ms after saccade offset). Participants performed 40 deg saccades either along the screen's horizontal meridian (control condition) or along the same line from a vertically eccentric orientation (+20 deg; test condition), producing approximately 2 deg of retinal rotation at maximum eccentricity. Participants were then asked to judge the direction of stimulus rotation relative to vertical in a two-alternative, forced choice task. On average, psychometric PSEs revealed that participants systematically perceived vertically eccentric stimuli on the left third of the screen as rotated by -1.7 deg (average predicted retinal rotation of -2.3 deg), in the middle of the screen as rotated by +0.5 deg (average predicted retinal rotation +0.8 deg), and on the right side of the screen as rotated by +1.6 deg (average predicted retinal rotation +2.0 deg). In comparison, control trials along the horizontal meridian yielded much smaller shifts in PSEs (left: +0.7 deg, middle: +1.1 deg, right: +1.2 deg), suggesting an eye-centered coding of orientation during saccades. Furthermore, for both control and test conditions a shift in the psychometric function began approximately 100 ms prior to saccade onset until about 100 ms after saccade onset, possibly indicating a pre-saccadic remapping effect consistent with previous work on spatial localization. Together, these findings suggest that during saccades in the absence of surrounding visual cues, perceptual processes rely

more heavily on retinal inputs than on extraretinal inputs that are ultimately required for a stable perception of the world.

Title: High-gain visual feedback impairs response time in older adults

Authors: ***M. KWON**, Y.-T. CHEN, E. A. CHRISTOU;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Older adults exhibit slower response time due to longer premotor time. Premotor time has been associated with visual information processing. It remains unknown whether and how a task with greater visual information processing requirements will influence response time in older adults. The purpose of this study, therefore, was to determine the effect of visual information processing on response time in older adults and the underlying activation of the motor neuron pool. Participants conducted a submaximal constant force task (15 % of maximum) with ankle dorsiflexion for 20 s and dorsiflexed their ankle as fast as possible in response to a visual stimulus. The visual information processing was manipulated by changing the amount of force visual feedback into a high-gain (1.2°) or low-gain (0.5°) condition. There are three novel findings from this study. 1) High-gain visual feedback slows the response time in older adults because it lengthens pre-motor time. 2) High-gain visual feedback further slows response time in older adults because it increases force variability. 3) The slower response in older adults with high-gain visual feedback is related to altered modulation of the motor neuron pool. Specifically, older adults exhibited less oscillations within 4-10 Hz and greater oscillations from 10-35 Hz with high-gain visual feedback. This findings provide novel evidence that high-gain visual feedback contributes to slower response times in older adults. The slower response time is likely mediated by impaired visual information processing and altered modulation of the motor neuron pool.

Title: Magnifying the scale of visual biofeedback improves posture

Authors: *D. A. JEHU[1], J. THIBAULT[2], Y. LAJOIE[2];
[2]Human Kinetics, [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Biofeedback (BF) has been evidenced to minimize body sway during quiet standing situations as well as cognitively demanding situations. However, limited research has reported the optimal sensitivity parameters of visual BF related to the center of pressure (COP) sway. Therefore, the main purpose of this study was to further investigate the scale of sensitivity required for optimal visual BF. Accordingly, 19 young adults (6 males; 13 females; aged 21.3 ± 2.5) stood with feet together on a force platform for 60 seconds and performed three visual BF intensities (BF magnified by 1 (BF1), BF magnified by 5 (BF5), BF magnified by 10 (BF10)), along with control trials with no BF (NBF). For example, the gain was set such that 1 cm of COP movement corresponded to 1 cm of movement on the visual BF display for the BF1 condition. The visual BF was displayed on a computer monitor placed 1 meter in front of the participant. During the BF conditions, participants were asked to keep a dynamic rectangle with an area of 2 mm by 2 mm within the limits of a static, 2 mm by 3 mm square which remained in the middle of the screen; the dynamic visual display represented their current COP position. Participants were instructed to stand as still as possible while minimizing the movements of the visual target. The findings revealed that the BF1 scale produced significantly greater COP displacement in both the anterior-posterior (AP) (BF5: $p=0.014$; BF10: $p=0.007$) and medial-lateral (ML) (BF5: $p=0.014$; BF10: $p=0.007$) directions, as well as greater standard deviation (SD) of the COP in the AP direction (BF5: $p =0.012$; BF10 $p=0.013$). Additionally, NBF showed significantly greater 95% Area Ellipse than BF1 ($p <0.001$), BF5 ($p <0.001$), and BF10 ($p <0.001$) intensity. Therefore, the most sensitive COP scales generated the least amount of postural sway. However, there were no significant differences on any of the COP measures between BF5 and BF10. This suggests that the BF5 intensity is sufficient to improve body sway. This research may provide insight with respect to the proper scale on which biofeedback should be given in order to improve postural control. Thus, this study may have implications in both research and rehabilitation settings.

Title: Enhancement of eye movements in Parkinson's disease as a result of CN-NINM intervention

Authors: *Y. I. VERBNY, G. VISHWANATHAN, K. SKINNER, M. TYLER, K. KACZMAREK, Y. DANILOV;
Dept. Biomed. Engineering, Univ.Wisconsin-Madison, Madison, WI

Abstract: Objective: The neurorehabilitation of sensory and motor functions in Parkinson's disease (PD) patients is undeveloped and unexplored. There are very few methods that show the possibility of recovery of eye movements affected by PD. The goal of this research was to investigate how well Cranial-Nerve Non-Invasive Neuromodulation (CN-NINM) can reduce the effects of PD-induced impairments of oculomotor function and help to recover eye movement control. Methods: We completed a 4-month intervention with a 66-year-old male 6 years after he was diagnosed with PD-symptoms. The CN-NINM intervention used a combination of both physical and cognitive exercises with electrotactile stimulation to the tongue using a Portable Neuromodulation Stimulator (PoNS). Assessment of oculomotor function was performed before and after the CN-NINM intervention using special 4-channel binocular eye tracking goggles (VisualEyes, Micromedical Inc.). To evaluate the state of subject’s eye movements we used three static nystagmus tests (vertical and horizontal gaze, and spontaneous nystagmus) and three dynamic tests (random saccade, smooth pursuit and optokinetic). All of the tests were performed without tongue stimulation. Results: The CN-NINM intervention resulted in the gradual enhancement of patient eye movement control in all 6 tests. We observed improvement of eye fixation, accuracy and stability in nystagmus and gaze tests, increased eye movement accuracy and precision, improved gain and velocity of target tracking, and changes in both smoothness and synchronization of binocular movement control in oculomotor tests. The most significant improvements in eye movement control were found during performance of smooth pursuit and random saccade testing. Conclusions: Our study establishes a proof of concept and effectiveness of a new non-invasive neuromodulation therapy for rehabilitation of eye movement control. A

combination of exercise and tongue-based neurostimulation may benefit people affected by PD and would offer a novel treatment option for this disease. (No Image Selected) Layman Abstract (optional): Provide a 50-200 word description of your work that non-scientists can understand. Describe the big picture and the implications of your findings, not the study itself and the associated details.: Our study establishes a proof of concept and effectiveness of a new non-invasive neuromodulation therapy. The improvements of eye movement control demonstrated by this individual suggest that rehabilitation using a combination of exercises and tongue-based neurostimulation may benefit people affected by PD and would offer a novel treatment option for this disease.

Title: Temporal coupling of action and perception in Parkinson's disease

Authors: E. PRETEGIANI[1], N. VANEGAS-ARROYAVE[2], E. J. FITZGIBBON[1], M. HALLETT[2], *L. M. OPTICAN[1];
[1]Natl. Eye Inst., Bethesda, MD; [2]Human Motor Control Section, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Previously, we showed that action and perception are temporally coupled in healthy subjects. Saccadic and perceptual report reaction times (SRT and PRT) share the same time-change dependence upon the temporal asynchrony (TA) between target onset and fixation point offset. We also showed a novel illusion, the misperception of small overlaps as gaps. We hypothesized that the temporal coupling might depend on a prominence map located in the intermediate layer of the superior colliculus (SC). The same mechanism might delay the perception of a target in the presence of competitive stimuli, causing the misperception of briefly overlapping stimuli as separated in time. In Parkinson's disease (PD), increased activity of the substantia nigra pars reticulata induces an excessive inhibition of the SC, which is considered to be responsible for typical eye movement abnormalities. We predicted that increased inhibition of the SC in PD should affect the mechanism that couples action and perception. Six PD patients performed a gap/overlap paradigm. Subjects made saccades to targets with different TA and reported whether they perceived the stimuli as separated by a gap or overlapped in time. SRT, PRT and perceptual transition thresholds were analyzed as functions of TA. SRT and PRT in PD did not show the same time-change dependence upon TA as controls. Although SRT in PD was dependent upon TA, the effect of the SRT dependence (longest minus shortest reaction time) was smaller than in normal subjects. In contrast, PRTs were much longer than normal, with a bigger time-change dependence upon TA. Moreover, PD subjects misperceived small overlaps as gaps for much longer overlapping TAs (< 300 ms) than did controls (< 100ms). Increased basal ganglia inhibition in PD may be responsible for decoupling action and perception and causing a misperception of longer overlaps as gaps than in normal subjects. This action/perception decoupling and the misperception in PD could affect complex functions such as visual search, attentional performances and other tasks that require fine action-perception coordination such as locomotion. A model that explains our results needs greater caudal than rostral inhibition of the SC in PD. This would also explain some typical abnormalities of PD, such as the facilitation of small saccades, staircase saccades, and large square wave jerks. The rostral/caudal activity ratio might be a marker of inhibitory BG output and, therefore, of disease progression.

Title: Age-dependent alterations in the excitability of small-diameter IB4-negative mouse dorsal root ganglia neurons

Authors: M. A. MIś[1], E. B. STEVENS[2], *A. D. RANDALL[3,1];
[1]Sch. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom; [2]Pfizer Neurosci. and Pain Res. Unit, Cambridge, United Kingdom; [3]Inst. of Biomed. and Clin. Sci., Univ. of Exeter, Exeter, United Kingdom

Abstract: Dorsal root ganglia (DRGs) house the cells bodies of nociceptive afferent neurons, which react to potentially harmful stimuli. Age dependence of nociceptor excitability is an understudied area of pain research and has become particularly relevant with the ageing demographic. The objective of this study was to determine any neurophysiological differences in small-diameter IB4-negative DRG neurons from adolescent, middle-aged and aged male mice. Methods: Dorsal root ganglia cells from 1 month, 8 months and 18 months old male C57/BL6 mice (Charles Rivers, UK) were enzymatically dissociated and cultured for up to 48 hours. Whole-cell voltage- and current-clamp recordings were performed at 35°C. Results: Age-dependent changes in biophysical properties of the small-diameter unlabelled DRG neurons were far less pronounced than the previously reported alterations in the IB4-positive neurons (Miś et al, 2013). There were no significant shifts in the activation or inactivation curves or in the ratio of the tetrodotoxin-sensitive to tetrodotoxin-resistant sodium current. In the current-clamp data, the cells from all three ages were found to have a resting membrane potential of around -55mV. However, input resistance, membrane time constant, sag and firing frequency were all subject to age-dependent changes, with the cells from the middle-aged animals exhibiting the highest levels of excitability. Conclusion: Both passive and spiking properties of mouse small-diameter IB4-negative sensory afferent neurons are age dependent. These results, combined with the previously reported results on IB4-positive neurons, make it feasible to assume that different groups of nociceptors age in disparate ways. References: Miś et al. (2013) Temperature-dependence of tetrodotoxin-sensitive and -resistant Na+ current in IB4+ve neurones from adolescent and adult mouse dorsal root ganglia. 8th Congress of the European Federation of IASP Chapters - PAIN IN EUROPE VIII Florence, Italy, October 9 - 12, 2013.

Title: PSD-95-immunoreactivity in epithelial cells and nerve fibers of the rat cornea

Authors: *B. K. CARR[1], S. A. GEURKINK[2], K. E. MILLER[2];
[1]Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK; [2]Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Background: Upon high threshold stimulation, nociceptive sensory afferents release glutamate from peripheral nerve terminals. Glutamate causes auto- or paracrine activation and sensitization of sensory nerve terminals via excitatory amino acid receptors (EAARs; Miller et al, 2011). Furthermore, glutamate interacts with EAAR's expressed by cells in peripheral tissues, e.g., epithelial cells. In the cornea, immunohistochemical studies have determined that EAAR subunits for NMDA, AMPA, and Kainate (KA) are present on nerve terminals and corneal epithelial cells. Efficient neurotransmitter signaling often relies on scaffold proteins, such as postsynaptic density protein 95 (PSD-95), to anchor postsynaptic receptors and associated proteins. In the current study, we used immunohistochemistry in rat cornea to detect PSD-95 as an initial step in dissecting protein scaffolds used by peripheral nerve fibers and corneal epithelial cells. **Aim:** To determine the distribution of PSD-95 in the rat cornea. **Method:** Sprague Dawley rats were anesthetized and perfused transcardially using fixative. Corneas were collected and corneal cross sections were processed for immunohistochemistry with rabbit antisera for PSD95. Double immunohistochemistry also was performed with anti-PSD and several nerve fiber markers, e.g., PGP 9.5, TRPA1. A Leica confocal microscope was used to evaluate immunolabeling. **Results**: Strong PSD-95 immunoreactivity was observed in the epithelial cell membrane, whereas moderate PSD-95 immunoreactivity occurred in the nerve fibers of the cornea. **Conclusion**: The localization of PSD-95 in the cell membrane of corneal epithelial cells indicates that these cells have a highly organized, intracellular protein scaffold for distribution and localization of extracellular receptors. Exploration of the co-localization of EAAR subunits with PSD-95 and other scaffolding proteins may help to understand the interaction between peripheral afferents and corneal epithelial cells.

Title: Investigating the trafficking mechanisms of TRESK, a two-pore domain potassium channel implicated in pain

Authors: *J. P. GIBLIN, D. SUDRIA, A. CASTELLANOS, A. ANDRES, G. CALLEJO, X. GASULL;
Fac. of Medicine, Dept. Ciencies Fisiologiques I, Univ. of Barcelona, Barcelona, Spain

Abstract: The two-pore domain potassium channel TRESK (K2P18.1) has been implicated in pain perception pathways and changes in channel expression and function alter sensory neuron excitability. TRESK has emerged as a therapeutic target with potential use in treatment of pain-related disorders. Despite the importance for overall current density, the mechanisms determining TRESK channel number at the cell surface are not well understood. To investigate factors affecting TRESK trafficking to and from the cell surface we developed a surface biotinylation assay for use in conjunction with electrophysiological analysis. The study described has two objectives (i) to determine the role of the TRESK C-terminus in channel trafficking and (ii) to determine whether TRESK trafficking could be altered by treatment with the Protein Kinase C (PKC) activator Phorbol 12-myristate 13-acetate (PMA). The C-terminus of TRESK contains a conserved tyrosine-based endocytic motif. We hypothesised that this motif is an important determinant of channel endocytosis and that mutation of this motif would increase channel surface expression due to impairment of endocytic internalisation. When surface expression of rat TRESK (rTRESK) and rTRESK with a mutated endocytic motif (rTRESKY389A_V392A) were compared in transfected HEK293 cells by surface biotinylation and patch clamp electrophysiology, significant changes in surface expression and whole-cell currents were not observed. These results suggest that the conserved endocytic motif in the C-terminus of TRESK is not an important determinant of channel expression at the cell surface. Several mediators of inflammation activate Protein kinase C (PKC) dependent signalling pathways. We hypothesised that, as reported for other ion channels expressed in sensory neurons, PKC activation could affect TRESK trafficking. In the study we treated HEK293 cells

transfected with rTRESK with PMA and analysed the effect on the surface expression of TRESK. Treatment with 100nM PMA increased rTRESK surface expression and whole-cell currents. These results raise the possibility that inflammatory mediators may modulate TRESK trafficking, providing a potential mechanism by which sensory neurons can limit hyperexcitability in response to tissue damage.

Title: Osmolarity changes contribute to nociceptive sensitization induced by activation of Protease-Activated Receptor 2 (PAR-2) in the rat

Authors: ***K. KIDO**, E. MASAKI;
Tohoku Univ. Hospital, Dept. of Dent. Anesthesia, Sendai, Miyagi, Japan

Abstract: Background- We previously demonstrated that the activation of proteinase-activated receptor 2 (PAR-2) on afferent nerves caused stronger guarding pain, mechanical and heat hyperalgesia in rat, although the mechanism was unknown. Recently, it has been reported that the activation of PAR-2 causes sensitization of the ion channel transient receptor potential vanilloid 4 (TRPV4) and induces guarding pain and mechanical hyperalgesia. This channel has functions as a transducer of hyper/hypotonic stimuli in primary afferent nociceptive neurons and contributes to inflammatory and neuropathic pain. Therefore, we hypothesized that: (1) incision induces the release of tryptase from mast cell which activates PAR-2; (2) the activation of PAR-2 sensitizes TRPV4; (3) the change of osmolarity in wounds stimulates TRPV4 and increases postoperative pain. In this study, we examined whether the combination of PAR-2 agonist and hyper/hypotonic stimuli increases guarding pain, mechanical and heat hyperalgesia *in vivo* and vitro. Method- The PAR-2-activating peptide, SLIGRL-NH2 was administered by the intraplantar route in the rat with/without hyper/hypotonic solution. Guarding behavior (biting and licking) was observed after administration of SLIGRL-NH2 for 30 minutes. Mechanical thresholds were assessed using von Frey filaments. Withdrawal latencies to heat were assessed

applying a focused radiant heat on the injected area of plantar skin. Using the rat glabrous *in vitro* skin-tibial nerve preparation, afferent activities from single mechanosensitive nociceptors were recorded. Ongoing activities and responses to mechanical stimuli were recorded before and after SLIGRL-NH2 with /without hyper/hypotonic solution application or vehicle. Responses to heat and cold stimuli were recorded once after exposure to either with SLIGRL-NH2 application or control. Results- Hypertonicity and Hypotonicity caused a four-fold increaase in nociceptive behavior by PAR-2 agonist. Also changes of osmolarity increased mechanical and thermal hyperalgesia. *In vitro* skin-nerve preparation, SLIGRL-NH2 with hyper and hypotonic solution increased ongoing activities in 55-60 % C-fibers within 5 minutes. SLIGRL-NH2 application also enhanced the responses to mechanical and heat stimuli in C- fibers. Conclusion- PAR-2-mediated excitation and sensitization of peripheral primary nociceptors was enhanced by hyper and hypotonic stimuli via TRPV4.

Title: *In vivo* inflammation causes increased current amplitude in myelinated sensory neurons through mechanosensitive proteins

Authors: *A. M. REYNOLDS, A. D. WEYER, C. L. O'HARA, C. L. STUCKY;
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Traditionally, unmyelinated C-fibers and thinly myelinated Aδ fibers are thought to be responsible for achy, dull pain and sharp pain, respectively. However, evidence suggests some heavily myelinated Aβ fibers may encode painful stimuli. Myelinated neuron subtypes have diverse responses to mechanical stimuli, yet the mechanisms underlying the heterogeneity in the responses in the populations are unknown. Furthermore, there is a lack of data on mechanotransduction sensitization after *in vivo* inflammation. To address these questions, we identified subtypes of A fiber-types that possess distinct electrical and chemical properties;

Calcitonin Gene-Related Peptide, CGRP-positive and CGRP-negative large diameter neurons. To distinguish between cutaneous and muscle afferents, a retrograde tracer was used; wheat germ agglutinin conjugated to an Alexa Fluor dye. The retrograde tracer was injected into either the saphenous nerve for cutaneous afferents, or into the gastrocnemius muscle. Cutaneous inflammation was induced with a subcutaneous plantar hindpaw injection of Complete Freud's Adjuvant (CFA), whereas muscle inflammation was produced by either CFA or acid injection into the gastrocnemius muscle. Cutaneous and muscle CGRP-negative and -positive projecting neurons were tested by patch clamping and focal stimulation before and 2 days after inflammation. Before inflammation, both the cutaneous and muscle afferents had similar properties; CGRP-negative neurons had significantly larger rheobases and mechanically-induced currents than CGRP-positive neurons. This differed after inflammation. Cutaneous CGRP-negative neurons showed no mechanical sensitization to inflammation, yet CGRP-positive neurons displayed a 2.5 fold increase in current amplitude. Muscle-projecting large CGRP-negative neurons displayed a 3-fold increase in mechanical current amplitude in response to CFA, whereas CGRP-positive neurons had no sensitization. We used Fluorescence Activated Cell Sorting to differentiate the neurons (CGRP-positive vs CGRP-negative, cutaneous inflamed vs uninflamed, and muscle inflamed vs uninflamed). Transcriptomes were compared between groups using microarrays. None of the upregulated genes were known mechanosensitive proteins, suggesting that there may be unidentified mechanosensitive proteins responsible for the sensitization. Overall we showed for the first time that mechanosensitive proteins can be sensitized after *in vivo* inflammation and that A fiber-type large myelinated neurons can be sensitized.

Title: Gender differences in nerve fiber conduction parameters in human and rodent C-nociceptors

Authors: R. SOLÀ, M. SUMALLA, *J. SERRA;
Neurosci. Technologies, Barcelona, Spain

Abstract: Background: Pain sensitivity is thought to be mediated by a combination of biological, psychological and sociocultural factors. It has consistently been shown that women perceive noxious stimuli as more painful than men. This difference has also been shown in rodents. Although it is known that sex hormones influence pain sensitivity depending on the stage of the menstrual cycle, no electrophysiological study has shown any consistent gender difference in the conduction properties of primary nociceptors. Objective: To test whether peripheral C-nociceptors show any gender difference in their conduction properties, both in humans and in rats. Methods: We measured activity-depending slowing of conduction velocity (ADS) and conduction velocity (CV) in a group of healthy human subjects (n=22, females 12, age 38.9±3.3 years; males 10, age 37.7±3.7 years) and a group of control healthy Sprague-Dawley rats (n=52; females n=25; males n=27) using microneurography from the superficial peroneal nerve or the sciatic nerve, respectively. Results: We recorded a total of 141 C-nociceptors (75 mechano-heat-sensitive [CMH], 66 mechano-insensitive afferents [MIA]) from the humans and 87 C-nociceptors (42 CMH, 45 MIA) from the rats. We detected a striking statistically significant difference in CV of C-nociceptors between males and females in humans (male 0,70 ± 0,18 m/s; female 0,51 ± 0,25 m/s; t-test $P<0.001$) and rats (male 0.81±0.4 m/s; female 0.7±0.02 m/s; $P<0.0046$). Also, dispersion was higher for human females CMH units (SD=0.29) than for males (SD=0.12). Discussion: Our results show a clear gender difference in the conduction velocity of C-nociceptors in human and rat. This difference may be of importance in explaining the higher pain sensitivity of females. The slower CV and greater dispersion of conduction velocities of female C-nociceptors could enhance temporal summation of the peripheral input into the spinal cord. Conclusion: CV of peripheral C-nociceptors is slower in females than in males. This electrophysiological feature could contribute explain differences in pain perception between genders in humans and rodents.

Abstract: Nerve injury frequently leads to hyperalgesia and allodynia, which depend partially on increased sensitivity in primary sensory afferents to thermal and mechanical stumuli. We have previously characterized functional changes in histologically identified cutaneous afferents following nerve cut and regeneration, and investigated potential molecular mechanisms for the development of hypersensitivity using qPCR on whole dorsal root ganglion (DRG) homogenate. This process was fruitful and indicated several significant changes in expression of genes that were necessary components in the development of hypersensitivity. However, examination of expression levels from whole DRGs potentially misses subpopulation-specific changes that are either eliminated by contrary changes in other subpopulations or diluted to insignificance by the many cells in the DRG unaffected by the manipulation. In this study, we use single cell qPCR to survey the expression profiles of over 160 small diameter DRG afferents backlabeled from the saphenous nerve before and after injury, and identify new targets that may be involved in the development of mechanical and thermal hypersensitivity after injury in specific subpopulations. Our interpretation of this data was informed by transcriptional profiles of more than 40 functionally identified cells collected using our *ex vivo* saphenous preparation. The results obtained in these studies demonstrate expression changes following injury and regeneration, which vary starkly between different subpopulations of cutaneous afferents. For example, peptidergic afferents show significant increases in GFRα1, P2X3, ASIC2, and Piezo2, while non-peptidergic afferents express decreased GFRα2 but increased GFRα3, P2Y1, and P2X3. These results also show that several of the changes detected in whole DRG homogenate PCR were specific to subpopulations of afferents, and that single cell PCR has unmasked novel population-specific changes that are strongly correlated with the development of mechanical and thermal hypersensitivity of specific subsets of cutaneous nociceptors following injury.

Title: Heating of deeper skin layers might detect spontaneously active heat-sensitized nociceptors

Authors: M. I. NEMENOV[1], B. NAMER[2], R. SCHMIDT[3], I.-P. KLEGGETVEIT[4], M. BACKONJA[5], E. JORUM[4], *M. SCHMELZ[6];
[1]Anesthesiol., Stanford Univ., Stanford, CA; [2]Physiol., Univ. Erlangen/Nuremberg, Erlangen, Germany; [3]Clin. Neurophysiol., Univ. Uppsala, Uppsala, Sweden; [4]Neurol., Oslo Univ., Oslo, Norway; [5]Neurol., Univ. of Wisconsin-Madison, Madison, WI; [6]Heidelberg Univ., Mannheim, Germany

Abstract: Spontaneous pain is cardinal symptom of painful peripheral neuropathy (PPN). However, in preclincal neuropathic pain models mainly mechanical allodynia is used to differentiate painful from non painful neuropathy, though only fraction of the PPN patients develops mechanical allodynia. This disconnect hinders development of novel analgesics. In contrast, spontaneously active (SA) C nociceptive fibers were found in patients with PPN of different origin as well as in rodent neuropathic pain models, but SA of C fiber is not used widely in translational research. Compared to superficial inflammatory pain where SA C fibers are usually sensitized as tested by contact or radiant heat, contact thermode QST demonstrated increased pain thresholds in PPN indicating sensory thermal deficit. However, diode laser C fiber type selective heat stimulation (C-DLss) reaches deeper skin layers as compared to radiant heat (Moeller-Betram et al., 2003). Using such heat stimuli, we found pain thresholds in patients with diabetic and chemotherapy-induced PPN were not increased compared to healthy control. This result could suggest sensitization of deeper located nociceptors to heat. Indeed, the majority of SA fibers in PPN patients were found among heat sensitive, but mechanically insensitive C-fibers (CMi), that are located subepidermally. In patients with diabetic and chemotherapy induced PPN, sensory fibers “die back”, decreasing fiber density. Thus, higher surface temperatures are required to activate the partly degenerated intraepidermal C polymodal nociceptors, but still they might not activate subepidermal SA CMi fibers. Microneurography data from PPN patients show heat sensitization of spontaneously active CMi fibers. Their activation threshold upon radiant heat was only 40°C (median, n=21, 52% heat positive) as compared to a median of 45°C in non-spontaneously active CMi fibers (n=53, 47% heat positive). However, the surface temperature required to active SA C fibers varies substantially due to different depths of sensory endings, steep temperature gradient of radiant heat stimulation and different degree of sensitization. Thus, DLss activating both, superficial and deep cutaneous nociceptors, should uniquely permit direct activation of subepidermal, spontaneously active CMi fibers in animal models of peripheral neuropathy as well as terminals of these nociceptors in the skin of PPN patients. DLss-based C fiber selective QST and C fiber behavioral tests might therefore provide a more reliable biomarker of painful peripheral neuropathy in the clinics and for preclinical tests assessing efficacy of analgesic compounds.

Title: Stimulated CGRP release from GDNF-responsive procine DRG neurons is higher compared to NGF-responsive ones both in somata and neurites, *in vitro*

Authors: S. SAUER[1], A. KLUSCH[2], C. GORZELLANY[4], R. JONAS[3], *P. W. REEH[5], S. SCHNEIDER[4], M. SCHMELZ[3], M. PETERSEN[3];

Abstract: The neuropeptide CGRP is a marker for heat- and itch-sensing nociceptors. Its release at their peripheral terminals mediates neurogenic inflammation. In rodents, trkA-expressing neurons are mostly CGRP positive, whereas GFRα /cRET expressing neurons are negative or only weakly positive. We investigated CGRP release from outgrown neurites and somata of NGF- and GDNF responsive neurons and growth factor dependent neurite morphology. Dissociated porcine DRG neurons were seeded into the central lumen of a 3-compartment Campenot chamber. Neurites growing into the distal comp. were thus spatially separated from their somata and both could be exposed to different growth factors. Somata and neurites were cultured under three conditions: (I) NGF in central and side comp., (II) NGF in central and GDNF in side comp., and (III) GDNF in the central comp. and no growth factor in the side comp. After 7 d in culture, K+ (60 mM, 5 min) was added either to the central or to the side comp. Thus, in the high K+ containing comp. neuronal structures were stimulated by membrane depolarization whereas in the adjacent comp. presumably via conducted action potentials. CGRP concentration in the supernatant was determined by ELISA. Total length of outgrown neurites was measured from microphotographs. Morphology of neurite endings was visually classified into those with thin tips or pronounced growth cones. CGRP release from neurites in the side comp. could be detected both after central or side comp. K+-stimulation. Likewise, CGRP release from somata could be detected also with both stimulation modes. Under conditions I and

II, CGRP release from the neurites was not significantly different (calc. 1.1 and 0.6 pg/ml/mm neurite length, respectively), but surprisingly, the highest release was found in neurites cultured under condition III (3.2 pg/ml/mm). Neurites from NGF dependent somata developed pronounced growth cones when cultured under GDNF (II) compared to the other conditions. Our results provide evidence that in pig NGF-responsive neurons GDNF availability at the neurite ending regulates neurite morphology, but does not affect CGRP release. Surprisingly, in pig also GDNF-responsive neurons are peptidergic and exhibit even significantly higher CGRP release than in NGF-responsive neurons.

Title: Mechanisms of gpcr-gq-induced action potential discharge in vagal c-fiber terminals

Authors: H. SUN[1], S. MEEKER[2], M. KOLLARIK[1], F. RU[2], *B. J. UNDEM[3];
[1]Med., [2]Johns Hopkins, Baltimore, MD; [3]Dept Med., Johns Hopkins Asthma Ctr., Baltimore, MD

Abstract: Many inflammatory mediators evoke action potential (AP) discharge in visceral and somatosensory nociceptive C-fibers via activation of GPCRs. At the level of the cell body, TRPV1 and TRPA1 have been implicated as principle depolarizing charge carriers for GPCR-Gq activation. We evaluated the mechanisms underlying GPCR activation-induced AP discharge at the terminals in a vagally innervated mouse (C57B6) lung preparation. An RNAseq analysis specifically of nodose vagal C-fiber neurons in the nodose/jugular ganglia of C57B6 mice revealed that ~70% of the phospholipase C transcripts were of the PLCβ3 isotype. Bradykinin (10 μM) stimulated AP discharge in nodose C-fiber terminals with an average frequency of 14 ± 2 Hz Hz (n=14), and TFLLR (30 μM), a selective protease activating receptor 1 (PAR-1) agonist, stimulated AP discharge at 17 ± 2 Hz. Neither agonist activated the nerve terminals in PLCβ3 -/- animals (n=6). The GPCR-induced AP discharge at the terminals was not different between wild type and trpc3/trpc6 double -/- animals (obtained from Dr. L. Birnbaumer,

NIEHS), nor was different (P>0.1, n= 8) between wild type and trpa1/trpv1 double -/- animals (the response to capsaicin and mustard oil was absent in these animals). The nonselective cation channel blocker ruthenium red (RR) (10 μM) also failed to inhibit the AP discharge in response to the GPCR agonists (P>0.1, n=6), but blocked the capsaicin response. The Clca channel blocker niflumic acid (100 μM) did not inhibit the GPCR activation of the terminals (P>0.1, n=6). By contrast, the K+ channel blocker 4-AP (300-1000 μM, n=4) mimicked the AP discharge evoked by the GPCR agonists. At the cell bodies the PAR1 agonist evoked a strong calcium response in 21% of neurons (232 out of 1084 cells) isolated from mouse nodose ganglia. The TRPA1 antagonist HC-030031 reduced the number of cells responsive to TFLLR by ~50% (to 9.95±3.78%, P<0.001). The TRPV1 blocker AMG 9810 alone had no significant effects on the response, but combined use of HC-030031 and AMG 9810 further reduced the number of cells responding to PAP1 agonist compared to HC-030031 alone (to 5.76±2.39%, P<0.01). We conclude that TRPA1and VI contribute to the GPCR-Gq-induced calcium responses at the soma of vagal sensory neurons. However, the generator potential in vagal C-fiber terminals evoked by GPCR-Gq agonists depends entirely on PLCβ3 but not on TRP-V1, A1, C3, C6, other RR sensitive cation channels, or Cl- channels. It remains possible that inhibition of a resting K+ current is the primary driver of the generator potentials. Our results also suggest that GPCR-Gq-induced activation of cell bodies and nerve terminals in vagal C-fibers may be different.

Title: Vascular afferents innervating lumbosacral veins have distinct immunohistochemical phenotypes in DiI-traced DRG neurons

Authors: V. HENAO[1], H. D. NGUYEN[1], V. P. DUGAN[1], B. Y. COOPER[2], *R. D. JOHNSON[3];
[1]Physiological Sci., [2]Oral Surgery, [3]Univ. Florida, Gainesville, FL

Abstract: Input from vascular sensory neurons has been implicated in painful conditions including migraine headache and deep tissue pain. Our previous work on DRG neurons used a combined *in vitro* electrophysiology and immunohistochemical phenotyping approach utilizing target-specific tracing from the periphery (skin, muscle, viscera, mucocutaneous, etc.) in the rat lumbosacral region. We have found distinct target-specific phenotypic patterns, and in the present report, extend this investigation to the vasculature. Under aseptic procedures in adult male Sprague-Dawley rats, the proximal segment of the left lateral tail vein was surgically isolated (1.5-2 cm), a glass microsphere luminal plug placed at the cranial end, and the vein sutured closed at the caudal end. The closed-end venous luminal space was filled with a fluorescent DiI-paste delivered through a 26-gauge catheter. After 13 days of tracer transport time, the animals were euthanized and perfused transcardially with 4% paraformaldehyde. The left and right L5-S2 DRGs were dissected free, post-fixed overnight and cryoprotected. The Di-I injection site was examined postmortem to verify that no dye leaked into non-vascular structures. Serial cryosections at 14 μm were thaw-mounted on alternating slides. Nucleated DiI-positive DRG neurons were directly visualized via multi-label fluorescence microscopy, digitally imaged with Zeiss optics, and measured with morphometric software. Using our previously published techniques (e.g. Petruska et al, 2000), slides were immunohistochemically processed for various cellular markers including CGRP, SubP, Neurofilament-M (NF-M), IB4, TRPV1, TRPV2. Di-I positive cells neurons (n=929) traced from the proximal tail vein were found almost exclusively in the ipsilateral L6 and S1 DRGs (some in S2) and exhibited small to medium cell diameters (96% between 15-45 μm). Only 19% were NF-M positive but had a significantly greater cell diameter (41.5 ± 1.1 μm) compared to NF-M negative cells (31.2 ± 0.5 μm; $p<.01$). The latter were mostly IB4 negative. While only 21% were typical peptidergic cells containing both CGRP and SubP, those containing only one peptide were CGRP+ (92%). Combined with our finding that one third of the total Di-I cells contained CGRP, our data support the known importance of CGRP in vascular control. Consistent with our *in vitro* patch clamp data from capsaicin-sensitive and -insensitive Di-I traced vascular DRG neurons (type 8, type 19 and type 20; Cooper et al., 2014), a portion of the vascular afferent population were positive for TRPV1 and TRPV2 with most CGRP+ cells co-labeled with the capsaicin-insensitive TRPV2 receptor (63%).

Title: Characterization of optogenetic activation of non-peptidergic C-fibers

Authors: *K. H. LEE[1,2], J. HACHISUKA[1,2], P. C. ADELMAN[1,2], S. E. ROSS[1,2,3], B. M. DAVIS[1,2,4], H. R. KOERBER[1,2];
[1]Neurobio., [2]Pittsburgh Ctr. for Pain Res., [3]Anesthesiol., [4]Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A critical function of the central nervous system is rapidly detecting harm or injury, signaling peripheral injury by sending pain or nociceptive signaling to the spinal cord and then to the brain to prevent further damage. Using an optogenetic approach that inserts light-activated channels (ChR2) in specific cell types, the current study characterized the afferent inputs that are activated by light in mouse genetic line expressing MrgD-Cre-Ai32, which selectively activate a non-peptidergic population of thermally and mechanically sensitive C-fibers. First, we characterized the behavioral responses to light stimulation, finding a distinct withdrawal of the hindpaw after light presentation to both the dorsal and ventral skin, verifying that light presentation can produce a response behaviorally similar to mechanical and thermal stimulation. Likewise, electrophysiological recordings show that blue light activation can evoke responses in MrgD fibers that mimic those observed following mechanical or thermal stimulation. Next, we examined the potential of these primary afferent inputs to activate lamina I projection neurons back-labeled from the parabrachial nucleus. We used the skin-nerve-DRG-spinal cord *ex vivo* preparation to record from tract cells while optically activating MrgD afferent fibers within the tract cell's receptive field. Preliminary data show that MrgD-Cre-Ai32 expressing light driven afferent inputs both directly and indirectly reach some lamina I tract cells. Finally, to examine the role of this population of non-peptidergic C-fibers in inflammatory pain, we measured response to blue light before and after CFA injection into the hindpaw (intradermal). Interestingly, we found no change in light intensity threshold after CFA injection in MrgD-Cre-Ai32 mice, even though the same mice demonstrated thermal hyperalgesia. Although unlikely, one possible interpretation of these results is that these MrgD fibers, which make up a large proportion of cutaneous nociceptors, are not involved in mechanical or thermal hyperalgesia following inflammation. Another interpretation would suggest that increased sensitivity in sensory transduction plays a major role in the hyperalgesia observed after inflammation rather than a general increase in afferent fiber excitability.

Title: A newly identified selective mechano-sensitive K2P opener reduces rat dorsal root ganglion (DRG) neuronal excitability

Authors: *A. J. LOUCIF[1], P.-P. SAINTOT[2], B. ANTONIO[3], S. ZELLMER[3], L. CAO[2], N. CASTLE[3], E. STEVENS[2];
[1]Neurosci. and Pain Res. Unit, Pfizer Ltd, Cambridge, United Kingdom; [2]Pfizer Neurosci. & Pain Res. Unit (NPRU), Cambridge, United Kingdom; [3]Pfizer Neurosci. & Pain Res. Unit (NPRU), Durham, NC

Abstract: TREK-1, TREK-2 and TRAAK channels belong to the mechano-sensitive family of two-pore domain (K2P) potassium channels which are sensitive to a variety of stimuli including temperature, mechanical activation. TREK-1, TREK-2 and TRAAK channels are highly expressed in rat dorsal root ganglia neurones and play a role in setting the threshold and range of nociceptor excitation in response to pain stimuli. Knock-out studies show that TREK-1 and TRAAK channels can be considered as molecular silencers of mechanical pain and both noxious heat and cold pain (Noel et al, 2009), while TREK-2 can be considered as a regulator of mechanical and moderate heat and cold pain (Pereira et al, 2014). In the present study we have characterised the action of a newly identified mechano-sensitive K2P opener in recombinant cell lines and cultured rat DRG neurones. Using manual patch clamp technique on HEK cells stably expressing rat TREK-1, the opener induced an outwardly rectifying current with a maximum enhancement of 5902% and an EC_{50} of 0.9μM (n=6). Using manual patch clamp in recombinant cell lines, little or no effects were observed against other potassium channels at 10 uM: TRESK (-2.0±3.5%, n=4), KCNQ1 (-24.6±8.9%, n=4), BK (-3.3x±6.7%, n=4) and hERG (-7.3±5.1%, n=5). The opener had no effects against other potassium channels TASK-2, KCNQ-1, KCNQ-2, KCNQ-3 and sodium channels Nav1.2, Nav1.7 and Nav1.8 using Rb^+ flux assays. Using current clamp recordings on cultured rat DRG neurones application of compound at 1μM (~EC50) resulted in a significant reduction in firing frequency as a result of a reduction in input resistance and a small hyperpolarisation of resting membrane potential (~2mV). This provides the first pharmacological evidence for the presence of mechano-sensitive K2P channels in sensory neurones and suggests that development of selective K2P channel openers could potentially lead

to novel analgesics. Noël et al., 2009 EMBO J. 28(9):1308-18. Pereira et al., 2014 155(12):2534-44.

Title: Elevated levels of glutaminase and aspartate aminotransferase in rat drg neurons during adjuvant-induced arthritis

Authors: *B. R. BOLT, Z. ZHANG, K. E. MILLER;
Anat. and Cell Biol., Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK

Abstract: The sensory neurons of the dorsal root ganglia (DRG) are glutamatergic, utilizing glutaminase (GLS) and aspartate aminotransferase (AST) for glutamate synthesis (Miller et al., Pharmacol Ther 130:283, 2011). We previously demonstrated that glutamate metabolism (↑ GLS, AST, glutamate levels) is altered in the rat DRG, sciatic nerve and skin during adjuvant-induced arthritis (AIA). Additionally, we have determined that AST is elevated in nociceptive, calcitonin gene-related peptide- (CGRP) containing DRG neurons during AIA. The aim of the present study is to evaluate alterations of GLS in AST-containing DRG neurons during AIA. Complete Freund's adjuvant was injected into the rat right hindpaw to induce AIA and DRG's were analyzed at 2, 4 and 8 days. Rats were anesthetized and transcardially perfused with fixative. AST and GLS colocalization was evaluated in L4 DRG's with immunohistochemistry, followed by quantitative image analysis with Image J. At 2 and 8 days AIA, GLS-immunoreactivity (ir) in AST-positive DRG neurons was elevated when compared to naïve controls, demonstrating a biphasic pattern of expression. In a similar biphasic pattern, AST-ir in GLS-positive neurons was elevated at days 2 and 8 of AIA, but was a control levels at day 4 AIA. Analysis demonstrated strong positive correlation in GLS-AST elevation in DRG neurons at 2 and 8 days of AIA. Elevated AST and GLS levels in DRG neuronal bodies leads to increased glutamate production in peripheral and central terminals. The elevation observed for both AST and GLS, therefore, may be due to similar mechanisms regulating transcription, translation, and trafficking in DRG neurons. Novel therapies that decrease AST and GLS levels

may hold promising treatment for alleviating inflammatory pain caused by increased glutamate synthesis in nociceptive primary afferents following injury.

Title: Molecular profiling of sensory neurons innervating different peripheral tissues following *in vivo* retrograde labeling and laser capture microdissection

Authors: R. S. BREESE, Y. BAI, W. FURY, Y. WEI, M. NI, C. ADLER, C. LIN, A. J. MURPHY, L. E. MACDONALD, *N. ALESSANDRI-HABER;
Regeneron Pharmaceuticals, Tarrytown, NY

Abstract: Chronic painful conditions affect millions of people worldwide. Unlike the transitory unpleasant sensation of acute pain, inflammatory and neuropathic pain are often chronic, persistent states. Patients suffering from chronic pain often experience hypersensitivity to mechanical, thermal and/or chemical stimulation in the form of hyperalgesia and/or allodynia. This hypersensitivity is mediated, at least in part, by sensitization of signaling processes in different subpopulations of primary sensory neurons known as nociceptors. The cell bodies of these neurons are clustered in nodules on dorsal roots of the spine known as dorsal root ganglia (DRG). The axons of these neurons split into two branches; one branch innervates the peripheral tissues (skin, muscles, joints and organs) and the other connects to the spinal cord to carry signals to the appropriate integration center in the brain. Nociceptors fall into different subpopulations based on their conduction properties, molecular profile and whether they respond to a single type of physical stimulus or integrate and generate a response to different types of physical stimuli. Although the development of chronic pain has been associated with increased excitability of nociceptors, their molecular complexity has made it difficult to fully elucidate the mechanisms underlying persistent pain. We hypothesized that molecular profiling of subpopulations of nociceptors innervating distinct peripheral tissues in different animal models of pain would improve our understanding of the mechanisms underlying the establishment of chronic pain and potentially unravel new targets for pain therapeutics. Thus, we developed a technique to isolate neurons innervating peripheral tissues using laser microdissection after *in vivo* retrograde labeling. We first determined which DRGs innervated the gastrocnemius muscle,

the skin of the footpad, the knee joint or the femoral bone using fluorescently labeled Cholera toxin subunit B. Retrograde tracers clearly showed that primary afferent neurons originated from multiple DRG levels along the spine with a pattern specific to each peripheral tissue. We then investigated the molecular profiles of DRG neurons innervating peripheral tissues in two animal models of pain; a model of inflammatory muscle pain (repeated acid injection into the gastrocnemius muscle) and a model of knee joint inflammation (Complete Freud's Adjuvant injection into the knee joint). We show here that laser capture microdissection of retrogradely labeled sensory neurons in combination with RNA-seq can successfully be used for molecular profiling of specific subpopulations of nociceptors.

Title: Flotillin 1 is enriched in nociceptive sensory neurons and its interactome is altered in response to inflammation

Authors: B. K. DRAGOO, R. GEGUCHADZE, *D. C. MOLLIVER;
Biomed. Sci., Univ. New England, Biddeford, ME

Abstract: Flotillins 1 and 2 are ubiquitously-expressed membrane-associated proteins that segregate in specialized membrane "lipid raft" cholesterol-rich compartments. Flotillins appear

to act as scaffolding proteins that organize signal transduction complexes associated with raft microdomains and may mediate interactions between the plasma membrane and the cytoskeleton. Roles of flotillins as well as their binding partners are likely to vary based on cell type. Here, we examined the distribution of flotillin 1 and 2 in sensory neurons of the mouse dorsal root ganglia (DRG) and their central projections in the spinal cord. As expected, immunohistochemical staining for both proteins was ubiquitous in neuronal cell bodies. However, in contrast to flotillin 2, which was homogenously distributed, flotillin 1 showed a range of intensities in different neurons and was markedly more intense in small diameter neurons positive for the plant lectin IB4 and the heat-gated ion channel TRPV1, markers commonly associated with nociceptors. Furthermore, although flotillin 1 staining was widespread across the lumbar spinal cord, labeling was much more intense in the superficial dorsal horn (the principal target region for unmyelinated nociceptors), and colocalized with staining for both IB4 and TRPV1. A second polyclonal antibody generated against a different region of the protein yielded essentially identical results and staining was eliminated by incubation of the primary antibody with the antigenic peptide. These results are consistent with a high level of flotillin 1 expression in nociceptors compared to other sensory neurons. Western blot analysis of lumbar L2-5 DRG of mice injected with either vehicle or complete Freund's adjuvant (CFA) to produce inflammatory hyperalgesia did not reveal substantial changes in flotillin 1 levels in response to inflammation. To identify proteins interacting with flotillin 1 in DRG under normal and inflamed conditions, we performed flotillin 1 coimmunoprecipitation from lumbar DRG of mice treated with vehicle or CFA. Eluted samples were compared by 2 dimensional difference gel electrophoresis (2D DIGE). In preliminary analysis of naive samples, 14 unique protein spots were identified, of which 2 were highly enriched in the eluted fraction compared to the lysate flow-through fraction. Twelve spots were identified in inflamed samples, 2 of which were distinct from those identified in naïve samples. All spots are undergoing protein sequencing by MALDI-Tof mass spectrometry. These results suggest that signaling complexes organized by flotillin 1 at the sensory neuron plasma membrane are altered in response to inflammatory injury.

Title: Cage bedding material affects mechanical behavioral thresholds, heat thresholds and texture preference in mice

Authors: *F. MOEHRING, C. L. O'HARA, C. L. STUCKY;
Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: It has long been known that the bedding material animals are housed on can affect breeding behavior and cage environment. Yet little is known about its effects on evoked behavior responses or non-reflexive behaviors. In recent years, we noticed that the median von Frey thresholds obtained by our laboratory from non-injured wild type mice are typically lower (2-3 fold) than those obtained by other groups. Therefore we housed C57bl6 mice for two weeks on various bedding types (Aspen Sani Chips® (standard bedding for our institute), ALPHA-Dri®, Cellu-Dri™, Pure-o'Cel™ or TEK-Fresh bedding) and tested the animals with an array of behavior assays. Mice housed on Aspen bedding exhibited the lowest mechanical thresholds, while those housed on TEK-Fresh exhibited 3-fold higher thresholds. TEK-Fresh housed animals also exhibited greater responsiveness in a noxious needle assay, whereas bedding type had no effect on responses to punctate or dynamic light touch stimuli. Heat sensitivity was also affected by bedding; animals housed on Aspen Sani Chips® exhibited the shortest latencies to withdrawal, whereas those housed on TEK-Fresh had the longest latencies to response; similar results were observed in a moderate cold temperature preference assay. A modified tactile conditioned place preference chamber assay revealed that animals preferred TEK-Fresh to Aspen bedding. Bedding type had no effect in a non-reflexive wheel running assay. Two days after peripheral inflammation induced by injection of Complete Freund's Adjuvant (CFA) in the hindpaw, mechanical thresholds were reduced in all groups regardless of bedding type, but TEK-Fresh and Pure-o'Cel™ housed groups exhibited a greater dynamic range between controls and inflamed cohorts as compared to Aspen housed mice. For the Hargreaves test, all animals receiving CFA had shorter heat withdrawal latencies, however the bedding type did not significantly affect the dynamic range. These findings indicate that the bedding type that animals are routinely housed on can markedly affect the dynamic range of mechanical and heat behavior assays under both normal, non-injured and tissue injury conditions. Therefore, careful consideration should be used when selecting bedding material, because a softer bedding material may allow for the utilization of fewer animals through less intra-animal variability, and therefore decrease the time and money required for somatosensory studies.

Title: Growth hormone regulates the age-dependent sensitization of cutaneous nociceptors during developmental inflammation through an insulin-like growth factor receptor type 1 dependent mechanism

Authors: *X. LIU[1,2], L. QUEME[1], P. LU[1], K. GREEN[1], F. LEE[1], A. SHANK[1], R. HUDGINS[1], M. JANKOWSKI[1,3];
[1]Cincinnati Children's Hosp., Cincinnati, OH; [2]Shaanxi Univ. of Chinese Med., Xi'an, China; [3]Univ. of Cincinnati, Cincinnati, Cincinnati, OH

Abstract: We have previously found that cutaneous nociceptors are age-dependently sensitized to heat and mechanical stimuli in neonatal mice during inflammation of the hairy skin. The patterns of sensory neuron gene expression likely underlying alterations in afferent function were also found to be age-dependent. We therefore sought to determine if there was a common upstream modulator of peripheral sensitization that age-independently regulated neonatal pain. Previous reports have shown that up to 55% of children with growth hormone deficiency (GHD) have resting pain in their limbs and treatment with GH relieves their pain. In order to determine if GH signaling played a role in modulating sensory neuron function and pain during developmental inflammation in mice, we examined the response properties of cutaneous afferents using an *ex vivo* hairy skin-saphenous nerve-dorsal root ganglion (DRG)-spinal cord preparation and also tested behavioral hypersensitivity. Analyses were performed one day after injection of 3% carrageenan into the hairy hindpaw skin at postnatal days 7 and 14 in mice with or without GH treatment and compared to naïves. We found that cutaneous inflammation produced a GH deficient state in the affected skin and treatment of inflamed mice with exogenous GH reversed mechanical and thermal hypersensitivity. In addition, all of the age-dependent alterations in cutaneous afferents were blocked by this GH treatment in mice with cutaneous inflammation. Since GH is known to mediate its actions by regulating the insulin-like growth factor 1(IGF1)/IGF receptor type 1 (IGFr1) pathway, we wanted to determine if a similar mechanism of GH action was found in primary afferents. We found that the GHD produced in

the skin during developmental inflammation induced a compensatory upregulation of IGFr1 in the DRGs. Afferent selective, siRNA-mediated knockdown of IGFr1 during neonatal inflammation also prevented the observed age-dependent alterations in cutaneous afferents in addition to mechanical and thermal hypersensitivity. These results suggest that GH blocks the inflammation induced changes in thermal and mechanical sensitivity in cutaneous afferents at different postnatal ages leading to reduced pain behaviors through an IGFr1 dependent mechanism in the DRGs.

Title: Muscle IL-1β mediates ischemia and reperfusion injury-induced sensitization of group III and IV muscle afferents

Authors: *J. L. ROSS[1], L. F. QUEME[1], P. LU[1], E. R. COHEN[1], R. C. HUDGINS[1], M. P. JANKOWSKI[2];
[1]Anesthesia, [2]Anesthesia, Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: We have previously shown that ischemia and reperfusion injury (I/R) in the forepaw muscles of adult Swiss Webster mice altered sensory behaviors and muscle function *in vivo*. I/R also decreased mechanical thresholds and increased firing to chemical stimuli in group III and IV muscle afferents as assessed by an *ex vivo* muscle-nerve-dorsal root ganglion (DRG)-spinal cord recording preparation. Additionally, I/R induced a significant increase in the number of muscle afferents that responded to both non-noxious (low lactic acid and ATP concentrations; pH 7.0) and noxious (high lactic acid and ATP concentrations, pH 6.6) metabolite solutions. These functional changes were thought to be mediated through an acid sensing ion channel 3 (ASIC3)-dependent mechanism in the affected sensory neurons. We have recently found that the

inflammatory cytokine interleukin 1β(IL1β) was upregulated in the injured muscles and its receptor IL1r1 displayed enhanced expression in the DRGs after I/R. IL1β treatment of dissociated muscle afferents also significantly increased expression of ASIC3 in single cells. Therefore, to further determine the mechanistic role of IL1β in the generation of muscle pain after I/R, we coupled our injury model with an afferent-specific siRNA knockdown of IL1r1, and performed molecular, electrophysiological and behavioral analyses. Not only did nerve specific IL1r1 knockdown inhibit I/R-induced upregulation of IL1r1, but it also inhibited the upregulation of ASIC3 expression in the affected DRGs *in vivo*. Furthermore, *ex vivo* recording revealed that knockdown of IL1r1 blocked the I/R-induced changes in mechanical thresholds and in the altered prevalence of chemosensitive muscle afferents. siRNA-mediated inhibition of IL1r1 also blocked I/R-induced alterations in spontaneous (guarding) and evoked (von Frey mechanical stimulation) pain behaviors, as well as attenuating I/R-induced deficits in grip strength and voluntary activity. This suggests that enhanced IL1β in the muscle during I/R upregulates ASIC3 expression in muscle afferents via IL1r1, altering neuronal responsiveness and phenotypic identity, and leading to the development of muscle pain. These data provide a potential peripherally restricted therapeutic target for the treatment of ischemic myalgias.

Title: Ionic mechanisms of peripheral analgesic effect of Substance P

Authors: *N. GAMPER[1,3], D. HUANG[3], L. OOI[1], J. LINLEY[1], C. PEERS[2], H. ZHANG[3]; [2]Fac. of Med. and Hlth., [1]Univ. Leeds, Leeds, United Kingdom; [3]Dept. of Pharmacol., Hebei Med. Univ., Shijiazhuang, China

Abstract: Neuropeptide substance P (SP) is both produced and released by a subset of peripheral sensory neurons that respond to tissue damage (nociceptive neurones); these neurons also express SP receptors (neurokinin receptors 1-3, NK1-3). SP exerts excitatory effects in the CNS but peripheral SP actions are still under investigation. We show that SP inhibits excitability of small-diameter dorsal root ganglion (DRG) neurons *in vitro* and produces a peripheral analgesic effect *in vivo*. Furthermore, we demonstrate that this effect can be attributed to the acute modulation of two ion channels that control sensory neuron excitability: potentiation of anti-excitatory M-type K+ channels and inhibition of pro-excitatory T-type voltage-gated Ca2+. Both effects were sensitive to Gi/o inhibitor pertussis toxin and were mediated by NK1 receptor-induced stimulation of intracellular release of reactive oxygen species (ROS) as these were prevented or reversed by the reducing agent dithiothreitol and mimicked by exogenous or endogenous ROS delivery. Fluorescent imaging utilizing superoxide-sensitive fluorescent protein mt-cpYFP revealed that in DRG neurons SP induced mitochondrial release of superoxide radical, which explains the action of SP on both channel types as both are redox-sensitive (although in opposite directions). Focusing on the T-type channels, we further demonstrate that the SP-induced and redox-mediated T-type channel inhibition in DRG neurons operated through the modulation of Cav3.2 channel sensitivity to ambient zinc as it was prevented or reversed by zinc chelation and mimicked by exogenous zinc. Moreover, elimination of the zinc binding site in Cav3.2 rendered the channel insensitive to SP-mediated inhibition. Using behavioural tests we demonstrate that peripheral injections of SP into rat hind paw produced no nocifensive behaviour but pre-injection of SP significantly attenuated nocifensive behaviour produced by injection of inflammatory mediator bradykinin. This effect of SP was partially mimicked by the peripheral injections of the M channel opener retigabine and by the T-type channel inhibitor Z944. Thus, our study establishes a convergent mechanism by which SP exerts its peripheral analgesic effect by simultaneous inhibition of pro-algesic T-type Ca2+ current and enhancement of anti-algesic M-type K+ current. These findings will lead to better understanding of mechanisms of endogenous analgesia.

Title: Translation of the atypical protein kinase C, PKMζ, mediates the enhancement of excitability and the development of mechanical hyperalgesia produced by Nerve Growth Factor

Authors: *A. KHODOROVA[1], J. KAYS[2], Y.-H. ZHANG[2], S. YOUNG[3], R. WEK[3], G. R. STRICHARTZ[1], G. D. NICOL[2];
[1]Harvard Med. Sch. Brigham and Women's Hosp, Boston, MA; [2]Dept. of Pharmacol. and Toxicology, [3]Dept. of Biochem. and Mol. Biology, Sch. of Med., Sch. of Medicine, Indiana Univ., Indianapolis, IN

Abstract: PKM ζ is a key effector in the maintenance of long-term memory. Our recent studies indicate that an atypical PKC, PKM ζ, contributes to nociceptive sensitization by NGF (Zhang et al., 2012; Khodorova et al., 2013; SfN 2014). Here we evaluate whether these sensitizing effects result from the translation of PKM ζ. We found that pre-treatment of rat sensory DRG neurons with inhibitors of protein translation cyclohexamide (CHX) or rapamycin (RAPA) prevented the increase in excitability produced by exposure to 100 ng/ml NGF, whereas actinomycin-D, a transcription inhibitor, had no effect. Moreover, pre-treatment with 4EGI-1, a small molecule inhibitor of cap-dependent translation (specifically blocks the interaction between eIF4E and eIF4G), also blocked the NGF-induced increase in excitability. In polysomal profiling experiments on isolated sensory neurons, NGF significantly augmented the amount of mRNA for PKM ζ in the peak polysomal fraction, and increased the ratio of the mRNA content of the combined polysomes to the combined monosomes. No increase was detected for other atypical PKCs (PKC ζ or PKCλ/ι). Importantly, RAPA reduced the levels of PKM ζ mRNA found in the peak polysome fraction to values measured in untreated control neurons. Western blotting showed that exposure of the neurons to 100 ng/ml NGF (30 min) significantly increased the density of the ~49 kDa band, previously identified as PKM ζ; a 1 h pre-treatment with CHX reduced the density of this band to untreated control levels. In rats, either CHX or RAPA, pre-injected before NGF into the plantar hind paw, delayed the development of mechano-hyperalgesia at that locus. A significant hypersensitivity from NGF (500 ng) was not detected until 3.5 h or later after CHX, or RAPA, with the mechanical hypersensitivity returning to the normal NGF-elevated value by 22 h. RAPA pre-treatment also decreased the NGF-induced thermal hyper-responsiveness, but only at the 1 h time (compared to responses of vehicle pre-treated controls). Intraplantar injection of the pseudosubstrate inhibitor of the atypical PKCs (mPSI) or RAPA 3 days after NGF treatment (1-4 μg), reversed the persistent mechano-hypersensitivity measured 1 day later. By day 5 the responsiveness had recovered to its enhanced, pre-mPSI level. These results demonstrate that the ability of NGF to sensitize sensory neurons and enhance painful sensitivity in rat glabrous skin is mediated by the protein translation of PKM ζ and that the persistent hypersensitivity may depend, in part, on the continued synthesis of PKM ζ.

Title: Peripheral glutamate receptors contribute to Fos expression in the spinal dorsal horn through interaction between peripheral nerve terminals

Authors: **A. LI**[1], *D.-Y. CAO[1], Y. GUO[2], Y. ZHAO[2];
[1]Stomatological Hospital, Xi'An Jiaotong Univ., Xi'an, China; [2]Dept. of Physiol. and Pathophysiology, Sch. of Basal Med. Science, Xi'an Jiaotong Univ. Hlth. Sci. Ctr., Xi'an, China

Abstract: Glutamate receptors localize on the peripheral terminals of primary afferent neurons. Exogenous glutamate can excite peripheral sensory nerve terminals and electrical stimulation of primary afferents evokes the release of glutamate peripherally. Our previous studies have shown that spontaneous nerve discharges increase in a cutaneous branch from a spinal dorsal ramus in the thorax following antidromic electrical stimulation (ADES) of a cutaneous branch at the adjacent spinal segment. The enhanced activity can be blocked by local application of NMDA and non-NMDA receptor antagonists into the receptive field of the recorded nerve. It is well known that the dorsal cutaneous branches of the thoracic nerves run parallel to each other and there is no synaptic contact at the peripheral. The aim of the present study was to investigate whether endogenous glutamate with its receptors has a role in the interaction between the peripheral nerve terminals thus inducing Fos protein expression in the dorsal horn of spinal cord at adjacent spinal segments. Male rats were anesthetized with pentobarbital sodium (50 mg/kg, intraperitoneally). A left paramedian incision at 1 cm lateral to the medline on dorsal skin was made longitudinally to expose T10 right dorsal cutaneous branch. ADES (amplitude 0.6 mA, duration 0.5 ms, frequency 20 Hz, lasted for 30 min) was applied on T10 dorsal cutaneous branch. Rats were perfused with 4% paraformaldehyde 1.5 h after ADES. The T8-T12 spinal cord segments were removed, 30-mm sections cut, and every fourth section labeled for c-Fos using standard immunocytochemical protocols. The Fos exprssion in ADES rats was significantly higher than that in the sham ADES rats in the ipsilateral and contralateral dorsal horn of T8-T12 spinal cord. In separated groups, subcutaneous injection of NMDA receptor

antagonist MK-801 or non-NMDA receptor antagonist DNQX (0.1 mmol/L, 30 μl/30min for each drug) into the receptive field of T11 dorsal cutaneous branch during ADES blocked the Fos expression in T11-T12, but not in T8-T10 spinal cord dorsal horn. As the increase of Fos expression is the indication of central sensitization in the spinal cord, these results suggest that endogenic glutamate and its receptors contribute to peripheral sensitization inducing central sensitization in the spinal cord at adjacent spinal segments.

Title: P38 MAPK activation is required in glial P2X7-dependent and neuronal P2Y1-mediated inhibition of P2X3 expression in dorsal root ganglion neurons

Authors: *Y. CHEN, G. LI, L.-Y. HUANG;
Dept. of Neurosci. & Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: We have previously shown that activation of purinergic P2X7 receptors (P2X7Rs) in satellite glial cells (SCGs) of dorsal root ganglia (DRGs) stimulate ATP release. The ATP activates P2Y1Rs located in the enwrapped neuronal somata, resulting in down-regulation of P2X3Rs. This P2X7R-P2Y1-P2X3R inhibitory control significantly reduces P2X3R-mediated nociceptive responses. The underlying mechanism by which the activation of P2Y1Rs inhibits the expression of P2X3Rs has not been explored. Examining the effect of activation of p38 mitogen-activated protein kinase on the expression of P2X3R in DRGs, we found that the p38 activator, anisomycin (Anis), reduced the expression of P2X3Rs. The effect of Anis was not altered when the activity of SGCs was blocked by the glial Krebs cycle inhibitor, fluorocitrate. These results suggest that neuronal p38 plays a major role in controlling the P2X3R expression. Antagonizing P2Y1R by MRS2179 (MRS) and blocking P2X7Rs by A740003 inhibited the phosphorylated p38 and increased the P2X3R expressions in DRGs.These observations suggest that activation of P2X7Rs and P2Y1Rs promotes p38 activity to exert inhibitory control on

P2X3R expression. Since activation of p38 by Anis in the presence of either A740003 or MRS could overcome the block of P2X7R-P2Y1R inhibitory control, p38 in DRG neurons is downstream of P2Y1Rs. In addition, inhibition of p38 by SB202190 was found to prevent the P2X7R-P2Y1R block of P2X3R expression and increase P2X3R-mediated nociceptive flinch behaviors. These results led us to conclude that P38 in DRG neurons downstream of P2Y1R is necessary and sufficient for the P2X7R-P2Y1R inhibitory control of P2X3R expression.

Title: Effect of bisphosphonates and bisphosphonates-induced ATP analogues on P2X receptors

Authors: Y. ISHCHENKO, A. SHAKIRZYANOVA, R. GINIATULLINA, P. TURHANEN, J. MÄÄTTÄ, J. MÖNKKÖNEN, *R. GINIATULLIN;
Univ. of Eastern Finland, Kuopio, Finland

Abstract: Accumulating evidence suggests involvement of ATP-gated P2X3 receptors in bone cancer pain. Bisphosphonates are widely used anti-cancer drugs, which also show analgesic effects. Using patch-clamp technique and ATP biochemical assays, we explored molecular mechanisms of the potential direct action of two different bisphosphonates and the bisphosphonate zoledronate-induced metabolite such as triphosphoric acid 1-adenosine-5’-yl ester 3-(3-methylbut-3-enyl) ester (ApppI) on ATP release, on ATP-gated P2X3 and P2X7 receptors expressed in nociceptive system. We found that ApppI inhibited pro-nociceptive P2X3 receptors in low nanomolar concentrations. Unlike ApppI, we established that its precursor isopentenyl pyrophosphate (IPP) known as the inhibitor of TRPV3 and TRPA1 channels (Bang at al., 2011) did not show any activity at the P2X3 receptor consistent with a specific inhibitory potency of the full ApppI molecule. We further demonstrated selectivity of ApppI action on P2X3 receptor by lack of its activity on P2X2 or P2X7 receptors. In line with the specific blocking activity of ApppI, the bisphosphonates zoledronate or clodronatedid not act on P2X3 or

P2X7 receptors directly. Importantly, on human P2X3 receptors the inhibitory action of ApppI was even stronger than on the rat homologue. In addition, no changes in extracellular ATP were found after short (2 h) treatment with zoledronate whereas after 24 h treatment with this bisphosphonate the level of extracellular ATP was significantly enhanced without changes in intracellular ATP content. In contrast, clodronate induced no changes in the level of ATP. We propose that ApppI generated after cancer treatment with nitrate-containing bisphosphonates (like zoledronic acid) can contribute to pain relief via selective ApppI-mediated inhibition of ATP-gated P2X3 receptors natively expressed in nociceptive sensory neurons.

Title: A possible role for P2X7 receptors expressed by satellite glial cells from dorsal root ganglia in nociceptive responses

Authors: *A. F. NEVES[1], F. S. OLIVEIRA[2], C. M. C. LOTUFO[3], C. A. PARADA[1]; [1]Dep Structural and Functional Biol., Biol. Inst. / UNICAMP, Campinas, Brazil; [2]Fac. of Med. - UFU, Uberlandia, Brazil; [3]Inst. of Biomed. Sci. / UFU, Uberlandia, Brazil

Abstract: P2X7 purinergic receptors (P2X7R) are selective cation channels activated by ATP that may play an essential role in inflammatory pain. P2X7R are expressed mainly by immune and glial cells. In dorsal root ganglia (DRG), these receptors are expressed by satellite glial cells (SGC). Studies indicate that electrical stimulation of DRG neurons promotes vesicular ATP release from their soma and this could be the major transmitter used for neuron-SGC communication in sensory ganglia. Glial cells are non-electrically excitable, however they could display excitability based on changes in intracellular Ca2+ concentration ([Ca2+]i). Then our aim was to verify if P2X7R activation in SGC are involved in neuronal-SGC communication during nociception. P2X7R activation was tested in primary cultures of adult rat DRG (n=3-5 cultures/group). Changes in [Ca2+]i were assessed by confocal microscopy using Fluo-3 AM (5 μM). P2X7R was activated by BzATP (100 μM) and the TRPV1 agonist capsaicin (1 μM) was

used in order to selectively activate nociceptive neurons. P2X7R was blocked by antagonist A740003 (1 μM), added to cultures 5 min before BzATP or capsaicin. Histological characterization was performed by immunofluorescence in paraformaldehyde-fixed rat DRG using: rabbit anti-P2X7R (1:200, Alomone), goat anti-TRPV1 (nociceptive neuronal receptor; 1:100, R&D System), mouse anti-glutamine synthetase (glial specific enzyme; 1:200, Millipore) and Alexa Fluor conjugated secondary antibodies (1:1000, Invitrogen). Nuclei were stained with DAPI (SIGMA). *In vitro*, BzATP increases [Ca2+]i in SGC but not in neurons. As expected, capsaicin induced a [Ca2+]i surge in nociceptive neurons, but we also observed a calcium transient in SGC about 5 seconds after neuronal response. When cultures were treated with A-740003, the responses of SGC both from BzATP or capsaicin were blocked. The P2X7R antagonist did not affect capsaicin-induced responses in neurons. This result corroborate with the hypothesis that capsaicin responses observed in SGC are indirect through ATP release. Immunofluorescence showed several nociceptive neurons TRPV1-positive and a co-staining of P2X7R and glutamine synthetase surrounding neurons. DAPI staining allowed differentiating neuronal membrane from SGC. This result confirmed that P2X7R are localized only in SGC surrounding most neurons in the DRG. Concluding, the present study suggests that, in the DRG, activated nociceptive neurons release ATP, which activates surrounding SGC. Therefore our data indicate that ATP, through P2X7R, might be involved in the communication between neurons and SGC during nociceptive responses.

Title: *In vivo* regulation of P body dynamics in mouse dorsal root ganglion neurons by AMPK activation and peripheral nerve injury

Authors: ***G. L. MEJIA, JR**[1], K. FIOCK[1], O. K. MELEMEDJIAN[2], G. DUSSOR[1], T. J. PRICE[1];
[1]Univ. of Texas At Dallas, Richardson, TX; [2]Univ. of Maryland, College Park, MD

Abstract: *In vivo* regulation of P body dynamics in mouse dorsal root ganglion neurons by AMPK activation and peripheral nerve injury. Galo L Mejia[1], Kimberly Fiock[1], Ohannes K Melemedjian[2], Gregory Dussor[1], Theodore J Price[1] [1]University of Texas at Dallas, School of Behavioral and Brain Sciences [2]University of Maryland, School of Dentistry, Department of Neural and Pain Sciences P bodies are cytoplasmic RNA granules and hotspots for mRNA turnover. Their specific role in neurons is not known but they have been hypothesized to act as sites of mRNA decay and/or mRNA storage in response to cellular stress and activation of signaling pathways. A function for P bodies in pathology of the nervous system has not been described in detail. We have previously shown that stimuli that increase translation in dorsal root ganglion (DRG) neurons decrease P bodies and activation of signaling pathways that decrease translation (e.g. adenosine monophosphate-activated protein kinase (AMPK) activation) increase P body formation. However, this work has thus far been limited to *in vitro* findings in DRG neurons. To query regulation of P bodies in DRG neurons *in vivo* we treated mice with the AMPK activator metformin for 7 days at a dose of 200 mg/kg. This treatment regimen led to a robust increase in P body formation in DRG neurons. We then asked if peripheral nerve injury with the spared nerve injury (SNI) model in mice altered P body dynamics. We hypothesized that SNI should decrease P body formation because our previous results have shown that SNI increases translation and translation control signaling in DRG neurons. We observed results consistent with this hypothesis 14 days after SNI surgery. Ongoing experiments are examining whether these effects also occur in axons and whether SNI effects on P bodies are reversed by metformin treatment. These findings provide support for a role of P bodies in regulating mRNA turnover and translation control in DRG neurons *in vivo*.

Title: Pronociceptive role of metabotropic P2Y1 receptor in different models of neuropathic pain

Authors: *V. GRANADOS-SOTO[1], J. B. PINEDA-FARIAS[2], P. BARRAGAN-IGLESIAS[2]; [1]Dept. de Farmacobiologia, Cinvestav, Sede Sur, Mexico, DF, Mexico; [2]Dept. de Farmacobiologia, Cinvestav, Sede Sur, Mexico, DF, Mexico

Abstract: P2Y1 receptor (P2Y1R) is a member of the P2Y family of Gq protein-coupled receptors expressed in peripheral sensory neurons and spinal cord. It has been suggested that P2Y1R has an important role in nociception and inflammatory pain. However, its role in neuropathic pain remains elusive. Here, we investigated the role of the P2Y1R in the modulation of neuropathic pain by using the spinal nerve ligation (SNL), chronic constriction of sciatic nerve (CCI) and spared nerve injury (SNI) models. By Western blot, we found that P2Y1R protein is constitutively expressed in L4-L6 DRGs and lumbar spinal cord. However, the time course of P2Y1R protein expression in L4-L6 ipsilateral DRGs following SNL, CCI or SNI was quite different. SNL and CCI models produced a significant up-regulation of P2Y1R in DRG, but not in spinal cord, at 3 days after nerve injury. On the other hand, SNI produced an early strong up-regulation in DRG, but not in spinal cord, at 1 day post-injury. Intrathecal administration of MRS2500 (19-190 ng/rat) at 3 days (in SNL and CCI models) attenuated tactile allodynia. Moreover, intrathecal administration of MRS2500 (19-190 ng/rat) produced a marked antiallodynic effect in the SNI model 1 day post-injury. Importantly, the antiallodynic effect of MRS2500 (19-190 ng/rat) was lower when it was intrathecally administered at day 14, compared to day 1 and 3 post-injury. The antiallodynic effect of MRS2500 (190 ng/rat) at 3- or 1-day post-injury was associated with a reduction of P2Y1R protein expression in DRG in all models. Results suggest that peripheral and spinal activation of P2Y1R contributes to initiation and, at a lesser extent, to maintenance of neuropathic pain. Furthermore, the pronociceptive effect of P2Y1R depends on the time course of protein expression and the type of nerve injury produced in peripheral sensory nerves.

Title: Differential accumulation of Nav1.8 mRNA with de novo long 3'UTR in sensory axons after peripheral nerve injury

Authors: ***T. HIRAI**[1,2], Y. MULPURI[3], I. SPIGELMAN[2], I. NISHIMURA[2,4];

Abstract: Axonal transport of mRNA associated with mechanism of neuropathic pain remains unclear in peripheral sensory neuron. We found that Nav1.8 mRNA with novel long 3' untranslated region (UTR), but not conventional short 3'UTR, is exclusively transported and accumulates in peripheral axon using RNA-seq and 3'RACE-PCR. Additionally, Nav1.8 mRNA with the long 3'UTR increases after nerve injury, indicating that this transcriptional variant might be a target of neuropathic pain.

Title: eIF4E phosphorylation links BDNF translation to pathological pain plasticity

Authors: ***J. K. MOY**[1], A. KHOUTORSKY[2], M. N. K. ASIEDU[1], C. G. GKOGKAS[3], G. DUSSOR[1], T. J. PRICE[1];
[1]Univ. of Texas At Dallas, Richardson, TX; [2]Biochem., McGill Univ., Montreal, QC, Canada; [3]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Translational control of gene expression is a key process for the regulation of plasticity in the nervous system. Multiple lines of evidence indicate that translation control plays a critical role in pathological pain plasticity but precise gene targets have thus far not been elucidated. We have previously shown that brain-derived neurotrophic factor (BDNF) is required

for the initiation and maintenance of hyperalgesic priming, a model of pathological pain plasticity. Mice harboring a mutation in eIF4E at Ser209 (eIF4ES209A), rendering the protein non-phosphorylatable by its upstream kinase, mitogen activated protein kinase interacting kinase (MNK), fail to demonstrate hyperalgesic priming to a range of stimuli including nerve growth factor (NGF) and proteinase activated receptor type 2 (PAR2) agonists. We therefore tested the hypothesis that eIF4E phosphorylation regulates BNDF translation. eIF4ES209A mice show no differences in expression of a wide variety of cell population markers in the dorsal root ganglion (DRG) or spinal cord compared to wild-type littermates. On the other hand, while BDNF transcription was similar for both genotypes, BDNF mRNAs were associated with lighter polysomes and BDNF protein was markedly reduced in eIF4ES209A DRG neurons, indicating that inhibition of eIF4E phosphorylation reduces the translation of BDNF mRNA. Importantly, although hyperalgesic priming to NGF and PAR2 agonists is strongly decreased or absent in eIF4ES209A mice, bypassing afferent-evoked release of BDNF with direct spinal injection of BDNF produces robust hyperalgesic priming in eIF4ES209A and wild-type mice. Our findings demonstrate that eIF4E phosphorylation plays a crucial role in BDNF translation and pathological pain plasticity following injury. Therefore, targeting eIF4E phosphorylation via the ERK/MNK pathway is a novel target for the manipulation of BDNF translation and pain plasticity.

Title: Analyzing axons within normal human skin biopsies reveals demographic differences and developmental pruning until the mid-20's

Authors: *A. L. OAKLANDER, H. M. DOWNS, M. M. KLEIN;
Dept Neurol., Mass Gen Hosp, Harvard Med. Sch., Boston, MA

Abstract: Background: “Small-fibers” are the unmyelinated C fibers and thinly myelinated Aδ PNS neurons that regulate body homeostasis and injury responses including pain sensation. Small-fiber polyneuropathies (SFPN) cause somatosensory (eg chronic pain, itch) and dysautonomic symptoms. Physicians diagnose SFPN with tiny skin biopsies from patients’ lower legs. These are immunolabeled to permit counting epidermal nerve fibers (ENF), which are predominantly small-fibers. Each patient’s ENF density is then compared to a distribution curve modeled from biopsying normal volunteers, and those with densities ≤ 5^{th} centile are diagnosed and treated for SFPN. These normative skin biopsies can also inform about normal neuroanatomy. **Methods:** With IRB permission, we biopsied distal-leg skin of 373 normal volunteers aged 8-92 years. They had been screened to exclude any with possible neuropathy, and adults had glucose-tolerance tests to exclude any with diabetes or pre-diabetes. Biopsies were vertically sectioned (50μm), PGP9.5-immunolabeled (Chemicon), and had ENF density measured by standard methods. 20 subjects had 2nd biopsies later for longitudinal study. **Results:** The 102 subjects younger than age 24 had far denser innervation than older adults (426 vs. 227 ENF/mm^2; $p<0.001$). Females had denser innervation than males (314 vs. 247/mm^2; $p<0.001$) and values from Asians were higher than from age-matched non-Asians (336 vs. 237/mm^2; $p<0.001$). Among the 13 subjects with repeat biopsies before age 24, mean density dropped by 46 ENF/mm^2/year, whereas in older subjects (n=9) losses slowed, averaging 13 ENF/mm^2/year. So we developed and use a multivariate normative model that incorporates age, gender, and race. We compared its diagnostic performance to the single normative threshold that most labs use (3.8 ENF/mm or 76 ENF/mm^2). In 2012-2013 our multivariate model identified ENF densities ≤ 5^{th} centile in 105 biopsies from patients under 41 years. In contrast, the single-threshold model only identified 26 among them (25%) as below the 5^{th} centile cutoff. Thus, labs that use this threshold may have a 75% false-negative rate that could hinder some SFPN patients from being diagnosed and treated. **Conclusions:** Skin-biopsy diagnosis of SFPN depends critically on having accurate norms for comparison. Adding demographic data into normative models improves diagnostic sensitivity, especially for younger, female, Asian patients. Evidence from both cross-sectional and longitudinal analyses suggest that children have superabundant epidermal innervation that is drastically pruned until the mid-20’s and then slowly declines throughout life, as occurs in the brain’s cortex.

Title: Hyperbaric oxygen produces antinociception in mice by activating CB1 cannabinoid receptors

Authors: *A. C. STOUDT[1,2], Y. ZHANG[1], D. Y. SHIRACHI[3], R. M. QUOCK[2,1];
[1]Integrative Physiol. and Neurosci., [2]Psychology, Washington State Univ., Pullman, WA;
[3]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: Exposure to increasing pressures of hyperbaric oxygen (HBO_2) produced a pressure-related antinociceptive response (Liu *et al.*, *Life Sci* 98:44-48, 2014). HBO_2 produces an acute antinociceptive effect in mice that is only partly antagonized by opioid receptor blockers (Heeman *et al., Brain Res* 1540:42-47, 2013). This study was conducted in order to determine whether HBO_2-induced antinociception might owe part of its effect to endocannabinoid mechanisms, which are also known to be involved in antinociception (Pertwee *et al.*, *Prog Neurobiol* 63:569-611, 2001). The antinociceptive responsiveness of male NIH Swiss mice to HBO_2 was assessed using the acetic acid abdominal constriction test. Different groups of mice were pretreated with the cannabinoid receptor type 1 (CB_1) antagonist/inverse agonist 1-(2,4-dichlorophenyl)-5-(4-iodophenyl)-4-methyl-N-1-piperidinyl-1H-pyrazole-3-carboxamide (AM 251); and the anandamine transport-inhibitor N-(4-hydroxyphenyl)-5Z,8Z,11Z,14Z-eicosatetraenamide (AM 404); or their respective vehicles. Pretreatment with AM 251 caused a dose-dependent reduction in the magnitude of the antinociceptive response. Pretreatment with AM 404, which increases the availability of anandamide, enhanced the antinociceptive response to HBO_2. These findings are consistent with the hypothesis that endocannabinoid systems may contribute at least in part to HBO_2-induced antinociception.

Title: ALGOGram™: a new research tool to valuate drugs in multiple pain areas

Authors: Y. DARBAKY, *L. DIOP;
ANS Biotech, Riom Cedex, France

Abstract: To evaluate the efficacy of exploratory compounds in different pain areas, various classical preclinical models are routinely used. For early drug discovery purposes, however, the full characterization package can be long and significantly expensive. To address this issue, we have developed an innovative screening tool, the ALGOGram™, a panel of behavioral pain models each validated with the most clinically relevant drugs. **Material and methods:** The ALGOGram™ is a battery of 11 validated animal models/tests spanning a broad range of pain areas (acute and tonic pain, neuropathic pain, inflammatory pain, post-operative pain, and visceral pain). The concept is an assessment of efficacy based on a group size of n=4 rats/model/test, thus providing a general pharmacological profile while reducing costs; assays/test are run in parallel, thus minimizing timelines. To validate the ALGOGram™, various reference drugs classically used in clinical pain practice (morphine, gabapentin, buprenorphine, tramadol, acetaminophen and diclofenac) were evaluated in the 11 pain models / tests (models: CCI, oxaliplatin, carrageenan, kaolin, post-operative and TNBS; tests: paw pressure, tail flick, writhing and formalin). Behavioral and acute toxicity were also evaluated (modified Irwin grid). Results are expressed for each group as a percentage of activity for each model/test calculated from the mean value of the vehicle-treated animals from our 9 year-historical database. **Results:** Buprenorphine, morphine and tramadol were active in all 11 different pain models. In contrast, gabapentin was active in several hypersensitive pain models. Diclofenac and acetaminophen displayed antinociceptive properties in some inflammatory pain models . Importantly, analgesic profiles obtained with n=4 animals in the ALGOGram™ were in line with those generated in various and repeated fully-powered studies as well as those described in the literature. **Conclusion:** The ALGOGram™ provides a rapid and predictive evaluation of investigational compounds in 11 different pain models/tests, enabling their prioritization for fully-powered studies. Shortened timelines and reduced costs are possible due to small group sizes that are run largely in parallel. In summary, the ALGOGram™ may prove to be useful in a signal detection exercise for a broad range of potential analgesic activity.

Title: The formalin test: initial excitation and biphasic activation

Authors: K. KISTNER[1], T. HOFFMANN[1], S. SAUER[1], T. KICHKO[1], P. REEH[1], *M. J. FISCHER[2];
[1]Inst. of Physiol. and Pathophysiology, Univ. of Erlangen-Nürnberg, Erlangen, Germany; [2]Univ. of Erlangen-Nuremburg, Erlangen, Germany

Abstract: In the formalin test, formaldehyde causes a characteristic biphasic pain behavior in rodents. We have recently hypothesized a mechanism explaining the occurrence of two phases. Initial excitation is rapidly followed by hyperpolarization due to a sodium current inhibition which silences primary afferents. Redistribution of formaldehyde recruits previously unexposed areas which leads to a secondary activation which is later terminated by further redistribution. Upon exposure to formaldehyde 30mM compound action potentials of nociceptive C-fibers showed a progressive increase in latency and decrease in amplitude, leading to complete and partially reversible conduction block. A-fibers showed slightly less sensitivity to formaldehyde but no recovery of conduction block. The mechanism of the initial activation phase by formaldehyde was so far unclear. The chemoreceptor channel TRPA1 was suggested as primary transducer, but the high concentrations used in the formalin test elicited a similar response in both TRPA1 wildtype and knockout animals. The present study addresses the cellular mechanism of the excitatory action of formaldehyde. We show via release of the neuropeptide CGRP from intact tissue that formaldehyde 40 mM causes a considerable activation in TRPA1 knockout animals. Formaldehyde 40 mM evokes a dose-dependent increase in cytosolic calcium. This calcium release stems from intracellular stores, as is present in the absence of extracellular calcium. This response and can be eliminated by depletion of intracellular calcium stores in the endoplasmic reticulum but not by depletion of mitochondrial calcium stores. The described mechanism was observed in all cells tested, including mouse sensory neurons and primary keratinocytes, but also in non-neuronal cell lines, and is therefore independent of TRPA1. Inhibition of the sarco/endoplasmic reticulum calcium-ATPase had a major contribution. Many cellular excitability pathways are calcium dependent. We thus hypothesize that the above TRPA1-independent mechanism may underlie formaldehyde-induced pan-neuronal excitation and subsequent inflammation in the peripheral nociceptive system.

Title: AMPAKines relieve both pain and pain-related depression by potentiating AMPA receptors in the nucleus accumbens

Authors: *C. SU[1], H. LIN[1], N. PAWLAK[2], J. WANG[1];
[1]Anesthesia, NYU Med. Ctr., New York, NY; [2]New York Universty, New York, NY

Abstract: Background: Pain and its associated comorbidities such as depression are a serious public health problem. Novel analgesic options that do not suppress the respiratory drive are urgently needed. AMPAkines potentiate AMPA receptor signaling and have been shown to oppose sedative-induced respiratory depression. Our previous study has shown that systemic administration of an AMPAkine, CX546, can relieve both sensory and depressive symptoms of chronic neuropathic and inflammatory pain in rats. However, the following questions remain unanswered. 1) Can AMPAkines relieve sensory and affective symptoms of acute pain as well? 2) What is the mechanism for AMKAkine analgesia? Recent human imaging and animal studies suggest that glutamate signaling in the nucleus accumbens (NAc) plays a critical role in pain regulation. Thus, we hypothesized that AMPAkines can relieve acute and chronic pain by potentiating glutamate transmission through AMPA receptors in the NAc. Methods: We used paw incision (PI) and spared nerve injury (SNI) to model acute pain and chronic neuropathic pain in rats. CX546 was administered systemically or locally infused into the NAc in both pain models. We used mechanical allodynia to assay the effect of AMPAkines on sensory pain symptoms. We used the forced swim test (FST) to assess the effect of AMPAkines on the depressive symptoms of pain. To further verify the specificity of the NAc as a pharmacologic target for AMPAkines, we infused 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f]quinoxaline-2,3-dione (NBQX), an antagonist of AMPA receptors, into the NAc to block the pain-relieving effects of systemic administration of CX546. Results: Compared with control, systemic administration of CX546 reduced sensory allodynia in the PI model. In addition, local infusion of CX546 into the NAc also reduced sensory allodynia. Furthermore, both systemic and local (intra-NAc) infusion of CX546 reduced depressive symptoms of acute pain, as shown by an improved performance on the FST test. Meanwhile, in the SNI model, local infusion of CX546 also reduced sensory and depressive symptoms of pain. Finally, we found that NBQX in the NAc blocked the effects of systemically administration of CX546 on mechanical allodynia and FST in both PI and SNI models. Conclusion: Our results demonstrate that CX546, an AMPAkine, can relieve both sensory and depressive symptoms of acute and chronic pain. Furthermore, the pain-

relieving property of the CX546 is likely mediated by its potentiating effect on AMPA receptors in the NAc. Thus, these drugs can be a novel class of analgesics for the treatment of both acute and chronic pain.

Title: Antinociceptive effects of JWH015, a synthetic cannabinoid

Authors: N. Z. GREENE, *R. M. CRAFT;
Washington State Univ., Pullman, WA

Abstract: The primary psychoactive ingredient in marijuana, THC, is a cannabinoid that produces pain relief by acting at CB1 and CB2 receptors in the nervous system. However, THC's actions at CB1 receptors also result in unwanted side-effects such as sedation, anxiety, and feeling "high." Synthetic cannabinoids have been developed that have CB2 receptor selectivity, and these may be useful in the treatment of chronic pain while producing fewer unwanted side-effects than THC. While previous research has suggested that there are sex differences in THC's mechanism of action at CB1 and CB2 receptors, there is little data regarding potential sex differences in the mechanism of action of synthetic, CB2-preferring cannabinoids. Using the Complete Freund's Adjuvant (CFA) model of chronic inflammatory pain, the antinociceptive effects of the synthetic, CB2-preferring cannabinoid JWH015 were examined in rats of both sexes. Rats received an injection of CFA into one hind paw, creating a model of chronic inflammatory pain. Three days after CFA injection, rats received either vehicle or the CB2-preferring cannabinoid JWH015 (5 or 10 mg/kg), and pain tests were conducted at 15-240 minutes post-injection. In both sexes, JWH015 significantly decreased CFA-induced mechanical and thermal hypersensitivity, with no significant reduction in biased weight-bearing or in edema. In a subsequent experiment, cannabinoid antagonists were used to determine whether JWH015's antinociceptive effects are mediated by the CB1 and/or CB2 receptor. Three days after receiving CFA, vehicle, the CB1 receptor-selective antagonist rimonabant (1 mg/kg), or the CB2 receptor-selective antagonist SR144528 (1 mg/kg) was administered; 30 minutes later, vehicle or

JWH015 (10 mg/kg) was administered. Rimonabant and SR144528 each significantly reversed JWH015's effects in both sexes. This result indicates that JWH015's antinociceptive effects are mediated by both CB1 and CB2 receptors in both males and females. Therefore, despite its CB2-preferring binding profile, JWH015 may not provide any significant clinical advantage over THC in the treatment of chronic pain.

Title: Mechanism underlying oral ulcerative mucositis-induced pain in chemotherapy-received rat model

Authors: K. YAMAGUCHI, *K. ONO, S. HITOMI, N. HARANO, T. SAGO, S. WATANABE, K. INENAGA;
Kyushu Dent. Univ., Fukuoka, Japan

Abstract: In many cancer patients, oral ulcerative mucositis is developed as a side effect of chemotherapy and causes severe pain. However, oral ulcerative mucositis-induced pain following chemotherapy has not been studied well. In this study, we investigated pain-related behaviors in oral ulcer model of rats with intraperitoneal administration of the chemotherapeutic drug, 5-fluorouracil (cumulative dose: 120 mg/kg). Using our recently-developed assay system for intraoral pain in conscious rats, spontaneous pain, evoked pain, and mechanical allodynia were evaluated from spontaneous mouth rubbing time, evoked mouth rubbing time after drop of stimulus-containing solution on oral mucosa, and head-withdrawal threshold to mechanical stimulation to the mucosa, respectively. The model showed long-term leukopenia, severe oral mucositis, and excessive bacterial colonization in the ulcer region compared with saline administration. Oral ulcer-induced spontaneous pain and mechanical allodynia were exaggerated following 5-fluorouracil administration. Antibacterial pretreatment suppressed the spontaneous pain largely and mechanical allodynia partially. The spontaneous pain was largely suppressed by indomethacin administration, but the mechanical allodynia was not changed. Dropping application of the TRPV1 agonist capsaicin in the oral mucosa transiently evoked mouth rubbing

and the behavior was further exaggerated by 5-fluorouracil. In 5-fluorouracil administrated oral ulcer model, administration of the TRPV1 antagonist SB366791 significantly inhibited not only the capsaicin-evoked pain, but also spontaneous pain. From these results, spontaneous and capsaicin-evoked pain in the 5-fluorouracil-administrated model are mainly mediated by infectious inflammation via TRPV1 activation. Mechanical allodynia is caused by mucosal tissue injury and/or bacterial toxins, based on sensitivity to antibacterial pretreatment and resistant to indomethacin.

Title: Anti nociceptive effects of carica papaya leaves extract: modulation by dopaminergic, gabaergic and serotonergic receptors

Authors: ***B. V. OWOYELE**[1], R. A. AWEDA[2], A. A. BABALOLA[2];
[1]Physiol., Univ. of Ilorin, Ilorin, Nigeria; [2]Physiol., Univ. of Ilorin, Ilorin, Nigeria

Abstract: Pain is the most common factor for patients visit to the clinics. However, the available drugs can not treat all the various types of pain without the manifestations of side effects. Therefore, there is increasing research on alternative sources of therapeutic agents for the treatment of pain. The anti-nociceptive and anti-inflammatory effects of Carica papaya extracts (CPE) have been reported in the literature but the mechanism of action has not been fully described. The aim of the present study therefore, is to investigate the possible role of dopaminergic gabaergic and serotonergic receptor mechanisms on the analgesic effects of CPE in Wistar rats using the antagonists bicuculline, phaclofen, risperidone and haloperidol. The animals were divided into seven groups based on the drugs/saline administered. The control group received saline and the reference group received indomethacin (10 mg/kg). The other five groups received CPE (150 mg/kg), bicuculline (2mg/kg) + CPE (150 mg/kg), phaclofen (1mg/kg) + CPE (150 mg/kg), risperidone (2mg/kg) + CPE (150 mg/kg), and haloperidol (1 mg/kg)+CPE (150 mg/kg). Anti nociceptive activities were accessed by tail immersion and formalin-induced paw licking models. The results showed that all the antagonists used enhanced the anti nociceptive effect of CPE in the thermal pain but the effects of bicuculline was more

pronounced. However, the antagonist only enhanced the antinociception in the late phase of the formalin induced pain. In conclusion, the analgesic effects of CPE is not via stimulation of dopaminergic, gabaergic and serotonergic receptors but blockage of these receptors can enhance the anti-nociceptive effect of CPE.

Title: Oxytocin alleviates orofacial hypersensitivity following infraorbital nerve injury in rats

Authors: ***A. KUBO**[1], M. SHINODA[1], D. C. YEOMANS[2], K. IWATA[1];
[1]Dept. of Physiol., Nihon Univ. Sch. of Dent., Tokyo, Japan; [2]Fac. of Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Oxytocin (OXT) is one of the neuropeptides synthesized and secreted from neurons in the paraventricular nucleus and supraoptic nucleus of hypothalamus. Many reports have suggested that OXT plays an important role in pain modulation and analgesia. However, the underlying mechanisms regarding anti-nociceptive effect on neuropathic pain are not fully understood. We examined the effect of OXT on trigeminal neuropathic pain associated with partial ligation of the infraorbital nerve in rats. The head-withdrawal threshold to mechanical stimulation (MHWT) of the maxillary whisker pad skin on the side ipsilateral to the ligation was measured using von Frey filaments. After confirming of the reduced MHWTs 5-8 days after nerve ligation (the mean of reduced MHWTs, 10.8 ± 5.3 g), MHWTs were measured 2, 5, 8 and 24 hrs after OXT (1 mM, 1 μl) administration into the trigeminal ganglion (TG) using the injection-cannula set. The reduced MHWTs were significantly recovered at 2 and 5 hrs after the OXT administration compared with that of vehicle (PBS) (2 hrs after: OXT group, 35.4 ± 4.2 g; PBS group, 10.8 ± 3.9 g; $p < 0.01$; 5 hrs after: OXT group, 35.6 ± 10.9 g; PBS group, 14.8 ± 5.2; $p < 0.05$; $n = 5$ in each group). This effect did not sustain until 8 hrs after and completely

returned to the pre-administration level 24 hrs after the OXT administration. We also examined the change in the excitability of TG neurons acutely isolated from the neuropathic pain model rats. Ten μM of OXT was applied in the culture medium 2-5.5 hrs before patch-clamp recording. The resting membrane potentials of OXT-treated TG neurons were significantly decreased (OXT group, -63.4 ± 1.1 mV; PBS group, -56.2 ± 2.2 mV; $p < 0.01$; $n = 12$ in each group). Threshold currents in OXT-treated neurons for spike generation during current injection were also significantly greater than that of PBS (OXT group, 163.3 ± 27.6 pA; PBS group, 89.2 ± 12.4 pA; $p < 0.05$; $n = 12$ in each group). Present findings suggest that OXT could be at least partially effective on the suppression of hyperexcitability of TG neurons and exert analgesia on orofacial neuropathic pain.

Title: Novel methylcyclohexyl benzene derivatives: functional cannabinoid receptor mediated antinociception vs cannabimimetic effects in mice

Authors: *J. L. WILKERSON[1], T. GRIM[1], A. MORALES[1], M. BHOWMICK[2], A. MAHADEVAN[2], A. H. LICHTMAN[1];
[1]Dept. of Pharmacol. & Toxicology, Virginia Commonwealth Univ. MCV, Richmond, VA;
[2]Organix Inc., Woburn, MA

Abstract: Aims: Therapeutic options that lack potential abuse liability for the treatment of pathological pain are desperately needed. Novel methylcyclohexyl benzene derivatives have been synthesized for the intended therapeutic development of new analgesics that may activate cannabinoid receptors. Activation of the cannabinoid receptors, either the cannabinoid 1 receptor

predominately found on neurons (CB1R) or the cannabinoid 2 receptor (CB2R), predominately found on immune cells, have shown promise in preclinical animal models for pain control. However, activation of the CB1R leads to cannabimimetic effects, and is undesirable for pain therapeutics. Here we sought to characterize the antinociceptive effects of novel methylcyclohexyl benzene derivatives, determine the degree to which CB1R and/or CB2R mediates these effects, and examine common cannabimimetic side effects that would dampen enthusiasm for clinical development. Methods: The chronic constriction injury (CCI) of the sciatic nerve model of neuropathic pain or sham surgeries were performed in male ICR mice. CCI produces robust increases in sensitivity to light mechanical touch, or allodynia, as assayed with the von Frey test, and increased thermal sensitivity, or thermal hyperalgesia, as assayed with the hotplate test. Cannabimimetic effects were inferred by the occurrence of hypothermia, catalepsy, and antinociception in ICR mice. The dose response of each drug was assessed in each assay, and all compounds were administered intraperitoneally. Results: The novel methylcyclohexyl benzene derivatives O-9598, O-9599, and O-9603 produced dose-dependent and time-dependent reversal of allodynia and thermal hyperalgesia, with the calculated ED50 for anti-allodynic effects being 0.54, 12.43, and 53.17 mg/kg, respectively. The anti-thermal hyperalgesia ED50 for O-9598, O-9599 and O-9603 were calculated to be 3.48, 15.02, and 51.59 mg/kg, respectively. The CB1R antagonist rimonabant, but not the CB2R antagonist SR144528, fully blocked in both ipsilateral and contralateral paws the anti-allodynic and anti-thermal hyperalgesic effects of O-9598 and O-9602. Interestingly, whereas in the ipsilateral paw, the anti-allodynic effects of O-9599 were blocked by rimonabant, SR144528 blocked the anti-allodynia effects in the contralateral paw and in the hotplate test. Finally, O-9598, but not O-9599 or O-9603 produced significant cannabimimetic effects. Conclusions: Novel methylcyclohexyl benzene derivatives show efficacy in the CCI preclinical model of neuropathic pain. Out of the compounds assessed thus far, O-9599 displays the best profile as a potential lead compound.

Title: Influence of GPR40/FFA1 on the regulation of central post-stroke pain

Authors: *S. TOKUYAMA, S. HARADA, K. NAKAMOTO;
Kobe Gakuin Univ., Kobe, Japan

Abstract: Central post-stroke pain (CPSP) is one of the complications of cerebral ischemia and neuropathic pain syndrome. In this study, we assessed the role of GPR40/FFA1, a long-chain fatty acid receptor, showing anti-nociceptive effects mediated by the release of β-endorphin, in CPSP. We also examined the role of astrocytes in CPSP due to their effects in mediating the release of polyunsaturated fatty acids. The aim of this study was to determine the interactions between CPSP and astrocyte/GPR40 signaling. Male ddY mice were subjected to 30 min of bilateral carotid artery occlusion (BCAO). The development of hind paw mechanical hyperalgesia was measured using the von Frey test. Neuronal damage was estimated by histological analysis on day 3 after BCAO. Analysis of free fatty acids (FFAs) in the mouse hypothalamus used LC-ESI-MS/MS methods. The thresholds for hind paw mechanical hyperalgesia were significantly decreased on days 1-28 after BCAO when compared with pre-BCAO assessments. BCAO-induced mechanical hyperalgesia was significantly decreased by intracerebroventricular injection of docosahexaenoic acid or GW9508, a GPR40/FFA1 agonist; furthermore, these effects were reversed by GW1100, a GPR40/FFA1 antagonist. The expression levels of glial fibrillary acidic protein, an astrocytic marker, were significantly decreased 5 h after BCAO, but not hypothalamic GPR40/FFA1 protein expression. At 5 hr after BCAO, some FFAs (palmitate, stearate, oleinic acid, linoleic acid, arachidonic acid and DHA) were significantly decreased as compared with sham group. These results suggest that BCAO-induced mechanical hyperalgesia can be regulated by astrocyte activation and stimulation of GPR40/FFA1 signaling.

Title: Olfactory bulb evoked field potential by electrical stimulation of the olfactory epithelium in the anesthetised mouse: development of a potential Nav1.7 channel blocker assay

Authors: *J. ALLARD, W. MINER;
E-Phys, Clermont-Ferrand, France

Abstract: The voltage gated sodium channel 1.7 (Nav1.7) is mandatory for the transmission of action potentials from olfactory sensory neurons to their post-synaptic target in the olfactory bulb (OB). Thus, evoked field potential (EFP) in the OB to electrical stimulation of the olfactory epithelium (i.e. orthodromic OB EFP) should constitute a useful *in vivo* Nav1.7 channel blocker assay. The aim of this work was to set up such an assay in anaesthetised mice. Antidromic EFP generated by stimulation of the lateral olfactory tract (LOT) was performed as a control. C57BL/6J mice were anesthetised with urethane. The animal's head was placed in a stereotaxic frame. Holes were made above the parietal, frontal and nasal bones for access to the LOT, the OB or the nasal cavity, respectively. Electrical stimulation of the LOT and olfactory epithelium was conducted with bipolar concentric and paired platinum wire electrodes, respectively. A single parylene-coated tungsten electrode was used for recording. EFP were recorded at different depths in the OB. Stimulus intensity-response curves were constructed via recordings in the granule cell layer. Local application of lidocaine, CoCl2 and tetrodotoxin (TTX) at the surface of the site of recording, as well as neuromuscular blockade, were used to assess the specificity of the recorded EFP. The shape of the EFP was depth dependent. In the granule cell layer, both orthodromic and antidromic EFP were mainly characterized by a large positive deflection, with an average latency of 10.7 and 2.4 ms respectively, followed by a negative deflection. The amplitude of the positive deflection was approximately 5 times greater, and its duration 3 times shorter with antidromic stimulation compared with orthodromic stimulation. The negative deflection was also much larger (amplitude and duration) with antidromic stimulation. Stimulus intensity-responses of orthodromic EFP were right shifted compared to antidromic EFP. The area under the curve of the rectified orthodromic EFP was decreased by about 80% when 2% lidocaine was applied at the recording site, and by 40% when CoCl2 10 mM was used. It was virtually abolished when TTX was applied at 10 μM. In contrast, antidromic EFP was barely affected by local application of CoCl2 at the recording site, and less sensitive to the inhibitory effect of lidocaine. Neuromuscular blockade did not change EFP. The shape, latency and lidocaine sensitivity of the orthodromic OB EFP recorded suggest that the signal measured was not an artefact. Nevertheless, the high concentration of TTX necessary to abolish the response, and the partial sensitivity to CoCl2 requires further investigation to ensure specificity of the assay.

Title: A comparison between nonhuman primate and rat models of acute chemotherapy-induced peripheral neuropathy

Authors: Y. SHIDAHARA[1], S. NEMOTO[1], Y. AWAGA[1], M. TAKASHIMA[1], *A. HAMA[1], A. MATSUDA[1], H. TAKAMATSU[1], K. UMEMURA[2];
[1]Hamamatsu Pharma Research, Inc., Hamamatsu, Japan; [2]Pharmacol., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Oxaliplatin is a key platinum-based chemotherapeutic used in the treatment of colorectal cancer. Unique to other chemotherapeutics, oxaliplatin causes an acute cold hypersensitivity in the extremities which appears within hours or days after infusion. This peripheral neuropathy is disabling and is often a reason to limit or terminate treatment. Thus, there is a need for treatments that alleviate neuropathic symptoms so that fully efficacious oxaliplatin treatment can be utilized. There is currently a lack of treatments for oxaliplatin-induced peripheral neuropathy. The lack of treatments is due in part to a lack of confidence of the predictiveness of preclinical rodent models of chemotherapy-induced peripheral neuropathy. Thus, a nonhuman primate (NHP) model of oxaliplatin-induced peripheral neuropathy was developed and a comparison of the effects of clinical analgesics, between the NHP model and a rat model of oxaliplatin-induced peripheral neuropathy, was performed. In NHP, sensitivity of the feet to pressure was assessed using a hand-held pressure meter. In rats, sensitivity to cold was assessed by application of acetone to the hind paw and in NHP, tail withdrawal latency (in seconds) to cold water (10 oC) was measured. In oxaliplatin-treated rats, increased responding to acetone (“cold allodynia”) was observed 17 days after the first dose of oxaliplatin. In NHPs, a significant decrease in withdrawal latency to cold water (“cold allodynia”) was observed beginning 3 days after oxaliplatin infusion. In oxaliplatin-treated NHP, no significant change was observed in response to pressure. Pregabalin (30 mg/kg, p.o.), tramadol (30 mg/kg, p.o.) and duloxetine (30 mg/kg, p.o.) ameliorated oxaliplatin-induced cold allodynia in rats. While duloxetine (30 mg/kg, p.o.) ameliorated oxaliplatin-induced cold allodynia in NHP, pregabalin (30 mg/kg, p.o.) and tramadol (30 mg/kg p.o.) had no effect on cold allodynia. These results indicate that pain-related behavior seen in NHP is similar to that observed in clinical oxaliplatin-induced peripheral neuropathy. Furthermore, the efficacy of the drugs in the NHP model mirrors the efficacy observed clinically. The current NHP model could be highly useful in testing novel treatments for oxaliplatin-induced peripheral neuropathy.

Title: Microglia contribute to non-inflammatory pain in early phases of collagen-induced arthritis

Authors: F. R. NIETO[1], A. K. CLARK[1], J. GRIST[1], V. CHAPMAN[2], *M. A. MALCANGIO[3]; [1]The Wolfson Ctr. for Age-Related Dis., King's Col. London, London, United Kingdom; [2]Arthritis Res. UK Pain Centre, Sch. of Life Sci., Univ. of Nottingham, Nottingham, United Kingdom; [3]Wolfson CARD, The Wolfson Wing, London, United Kingdom

Abstract: Despite pain being a dominant feature of rheumatoid arthritis (RA), our understanding of RA pain mechanisms is modest. Specifically, the weak correlation between pain and swelling in patients, suggests that mechanisms other than overt inflammation contribute to pain in RA. This clinical observation is mirrored in the early development phase of collagen-induced arthritis (CIA) in the rat, in which mechanical hypersensitivity develops before inflammation in the hind paw. We hypothesised that in the CIA model of RA the early non-inflammatory pain behaviour is due to activation of nociceptors and spinal sensitization mechanisms, including a significant microglia response. Thus, we evaluated the extent of a microglial response in the dorsal horn and hind paw mechanical hypersensitivity in the absence and presence of swelling. Then, we quantified cyto(chemo)kine levels in the CSF as candidate pro-nociceptive mediators released by activated microglia. Finally, we tested the effect of microglial inhibitors on the development of pain as well as spinal microgliosis and cyto(chemo)kine levels in the cerebrospinal fluid (CSF). We observed that CIA rats, but not control rats, displayed significant microgliosis (increased

number of Iba1 p-p38 positive cells) in the dorsal horn from day 7 (before the onset of signs of arthritis e.g. swelling) up to day 18 post-immunization. At this time interval from immunization microgliosis had reached its highest levels which coincided with mechanical hypersensitivity and severe swelling in the hind paws. The levels of IL-1β in CSF of 7 day-CIA rats were significantly higher than in controls and just detectable in plasma (Multiplex assay). Similarly, FKN levels in CSF of 13 day-CIA rats were higher than in controls (ELISA). These data suggest that there is a central source for these cyto(chemo)kines and microglia are likely to contribute to the release and effect of these pro-nociceptive mediators. Consistently, intrathecal delivery of the microglial inhibitor LHVS (from 24 h prior to 13 days after immunization) attenuated i) development of mechanical hypersensitivity, ii) spinal microglial response and iii) increment of FKN in the CSF. In addition the delivery of a FKN-neutralising antibody (from 24 h prior to 13 days after immunization) attenuated the development of mechanical hypersensitivity and spinal microglial response in CIA rats. However neither treatment affected hind paw swelling. Altogether these data suggest that microglia play a key role in the central mechanisms of non-inflammatory pain in arthritis. Thus, the inhibition of microglia-driven mechanisms provides opportunities for the treatment of this early pain.

Title: [Leu11]-HK-1-derived peptides with D-Trp have longer antipruriceptive effects in rats

Authors: H. FUNAHASHI[1], R. NAONO-NAKAYAMA[2], Y. MIYAHARA[1], *Y. ISHIDA[1], T. NISHIMORI[1];
[1]Dep Psychiatry, Fac of Med, Univ. Miyazaki, Miyazaki, Japan; [2]Div. Integrative Physiology, Fac Medicine, Univ. Miyazaki, Miyazaki, Japan

Abstract: Hemokinin-1 (HK-1) is a mammalian tachykinin peptide consisting of 11 amino acids. Recently, it was demonstrated that the pretreatment with [Leu11]-HK-1, in which Met at the C-terminal of HK-1 was replaced by Leu, attenuated scratching induced by intrathecal administration of HK-1. In addition, the pretreatment with [Leu11]-HK-1 reduced the induction of scratching behavior by pruritogens such as histamine and serotonin, suggesting that [Leu11]-HK-1 may have an inhibitory effect on itch processing. Furthermore, it is believed that replacement of amino acids by D-tryptophan (D-Trp), prolongs the duration of effective time. Therefore, to clarify the duration of effective time of [Leu11]-HK-1-derived peptides, the effect of pretreatment with [D-Trp7]-[Leu11]-HK-1, [D-Trp9]-[Leu11]-HK-1 and [D-Trp7,9]-[Leu11]-HK-1 on the induction of scratching behavior by the intrathecal administration of HK-1 and by the intradermal injection of chloroquine was evaluated. The induction of scratching by intrathecal administration of HK-1 was significantly suppressed until 24 hours after pretreatment with [D-Trp7]-[Leu11]-HK-1 and [D-Trp9]-[Leu11]-HK-1 and 4 hours after [D-Trp7,9]-[Leu11]-HK-1 treatment. On the other hand, intrathecal administration of [D-Trp7,9]-[Leu11]-HK-1 and [D-Trp9]-[Leu11]-HK-1 similarly inhibited the induction of scratching behavior by intradermal administration of a pruritogen, chloroquine. Taken together, these results suggest that the antipruriceptive effects of [Leu11]-HK-1-derived peptides replaced by D-Trp may be unrelated to the number of D-Trp.

Title: Anti-allodynic effect of a sigma-1 antagonist in a model of neuropathic pain in rats

Authors: J. V. ESPINOSA-JUAREZ[1], O. A. JARAMILLO-MORALES[1], J. N. CORONA-RAMOS[1], J. G. NAVARRETE-VÁZQUEZ[2], *F. J. LOPEZ MUNOZ[1];
[1]CINVESTAV, Mexico, Mexico; [2]Univ. Atonoma del Estado de Morelos, Morelos, Mexico

Abstract: BACKGROUND. The treatment of neuropathic pain is performed according to the etiology, the most used drugs are neuromodulators, however exist others that may be potentially useful. The aim of this study was to compare the anti-allodynic effects (efficacy and potency) of a sigma-1 antagonist (BD-1063) and gabapentin using a model of neuropathic pain. METHODS: Wistar male rats were employed and subjected to chronic constriction injury (CCI), 10 days after surgery the anti-allodynic effect (acetone test) after single-dose of gabapentin (3.2-177.8 mg/kg p.o) and BD-1063 (5.6-56.2 mg/kg s.c.) were tested. RESULTS: In all cases the anti-allodynic effects increased in a dose-dependent manner. The time-course analysis shows that gabapentin (100 mg/kg) reached its maximum effect at 30 min after the treatment, producing an anti-allodynic effect of 65.5 ± 6.9 %, whereas BD-1063 (56.2 mg/kg) produced their maximum effect at 30 min with 90.8 ± 2.7 %; these anti-allodynic effects remained during 180 min of observation. Analyzing dose-response curves, BD-1063 exhibited similar efficacy to gabapentin. For its part regarding the analysis of pharmacological potency, we compare the ED50, BD-1063 antagonist showed higher potency than gabapentin. CONCLUSION: These results suggest that the antagonist of the sigma-1 receptor could be as effective as the reference drug gabapentin (similar efficacy and Emax) in the treatment of neuropathic pain. But the anti-allodynic effect could be achieved with lower doses of the sigma-1 antagonist (because its greater anti-allodynic potency).

Title: Investigating the antinociceptive effect of hyperbaric oxygen in an animal model of fibromyalgia: role of nitric oxide

Authors: *P. SMITH[1], A. L. BREWER[1], Y. ZHANG[2], D. Y. SHIRACHI[3], R. M. QUOCK[1]; [1]Psychology, [2]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA; [3]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: Hyperbaric oxygen (HBO_2) has been shown to produce antinociception in acute, chronic, and inflammatory pain models in animals [Chung *et al., J Pain,* 11:847-853, 2010; Gibbons *et al.*, *Brain Res.* 1537:111-116, 2013; Sümen *et al., Eur J Pharmacol* 431:265-268, 2001]. This antinociceptive effect of HBO_2 has been shown to last for up to two weeks in both chronic and acute pain models [Gibbons *et al.*, *ibid.*; Chung *et al., ibid.*]. The antinociceptive effect of HBO_2 is mediated by nitric oxide (NO) according to previous studies [Chung *et al., ibid.*]. It has been reported that HBO_2 is effective in reducing pain in human subjects suffering from fibromyalgia [Yildiz *et al., J Int Med Res* 32:263-267*,* 2004]. The mechanism of HBO_2-induced antinociception in fibromyalgia has not been investigated to our knowledge. The acidic saline model is a rodent model of fibromyalgia and has been shown to mimic some of the symptoms of the disease [Sluka *et al., Muscle Nerve* 24:37-46*,* 2001]. The aim of this work was to determine if treatment with HBO_2 treatment was effective in reducing nociception in an animal model of fibromyalgia and ascertain whether NO mediates the antinociceptive effect of HBO_2. Baseline paw pressure measures were taken, using a Randall-Selitto paw pressure analgesy-meter (Ugo Basile). Animals were injected unilaterally in the gastrocnemius muscle with 20 µl pH 4 acidic saline or pH 7 saline (vehicle). Two days later, animals were injected again with either acidic saline or saline. After 90 min recovery, animals were exposed to a single 60-min treatment of HBO_2 at 3.5 ATA or exposed to room air. After another 90 min, mice were assessed, using the paw pressure assay. Results indicate that a single 60-min treatment of HBO_2 significantly increased paw pinch thresholds compared to animals exposed only to the acidic saline model of fibromyalgia. Other groups of mice were injected s.c. with either L-N^G-nitro-arginine (L-NOARG) or vehicle 60 min before pain testing. We showed that the HBO^2-induced antinociceptive effect was reversed by inhibition of nitric oxide synthase. These data indicate that HBO_2 effectively reduces nociception caused in the acidic saline model and that the antinociceptive effect of HBO_2 may be mediated by production of nitric oxide.

Title: Hyperbaric oxygen suppresses paclitaxel-induced neuropathic pain through the rostral ventromedial medulla (RVM)

Authors: Y. ZHANG[1], D. Y. SHIRACHI[3], *R. M. QUOCK[2];
[1]Integrative Physiol. and Neurosci., [2]Psychology, Washington State Univ., Pullman, WA;
[3]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: Hyperbaric oxygen (HBO_2) treatment can produce antinociception in rats with various neuropathic pain conditions [Thompson *et al.*, *Neurosci Res* 66:279-283, 2010; Gibbons *et al.*, *Brain Res* 1537:111-116, 2013]. Recently we reported that HBO_2 suppressed paclitaxel-induced neuropathic pain via a supraspinal mechanism in rats [Zhang *et al.*, *4th Int Cong Neuropathic Pain*, 2013]. It is known that the rostral ventromedial medulla (RVM) is the output of the pain-modulating system in the brain, and sends descending signals to the dorsal horn to modulate nociception. The aim of this study is to examine whether the RVM is involved in the pathway by which HBO_2 suppresses neuropathic pain. Male Sprague Dawley rats developed neuropathic pain following four repeated injections of 1.0 mg/kg paclitaxel, which was assessed by both mechanical and cold allodynia. After the last injection of paclitaxel, the rats received a single or four daily 60-min treatments with HBO_2 at 3.5 atmospheres absolute. To test involvement of the RVM, 2% w/v lidocaine in 0.5 μL saline was delivered into the RVM by microinjection immediately before HBO_2 treatment [Saadé *et al.*, *Pain* 149:89-99, 2010]. The assessment of allodynic response was carried out every other day and lasted for 32 days after the first paclitaxel injection. Results showed that a single HBO_2 treatment suppressed paclitaxel-induced mechanical allodynia, but not cold allodynia. Four repeated HBO_2 treatments reduced the cold allodynia. However, the antinociceptive effect of HBO_2 on mechanical allodynia was blocked by the microinjection of lidocaine into the RVM. This demonstrated that HBO_2 indeed suppressed paclitaxel-induced neuropathic pain via the RVM.

Abstract: Much evidence from preclinical work suggests that activation of metabotropic glutamate 2/3 (mGlu2/3) receptors could be an effective analgesic in chronic pain conditions. In this account, the analgesic properties of a novel mGlu2/3 receptor agonist prodrug were investigated. After oral absorption, the prodrug LY2969822 rapidly converts to the brain penetrant, potent, and subtype-selective mGlu2/3 agonist LY2934747 [1]. Behavioral assessments of allodynia, hyperalgesia, or nocifensive behaviors in preclinical pain models, after administration of prodrug LY2969822 as active equivalent doses of 0.3 - 10 mg/kg were conducted 1-4 hrs post treatment. In addition, the ability of i.v. administrated LY2934747 to modulate dorsal horn spinal cord wide dynamic range (WDR) neurons in naïve and spinal nerve ligated (SNL) rats was assessed for effects on spontaneous activity, electrically-evoked wind-up, and resulting after-discharge. Following a 1 or 10 mg/kg i.v. dose of LY2934747, the spontaneous activity and the electrically-evoked wind-up of WDR neurons in rats that had undergone spinal nerve ligation and developed mechanical allodynia was suppressed. Also, following a 10 mg/kg i.v. dose of LY2934747, the electrically-evoked wind-up of WDR neurons in naïve rats was significantly decreased compared to baseline measurements. In a model of sensitization, LY2969822 (p.o.) or LY2934747 (i.p.) prevented the nociceptive behaviors induced with intraplantar formalin injection with ED_{50} values of 3.2 mg/kg and 0.7 mg/kg, respectively. The on-target nature of this effect was confirmed by demonstrating pharmacological blockade with the mGlu2/3 antagonist LY341495. A 10 mg/kg dose of LY2969822 prevented tactile hypersensitivity with intraplantar capsaicin and reversed the SNL-induced tactile hypersensitivity. In addition, LY2969822, over a similar dose range (3-10 mg/kg), decreased mechanical hyperalgesia seen with intraplantar Complete Freund's Adjuvant (CFA) injection. The mGlu2/3 agonist prodrug demonstrated efficacy in visceral pain models, including a colorectal distension model and partially preventing the nocifensive behaviors in the mouse acetic acid writhing model. Partial or inconsistent decreases in nocifensive responses were seen in rat capsaicin-induced thermal hyperalgesia and the tactile hypersensitivity assessed 24 hours after incision in a rat post-surgical pain model. In conclusion, the mGlu2/3 agonist LY2934747 (delivered either i.p. or i.v.) and the prodrug LY2969822 (delivered p.o.) attenuated

pain behaviors across a broad range of pre-clinical pain models. [1] Monn JA et al, J. Med. Chem. 58:1776-94, 2015.

Title: Possible involvement of spinal dopamine receptor subtypes in trigeminal nerve injury-induced mechanical hypersensitivity of rats

Authors: ***K. NAKAI**[1], A. NAKAE[2], T. KUBO[3], Y. MINEGISHI[1], Y. FUJINO[4], K. HOSOKAWA[3];
[1]Univ. of Fukui Hosp., Eiheiji-Cho, Fukui, Japan; [2]Lab. of Brain-Immune Interaction, WPI Immunol. Frontier Res. Center, Osaka Univ., Suita, Japan; [3]Dept. of Plastic Surgery, [4]Dept. of Anesthesiol. & Intensive Care Med., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: (Background) Peripheral branches of the trigeminal nerve may be damaged by maxillofacial injury or during surgical procedures and such damage may induce severe pain. Trigeminal neuropathic pain is very difficult to manage. Only antidepressants and anticonvulsants have been proved to be efficacious in treating trigeminal neuralgia. The dopamine receptor has been recognized to be important in the spinal modulation of nociceptive

transmission. Both pronociceptive and antinociceptive effects have been attributed to the dopamine receptor subtypes. The involvement of D1, D2, D3, and D4 receptors in trigeminal nociception and pain, particularly neuropathic pain, has been poorly investigated. Chronic constriction injury to the infraorbital nerve (ION-CCI) of rats induced mechanical hypersensitivity. It has proven a useful model for trigeminal neuropathic pain. The present study evaluated the possible role of spinal D1, D2, D3, and D4 receptors in ION-CCI rat model. (Material and methods) Male Sprague Dawley rats underwent unilateral CCI to the right ION. Two nylon (5-0) ligatures were tied around the ION. A series of von Frey filaments were used to determine pain hypersensitivity to mechanical stimulation on day 14 after surgery. The filaments were applied to skin innervated by the injured ION near the center of the vibrissal pad and surrounding the mystacial vibrissae. Head withdrawal, and touching or scratching of facial regions, were quantified as positive pain responses. A polyethylene (PE-10) catheter was implanted for upper cervical spinal injection of drugs. The rats were allowed to recover for 7 days. The time course of the antiallodynic effects and the dose-response effects of intrathecally administered a D1 receptor agonist SKF38393, a D1 receptor antagonist SCH23390, a D2 receptor agonist Sumanirole, a D2 receptor antagonist L-741626, a D3 receptor agonist 7-Hydroxy-DPAT, a D3 receptor antagonist PG01037, a D4 receptor agonist A 412997, and a D4 receptor antagonist L-745870 were examined. The time course data for the dose-response effects were analyzed by two-way analysis of variance and Tukey-Kramer multiple-comparison test. (Results and discussion) Intrathecal administration of SCH23390, L-741626, PG01037, and L-745870 increased mechanical thresholds in a dose dependent manner ($P < 0.05$). Intrathecal administration of SKF38393, Sumanirole, 7-Hydroxy-DPAT, and A 412997 did not alter mechanical thresholds. (Conclusion) The results indicated that spinal D1, D2, D3, and D4 receptors may play an important role in trigeminal nerve injury-induced mechanical hypersensitivity of rats.

Title: The contribution of Nucleus Raphe Magnus to the analgesia produced by centrally administered CDP-choline

Authors: *M. S. GURUN, M. K. GURBUZOGLU-ULKAN, D. BAGDAS, D. GOK-YURTSEVEN, O. EYIGOR;
Uludag Univ. Med. Fac., Bursa, Turkey

Abstract: Central cholinergic system and nicotinic acethylcholine receptor (nAChR) subtypes play significant roles in the process of pain control. These findings have been supported by pain studies in our laboratory in which we demonstrated the mediation of central nAChRs in analgesic and antihypereralgesic effects of CDP-choline. In addition, Nucleus Raphe Magnus (NRM), a region with dense cholinergic innervation which is localized to brainstem, has important functions including pain modulation, due to its strategic location and presence of connections. Therefore, the present study was designed to identify the possible role of NRM in analgesia elicited by intracerebroventricularly (icv) -administered CDP-choline and the underlying mechanism of its analgesic effect. For this purpose, we investigated whether or not cholinergic, opioidergic, Gabaergic and serotonergic antagonists microinjected into NRM alter the analgesic effects of CDP-choline (icv) in the acute pain model in rats. The effect of CDP-choline (icv) on acethylcholine and choline concentrations in NRM was analyzed by *in vivo* microdialysis study, as well. We found that the analgesic effect of intracerebroventricularly-administered CDP-choline in acute pain model was prevented by pretreatments with the nonspesific nicotinic receptor antagonist mecamilamine, the spesific α7 nicotinic receptor antagonist methyllicaconitin and the nonspesific serotonergic receptor antagonist methysergide microinjected into the NRM, while pretreatment with the nonspesific muscarinic receptor antagonist atropin microinjected into the NRM did not alter CDP-choline's effect. In addition, extracellular choline concentrations in NRM were incerased after intracerebroventricular CDP-choline admisinistration. In conclusion, our study shows for the first time the role of NRM and α7 nAChRs with serotonergic receptors located in the NRM in analgesic effect of intracerebroventricularly-administered CDP-choline in acute pain model. Title: A novel integrated EEG and neural modeling approach to uncovering the mechanisms of transcranial alternating current stimulation

Authors: *C. BLACK[1], U. AGRAWAL[1], M. LADOW[1], J. SANTOYO[1], J. VOIGTS[2], C. MOORE[1], S. JONES[1];
[1]Brown Univ., Providence, RI; [2]MIT, Cambridge, MA

Abstract: Transcranial alternating current stimulation (tACS), a non-invasive neuromodulation technique, has exhibited its utility as a therapeutic in a variety of applications: from enhancing vision in patients with optic neuropathy (Sabel 2011), to improving speech in patients with stroke (Fedorov 2010). While the benefits of tACS are evident, little is known of how these externally generated electric fields modulate on-going neural activity, making it difficult to select appropriate therapeutic stimulation parameters. Macroneurophysiological measures taken in conjunction with tACS will be crucial in this effort. Electroencephalography (EEG) provides a neural recording method with high-precision temporal resolution that can register the millisecond timescales inherent to neural activity, but concurrent EEG—tACS recording has many technical challenges, such as stimulation artifacts, amplifier irregularities, and long recording latencies, that impede effective incorporation of EEG. To elucidate the mechanism of action of tACS, we have designed and built a novel EEG – tACS technique to provide data for complementary biophysically realistic neural modeling. To create this technique, we developed a custom EEG system, based off the electrophysiology platform Open Ephys, with integrated real-time amplifier control and closed-loop capabilities. The amplifier control enables us to cycle our EEG amplifiers on and off within 200 microseconds. This means we can silence our recording amplifiers during tACS and then restart them in real-time to reliably capture the resulting neural data void of stimulation errors. Further, our closed-loop architecture provides a medium to drive parameterized stimulation from streaming neural data. This feedback allows us to probe the affect of tACS on EEG phase, amplitude, and frequency. We have implemented this technique to study the affects of tACS in primary somatosensory cortex (SI) on behavior during a non-painful tactile detection task. Preliminary results show modulation of tactile evoked responses and spectral dynamics in SI (see companion poster, J. Santoyo). To study the impact of tACS at cellular and network levels during tactile detection, we are employing a biophysically principled model of SI cortex that can emulate the recorded tactile evoked response and rhythms in SI (Jones et al, 2007, 2009, Ziegler et al 2010). Our goal is to link the observed changes in electrophysiology and behavior to the causal impact of tACS-induced electric fields on the underlying circuits. Ultimately, our combined methodologies will provide the framework to design rational stimulation protocols that optimize tACS-based therapies.

Title: The role of muscular beta oscillations and modulation with transcranial alternating current stimulation in predicting tactile detection

Authors: *U. AGRAWAL[1], C. BLACK[2], M. LADOW[1], J. SANTOYO[3], C. KERR[4], C. MOORE[1], S. JONES[1];
[1]Dept. of Neuroscience, Brown Univ., Providence, RI; [2]Biomed. Engin., [3]Cognitive, Linguistic, and Psychological Sci., [4]Family Med., Brown Univ., Providence, RI

Abstract: Oscillations in the beta (15 - 29 Hz) band observed in primary somatosensory cortex as well as in the muscles have been shown to be functionally relevant for sensory perception and can be modulated with attention (Jones et al. 2010, van Ede et al. 2011, van Ede and Maris 2013). Recent attempts have successfully utilized transcranial alternating current stimulation (tACS) to impose these rhythms in cortex (Feurra et al. 2011) as well as modulate corticomuscular beta coherence, a measure of coordination between the cortex and the muscles (Wach et al. 2013). In this study, we investigated the role of muscular oscillations in perception and the causal impact of tACS induced cortical oscillations on the muscles. We applied tACS over somatosensory cortex during a tactile detection task while recording simultaneous electroencephalography (EEG) and electromyography (EMG). Our team designed and created a customized EEG system using Open Ephys (open-ephys.org), an open source initiative that is both flexible and inexpensive (companion poster, C. Black et al.). Using this custom built system, we were able to obtain simultaneous EEG, tACS, and EMG. We have previously shown that pre-stimulus beta activity in the cortex is predictive of successful perception of a tactile stimulus (Jones et al 2010). Here, we show preliminary data that suggests pre-stimulus beta oscillations in the muscles are also predictive of detected vs. non-detected tactile stimuli. Ongoing studies are aimed at investigating the causal impact of tACS in the muscles and on perception. Our findings provide preliminary evidence for a causal role of sensorimotor oscillations at the level of the muscles. Future studies may ultimately elucidate a clinical role for

EMG in diagnosis and therapeutics in disorders characterized by maladaptive beta rhythmicity, such as Parkinson's disorder.

Title: Testing the modulation of cortical dynamics and somatosensory perception using alpha and gamma-band transcranial alternating current stimulation

Authors: ***J. F. SANTOYO**[1], C. BLACK[2], U. AGRAWAL[3], M. LADOW[3], B. GREENBERG[4], S. JONES[3], C. MOORE[3];
[1]Cognitive, Linguistic & Psychological Sci., [2]Biomed. Engin., [3]Neurosci., [4]Psychiatry and Human Behavior, Brown Univ., Providence, RI

Abstract: Alpha and gamma band oscillatory activity in the sensory cortices are thought to play mechanistic roles in the gating of sensory information. Specifically, alpha-band activity (7-14Hz) has been associated with inattention to task-irrelevant sensory signals and gamma-band activity (30-80Hz) has been associated with enhancing the processing of task-relevant sensory signals (Siegel 2012). Here, we use transcranial alternating current stimulation (tACS), a non-invasive technique for inducing oscillatory activity to examine the role of these oscillatory dynamics in human sensory perception. Participants (n=10) performed a tactile detection task before and after tACS stimulation at either alpha or gamma-band frequencies. tACS was localized anatomically to S1 on the cortical hemisphere contralateral to the hand used for the tactile detection task. We analyzed changes in behavioral performance as well as changes in post-cue and pre-stimuli Event-Related Potentials (ERPs) and Event-Related Spectral Dynamics (ERSP) before and after tACS and between alpha and gamma-band stimulation conditions. Distinct elements of the post-cue and pre-stimulus ERPs and ERSPs were modulated by alpha and gamma-band stimulation in contralateral S1 but not ipsilateral S1. However, there was no observable influence of tACS stimulation on somatosensory perception. These preliminary results suggest that tACS can modulate functionally relevant oscillatory rhythms but potentially not behavior.

Title: Robot-aided measurement of proprioceptive function in healthy and clinical populations

Authors: ***J. HOLST-WOLF**[1], I.-L. YEH[1], N. ELANGOVAN[1], J. AMAN[1], L. CAPPELLO[2,3], L. MASIA[3], J. KONCZAK[1];
[1]Kinesiology, Univ. of Minnesota, Minneapolis, MN; [2]Robotics, Brain and Cognitive Sci., Italian Inst. of Technol., Genova, Italy; [3]Robotics Ctr., Nanyang Technological Univ., Singapore, Singapore

Abstract: Diminished or absent proprioceptive information has severe consequences on many aspects of sensorimotor function leading to impairments in balance, locomotion and fine motor control. Despite the recognized importance of proprioception for intact motor behavior, the clinical assessment of proprioceptive deficits has been difficult. Recent advances in haptic robotic interfaces has enabled the use of such devices for the assessment of proprioceptive function. We recently demonstrated (Capello et al. 2015) that our patented wrist robotic system is capable of quantifying proprioceptive acuity of two degrees of freedom of the wrist. It yields thresholds that are valid (i.e., physiologically plausible), produces reliable data over repeated testing, and employs a protocol that generates objective data on proprioceptive status in less than 20 minutes (position or motion sense). Here we show that the system can be applied to a variety of clinical populations suspected of proprioceptive dysfunction by assessing the acuity of the wrist position sense. METHOD: From a neutral joint position, the wrist robot moved the wrist to two different joint positions (standard stimulus: 15 deg flexion, comparison stimuli > 15 deg) at a constant slow velocity of 6 deg/s. The participant then identified verbally which position had the larger amplitude. An adaptive algorithm generated the subsequent stimulus pair depending on the correctness of the previous responses. The assessment is typically complete after 30 trials. Based on the response and stimulus difference data a psychophysical just-noticeable difference threshold was determined. RESULTS: We here show exemplar threshold data of adult patients

with cortical stroke, Parkinson's disease, and peripheral sensory neuropathy and contrast their thresholds against a norm database of healthy adults (N = 22). We demonstrate that thresholds in these clinically populations can be quantified with precision in a timely manner. Expectedly, our data show that thresholds may be severely elevated with respect to a neurologically normal adult cohort. DISCUSSION: The purpose of this work is to demonstrate the clinical applicability of robot-aided proprioceptive assessment. From a clinical research perspective, this assessment system allows for the mapping of proprioceptive deficits in neurological disorders associated with proprioceptive deficits. From a clinical practitioner perspective, it allows for the objective assessment of proprioceptive function of individual patients. This implies that the system can be used as a diagnostic tool as well as a tool to monitor treatment efficacy.

Title: Robot-assisted assessment of proprioception: normative data in healthy adults

Authors: *I.-L. YEH[1], J. AMAN[1], N. ELANGOVAN[1], J. HOLST-WOLF[1], L. CAPPELLO[2], L. MASIA[3], J. KONCZAK[1];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Italian Inst. of Technol., Genova, Italy; [3]Nanyang Technological Univ., Singapore, Singapore

Abstract: Proprioception is essential to intact motor function. While it is important to characterize proprioceptive acuity in healthy adults, no measurement is accepted universally as a gold standard. We have recently developed a reliable and valid assessment to measure wrist position sense with a wrist robot system (Capello et al. 2015). The purpose of this study is to establish a normative data set of proprioception in healthy adults using the wrist robot system. METHOD: The subject's dominant hand was moved passively by the robot inducing wrist flexion. After experiencing two passive wrist movements (standard stimulus: 15 deg flexion, comparison stimuli > 15 deg) by the wrist robot system, the subject identified which of two stimuli had the larger movement amplitude. An adaptive algorithm then generates the next stimuli differences depending on the correctness of response and magnitude of the stimulus difference. The JND threshold was determined as the estimated value on the last trial. The psychophysical just-noticeable-difference (JND) threshold for wrist joint position sense was the measure of proprioceptive acuity. RESULTS: 22 healthy adults (Age: 21- 62 y/o, average 44.6 ± 10.8 y/o, 7 Male/15 Female) were recruited. On average the position sense threshold for wrist flexion/extension: 1.719° ± 0.619°. The correlation between age and threshold was not significant for this sample population. DISCUSSION: A normative data set of proprioceptive acuity was established for young and middle-aged adults. This normative data set serves as a reference to determine the degree of the impairment in wrist position sense in clinical populations with suspected proprioceptive dysfunction.

Title: Potential applicability of laryngeal vibrotactile stimulation as a noninvasive therapeutic method for spasmodic dysphonia

Authors: *S. KHOSRAVANI, Y. TSENG, I. YEH, J. AMAN, J. KONCZAK;
Univ. of Minnesota, Minneapolis, MN

Abstract: Spasmodic dysphonia (SD) is a chronic neurological disorder accompanied with the involuntary spasm of vocal cords, depriving patients from producing normal speech-related items. Currently, temporary symptomatic treatment in form of botulinum toxin injection is the most prominent therapy for SD. While the origins of the disease are still in debate, SD is categorized as a type of focal dystonia (FD). The mentioned point directed our attention towards taking advantage of current knowledge about FD, in order to find potential treatment opportunities for spasmodic dysphonia. Huge body of research has revealed altered somatosensory processing in different forms of FD, including SD. This, together with the studies confirming the effectiveness of vibro-tactile stimulation (VTS) for the improvement of somatosensory perception in FD (and resultantly reduction of a number of dystonic symptoms), led us towards examining the effectiveness of VTS in SD. Here we first examined the unknown effect of VTS on cortical activity in healthy volunteers and then applied VTS to SD patients to measure the change in voice quality. Microvibrators were attached unilaterally to the skin above the thyroid. Brain signals were recorded using a 64-channel scalp EEG system over 4 seconds of vocalization followed by 4 seconds of vocalization plus vibro-tactile stimulation (total of 100 trials). Time-frequency analysis of the results revealed bilateral suppression of cortical activity in somatosensory and motor areas after vibration was applied. Suppressions were more pronounced in β and μ bands and on the contralateral side with respect to the side of stimulation. Second, three SD patients participated in an assessment protocol comprising three sets of 15-minute stimulation: VTS-no vocalization (5 min.) and vocalization with VTS (10 min.). Vocal quality was evaluated at the end of each trial in both ‘on’ and ‘off’ vibratory conditions. Patient self-reports on voice quality and recorded audio signals were analyzed a posteriori by a blinded rater using the Consensus Auditory-Perceptual Evaluation of Voice (Cape-V). Results showed improvement of self-reported voice quality for all participants and up to 35% improvement in

average Cape-V scores. Both tests provide preliminary evidence for the potential capability of using VTS as a non-invasive clinical treatment for spasmodic dysphonia.

Title: Virtual reality visuomotor training improves proprioceptive acuity and transfers to untrained motor task

Authors: *N. ELANGOVAN[1], L. CAPPELLO[2], J. AMAN[1], L. MASIA[3], J. KONCZAK[1]; [1]Sch. of Kinesiology, Univ. of Minnesota, Minneapolis, MN; [2]Italian Inst. of Technol., Genova, Italy; [3]Nanyang Technological Univ., Singapore, Singapore

Abstract: BACKGROUND AND PURPOSE: When acquiring a new visuomotor skill, we face the challenge of aligning visual feedback with the movement-related proprioceptive feedback in order to generate motor commands that will eventually lead to precise movements that will achieve the movement goal. Here we address the question, if a training that relies on visual cues for learning will result in measurable changes in proprioceptive precision (acuity), and whether such improved proprioceptive function will translate into improved motor function. To address these questions, healthy adults engaged in a visuomotor training protocol requiring them to obtain precise wrist joint position. The purpose of the study was 1) to identify whether this training will improve proprioceptive acuity by quantifying training-related changes in limb position thresholds, and 2) to evaluate if proprioceptive changes are associated with motor performance of an untrained non-visuo motor task. METHOD: Using a wrist haptic robotic device, training involved tilting a virtual surface to position a virtual ball on a target by making small amplitude wrist flexion/extension movements. Tilt angle of the virtual surface reflected the participant's current wrist position. Proprioceptive acuity and precision of goal-directed active wrist movement in an untrained motor task were both assessed without vision before and after training. Specifically, wrist position sense discrimination thresholds were obtained using controlled passive robotic motion of the wrist. In addition, movement precision errors were determined as the difference between a 15° flexion target position and the final achieved joint position after an active movement to that same target. RESULTS: Improvements in

proprioceptive thresholds were found in all participants (N = 15; mean: pre/post = 2.1° ± 0.4°/ 1.4° ± 0.6°; a 33% improvement). Movement precision error improved in 82% of healthy participants (mean: pre/post = 3.1° ± 2.4° / 2.2° ± 2.4°; a 22% improvement). DISCUSSION: This study demonstrates: First, improvements in proprioceptive acuity are observable even after a brief sensorimotor training period. Second, enhanced motor performance in an untrained non-visuomotor task indicate that such improvements in proprioceptive function translate to improved movement precision. The results provide a scientific basis to apply such training to patients with known proprioceptive dysfunction.

Title: A push-pull pathway from somatosensory cortex to spinal trigeminal nuclei for motor control of the vibrissae

Authors: ***P. M. KNUTSEN**, N. MERCER LINDSAY, D. KLEINFELD;
Dept. of Physics, UCSD, La Jolla, CA

Abstract: Goal-directed behavior is an integral component of perception. Information transmitted by sensory afferents is shaped by external inputs as well as input from self-motion. In turn, sensory information guides motor output and thus the synthesis of behavior. Conceptually and anatomically, a sensorimotor system can be envisaged as a network of nested closed-loops that achieves postural stability during behavior. This control structure suggests the need for rapid computations of motor output based on the flow of sensory input. Vibrissa somatosensory cortex involves the convergence of exafferent, reafferent, and efference copy signals and is thus a candidate area for the computation of motor efferents. In particular, vibrissa somatosensory cortex (vS1) projects to and has been shown to influence both sensory input (Knutsen & Kleinfeld, SfN abstract 2013) and motor control (Matyas et al., Science 2010) via the brainstem spinal trigeminal complex (SpV). Here, we expand on prior observations of motor control via somatosensory cortex. Precise topographic maps of vibrissae representations in vS1 were obtained by imaging intrinsic optical signals through thinned-skull windows. These maps were used to guide through-skull, patterned optogenetic activation of L5b pyramidal cells in Thy1-ChR2 transgenic mice. We find that afferent and cortical activation of single units in the caudal aspect of spinal nucleus interpolaris (SpVIc) is topographically aligned. Further, units in the rostral aspect of SpVI (SpVIr) that were activated by stimulation of intervibrissal fur were also activated by optogenetic stimulation of the region of dysgranular cortex adjacent to the representation of E-row in vS1. Of particular interest, optogenetic activation of L5b cells in this region led to retraction of the vibrissae. Using a combination of anterograde indicators, we find that the activated cells project primarily into SpVIr and spinal oralis (SpVO), similar to projections seen from motor cortex (Mercer Lindsay et al., companion SfN abstract 2015). In contrast, the vibrissae responsive region of vS1 projects primarily into SpVIc (Sreenivasan et al., EJN 2015). In additional experiments, we find that activation of L5b cells in secondary somatosensory cortex (S2) led to protraction of the vibrissae. These cells project exclusively to spinal nucleus muralis (SpVM) that, like SpVIr, forms a direct connection with facial motoneurons (Pinganaud et al., JCN 1999; Matthews et al., JCN 2015). We conclude that the tandem combination of S1 and S2 enables bidirectional control of vibrissa movements via subregions of the spinal trigeminal complex, most likely via control of the set-point.

Title: Brainstem areas controlling exploratory nose motion in rodents

Authors: *A. KURNIKOVA[1], M. DESCHÊNES[2], J. D. MOORE[3], D. KLEINFELD[1]; [1]Neurosciences, UC San Diego, La Jolla, CA; [2]Univ. Laval, Québec, QC, Canada; [3]Harvard Univ., Boston, MA

Abstract: Rodents shift their nose from side to side when they actively explore. This motor action might be used to sample and lateralize odors efficiently in the space. Lateral motion of the nose appears to be correlated to breathing (Deschênes et al. Anatomical Record, 2014) and may contribute to odor sampling. The primary muscle responsible for nose deflection is the deflector nasi (Deschênes et al. Anatomical Record, 2014, Haidarliu et al. Anatomical Record, 2015). Motor neurons that drive deflection of the nose are located in the dorsal lateral division of the facial motor nucleus (Deschênes et al., manuscript in preparation). We study the premotor control of nose motion in order to further our understanding of synthesizing orofacial exploratory behaviors from individual motor actions. We identify putative premotor brainstem areas responsible for nose deflection through anatomical and functional characterization. Further study will examine how this circuitry is activated and modulated by the brainstem breathing centers and how the direction of nose motion is selected. Behaviorally, preliminary data show that air flow through the nares is modulated by lateral deflection of the nose. For anatomical tracing, we use replication competent rabies virus and pseudorabies virus to transsynaptically label secondary inputs to the deflector nasi muscle. We find secondary labeled cells in areas of the intermediate reticular formation (IRt), medial gigantocellular reticular formation (Gi), parvocellular reticular formation (PCRt) and rostral portion of the nucleus of the solitary tract (rNST). To determine the functional relevance of regions identified by anatomical tracing, we use AAV-ReaChR, a virally encoded red-shifted channelrhodopsin, to optogenetically activate cells in the candidate areas. We find that activating cells in a region that includes the IRt and Gi results in nose deflection towards the ipsilateral side in both awake and anesthetized mice. Ongoing studies will decipher the specific role of populations of neurons in these areas.

Title: Projections from vibrissa motor cortex to the spinal trigeminal nuclei

Authors: *N. MERCER LINDSAY, P. M. KNUTSEN, D. GIBBS, H. J. KARTEN, D. KLEINFELD;
UCSD, La Jolla, CA

Abstract: Behavior is an outcome of efferent and afferent activation, sensory feedback, and predictive control. Our objective is to understand how behaviors are synthesized from individual motor actions. Here we focus on the circuits that drive one such action, whisking of the mystacial vibrissa. We demonstrate that the vibrissa motor cortex (vMC) projects to the spinal trigeminal nuclei, coincident with regions that are pre-motor to the facial motor nucleus (FMN) that controls the mystacial muscles. Using a combination of anterograde and retrograde viral indicators, we find that vMC projects to three subdivisions of the spinal trigeminal complex: the pars oralis (SpVO), interpolaris (SpVI), and muralis (SpVmu). In detail, a synaptophsyin-GFP virus injected into vMC showed labeled vMC synapses were most concentrated in the rostral interpolar nucleus (SpVIr). Optogenetic activation of the vMC to SpVIr pathway, via lentivirus pseudotyped with rabies glycoprotein that encoded a red-shifted channelrhodopsin (ReaChR), elicited both vibrissae protraction and retraction. We conclude that vibrissa motor cortex, along with vibrissa somatosensory cortex (Matyas et al. Science 2010; Knutsen, Mercer Lindsay, and Kleinfeld, companion SfN abstract, 2015), integrate with sensory inputs and modulate vibrissa motor output, most likely through control of the set-point, with subdivisions of the spinal trigeminal complex serving as premotor nuclei.

Title: Designing an animal model to investigate corneal neurotization as a means of restoring sensation in patients with corneal anesthesia

Authors: *J. CATAPANO[1], M. P. WILLAND[2], A. ALI[2], T. GORDON[2], G. H. BORSCHEL[2]; [1]The Hosp. for Sick Children, North York, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Patients with corneal anesthesia are susceptible to corneal injury, causing corneal scarring with progressive vision loss. Standard therapy, including corneal transplantation, fails to prevent vision loss in these patients. Dr. Borschel and Dr. Ali have developed a novel surgical procedure to restore sensation to the cornea using nerve grafts and transfers from the contralateral sensate face. All patients have demonstrated improvements in corneal sensation and vision has stabilized or improved in all patients. An animal model of corneal neurotization is needed in order to investigate how nerve regrowth impacts corneal epithelial maintenance and healing. Here, we describe our initial work establishing a model of corneal denervation in the rat. Removing the corneal innervation is a necessary first step prior to reconstructing the corneal innervation with neurotization. Thy1-GFP+ rats, which express green fluorescent protein (GFP) in neurons and axons, were used to investigate a method of corneal denervation by transecting the ciliary branches of the trigeminal nerve, which innervate the cornea. Alcohol (90% and 100% EtOH) was applied to the transected ciliary nerves in a subset of animals to further damage the ciliary nerves following injury. The denervated and uninjured cornea were harvested at 1, 2, 3 and 4 weeks to assess the cornea for axon regeneration. Ciliary nerve transection resulted in complete loss of GFP+ axons in the cornea 1 week after injury and axon regrowth into the cornea was apparent at 2 weeks. Alcohol exposure to the ciliary nerves following transection delayed axon regrowth into the cornea, however at 4 weeks axon regrowth was also evident in those animals treated with alcohol. Ciliary nerve transection may be used as a model of spontaneous corneal nerve regeneration, however to investigate corneal neurotization in a model that recapitulates the clinical scenario, a method of corneal denervation that does not permit spontaneous corneal reinnervation must be developed.

Title: Proprioceptive tuning to appendage mechanics: a comparison of pectoral fin proprioception in fishes

Authors: *B. R. AIELLO, M. W. WESTNEAT, M. E. HALE;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Proprioceptive feedback is critical to the motor performance of many animals. While proprioception has been documented in the pectoral fins (forelimbs) of fishes, pectoral fin morphology, mechanics, and kinematics vary markedly among species and it is unclear how such variation is associated with sensory input. In other sensory systems, input has been shown to be tuned to the most likely range of stimuli that define the organism's behavioral repertoire. Here we test the hypothesis that neuromechanical tuning occurs in fin-based proprioception. To test this hypothesis, we compare the proprioceptive afferent response to fin ray bending in a pair of closely related wrasses that employ dichotomic swimming behavior, the rowing *Halichoeres bivittatus* and the flapping *Gomphosus varius*. In both species, phasic afferent activity was observed in response to sinusoidal stimuli between 3 and 6Hz, which corresponds to the range of fin beat frequencies observed in these species. This reveals that proprioceptive feedback can be encoded at biologically relevant fin bending frequencies that mimic natural swimming behavior. In response to step-and-hold stimuli, a burst of spikes occurred in both species when the fin was raised from and again when it was returned to its resting position. The duration and number of spikes of these bursts as well as the spike rate over the hold period of the stimulus (3.5s) increased with increasing bending amplitude. Spike sorting revealed the presence of both slowly and rapidly adapting afferent activity during the step-and-hold stimuli. An interspecific comparison of fin mechanics revealed that pectoral fin ray flexural stiffness of the flapper, *G. varius*, was an order of magnitude stiffer in comparison to the rower, *H. bivittatus*, which relates to the greater fin bending amplitude observed in *G. varius* during swimming. A comparison of the step-and-hold stimuli between species revealed that it required a four times larger bending

amplitude to elicit afferent activity in *H. bivittatus* than in *G. varius*. A larger bending amplitude was also required to elicit sustained activity during the hold period in *H. bivittatus*. The results of this study suggest that sensory physiology can be tuned to the fin mechanics through adapting sensitivity of the proprioceptive system.

Title: Tactile sensation in a flexible biological membrane: Investigating touch in fish pectoral fins

Authors: *A. R. HARDY, B. M. STEINWORTH, M. E. HALE;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Research on limb tactile sensation has focused on mammalian digits, yet studies of other limb structures may provide alternative prospective on how tactile sensors can be organized and function. In some fishes, pectoral fins (paired forelimbs) function as locomotor structures to provide thrust and/or maneuverability. It has been shown that the activity of sensory nerves innervating these propulsive fins reflects the amplitude and velocity of fin ray bending during locomotion, providing proprioceptive feedback on fin movement. In other taxa, fins do not function as propulsive locomotor structures but remain morphologically robust. We hypothesized that, in these cases, fins function primarily as flexible sensory membranes that provide tactile information about contacted objects and fluid movement. To test this novel idea about fin sensory function, we investigated the pectoral fins of the pictus catfish (*Pimelodus pictus*), a benthic species that lives in close association with the substrate. Behavioral, neuroanatomical, and electrophysiological data indicate the pectoral fin of *P. pictus* functions as a membranous sensory surface. During forward swimming, *P. pictus* holds its pectoral fins laterally at 33° ± 11.5° relative to the body axis. This relatively constant angle suggests that the pectoral fins are not primarily motor structures. Immunostaining revealed nerves and putative

mechanoreceptors present throughout the pectoral fin. Nerves run parallel to the fin rays and often terminate on structures that positively stain with an antibody to cytokeratin 20, a Merkel cell marker. In an effort to elucidate the role of this innervation and sensory morphology we performed multi-unit electrophysiological recordings from nerves innervating the pectoral fin. Fish were exposed to step-and-hold and ramp-and-hold stimuli to examine fin ray responses to shear along the fin ray surface, static pressure, and fin ray bending. Stimuli were chosen based on behavioral observations to mimic the hypothesized forces the pectoral fin might encounter during swimming. Nerves respond with an increase in burst duration as fin ray bending amplitudes increase. In contrast to fishes that utilize their fins primarily for locomotion, pictus afferents also exhibit a vigorous response to both shear and static pressure. This ability to perceive tactile stimulation suggests that fish receive ample mechanosensory feedback about their environment as the pectoral fin moves over the substrate. Their organization and physiology may inform the design of engineered sensory surfaces, particularly for use in aquatic environments.

Title: Mechanical response of isolated rat whiskers to airflow: bending direction, bending magnitude and vibration frequency

Authors: ***Y. S. W. YU**[1], M. M. GRAFF[1], M. J. Z. HARTMANN[1,2];
[1]Dept. of Mechanical Engineering, Northwestern Univ., [2]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: Whiskers have been the subject of research in both rodents and pinnipeds, but studies in these two clades have generally focused on separate aspects of whisker function. Studies in rodents have focused primarily on the use of whiskers as contact sensors and have investigated questions in active tactile perception and sensorimotor integration. Studies in pinnipeds have

focused primarily on the use of whiskers as remote flow sensors. To date, few if any studies have investigated the possibility that rodents might also use their vibrissae as flow sensors. If air currents of the magnitude typically found in natural environments generate significant motion of the vibrissae, then an important component of rodent vibrissal sensation may have been overlooked. The present work takes the first steps towards investigating the possibility that vibrissae may play a role in airflow sensing in rats. We quantified the mechanical responses of five isolated rat whiskers obtained from a female Long-Evans rat. Whiskers were placed at different orientations relative to the airflow, and airflow speed was varied between 0.4 and 5.7 m/sec. Results indicated that the whisker bends in the direction of the airflow. The magnitude of the bending depends on airspeed, the orientation of the whisker relative to the airflow, and geometric parameters of the whisker. In the presence of airflow, the whisker also vibrates around its new static ("bent") position, with vibrations occurring near the whisker's resonance modes. We combined these results with an anatomical model of the rat head and whisker array to simulate how whiskers' mechanical responses to airflow will vary across the entire vibrissal array. Results are discussed in the context of a potential functional role for vibrissae in anemotaxic behavior.

Title: Responses of trigeminal ganglion neurons to the 3D mechanics of whiskers

Authors: *N. E. BUSH[1], L. A. HUET[2], A. E. T. YANG[2], P. KUMARAPPAN[3], J. A. ELLIS[1], M. J. Z. HARTMANN[2,3];

[1]Interdepartmental Neurosci. Program, Northwestern Univ., Chicago, IL; [2]Mechanical Engin., [3]Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: During tactile exploration, rats and mice rhythmically brush and tap their whiskers (vibrissae) against objects in a behavior known as whisking. Although whisking motions are primarily rostrocaudal, contact with an object will often deflect the whisker significantly out of its plane of rotation. This deflection will cause significant forces and torques in all three dimensions (3D). These mechanical signals will be transmitted to the primary sensory neurons that respond to whisker deflection, which reside in the trigeminal ganglion (Vg). At the same time, it is well known that Vg neurons exhibit strong angular tuning. In other words, they respond more strongly to whisker deflections in one direction than the others. It is therefore clear that an understanding of coding properties of Vg neurons hinges on characterizing their response to whisker deformations in 3D. To this end, our laboratory has developed a mechanical model of whisker bending that allows us to compute all three components of force and all three components of torque at the whisker base given the whisker's 3D shape. The present work takes the first steps towards characterizing how Vg neurons encode both large and small angle deflections in response to forces and torques in 3D. We record from Vg cells in the anesthetized rat while manually deflecting the whisker in multiple directions and while varying deflection amplitude and velocity. To quantify the mechanical stimuli applied to the whisker, we record high-speed video of the whisker in multiple high-speed cameras. We track the whisker in these separate videos and create a 3D reconstruction of whisker shape using stereo videography techniques. Finally, we apply our 3D mechanical model to the extracted shape of the whisker to compute the forces and the torques at the base of the whisker. We describe initial efforts to correlate these mechanical and geometrical signals with the responses of Vg neurons.

Title: Evidence for tuning to stimulus directionality in the responses of neurons with multi-whisker receptive fields in spinal trigeminal nucleus interpolaris

Authors: *C. S. BRESEE[1], N. E. BUSH[1], A. S. KALOTI[1], E. C. JOHNSON[4], S. N. NAUFEL[2], M. G. PERICH[2], D. L. JONES[4], M. J. Z. HARTMANN[2,3];

Abstract: The rat vibrissal-trigeminal system is an important model for the study of somatosensation, yet to date we have little understanding of how tactile information from multiple whiskers is integrated at various stages of the system. It is well-established that primary sensory neurons in the trigeminal ganglion respond to one and only one whisker. It is also well known that trigeminal ganglion neurons exhibit strong angular tuning, meaning that responses are much stronger when the whisker is displaced in one direction compared to others. Trigeminal ganglion neurons send signals to the trigeminal brainstem nuclei, the first structures that exhibit multi-whisker receptive fields. In the present work, we aimed to begin to quantify responses of neurons in spinal trigeminal nucleus interpolaris (SpVi) of awake rats under a wide variety of behavioral conditions. We were particularly interested in assessing how the strong angular tuning seen in ganglion responses might be reflected in the multi-whisker responses of SpVi neurons. We recorded from SpVi during behaviors that included non-contact whisking, nose-poking, whisking against a flat vertical surface (a wall), and grooming. We simultaneously recorded electromyographic (EMG) activity from both intrinsic and extrinsic musculature. Results showed that very little if any spiking occurred during non-contact whisking, despite robust and rhythmic EMG activity. Activity levels increased during multi-whisker contact with objects, including nose poking and contact with the wall. Activity appeared to be particularly enhanced during grooming behavior, in which the paws typically stimulate many whiskers across the array in a directional sequence. To more carefully quantify the extent to which multi-whisker receptive field neurons in the trigeminal nuclei reflected the direction of stimulation across the array, we performed experiments in the anesthetized animal. A vertical rod was swept through the full vibrissal array at varying speeds in the rostral-caudal and caudal-rostral directions. Recordings from 15 neurons in the brainstem trigeminal complex showed that majority of cells (80%) were tuned for stimulus direction, typically responding more strongly when stimulated from caudal to rostral. Together, results from the awake and anesthetized animal provide some preliminary support for the hypothesis that SpVi neurons integrate information about the angular tuning of single whiskers into a code for stimulus directionality across larger groups of neighboring whiskers.

Title: Inferring the neural representations underlying perceptual invariance in touch

Authors: ***H. P. SAAL**, J. D. LIEBER, Z. M. BOUNDY-SINGER, A. I. WEBER, S. J. BENSMAIA;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: A crucial aspect of perception is the recognition of invariant features based on an ever-changing stream of sensory input. For example, we can tell an object's identity from different viewpoints, or recognize a friend's voice independent of the exact words spoken. In the sense of touch, the perceived roughness of a surface is remarkably independent of the movements that are used to probe the surface. While roughness ratings have been shown to be invariant to scanning speed, the peripheral neural representation of texture is not: changes in speed affect both the firing rates and the timing of afferent responses, raising the question of how the well-documented perceptual invariance arises. One possibility is that information about scanning speed, which is also conveyed in peripheral responses, is extracted by the brain and then used to interpret the texture signal. However, our perception of scanning speed turns out to be biased and imprecise, especially for finer textures, so it is unclear whether it can support this hypothetical process. Here, we take a different approach and ask whether we can arrive at speed-independent texture representations without the need for a precise estimate of scanning speed. To this end, we record the responses of cutaneous mechanoreceptive afferents - namely SA1 (slowly-adapting type 1), RA (rapidly-adapting), and PC (Pacinian) fibers - to a diverse set of textured surfaces delivered to the fingertip skin at three different scanning speeds. We also present subsets of these textures at different speeds to human subjects and ask them to rate either the roughness of the texture or the speed at which it is scanned across the skin. We consider the peripheral input as consisting of three signals, namely the SA1, RA, and PC population responses, and then try to separate speed and texture information using different linear combinations of these signals. We find that it is possible to derive features that are almost

completely speed-invariant. Furthermore, speed-invariant features mirror perceptual ratings of roughness and speed-dependent features mirror perceptual ratings of scanning speed. Our results explain how roughness ratings can be invariant with respect to scanning speed without a precise estimate of scanning speed. Furthermore, we offer a new interpretation of roughness as a perceptual signal that arises from simultaneously optimizing the information about texture and its invariance with respect to exploratory parameters.

Abstract: The ability to dexterously manipulate objects relies heavily on somatosensory signals from the hand. Without these signals, activities of daily living like turning a doorknob or brushing one's teeth would be slow, clumsy, and effortful. A unique aspect of somatosensory system is that it comprises a deformable sensory sheet: cutaneous signals must be integrated with proprioceptive ones to achieve a three-dimensional representation of objects grasped in the hand. To begin to understand how this integration happens, we must first understand how hand postures and movements are encoded in primary somatosensory cortex (S1). To this end, we record the responses of S1 neurons and track hand movements while monkeys grasp objects varying widely in shape and size, thereby eliciting different hand movements. We use a variety of analytical methods to determine what aspects of the kinematics drive individual proprioceptive neurons. We find that proprioceptive neurons respond to movements of multiple joints of the hand. Furthermore, proprioceptive neurons are driven not only by hand postures (angles of several joints) but also by movements (the derivatives of joint angles). Our results are

consistent with the idea that S1 neurons encode complex hand postures distributed over multiple digits with the ultimate goal of encoding the positions of the fingertips relative to one another.

Title: The coding of natural textures in primate somatosensory cortex

Authors: *J. LIEBER, H. P. SAAL, S. J. BENSMAIA;
Univ. of Chicago, Chicago, IL

Abstract: A major question in sensory neuroscience is how we extract perceptually consistent experiences from continuously changing sensory input. This perceptual invariance is well-illustrated by the experience of tactile texture. Indeed, the response of cutaneous mechanoreceptors is highly dependent on the speed and force with which a texture is explored. In contrast, the perception of texture is almost completely independent of these exploratory parameters. Thus, somewhere along the neuraxis, texture information must be disentangled from these exploratory parameters to produce an invariant perceptual representation. To investigate the neural mechanisms underlying texture invariance, we scanned a large set of natural and artificial surfaces across the fingertip of Rhesus macaques while recording the responses evoked in single-units in primary somatosensory cortex (areas 3b, 1 and 2). Then, using machine learning approaches, we found that textures can be classified based on the responses they evoke in small populations of S1 neurons, showing that these neurons carry rich information about texture in both the strength and temporal patterning of their responses. Moreover, we found that, while the texture-specific temporal spiking patterns change with scanning speed, the mean rate elicited by textures is constant across different speeds. The speed-independence of firing rates in S1 stands in contrast to the strong speed dependence of peripheral responses. It suggests that the cortical representation of texture is more invariant to speed than is its peripheral counterpart. Finally, we evaluated the extent to which the texture representation in S1 could account for perceptual judgments of texture obtained from human subjects. We found that perceived

roughness is better predicted from the responses of neural populations in area 1 than in area 3b, further bolstering the hypothesis that there is a progressive elaboration of texture information as one ascends the somatosensory neuraxis.

Title: A model that simulates the response of the somatosensory nerves to arbitrary spatio-temporal deformations of the skin of the hand

Authors: *B. P. DELHAYE, H. P. SAAL, B. C. RAYHAUN, S. J. BENSMAIA;
Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Tactile information is conveyed by different classes of primary afferents in the somatosensory nerves. Afferent responses are driven by two processes: (1) stimulation applied to the skin's surface causes it to deform, producing time-varying stresses and strains at the location of mechanoreceptors, and (2) these stresses and strains are transduced by the receptors to produce highly precise and repeatable spike trains in afferents. Here, we built a model that simulates the response of afferents sampled over the entire hand to any arbitrary spatio-temporal deformations of the skin. To this end, the model replicates the two stages of mechanotransduction. First, the stresses resulting from the stimulus at the receptor location are estimated as the sum of two components: a quasi-static component caused by the redistribution of pressure applied at the skin's surface and a dynamic component resulting from the variation of pressure with time, taking into account the biomechanical properties of the skin and *in vivo* quantification of how vibrations propagate across the skin. Second, the resulting stresses are used as input to integrate-and-fire models that produce as output the spiking responses of individual afferents. We show that the model accounts for the response of all three classes of afferents (SA1, RA and PC) to both static and dynamic stimuli. We demonstrate that simulated responses replicate measured responses to complex spatio-temporal stimuli, such as scanned braille or natural textures. The model will be invaluable for providing biomimetic somatosensory feedback in hand neuroprostheses by converting the output of sensors into biomimetic responses that can

then be effected in the nerve through electrical stimulation. The model will also be an important tool in somatosensory research by providing a fast and accurate simulation of the response evoked in the entire population of cutaneous mechanoreceptive afferents by any tactile stimulus.

Title: What can bionic fingers tell us about objects? Extracting behaviorally relevant features from finger sensors output

Authors: B. P. DELHAYE[1], *E. W. SCHLUTER[2], M. S. JOHANNES[3], K. D. KATYAL[3], F. V. TENORE[3], S. J. BENSMAIA[1];

Abstract: Efforts are underway to restore sensorimotor function in amputees and tetraplegic patients using anthropomorphic robotic hands. For this approach to be clinically viable, however, not only must control signals be sent to the hands (through a neural or muscle interface), but sensory signals from the hand must also be conveyed back to the patient. To convey tactile feedback necessary for object manipulation, behaviorally relevant information must be extracted in real time from the output of sensors on the prosthesis. In the present study, we recorded the sensor output from two different bionic fingers (one by SynTouch, the other by APL) during the presentation of a variety of different tactile stimuli, including indentations, vibrations, textures, and moving gratings. Furthermore, the parameters of stimulus delivery (location, speed, direction, indentation depth, vibration frequency and amplitude, etc.) were systematically varied. We then developed simple algorithms to extract behaviorally relevant features from these outputs, such as the stimulus location, surface texture, motion speed, and motion direction. We then assessed the degree to which these algorithms could reliably extract these different types of sensory information across different conditions of stimulus delivery. Not only do our results have

important implications for the development of hand neuroprostheses, but they also shed light on the problems the brain has to solve to extract information from natural afferent responses.

Title: Do proprioceptive neurons in somatosensory cortex encode muscle length?

Authors: ***J. GOODMAN, JR**, G. A. TABOT, A. S. RAJAN, A. K. SURESH, N. G. HATSOPOULOS, S. J. BENSMAIA;
Univ. of Chicago, Chicago, IL

Abstract: Somatosensory signals from the hand are critical to our ability to dexterously manipulate objects. Proprioceptive signals from the hand convey information about hand posture and movements that are integrated with cutaneous signals to culminate in a three-dimensional representation of objects grasped in the hand. While tactile response properties in primary somatosensory cortex (S1) have been extensively characterized, their proprioceptive counterparts have not, particularly for the hand. To fill this gap, we record the responses of S1 neurons (areas 3a and 2) and track hand movements while monkeys grasp objects varying widely in shape and size, thereby eliciting different hand movements. Using a musculoskeletal model, we reconstruct the lengths of hand muscles and tendons during the grasp. We then assess the degree to which musculotendon lengths are related to S1 responses in two ways: First, we assess the degree to which neuronal responses can be predicted based on musculotendon lengths. Second, we assess the degree to which musculotendon lengths can be decoded from the activity of populations of S1 neurons. Finally, we compare the performance of the musculotendon-based models to models of S1 responses based on kinematics.

Abstract: Information about texture is acquired by the active scanning of the fingers across an object's surface. These scanning movements elicit high frequency, complex vibrations in the skin which are converted into neural signals by cutaneous mechanoreceptors. In non-human primates the frequency content of these skin vibrations are represented in the precise timing of the elicited action potentials both at the periphery, as well as at the earliest stages of cortical processing. While peripheral and cortical neurons exhibit similar responses to vibrations, there are also important differences. For example, the firing rates of peripheral afferents are modulated by both vibratory amplitude and frequency, while firing rates in cortex depend only on amplitude, independently of frequency. Furthermore, individual cortical neurons respond to a much wider range of frequencies than any one class of afferents, suggesting convergence of submodality input onto individual neurons in cortex. To better understand how information is transformed between the periphery and cortex, we deliver vibrations, ranging from simple sinusoids to band-pass noise stimuli and varying in intensity and frequency composition, while recording the responses evoked in individual neurons of the ventral caudal nucleus (Vc, equivalent to VPL/VPM) in awake human patients undergoing deep brain stimulation surgery for essential tremor. We then characterize the strength and temporal patterning of thalamic responses to the wide range of stimuli and compare these to their peripheral and cortical counterparts. We show that the thalamus is not a simple relay for sensory information but rather contains an elaborated representation of tactile stimuli.

Abstract: A central question in neuroscience is how sensory representations are transformed as they ascend the neuraxis. In primates, the coding of tactile information has been extensively studied in primary afferents and in primary somatosensory cortex (S1). The general picture that emerges from this previous work is that the responses of neurons in S1 explicitly encode certain behaviorally relevant stimulus features - for example edge orientation or direction of movement - that are either not encoded in the responses of individual afferents, or are encoded in a much more primitive way. A fundamental question, then, is to what extent this process of elaboration of sensory representations occurs at intermediate processing stages. Very little is known about the response properties of neurons in the two nuclei that are interposed between the periphery and cortex, namely, the cuneate nucleus (CN) and the ventroposterior lateral nucleus of the thalamus. In the present study, we seek to fill this gap by investigating the response properties of neurons in the cuneate nucleus (CN) of awake behaving monkeys. We seek to understand (1) whether single neurons in CN receive convergent input from different cutaneous submodalities, and (2) whether CN responses are selective for the higher order stimulus features encoded by cortical neurons. To this end, we have developed an approach to implant electrode arrays chronically in the CN and recorded the responses of CN neurons to a wide variety of stimuli that have previously been used to investigate tactile coding at the periphery and in cortex, including skin vibrations, oriented edges, moving gratings, and textures. We find that that individual CN neurons exhibit properties that are indicative of convergent input from multiple cutaneous submodalities and exhibit tuning for behaviorally relevant features, properties that are not observed at the periphery. Our results demonstrate that the CN is not simply a relay station for somatosensory information but rather is instrumental in its processing and elaboration.

Title: Depression of corticostriatal transmission and responsiveness of striatal projection neurons to phosphodiesterase 10A inhibition in neuronal nitric oxide synthase knockout mice

Authors: *F. E. PADOVAN NETO[1], S. CHAKROBORTY[1], J. F. HARMS[2], C. J. SCHMIDT[2], A. R. WEST[1];
[1]Rosalind Franklin Univ., North Chicago, IL; [2]Pfizer Global Res. and Develop., Groton, CT

Abstract: The striatum contains a rich variety of cyclic nucleotide phosphodiesterases (PDEs) which play a critical role in the regulation of cAMP and cGMP signaling. PDEs modulate striatal medium-sized spiny neuron (MSN) excitability, as well as glutamatergic corticostriatal transmission by limiting the diffusion of cAMP/cGMP within subcellular domains. We previously demonstrated that pharmacological inhibition of PDE10A robustly increases the responsiveness of MSNs recorded *in vivo* to excitatory corticostriatal transmission driven by stimulation of the frontal cortex. However, the signaling mechanisms underlying PDE10A inhibitor-induced changes in corticostriatal transmission are only partially understood. The current studies assessed the role of the nitric oxide (NO)-cGMP signaling pathway in the above effects using wild type (WT) and neuronal NO synthase (nNOS) knock-out (KO) mice. WT and KO mice were treated with vehicle or the potent and selective PDE10A inhibitor TP-10 (3.2 mg/kg, s.c.). Biochemical studies showed that basal and TP-10-evoked tissue cAMP levels were similar in WT and nNOS KO mice. Conversely, both basal and TP-10-evoked cGMP levels were robustly decreased in nNOS KO mice as compared to WT controls. In electrophysiological studies, WT and nNOS KO mice were anesthetized with urethane and single-unit spike activity was isolated during low frequency electrical stimulation of the ipsilateral motor cortex.

Recordings of MSNs performed in nNOS KO mice revealed that both population firing activity and cortically-evoked responses were depressed as compared to WT controls, indicating that in the intact striatum NO signaling plays a key role in mediating synaptic facilitation during stimulation of corticostriatal pathways. We next tested if upstream NO derived from nNOS is necessary for the facilitatory effects of PDE10A inhibition on cortically evoked firing. Comparisons of the effects of TP-10 administration across genotypes indicated that MSNs recorded in nNOS KO mice were considerably less responsive to drug than WT controls, indicating that NO-derived from nNOS is necessary for the facilitatory effects of PDE10A inhibition on cortically evoked firing. Taken together, these observations provide further evidence that tonic NO signaling acts to facilitate corticostriatal transmission in the intact striatum via a cGMP-dependent mechanism. Furthermore, PDE10A acts to filter asynchronous or weak cortical input to MSNs by specifically suppressing this facilitatory influence of NO-sGC-cGMP signaling.

Title: Intrinsic properties of striatal neurons determine similar corticostriatal and thalamostriatal postsynaptic suprathreshold responses

Authors: *M. A. ARIAS, J. BARGAS, D. TAPIA, E. GALARRAGA;
Inst. de Fisiología Celular UNAM, México D.F., Mexico

Abstract: The striatum integrates cortical and thalamic inputs. Striatal projection neurons (SPNs) are a target of both cortical and thalamic projections. Also, different types of

interneurons are targeted by these afferents. The center lateral /parafascicular (CL/Pf) complex, is the main source of thalamostriatal connections, providing only minor inputs to the cerebral cortex. Using whole cell patch clamp recordings in mouse brain slices where both cortical and thalamic inputs were preserved, we compared corticostriatal and thalamostriatal synaptic responses in both classes of striatal projection neurons, direct (dSPNs) and indirect (iSPNs), in fast spiking interneurons (FS), cholinergic interneurons (TAN) and interneurons exhibiting low threshold spikes (LTS). Field stimulation with a concentric bipolar electrode (tip: 50 µm) or illumination of channelrhodopsin-2 (ChR2) delivered to the CL/Pf complex or the cerebral cortex, by transfection with adeno-associated virus containing the double-floxed sequence for ChR2-YFP-CAMKII, were used. ChR2 illumination allowed the exclusive activation of desired neurons or synapses with a blue (473 nm) laser or a LED light. Previous work (Vizcarra-Chacón et al, 2013) showed the complexity of the polysynaptic activation of corticostriatal responses made of several synaptic and voltage-gated currents. Here, we show that polysynaptic suprathreshold responses when stimulating the CL/Pf complex are as complex as corticostriatal responses. Moreover, both thalamic and cortical responses were similar although the differences between dSPNs and iSPNs remain. Similar orthodromic responses were observed after optogenetic cortical or CL/Pf stimulation. Different genres of interneurons were similarly activated by the thalamus or the cortex. We conclude that a great part of striatal synaptic integration depends on the postsynaptic intrinsic properties of striatal neurons and largely independent on the class of afferent (cortical or thalamic). These results also reinforce the view that each neuron class has a particular way to process the same inputs and that striatal output has to be studied in terms of circuitry processing between different neuron classes.

Title: Alterations in gating of hippocampal and amygdalar inputs to the nucleus accumbens induced by disinhibition of the prefrontal cortex

Authors: ***M. TSE**[1], M. AUGER[1], S. B. FLORESCO[2];
[2]Psychology and Brain Res. Ctr., [1]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Pathophysiological alterations in prefrontal cortex (PFC) GABA transmission have been proposed to underlie various psychiatric disorders. Pharmacological reduction of PFC GABA signalling can produce a variety of cognitive, affective and dopaminergic abnormalities that resemble schizophrenia, including impaired spatial reference memory (mediated by the hippocampus) and aberrant attributions of salience to fear-related stimuli (mediated by the amygdala). Inputs from the PFC, hippocampus and amygdala converge within the nucleus accumbens (NAc), yet the manner in which disinhibitory increases in PFC outflow may affect ventral striatal integration of cognitive and emotional information arising from these temporal lobe inputs remains to be elucidated. We recorded from NAc neurons that received inputs from either the hippocampus or the basolateral amygdala (BLA) in urethane-anesthetized rats. Under basal conditions, stimulation of fimbria/fornix (conveying hippocampal output) and the BLA reliably evoked spike firing in separate populations of NAc neurons. Disinhibition of the PFC via local infusion of the GABA-A antagonist bicuculline (25 or 50ng) attenuated hippocampal-evoked firing in 100% of neurons tested. In contrast, reducing PFC GABA with a lower (25 ng) dose of bicuculline enhanced BLA-evoked firing. In comparison, intra-PFC infusions of a higher, 50 ng dose, revealed two populations of NAc neurons, one (66%) where BLA-evoked firing was suppressed and another (33%) where BLA-evoked activity was unchanged or increased. In neurons that received convergent input from both hippocampal and amygdala inputs, disinhibition of the PFC reduced firing evoked by both inputs. These data suggest that reduced PFC GABA activity may differentially gate mnemonic and emotional signals originating from different regions within the temporal lobes and converging in the NAc. Furthermore, this suggests that perturbations in PFC GABA transmission similar to those that may occur in schizophrenia can lead to altered gating of these inputs to the NAc. This in turn may contribute to impairments in hippocampal-mediated cognitive function and aberrant affective salience attribution and increased anxiety associated with the disorder. Future studies will investigate the potential contribution of increased activation of midbrain dopamine neurons in mediating the gating of hippocampal and amygdala inputs into the NAc, and how PFC disinhibition may induced differential patterns of immediate early gene expression in downstream targets.

Title: Action of parvalbumin expressing interneurons in the striatal microcircuit

Authors: *M. DUHNE, E. LARA, A. LAVILLE, J. BARGAS;
Neurociencia Cognitiva, Inst. De Fisiologia Celular UNAM, Mexico DF, Mexico

Abstract: The striatum is mainly composed of striatal projection neurons (SPNs). Here, we used optogenetic techniques and dynamic calcium imaging to search into the function of parvalbumin (PV+) expressing interneurons within the striatal microcircuit activity. We injected PV-Cre mice with adeno-associated viral vector: pAAV-EF1a-DIO-hChR2(H134R)-EYFP-WPRE-HGHpA. ChR2 stimulation allowed the exclusive activation of PV+ neurons with a blue (473 nm) laser or a LED light, while recording the activity of dozens of neurons simultaneously with single cell resolution. As previously described, striatal network activity in the presence of micromolar NMDA consisted on the presence of correlated firing or the spontaneous co-activation of several neurons in the same time window (network states). Recurrence, alternation among network states and reverberant behavior following so-called Hebbian sequences were observed (Carrillo-Reid et al. 2008). During the optogenetic activation of PV+ neurons network activity was inhibited by a few milliseconds. Thereafter, a rebound activation of the circuit was noticed together with a resetting of the striatal microcircuit activity: a transient new network state appeared. This new state was composed by previously active and inactive neurons and its appearance disrupted the control Hebbian sequence which was then substituted by a new sequence that lasted for a few minutes before returning to the control sequence. We hypothesize that activation of PV+ neurons causes a temporal switch in a sequence of motor commands to rapidly change or introduce a different motor act or sequence.

Title: Coinciding decreases in discharge rate suggest that spontaneous pauses in firing of external pallidum neurons are network driven

Authors: *E. SCHECHTMAN[1], A. ADLER[2], M. DEFFAINS[3], H. GABBAY[3], S. KATABI[3], A. MIZRAHI[3], H. BERGMAN[3];

Israel-Canada,, Hebrew University-Hadassah Sch. of Med., Jerusalem, Israel

Abstract: The external segment of the globus pallidus (GPe) is one of the core nuclei of the basal ganglia, playing a major role in normal control of behavior and in the pathophysiology of basal ganglia related disorders such as Parkinson's disease. In-vivo, most neurons in the GPe are characterized by high firing rates (50-100 sp/s), interspersed with long (~0.6 s) periods of complete silence termed GPe pauses. Previous physiological studies of single and pairs of GPe neurons have failed to fully disclose the physiological process by which these pauses originate. We examined 1001 simultaneously recorded pairs of high frequency discharge GPe cells recorded from 4 monkeys during task-irrelevant periods, considering the activity in one cell while the other is pausing. We found that pauses (n=137,278 pauses) coincide with a small (0.78±0.136 spikes/s) yet significant reduction in firing rate in other GPe cells. Additionally, we found an increase in the probability of the simultaneously recorded cell to pause during the pause period of the "trigger" cell. Importantly, this increase in the probability to pause at the same time does not account for the reduction in firing rate by itself. Modelling of GPe cells as class 2 excitability neurons (Hodgkin, 1948) with common external inputs can explain our results. We suggest that common inputs decrease GPe discharge rate and lead to a bifurcation phenomenon (pause) in some of the GPe neurons.

Title: Synaptic properties of projections from primary somatosensory cortex onto different types of striatal neurons

Authors: *Y. M. JOHANSSON, G. SILBERBERG;
Karolinska Institutet, Stockholm, Sweden

Abstract: Sensory information is highly crucial for the selection and generation of behavior. The striatum constitutes a key component of sensorimotor functions as it integrates information from the motor and somatosensory cortex for generating appropriate movements. Projections from the primary somatosensory cortex (S1) provide sensory information to medium spiny neurons (MSN) and various types of interneurons in the striatal microcircuit. These interneurons exert a powerful control of the MSN, which in turn convey the final output to downstream targets. While the synaptic properties of somatosensory input to MSN are well established, only little is known about the input to the different striatal interneurons. Here, we studied the synaptic properties of somatosensory projections to distinct types of striatal interneurons in Lhx6 mice. We obtained simultaneous whole-cell recordings of MSN and neighboring interneurons in acute striatal slices while selectively activating somatosensory terminals with optogenetics. In the presence of gabazine, monosynaptic responses were recorded following to brief stimulations or trains of stimulations of the presynaptic terminals. We found that light-evoked activation of somatosensory input elicited excitatory postsynaptic potentials (EPSPs) in MSN as well as fast-spiking (FS), low-threshold spiking (LTS) and cholinergic interneurons. The synaptic strength of these connections varied depending on the postsynaptic cell type. FS interneurons received stronger input than simultaneously recorded MSNs whereas both LTS and cholinergic interneurons displayed smaller responses. The dynamics of these cortico-striatal synapses were studied by activating the somatosensory terminals repetitively at different frequencies. Interestingly, activity-dependent depression of synaptic efficacy was more pronounced in MSN than in FS. The response of LTS interneurons was characterized by a comparatively shorter time constant of recovery from depression and by lower release probabilities. Additionally, the

number and conductance of postsynaptic AMPA receptors that were activated upon somatosensory input were assessed for MSN and FS cells. Taken together, these findings indicate that input from S1 elicits cell-type specific responses in the striatum and that both pre- and postsynaptic mechanisms contribute to the unique response pattern of the respective cell types.

Title: Up-states in striatal medium spiny neurons depend on spatial and temporal distribution of cortical input

Authors: *D. B. DORMAN, K. T. BLACKWELL;
Krasnow Inst. For Advanced Study, George Mason, Fairfax, VA

Abstract: Medium spiny neurons (MSNs) of the striatum, by integrating cortical, thalamic, and dopaminergic input, underlie goal-directed learning and habit formation. These neurons exhibit state transitions *in vivo* between a hyperpolarized down-state and a subthreshold depolarized up-state that is driven by spontaneous, asynchronous synaptic activity. Experimental work has shown these MSNs exhibit spike timing dependent plasticity; however, most of those studies were performed in brain slices, in which the MSNs are persistently in the down-state. In contrast, synaptic plasticity during the up-state is not well understood. A critical question underlying MSN plasticity is: how do MSNs respond consistently and selectively to spatially- and temporally-distributed excitatory input? Their ability to respond selectively to a subset of cortical inputs during an up-state may underlie their context-dependence in learning and behavior. Recent experimental work (Plotkin et al., 2011) has shown that temporally aligned synaptic stimulation of ~11 adjacent spines on a distal tertiary dendrite produces a regenerative up-state like depolarization at the soma, which is dependent on NMDA and voltage-gated calcium channels. To address spatiotemporal dependence of the MSN response to cortical input, we developed a

biophysical, multi-compartment MSN model with a branching dendritic structure consisting of primary, secondary, and tertiary branches. Additionally, we explicitly model dendritic spines (density of 0.3/μm) consisting of a spherical head and cylindrical neck. Our model uniquely incorporates complex calcium dynamics including buffers, pumps, and diffusion. We tune the model with experimental data, including IV and IF curves, calcium imaging demonstrating a distance-dependent calcium response to back-propagating action potentials, calcium imaging of spine and dendrite responses to synaptic stimulation, and voltage-clamp investigations of calcium-dependent inactivation of voltage gated calcium channels. We validate the model by reproducing the experimentally-observed upstate-like response to closely aligned synaptic stimulation of distal but not proximal dendritic spines (Plotkin et al., 2011). Using this validated model, we conduct simulation experiments beyond current experimental knowledge to investigate the spatial and temporal dispersion of synaptic stimulation necessary to produce an up-state-like response. In addition, to understand how MSNs may consistently respond to cortical input during repeated behavioral trials, we investigate the sensitivity of calcium elevation in spines to inter-trial variability of cortical input.

Title: Optogenetic assessment of dynamic input integration in the ventral striatum

Authors: *J. M. BROOKS, P. O'DONNELL;
Pfizer, Cambridge, MA

Abstract: Striatal medium spiny neurons (MSN) serve as a site of convergence for multiple brain regions involved in goal-directed behavior, including the prefrontal cortex (PFC) and hippocampus (HP). These distinct excitatory inputs are believed to differentially influence striatal circuitry in an activity dependent manner. Electrophysiological recordings from anesthetized rats showed that robust PFC stimulation leads to a reduction in ongoing HP-evoked MSN responses, in part, through the recruitment of local inhibitory mechanisms within the ventral striatum (VS). These data indicate that burst-like cortical activity is capable of attenuating weaker, less salient excitatory input within the striatum. Here, we explored the heterosynaptic mechanisms involved in cortical suppression of competing excitatory synaptic

inputs on ventral striatal MSNs. Whole-cell current-clamp recordings were performed from rats receiving bilateral hippocampal injections of a viral vector (AAV) expressing channelrhodopsin 2 (ChR2) under the CamKinase II promoter. Input interactions were assed in VS MSNs through electrical stimulation of PFC fiber tracts and light pulse stimulation of HP inputs expressing ChR2. We have demonstrated that optogenetically evoked HP EPSPs are greatly attenuated after a short latency (50 ms) following burst-like corticostriatal stimulation (5 pulses, 20 Hz, 0.1-0.5 mA) but not a longer (500 ms) delay. Bath application of picrotoxin (100 uM), but not saclofen (2 uM), reduced the magnitude of suppression suggesting inhibitory $GABA_A$, but not $GABA_b$, receptor activation is likely to play a role. As the reduction is not complete, we assessed the role of two signaling molecules which are known to modulate striatal neurotransmission in a retrograde manner. In the VS, endocannabinoid activation of CB1 receptors reduces presynaptic glutamate and GABA release. In addition, subsets of VS MSNs contain dynorphin which, upon release, could decrease glutamate release through activation of presynaptic kappa opioid receptors (KOR). We found that bath application of the CB1 receptor antagonist AM251 (2 uM) enhanced cortical suppression of optically evoked HP responses suggesting the locus of action for AM251 is on inhibitory interneurons. Similar experiments are being conducted using the KOR antagonist nor-BNI. These findings further substantiate the assertion that shifts in VS neuronal activity involve local suppression of competing afferent inputs converging on the same MSN. Furthermore, these data suggest local heterosyanptic suppression involves several signaling pathways.

Abstract: Basal ganglia are a group of interconnected nuclei, that contribute to cortico-cortical loops to control several functions, e.g. voluntary motor behavior. The functions of the basal ganglia are classically thought to rely on the opposite role of two pathways. In this view, the major input stage of the basal ganglia is the striatum. Excitatory corticofugal fibers target two neuron populations in the striatum, forming the divergent direct and indirect pathways. However, corticofugal fibers also target the subthalamic nucleus (STN), a component nucleus, and the sole glutamatergic nucleus in the basal ganglia. The cortico-subthalamic (cortico-STN) connection is also known as the 'hyperdirect pathway'. It is thought to contribute in stopping an already planned action and to be involved in reinforcing the influence of cortex on STN in Parkinson's disease. If subthalamic neuron firing properties are well described, few studies focused on the pre-synaptic side of the hyperdirect pathway, layer 5 pyramidal cortico-STN neurons. The input-output properties of the cortico-STN neurons and the short-term plasticity of the cortico-STN synapses are still unknown. Furthermore, it is not yet understood how STN neurons receive and process cortical input. Using patch-clamp in rodent brain slices combined to two different approaches both relying on stereotaxically-driven viral transfection *in vivo*, we studied (i) the electrophysiological properties of the cortico-STN neurons and (ii) the short-term properties of the cortico-STN synapses. First, we injected a recombinant Rabies-based retrograde virus into the STN to drive the expression of the reporter protein mCherry in cortico-STN neurons. Then, we identified the mCherry-positive neurons in motor cortex and recorded their electrophysiological properties. Second, we injected an anterograde virus expression vector into motor cortex to express the ChR2-mCherry or ChR2-EYFP fusion proteins. Our results in cortex showed that layer 5 pyramidal neurons firing was reliably driven up to 40 Hz using trains of flashes. Furthermore, this approach produced glutamate release from the corticofugal fibers in the STN when we illuminated the internal capsule or the STN with blue light flashes (473 nm). We recorded the resulting excitatory post-synaptic currents in STN neurons and examined the short-term plasticity profile of the motor cortico-STN synapses between 0.05 Hz and 40 Hz. These results shed light on the pre-synaptic properties of the cortico-STN synapses. Together with investigations in the 6-OHDA rat model, these results will help to understand basal ganglia functioning in normal and pathological state.

Title: Distinct cortical GABAergic projecting neurons differentially modulate the activity of striatal neurons

Authors: *S. MELZER[1,2], M. GIL[2], M. MICHAEL[2], H. MONYER[2];
[1]Dept. of Neurobio., Howard Hughes Med. Institute, Harvard Med. S, Boston, MA; [2]Dept. of Clin. Neurobio., Med. Fac. of Heidelberg Univ. and German Cancer Res. Ctr. (DKFZ), Heidelberg, Germany

Abstract: Intricate interactions between cortical areas and striatum are essential for the integration and transformation of sensory inputs and past experiences into value-based decisions and motor outputs. It is long known that excitatory neurons from essentially all cortical areas project to the striatum. Excitatory connections are therefore thought to underlie executive processes in the basal ganglia loop. Using optogenetics combined with *in vitro* electrophysiology and histochemistry, we show here that GABAergic long-range projections constitute a substantial component of cortico-striatal connections. GABAergic projecting neurons are located presumably in all cortical areas and constitute subpopulations of parvalbumin (PV)- and somatostatin (SOM)-expressing neurons. A closer look at the target specificity of GABAergic projections from primary motor cortex revealed that projecting neurons have diverse innervation patterns. While PV-expressing neurons targeted preferentially direct pathway striatal projecting neurons, SOM-expressing neurons were less selective. Additional variability was observed when comparing GABAergic projections from different cortical areas. Our data suggest that cortico-striatal GABAergic neurons are important for the modulation of striatal output and motor activity.

Abstract: The basal ganglia receive cortical inputs and control voluntary movements. The motor cortex sends afferents to input stations of the basal ganglia, i.e., the striatum and subthalamic nucleus (STN). Both of cortico-striatal and cortico-STN neurons are glutamatergic, and neither specific gene markers nor specific receptors are known. Therefore, it is difficult to selectively manipulate the activity of cortico-striatal or cortico-STN neurons. In the present study, we have applied optogenetics combined with retrograde transport of viral vectors to selectively modulate the activity of cortico-striatal neurons. To induce the selective expression of channelrhodopsin-2 (ChR2) in cortico-striatal neurons, lentiviral vector termed neuron-specific retrograde gene transfer (NeuRet) was injected into the mouse striatum to induce the expression of Cre recombinase in cortico-striatal neurons. Then, adeno-associated viral vector containing a double-floxed inverted open reading frame encoding ChR2 was injected into the motor cortex. The expression of ChR2 is observed in cortico-striatal neurons and laser illumination to the motor cortex induced excitation in these neurons. We gave photostimulation to the motor cortex and recorded neural activity in the basal ganglia. Photostimulation mainly induced biphasic responses composed of inhibition and late excitation in the external segment of the globus pallidus (GPe) and the substantia nigra pars reticulata (SNr), while electrical stimulation to the motor cortex induced triphasic responses composed of early excitation, inhibition and late excitation in these nuclei. These data indicate that inhibition and late excitation in the GPe and SNr evoked by cortical photostimulation are mediated by the cortico-striatal neurons, and that early excitation evoked by electrical stimulation is mediated by other neurons, such as the cortico-STN neurons.

Title: Plasticity in collateral connectivity of striatal projection neurons follows learning of a skilled motor task

Authors: *V. G. LOPEZ HUERTA[1], Y. NAKANO[2], M. GARCIA-MUNOZ[2], G. W. ARBUTHNOTT[2];

Abstract: Neostriatum, the main nucleus of the basal ganglia, participates in motor sequence selection and performance. During acquisition and consolidation of a motor task neostriatal neuronal activity changes dynamically suggesting that changes in synaptic plasticity and synaptic contact reorganization are taking place (Yin et al, 2009). SPNs make up 90% of neostriatum in rodents, they divide in two groups giving origin to parallel output systems the direct (dSPNs) and indirect (iSPNs) pathways of the basal ganglia. Both populations of SPNs connect locally by extensive axon collaterals that exert inhibition on neighboring neurons (Taverna et al, 2008, Lopez-Huerta, et al. 2013). Connections between neurons of either output pathway are important for information processing and final neostriatal output. To test the relevance of these pathways and their synaptic changes following motor skill acquisition has been challenging. In order to address this issue, we trained mice for six days on a single-pellet-retrieval task. We used adenoviral gene transfection of ChR-2 in D1-Cre and A2a-Cre mice. Optogenetic stimulation of dSPNs or iSPNs allowed us selective and widespread activation of each neuronal population. Optical stimulation combined with patch-clamp whole cell recordings of inhibitory postsynaptic currents (IPSCs) were performed in tissue obtained from control and trained mice. We tested collateral connectivity of both spiny neuron populations and evaluated 1) the strength of collateral input from each group of SPN and 2) connectivity rules within the striatal microcircuit under different conditions. Comparison between groups indicates a drop in the number of iSPN to dSPN connections between control and trained groups particularly on the side ipsilateral to the preferred paw with an associated progressive increase in the amplitude of the IPSC. The dSPN to iSPN connections between control and trained animals suffer a smaller decrease and differ less between sides. We are grateful for permission to use the A2a-cre mice from Dr. Alban de Kerchove, Laboratory of Neurophysiology, Université libre de Bruxelles, Belgium.

Title: Modulatory role of dopamine D4 receptor on methamphetamine-induced dopamine release

Authors: ***J. BONAVENTURA**[1], C. QUIROZ[1], M. RUBINSTEIN[2], G. TANDA[1], S. FERRÉ[1]; [1]NIDA/NIH, Baltimore, MD; [2]Inst. de Investigaciones en Ingeniería Genética y Biología Molecular, Consejo Nacional de Investigaciones Científicas y Técnicas, Buenos Aires, Argentina

Abstract: The human dopamine (DA) D4 receptor gene contains a large number of polymorphisms in its coding sequence. The most extensive is found in the region coding the third intracellular loop of the receptor and consists of a variable number of tandem repeats, in which a 48-bp sequence is repeated from 2 to 11 times. The two most common variants contain four repeats (D4.4) or seven repeats (D4.7), with allelic frequencies of about 60% and 20%, respectively. D4.7 has been consistently associated with low constraint, constituting a risk factor for ADHD and substance use disorder (SUD), but little is known about the underlying

mechanisms. Nevertheless it is generally assumed that D4.7 is “less functional” that D4.4 receptor. D4 receptors are highly expressed by pyramidal cortico-striatal glutamatergic neurons of the prefrontal cortex (PFC), including their striatal terminals. Cortico-striatal neurons -in particular those connecting the medial PFC and the medial Nucleus Accumbens (mNAc) shell- play an important role processing cues and events involved in drug seeking. Cortico-striatal glutamatergic neurotransmission seems to also be involved in the acute effects of some drugs of abuse, particularly THC and methamphetamine (METH). Apart from producing a large increase in DA release, METH has been reported to increase the extracellular concentration of glutamate (GLU) in the NAc by not yet well understood mechanisms. We sought to bring new clues into those mechanisms by using knock-in mice carrying a humanized 7-repeat intracellular loop identical to that found in the human D4.7 variant. Extracellular concentrations of DA and GLU were analyzed in the mNAc shell with *in vivo* microdialysis upon acute administration of METH or cocaine. METH (1 mg/kg, i.p.), but not cocaine (1-10 mg/kg, i.p.), produced a significantly lower increase in NAc DA in D4.7 knock-in mice compared to their WT littermates. Interestingly, METH also increased NAc GLU in D4.7 mice but not in WT littermates. Our hypothesis is that this differential effect on both NAc DA and GLU depends on the reduced inhibitory control of NAc GLU release by D4.7. The reduced DA release would be secondary to an increased GLU-mediated feedback inhibition of VTA DA cells by GABAergic striatal-mesencephalic neurons. This hypothesis will be tested by a new microdialysis-optogenetic approach that allows the measurement of GLU induced by the local selective optogenetic stimulation of the glutamatergic terminals innervating the mNAc shell from the infralimbic cortex. We expect to find a reduced control of GLU release in D4.7 mice compared to WT littermates.

Title: Functional anatomy of the infralimbic-accumbens pathway: a microdialysis-optogenetic approach

Authors: *C. R. QUIROZ, M. ORRU, W. REA, A. CIUDAD, S. FERRE;
Medications Discovery Br., NIDA, IRP, NIH, DHHS, Baltimore, MD

Abstract: The glutamatergic pathway that connects the medial prefrontal cortex (MPC) with the nucleus accumbens (NAc) has received substantial attention due to its involvement in the acquisition and elicitation of approach or withdrawal behaviors. It is generally assumed that the prelimbic (PL) and infralimbic (IL) cortices are the corresponding cortical areas projecting to the NAc core and NAc shell. However, there is evidence for a predominant latero-medial striatal functional compartmentalization, dependent on differential connectivity. In this way NAc shell can be functionally divided into lateral and medial portions. The medial portion of the NAc shell (mNAc shell) seems to be preferentially innervated by the IL cortex and by the most caudal and medial part of the ventral tegmental area. Yet, a clear functional distinction exists between the rostral and caudal portions of the mNAc shell, with differential involvement in appetitive and fearful behaviors, respectively. We initially aimed at establishing a neurochemical correlate of the differential function between the rostral and caudal portions of the mNAc shell. Combining electrical stimulation with immunohistochemistry (P-ERK1/2) and *in vivo* microdialysis (glutamate and dopamine release) we found evidence for a selective functional connection between the IL cortex and the caudal (2/3) but not more rostral (1/3) portion of the mNAc shell. Thus, the IL cortex innervates the whole “fear”-related and a fraction of the “desire”-related portion of the mNAc shell. Therefore, the established “anatomical” separation between PL and IL cortices should be changed to a more functional demarcation. As previously reported for other areas of the MPC, IL electrical stimulation was associated with glutamate and also dopamine release in the mNAc shell. The introduction of a new microdialysis-optogenetic approach allowed solving the controversy about the role of MPC afferents to the VTA versus local activation of glutamate receptors localized in NAc dopaminergic terminals in the elicitation of dopamine release in the NAc induced by MPC stimulation. Optogenetic stimulation of IL-mNAc shell terminals elicited glutamate and dopamine release, which were completely counteracted by the local perfusion of a blocker of glutamate release (an adenosine A2A receptor antagonist). On the other hand, the A2A receptor antagonist counteracted glutamate but only partially dopamine release in the mNAc shell induced by IL electrical stimulation. The results indicate that the IL cortex controls the extracellular levels of dopamine in the mNAc shell by means of both the direct IL-NAc pathway and an indirect IL-VTA-NAc pathway.

Title: Corticostriatal pathways underlying bilateral sensory integration in the mouse striatum

Authors: *R. REIG, G. SILBERBERG;
Karolinska Institutet, Stockholm, Sweden

Abstract: Rodents use their whiskers to actively explore their surroundings, simultaneously engaging sensory and motor processes. Cortical somatosensory and motor areas provide glutamatergic input to the basal ganglia via corticostriatal pathways. Individual projection neurons and interneurons in dorsal striatum integrate tactile sensory input from both ipsi- and contralateral whiskers (Reig & Silberberg 2014). The pathways underlying this integration are, however, largely unknown. The aim of this study is to understand the sensory pathways underlying the ipsi- and contralateral tactile responses in striatal neurons. To that end, we used simultaneous *in vivo* whole-cell patch-clamp recordings in striatum as well as extracellular recordings in the neocortex of anesthetized mice. In order to investigate corticostriatal projections, we recorded sensory responses before and after selectively silencing different cortical areas by local TTX injections. Inactivation of the ipsilateral cortical barrel field resulted in strong bilateral decrease of sensory responses. Inactivation of the contralateral barrel field did not affect the response to contralateral whisker deflection but reduced the response to ipsilateral whisker by more than 70%. Inactivation of motor cortex affected only later (> 200 ms) components of the response but not the early stage. We showed that whereas responses to contralateral whisker stimulation are mediated by ipsilateral corticostriatal projections from the barrel cortex, responses to ipsilateral whisker stimulation are mediated mainly by parallel cortico-cortical pathways (mainly cross callosal projections between barrel fields), rather than a direct corticostriatal projection from the contralateral barrel field.

Title: Thalamostriatal system controls selection and flexibility of motor actions

Authors: *K. KOBAYASHI[1], S. KATO[1], M. OKAMOTO[2], S. EIFUKU[2];
[1]Fukushima Med. Univ., Fukushima 960-1295, Japan; [2]Systems Neurosci., Fukushima Med. Univ., Fukushima, Japan

Abstract: The basal ganglia circuitry plays important functions in the appropriate selection and flexible switching of behaviors. The dorsal striatum is a principle structure of the basal ganglia circuitry and mediates learning processes of instrumental motor actions. Anatomically, the dorsal striatum receives glutamatergic excitatory afferents from many cortical areas and the intralaminar thalamic nuclear groups, including the central lateral nucleus (CL) and parafascicular nucleus (PF) as well as dopaminergic projections from the ventral midbrain. In rodents, the CL and PF are localized in the rostral and caudal regions of the intralaminar thalamic nuclear groups, which project directly to medium spiny neurons and interneurons in the striatum. We reported that the PF-derived thalamostriatal pathway is important for the acquisition and performance of sensory discrimination task in mice. To address the roles of the CL-derived thalamostriatal system in learning processes, we performed the selective neural pathway targeting by combining a highly efficient retrograde gene transfer (HiRet) vector and immunotoxin (IT)-mediated cell targeting. Human interleukin-2 receptor α-subunit (IL-2Rα), a receptor molecule for the recombinant IT, was expressed in the neurons innervating the striatum in mice by using the HiRet vector. Treatment with IT into the CL in the vector-injected mice induced a selective, efficient elimination of the thalamostriatal pathway, resulting in the lack of electrophysiological responses elicited by the CL stimulation. The elimination of CL-derived thalamostriatal pathway did not alter the acquisition of visual discrimination, whereas it impaired transiently the accuracy of motor responses and lengthened the response time. In addition, the pathway elimination disturbed the reversal of response discrimination and the set shifting from visual discrimination to response discrimination. These results suggest that the thalamostriatal system originating from the CL predominantly regulates selection and flexibility of motor actions, which requires the function of the prefrontal cortex-basal ganglia circuitry.

Title: Neuronal activity in the marmoset basal ganglia thalamocortical circuit during rest and spontaneous locomotion

Authors: *M. F. ARAUJO[1], R. MOIOLI[2], E. MORYA[2];
[1]Edmond and Lily Safra Intl. Inst. of Neurosci., Inst. Santos Dumont, Macaíba, Brazil; [2]Edmond and Lily Safra Intl. Inst. of Neurosci., Santos Dumont Inst., Macaíba, Brazil

Abstract: The basal ganglia thalamocortical pathway is involved in the regulation of motor function. Dysfunction in this pathway is related to a number of movement disorders such as Parkinson and Huntigton diseases. The description of the neuronal dynamics and firing patterns in this circuit is therefore essential to better understand the patophysiology of such disorders. The present work aimed at describing the activity of neurons in the basal ganglia thalamocortical circuit in the common marmoset. Two microelectrode arrays of 32 microelectrodes were bilaterally implanted in a female marmoset. The arrays were designed to to simultaneously record from the motor cortex and 3 basal ganglia nuclei: putamen, internal globus pallidus and external globus pallidus. Local field potentials (LFPs) and single and multi-unit activity were recorded from all the implanted structures while the animal freely moved inside a plexiglass box (45 x 45 cm). Her behavior was recorded by 2 video cameras positioned at the top and at the front of the box. Each experimental session lasted 10 min. All procedures were approved by the Institution's Ethics Comittee for Animal Use (Protocol 11/2011). On average, 33.9 units were recorded at each of the 8 experimental sessions. Rest and spontaneous locomotion periods were extracted from the video and synchronized with spike data. We describe and compare the neuronal activity patterns found in the 4 recorded structures during these 2 conditions. These

results contribute to the understanding of the basal ganglia thalamocortical circuit functioning during rest and spontaneous movement execution and provides grounds for future studies using common marmosets as models to study movement disorders.

Title: Exclusivity in the connections of the rostral division of the zona incerta

Authors: *D. S. ZAHM, M. T. DESTA;
Pharmacol. and Physiological Sci., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: The zona incerta (ZI) in the rat extends from the dorsolateralmost part of the lateral hypothalamus over the entopeduncular and subthalamic nuclei (EPN and STN) and into the interstice between the internal capsule/cerebral peduncle and basal thalamus from about the level of the EPN to the rostral midbrain. It comprises rostral, caudal and middle divisions, the latter having dorsal and ventral parts. Diverse functions in four categories - visceral response, arousal, attention and postural/locomotion - have been attributed to ZI and, consistent with this, its widespread and diverse connections are reported to involve nearly all part of brain (Mitrofanis, Neuroscience 130:1-5, 2005). Thus, we were surprised in preparing a recent paper on the connections of the midbrain dopaminergic complex (JCN 519:3159-88, 2011) to observe that the density of outputs from the rostral (r) division of ZI drops abruptly to negligible precisely at the dorsal border of the ventral tegmental area, and that ZIr outputs also are few among the dopamine neurons of the substantia nigra compacta and retrorubral field. This effect was more striking in subsequently prepared cases showing anterogradely transported cholera toxin β subunit (Ctβ), which, compared to other tracers, provides minimal definition of axons but a better estimation of projection density. In contrast, projections to numerous other brainstem structures including the mesopontine reticular formation, dorsolateral periaqueductal gray and deep superior colliculus, and thalamic nuclei, including ventral and intralaminar, were exceedingly dense. Ctβ-injected preparations also sensitively demonstrated the afferent projections of ZIr, which, consistent with the cited review, we found to be widespread and

numerous. However, we were again surprised that several basal ganglia structures including the caudate-putamen, accumbens, ventral pallidum, globus pallidus and subthalamic nucleus exhibited zero retrogradely labeled neurons following injections of Ctβ into the ZIr, whereas the related EPN and substantia nigra reticulata had moderate numbers of retrogradely labeled neurons, as did, interestingly, central extended amygdala structures, including the central amygdaloid nucleus, sublenticular region and bed nucleus of stria terminalis, which, actually, exhibited moderate to strong retrograde and anterograde labeling following by ZIr injections of Ctβ. Other ZI divisions remain to be addressed in this way, but, nonetheless, this enigmatic anatomy should have interesting functional implications, particularly in view of recent keen interest in ZI as a target for deep brain stimulation in Parkinson's disease.

Title: Primary motor cortex leads globus pallidus in the encoding of kinematics in rhesus macaques

Authors: P. J. RICE[1], B. PASQUEREAU[2], O. DRINKWATER[3], *R. S. TURNER[2];
[1]Univ. of Washington, Seattle, WA; [2]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA;
[3]Weill Cornell Med. Col., New York City, NY

Abstract: Some theories propose that the basal ganglia (BG) plays a role in early processing of planned movement (requiring that activity in the BG leads the cortex in the encoding of movement kinematics), whereas others suggest a role in feedback control (i.e. the encoding of kinematics appears earlier in cortex than in the BG). To disentangle these potential functions, we compared the timing and strength of kinematic-related signals encoded in the spiking activity of neurons in the globus pallidus (GP) and primary motor cortex (M1). Single-unit activities were recorded in four rhesus monkeys trained to perform an extended series of multi-joint arm movements. A total of 364 cortical neurons and 554 pallidal neurons were collected across the

four animals. To determine the latency of kinematic encoding three independent analytic methods were applied. In the first, the averaged movement-related activities around the time of movement initiation were used to determine response onset latency for each cell recorded within the two structures. In the second, a generalized linear model (GLM) regression analysis was performed on unit activity around the time of the first movement to determine the timing and strength of encoding of the observed kinematics (including direction, maximum speed, extent, duration, and reaction time). The third method applied a GLM to study the temporal relationship between neuronal activity and the ongoing series of movements. This model estimated the degree to which spike rate encoded continuous measures of hand position, velocity, acceleration, and speed at a temporal offset τ, thereby allowing an estimation of the lead or lag between spike firing and the observed kinematics. For all three methods, an ROC analysis was applied to compare latencies between the two populations. The first analysis found no difference in response onset latencies (median M1: -121ms, GP: -110ms; AUC=0.53 P=0.13). The encoding of kinematics, however, appeared earlier in M1 than in GP both around the time of movement initiation (second method; median M1: -89ms, GP: -20ms; AUC=0.66 $P<0.001$) and also during ongoing movement (third method; median τ M1: -100ms, GP: -20ms; AUC=0.71 $P<0.001$). While our results do not support a role of the BG in generating or selecting the motor command, they do suggest an involvement in the monitoring or evaluation of motor performance.

Title: Loss of neuropilin 2 induces aberrant corticostriatal circuit activity and impairs goal-directed instrumental behavior in mice

Authors: M. W. SHIFLETT[1], M. ASSOUS[2], E. MARTINEZ[3], E. CHOE[3], J. M. TEPPER[2], *T. S. TRAN[3];
[1]Psychology, [2]Ctr. For Mol. And Behavioral Neurosci., [3]Biol. Sci., Rutgers Univ., Newark, NJ

Abstract: Neuropilin 2 is an obligate binding partner to class 3 secreted semaphorins (Sema3s) and has been demonstrated to play an important role in dendritic morphogenesis and synapse refinement in the mammalian nervous system. Our previous findings show Semaphorin 3F (Sema3F) acting through the Neuropilin 2/Plexin-A3 (Nrp2/PlexA3) holoreceptor complex signals *in vivo* to restrain layer 5 cortical neuron dendritic spine morphogenesis. Loss of semaphorin signaling produces exuberant spines on apical dendrites of Layer 5 cortical pyramidal neurons that project axons to the striatum. The effects of Neuropilin 2 signaling on corticostriatal circuit function are unknown. Using mice that harbor a mutation in the locus encoding neuropilin 2 (Nrp2), we investigated cortical synaptic input as well as performance in an instrumental learning task known to depend on corticostriatal circuit function. Whole cell recordings from corticostriatal coronal brain slices revealed that Nrp2-/- mutants displayed impaired pair pulse ratio compared to wild type (WT) littermate controls. In addition, striatal spiny projection neurons in Nrp2-/- mutant mice showed significantly higher excitability in terms of rheobase current, input resistance, and firing frequency in comparison with the WT littermates. These results suggest both a presynaptic and a postsynaptic impairment. Furthermore, in the instrumental learning task, Nrp2-/- mutants mice showed insensitivity to changes in outcome value when compared to age-matched controls, suggesting their behavior was not goal-directed but rather was controlled by antecedent stimuli. Collectively, these results coupled with previous cellular, molecular and electrophysiological findings suggest that loss of Nrp2 may induce aberrant activity within the corticostriatal pathway giving rise to behavioral and cognitive impairments. This work was supported, in part, by NS034865 to JMT and the Charles and Johanna Busch Biomedical Fund to TST.

Title: Dysfunction of subthalamic nucleus neurons in mouse models of Huntington's disease

Authors: *J. F. ATHERTON[1], E. MCIVER[1], V. BEAUMONT[2], D. J. SURMEIER[1], M. D. BEVAN[1];
[1]Physiol., Northwestern Univ., Chicago, IL; [2]CHDI Fndn., Los Angeles, CA

Abstract: Huntington's disease (HD) is a hereditary neurodegenerative disorder caused by an expansion of a CAG repeat within the huntingtin (htt) gene. In its early stages HD leads to striatal degeneration, with profound effects on basal ganglia circuitry. The BACHD transgenic and Q175 knock-in mouse models of HD, which express full length human mutant htt with 97 and ~179 CAG repeats respectively, are associated with abnormal intrinsic and synaptic properties in cortical and striatal neurons together with neuronal degeneration and behavioral abnormalities. The subthalamic nucleus (STN) is a key element of the basal ganglia, but its properties are relatively uncharacterized in these models. Thus, the aim of this project was to determine whether STN neurons exhibit alterations that may contribute to abnormal behavior. The frequency and precision of autonomous activity of STN neurons in brain slices from BACHD and Q175 mice were compared with wild type (WT) littermate controls at <2 and 6 months for BACHD and at 6 months for Q175. At 2 and 6 months the firing frequency of BACHD and Q175 neurons was reduced and the proportion of inactive neurons increased. Disrupted firing in BACHD was rescued to WT levels by application of the KATP channel antagonist glibenclamide or decomposition of H2O2 by catalase. When co-applied, each occluded the other, suggesting that H2O2 activates KATP channels. Assessment of mitochondrial redox state using 2-photon imaging of roGFP confirmed increased oxidation in BACHD. In BACHD, NMDA receptor (NMDAR)-mediated mEPSCs exhibited prolonged decay times at both <2 and 6 months. Blockade of the excitatory amino acid transporters EAAT1/GLAST and EAAT2/GLT-1 with TFB-TBOA prolonged decay times of NMDAR-mediated EPSCs elicited by optogenetic stimulation of M1 motor cortical axons in WT but not in 6-month-old BACHD, suggesting that dysfunctional glutamate transport may result in excessive NMDAR activation. NMDAR activation can activate KATP channels through NO signaling, implying that abnormal NMDAR activation could underlie firing disruption. Indeed, incubation of WT slices in NMDA for 60 minutes also produced a persistent KATP channel-dependent disruption in firing. Furthermore, application of the NOS blocker L-NAME partially rescued firing in BACHD. Together, these data suggest that disrupted autonomous activity in these models may be triggered by abnormal NMDAR function leading to increased NO production, mitochondrial dysfunction and KATP channel activation.

Title: A new task to characterize striatal mechanisms for running control in mice

Authors: C. SALES-CARBONELL, L. KHALKI, *D. M. ROBBE;
Inst. de Neurobiologie de la Méditerranée, Marseille, France

Abstract: The exact role of the basal ganglia in motor control is still highly debated. D1- and D2-positive medium spiny neurons (MSN) of the dorsal striatum form respectively, the direct and indirect pathways of the basal ganglia. These two neuronal populations are classically though to play antagonistic roles in motor control. D1-MSN activation would initiate movement while D2-MSN would contribute to suppression of unwanted actions. Still, the specific contribution of these two pathways in a motor task that requires both active initiation and suppression of movements is still unresolved. Here we developed a new head-fixed behavioral task in which mice are trained to run a fixed distance upon presentation of a simple stimulus in order to obtain a liquid reward. Importantly, upon successful completion of a run, the presentation of a new stimulus is conditioned on the animal being completely immobile for a few seconds and this at a fixed time interval after reward delivery. Once fully trained, mice develop a stereotyped running sequence during which they successively accelerate, run at steady speed, decelerate and completely stop running. Recording of spiking activity was performed in the dorsal striatum of trained mice using silicon probes. We found that a majority of units had their activity strongly modulated at different phases of the task both during running and immobility period. Ongoing statistical analyzes and experiments using optogenetic-based identification of D1 and D2 MSN will reveal the specific contribution of the two populations of MSN in the execution of the distinct phases of our motor task.

Title: Plasticity of motor cortex-subthalamic nucleus transmission in experimental Parkinson's disease

Authors: *H.-Y. CHU[1], M. D. BEVAN[2];
[1]The Feinberg Sch. of Medicine, Dept. of Physiol., [2]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The basal ganglia are a group of subcortical brain nuclei critical for voluntary movement and a major site of dysfunction in movement disorders like Parkinson's disease (PD). To determine how the movement suppressing hyperdirect pathway from the motor cortex (MC) to the subthalamic nucleus (STN) is altered in experimental PD, we interrogated *ex vivo* brain slices derived from 6-hydroxydopamine- or vehicle-injected mice using electrophysiological, optogenetic and immunohistochemical approaches. The properties of MC-STN transmission were significantly altered by the chronic loss of dopamine. Thus, 1) the amplitude of maximal optogenetically stimulated MC-STN AMPA receptor (R)-mediated transmission was reduced by ~70%; 2) the amplitude and frequency of miniature MC-STN transmission, optogenetically evoked in the presence of Sr^{2+}, were reduced by ~15% and ~60% respectively; 3) MC-STN AMPAR-mediated EPSCs exhibited greater inward rectification and sensitivity to 1-naphthyl acetyl spermine trihydrochloride, a selective GluA2 subunit-deficient AMPAR antagonist, indicating an increase in the expression of Ca^{2+} permeable AMPARs; 4) the ratio of NMDAR:AMPAR MC-STN transmission was slightly decreased; 5) the density of vesicle glutamate transporter 1 expressing (cortex-STN) axon terminals was reduced by ~40%. The structural and morphological changes associated with dopamine depletion-induced plasticity of MC-STN synaptic transmission are being investigated further through confocal and 2-photon imaging. Together these data suggest that excessive cortical patterning of the STN in PD is not due to an increase in the strength of MC-STN transmission.

Title: Calcium dynamics predicts direction of synaptic plasticity in striatal spiny projection neurons

Authors: *J. JEDRZEJEWSKA-SZMEK[1], S. DAMORADAN[2], D. B. DORMAN[2], K. T. BLACKWELL[3];
[1]The Krasnow Inst. For Advanced Study, [3]Mol. Neurosci., [2]George Mason Univ., Fairfax, VA

Abstract: The striatum is a major site of learning and memory formation for both sequence learning and habit formation. One of the mechanisms used by the brain for memory storage is synaptic plasticity -- the long-lasting, activity dependent change in synaptic strength. All forms of synaptic plasticity require an elevation in intracellular calcium, and a common hypothesis is that the amplitude and duration of calcium transients can determine the direction of synaptic plasticity. The utility of this hypothesis in the striatum is unclear in part because dopamine is required by striatal plasticity and because of the diversity in stimulation paradigms. To test whether calcium can predict plasticity direction, we developed a calcium based plasticity-rule using a model MSN with sophisticated calcium dynamics including calcium diffusion, buffering, and pump extrusion. We utilize three spike-timing dependent plasticity (STDP) induction paradigms, in which postsynaptic potentials are paired withe precisely timed action potentials. Experimentally, the timing of such pairing determines whether potentiation or depression will occur. Our simulations show that, despite the variation in calcium for different protocols, a single, calcium-based weight change rule (plasticity rule) can explain the change in synaptic weights for all three STDP paradigms. Additional simulations show that the plasticity rule correctly predicts that long-term potentiation (LTP) elicited by forward pairing (but not long-term depression (LTD) induced by backward pairing) is blocked when NMDA receptors are blocked. In addition, the plasticity rule correctly predicts that blocking L-type channels does not influence LTP induced by forward pairing, but blocks LTD induced by backward pairing. Further simulations will explore the role of dopamine by implementing synaptic and ionic channel changes produced by D1 and D2 receptors. Elucidating the mechanisms underlying synaptic plasticity, especially the role and interplay of calcium and dopamine, will allow for better understanding mechanisms of memory storage in health and disease.

Title: Simultaneous functional imaging and neurochemical recording during subthalamic nucleus deep brain stimulation

Authors: ***E. K. ROSS**[1,2], H.-K. MIN[2], M. SETTELL[2], A. MCCONICO[2], S. CHO[2], C. BLAHA[2], S. CHANG[2], K. BENNET[2], K. LEE[2];
[1]Neurosci., Mayo Clin. Col. of Med., Rochester, MN; [2]Mayo Clin., Rochester, MN

Abstract: Introduction: Deep brain stimulation (DBS) within the basal ganglia complex is an effective neurosurgical approach to treat motor symptoms associated with Parkinson's disease (PD). Over 100,000 patients with neurologic and neuropsychiatric disorders have been successfully implanted with DBS systems to date, though the mechanisms still remain poorly understood. It is therefore a common critical goal in stereotactic and functional neurosurgery to elucidate the mechanisms of DBS in order to improve patient care. Here, we set out to address this issue by combining two powerful technologies, functional magnetic resonance imaging (fMRI) and *in vivo* neurochemical monitoring to investigate subthalamic nucleus (STN) DBS-mediated activation of basal ganglia network circuitry. Methods: MR image-guided stereotactic surgery was performed to deliver a chronic mini-DBS electrode to STN in three anesthetized rhesus macaques. 3D functional anatomical data were obtained from STN DBS-evoked blood oxygen level dependent (BOLD) increases during fMRI. Placement of the carbon fiber microelectrode (CFM) was based on the maximum intensity voxel within the respective activation cluster in sub-regions of the basal ganglia. For fast-scan cyclic voltammetry (FSCV), we used wireless instantaneous neurochemical sensing (WINCS Harmoni) system to apply a pyramidal voltage waveform (-0.4V to 1.45V) to the CFM with respect to an Ag/AgCl reference

electrode. All study procedures were compliant with the National Institutes of Health Guidelines for Animal Research and approved by Mayo Clinic IACUC. Results: STN DBS resulted in significant BOLD increases in basal ganglia and motor circuitry (FDR < 0.001), including ipsilateral motor cortex, cingulate gyrus, putamen, caudate nucleus, premotor cortex, and contralateral cerebellum. Additionally, we found stimulation time-locked dopamine release in both caudate and putamen, correlating with the maximum intensity voxel in each activation cluster based on the functional activation map seen in the fMRI. Conclusions: Here, we correlate STN DBS-evoked neurotransmitter release with simultaneous fMRI in the same sub-regions. The simultaneous combination of fMRI and electrochemistry offer a new and exciting approach that provides complementary anatomical mapping and neurochemical monitoring implicated in the therapeutic actions of STN DBS. Importantly, the STN DBS evoked dopamine release may be an important mechanism by which DBS improves PD symptomatology. Title: Beta oscillations between the subthalamic nucleus and substantia nigra pars reticulata during automatic and voluntary movement

Authors: *J. J. JANTZ, M. WATANABE, R. LEVY, D. P. MUNOZ;
Queen's Univ., Kingston, ON, Canada

Abstract: The basal ganglia network (BG) is implicated in switching between automatic and voluntary saccadic eye movements, and can influence saccade initiation via output to the superior colliculus and frontal eye fields. We provide complimentary neurophysiological

evidence by which this may occur, by examining changes in local field potential oscillation and coherence between simultaneously recorded electrodes in the subthalamic nucleus (STN; BG input) and substantia nigra pars reticulata (SNr; BG output). Two monkeys performed an interleaved pro- (look toward) and anti-saccade (look away) task, to recruit automatic and voluntary control, while STN and SNr activity was recorded (n = 15 acute electrode pairs, 1500+ trials per pair). First, we found that STN and SNr coherence was strikingly decreased from baseline in beta band frequencies (15-30 Hz) during the peri-saccadic period in pro- and anti-tasks. Second, we found a strong relationship between beta power and saccade latencies, by grouping trials according to high or low beta band power in either the STN or SNr. During the anti-saccade task, both STN and SNr beta power was inversely correlated with saccade initiation. In stark contrast, STN beta power had no effect on pro-saccade initiation, while SNr beta power was positively correlated with pro-saccade initiation. Overall, we found that STN and SNr beta power had the same effect during anti-saccades, but an opposite effect during pro-saccades. Local field potential recordings reflect the summation of local electrical fields, and an increase in oscillatory power reflects increased synchrony in local neuronal networks. Therefore, we suggest these differences may be attributable to changes in BG networked activity during the suppression of reflexive responses and volitional execution of saccades.

Title: Chemogenetic restoration of autonomous subthalamic nucleus activity ameliorates motor deficits in experimental Parkinson's disease

Authors: *E. MCIVER, J. ATHERTON, D. SURMEIER, M. D. BEVAN;
Northwestern Univ., Chicago, IL

Abstract: Parkinson's disease (PD) is associated with the degeneration of substantia nigra dopamine neurons, the development of abnormal, synchronous, rhythmic activity in the cortico-basal ganglia-thalamo-cortical circuit, and impaired movement. The origin of this abnormal activity pattern and its relationship to motor dysfunction remain poorly understood. However, the slow emergence of abnormal activity days to weeks after loss of dopamine in the 6-hydroxydopamine (6-OHDA) model of PD implies an important role for plasticity. The subthalamic nucleus (STN) occupies a key position in this circuit, at the intersection of the movement-inhibiting indirect and hyperdirect pathways. We hypothesized that the autonomous activity of STN neurons normally decorrelates indirect and hyperdirect pathway activity and that loss of autonomous firing following dopamine depletion promotes abnormal activity and motor dysfunction. 2-3 weeks after 6-OHDA treatment, *ex vivo* brain slice recordings confirmed that the autonomous firing of STN neurons was profoundly disrupted (sham: 10.2, 4.9-15.1 Hz, 12.6% inactive; 6-OHDA: 2.3, 0-7.4 Hz, 37.5% inactive; median, interquartile range). Disrupted activity was associated with an elevation of reactive oxygen species and was rescued by antagonism of ATP-sensitive potassium (KATP) channels. Activity disruption may be triggered by excessive activation of STN NMDA receptors (Rs) *in vivo*. Indeed, persistent KATP channel-dependent disrupted firing was reproduced *ex vivo* in control tissue by pre-incubation in 25 μM NMDA for 1 hour prior to recording. Furthermore, knockdown of STN NMDARs *in vivo* in 6-OHDA-treated mice prevented autonomous firing disruption and also ameliorated motor dysfunction. These data suggest that an NMDAR-triggered increase in whole-cell KATP channel conductance disrupts intrinsic STN firing in experimental PD and that preventing this disruption may be therapeutic. We next employed a chemogenetic approach to restore intrinsic STN activity in 6-OHDA-treated mice. DREADD activation restored autonomous STN firing *ex vivo* to control levels and reversed motor dysfunction *in vivo*. Together, these findings suggest restoration of intrinsic STN activity as a novel therapeutic approach in PD.

Title: Localization of glycinergic neurons in the rodent thalamus

Authors: *P. LOZANO[1], M. PANDO[2], M. MIRANDA[2];
[1]Biol., Univ. of Texas At El Paso, El Paso, TX; [2]Univ. of Texas at El Paso, El Paso, TX

Abstract: Localization of Glycinergic Neurons in the Rodent Thalamus The thalamus is considered a critical hub integrating a complex array of motor and sensory functions. The detailed anatomy of some neuronal networks, local circuits, inputs from and to the brain stem and cortex are well known. While the general topography is well understood, the position and contribution of glycinergic networks to thalamic functions need to be elucidated. Recent published data and our preliminary studies suggest the presence of glycinergic neurons in the thalamus, whether this immunoreactivity corresponds to glia cells or neurons is something that remains to be investigated. To address this question, we have stained mouse brain sections with anti-glycine transporter 1 antibody and detected strong immunoreactivity throughout the nuclei of the thalamus. The presence of GlyT1 was confirmed by western blotting. Further staining suggests co-localization of GlyT1 with the neuronal marker MAP2 and excluded from GFAP staining, suggesting expression in neuron. Future studies will focus in the characterization of these cells by delivery of the retrograde and anterograde tracers Fluoro-Gold and Fluoro-Ruby, respectively, into the different thalamic nuclei. These experiments should shed light into the glycinergic network in the thalamus. Understanding the neural pathways containing glycine transporters will allow us to have a better knowledge about the inhibitory inputs in the control of sensory-motor integration.

Title: Movement modulates phase-locking between neuronal discharge in human STN and cortical oscillations

Authors: *W. J. LIPSKI[1], R. S. TURNER[2], D. J. CRAMMOND[1], E. D. KONDYLIS[1], A. ALHOURANI[1], M. J. RANDAZZO[1], M. RICHARDSON[1];
[1]Dept. of Neurosurg., [2]Dept. of Neurobio., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Deficits in the initiation and control of movement account for many symptoms in Parkinson's disease (PD), including akinesia, bradykinesia, freezing, rigidity and tremor. The

underlying etiology in PD involves the degeneration of the dopaminergic nigrostriatal pathway, which results in increased activity in the subthalamic nucleus (STN). This pathological hyper-activity of STN, in turn, suppresses thalamocortical activity via the indirect pathway, and is thought to result in hypo-active movement deficits such as akinesia, bradykinesia, rigidity, and freezing for which deep brain stimulation (DBS) of the STN is an effective therapy. Recent findings implicate the interactions between sensorimotor cortex and the STN in the pathophysiology of PD, which may contribute to the generation of aberrant cortical-basal ganglia activity that disrupt movement control. However, the physiology of these interactions is not understood. In order to elucidate the role of cortico-subthalamic interactions in movement control, we recorded single neuron (spike) and local field potential (LFP) activity in the STN simultaneously with ECoG activity from sensorimotor cortex of PD patients undergoing STN DBS electrode implantation. Eight subjects performed a bimanual grip force reaction time task intra-operatively during data recording. In 10 of 28 STN neurons recorded from 8 patients, the discharge of single STN neurons was phase-locked to ECoG oscillations in sensorimotor cortex, within the beta (12-30 Hz; N=4) and theta (4-8 Hz; N=6) frequency bands. In a subset of 3 STN neurons showing phase locking, the strength of coupling was modulated during movement. For ipsilateral movements, phase locking, measured one second after grip force onset, was enhanced , while for contralateral movements phase locking was suppressed, relative to pre-movement baseline. Thus, STN neuronal activity became de-synchronized from ECoG oscillations during contralateral movement. Furthermore, cortico-subthalamic coupling become stronger during ipsilateral responses when movement was inhibited, suggesting that coupling may play a functional role in response inhibition. Understanding how motor function is disordered in PD, and investigating the neural substrates underlying this pathology is critical to improving the treatment of this disease. These findings demonstrate the functional significance of the coupling between sparse (30%) networks of neurons in both STN and sensorimotor cortex.

Title: How do the basal ganglia control reaching movements?

Authors: J. C. HOUK, *B. W. PETERSON;
Dept Physiol, Northwestern Univ. Med. Sch., Chicago, IL

Abstract: Basal ganglia (BG) output neurons (BGO - found in SNr and GPi) tightly control saccadic eye movements via direct disinhibition of superior colliculus. In somatic reaching, BGOs disinhibit thalamic input to motor cortex (M1) rather than M1 itself, raising questions about efficacy. During well-practiced reaching movements, primate BGOs respond only after the movement has been initiated (Turner & Desmurget 2010). As rodents learn a head-reaching task, most striatal neurons gradually cease firing until only 11% remain active (Tang et al 2007). These findings suggest that BG initiate unfamiliar reaching movements and then drive plastic changes that enable motor cortex to initiate reaching on its own (Exportation). In support, Roy et al (SfN 2008; 378.9) observed that while GPi neurons were only weakly modulated during primary movements monkeys made to a target, less predictable corrective movements were accompanied by large changes at latencies appropriate to trigger the correction. Confirmation of this exportation hypothesis was assembled in Houk et al (2007). We conclude that BG control reaching movements by learning appropriate commands and exporting them to M1 for quicker execution.

Title: Glutamatergic transmission blockade in the striatum reduces dyskinesias in Parkinsonian monkeys

Authors: *S. M. PAPA[1], A. SINGH[2];
[1]Neurol., Emory Univ., Atlanta, GA; [2]Yerkes Natl. Primate Res. Center, Emory Univ. Atlanta, Atlanta, GA

Abstract: Striatal glutamatergic hyperactivity is thought to play a crucial role in the mechanisms of levodopa-induced dyskinesia (LID) in Parkinson's disease (PD). Striatal projection neurons (medium spiny neurons, SPNs) are markedly hyperactive and often exhibit inverted

(bidirectional) firing frequency changes following dopaminergic stimulation. These abnormal physiological responses that are associated with LID expression can be reversed to stable, unidirectional responses by striatal micro-infusion of NMDA receptor antagonist. In addition, the systemic administration (s.c.) of NMDA antagonists reduces LID. However, the impact of localized striatal glutamatergic blockade on dyskinetic behavior has not been assessed. To this end, the NMDA receptor antagonist LY235959 (9 mM; total volume, 10µl) or vehicle (aCSF) was infused into the striatum in one side (0.33 µl/min) of the brain of awake advanced parkinsonian macaques. Striatal injection sites were determined by electrophysiological mapping targeting the posterolateral region of the putamen (the sensory-motor territory). The striatal infusion was followed by a systemic injection of levodopa at predetermined dyskinesigenic doses. Animals were then assessed for motor disability and LID severity using standardized rating scales for primates. Striatal LY235959 significantly reduced LID (total and peak dyskinesia scores) on the contralateral side without compromising the antiparkinsonian action (motor disability scores) of levodopa. The striatal infusion of vehicle did not change LID scores. These findings confirm that glutamatergic transmission in the dysfunctional striatum underlies the release of involuntary movements in advanced parkinsonism.

Title: Striatal oscillations in advanced Parkinsonian monkeys and their regulation by glutamatergic transmission

Authors: *A. SINGH[1], S. PAPA[2];
[1]Yerkes Natl. Primate Res. Center, Emory University,, Atlanta, GA; [2]Yerkes Natl. Primate Res. Center, Emory Univ. Atlanta, Atlanta, GA

Abstract: Dopamine depletion in Parkinson's disease (PD) has been associated with abnormal oscillatory activities in the cortico-basal ganglia network (i.e. cortex, globus pallidus, and subthalamic nucleus). However, oscillatory activity in the striatum following dopamine loss and chronic replacement therapy remains poorly defined. Here, we studied striatal oscillations during

"off", "on" and dyskinesia (LID) states in advanced parkinsonian primates. Additionally, glutamate receptor antagonists known to stabilize neuronal firing changes after L-dopa administration were used to regulate the abnormalities in striatal activity. Striatal local field potentials (LFPs) were recorded in MPTP-treated monkeys with standard techniques. The NMDA receptor antagonist LY235959 was injected into the striatum at the recording site before the systemic injection of levodopa. Striatal LFPs were analyzed during "off", "on" (after local artificial CSF or NMDA antagonist and systemic levodopa administration), and subsequently during "on"-with-dyskinesia state. A peak with the higher amplitude (relative power) in the 8-13 Hz (alpha frequency band) was recorded in the "off" state. This peak significantly decreased in the "on" state (local aCSF). However, a peak with higher amplitude in the 13-20 Hz (low-beta frequency band) was observed during "on" state. The NMDA antagonist reduced the peak amplitude in 13-20 Hz during the "on" state. No clear peak was observed in relation to LID. Therefore, reduced peak in 8-13 Hz and increased peak in 13-20 Hz could be associated with the dopamine response in chronically treated severe parkinsonian animals. These results also indicate that the reduction of glutamatergic transmission regulates abnormal striatal oscillations in response to levodopa in the advanced stage of PD.

Title: How the cerebellum and the basal ganglia cooperate together for sensorimotor learning ?

Authors: *L. PIDOUX[1,2], A. LEBLOIS[2];
[1]Ctr. De Neurophysiologie, Physiologie Et Patholo, Paris, France; [2]CNRS UMR 8119, Univ. Paris Descartes, Paris, France

Abstract: Human speech is a complex sensorimotor skill and vocal learning is one of the most striking cognitive abilities of the brain. As many other complex motor skills, vocal learning involves the basal ganglia (BG)-thalamo-cortical network and the cerebello-thalamo-cortical network in humans. While the BG and cerebellar sub-cortical loops have been shown to interact at least through two different pathways in mammals, the role of their interaction during sensorimotor learning, and in particular during vocal learning, remains undetermined. Songbirds are one of the few accessible animal models for vocal learning, as they have a specialized portion

of their BG-thalamo-cortical circuitry dedicated to song learning. Additionally, a cerebellar projection to the thalamic region adjacent to the song-related thalamic nucleus receiving BG input suggests that BG and the cerebellum may interact during song learning. However, very little is known about song-related circuits in the cerebellum, or about a putative cerebellar function in song learning. We are studying the interactions between BG and cerebellar sub-cortico-cortical loops involved in avian song learning. In order to determine to what extent the cerebellum is involved in song learning and dissect the cerebellar circuits interacting with thalamic and cortical song-related nuclei, we performed two sets of experiments. On one hand, we investigated the physiological mechanisms underlying the integration and transfer of cerebellar signals in the BG using electrophysiological recordings of evoked BG activity following electrical stimulation in the cerebellum. Stimulation of the deep cerebellar nuclei evoked fast excitatory responses in BG neurons located in the song-related BG nucleus Area X. With pharmacological experiments, we found that these responses are mediated by the thalamus before going to the BG and then transmitted to the cortical nuclei LMAN. Our results also suggest that another pathway, linking the cerebellum to the song system by MMAN and HVC, could exist in songbird. On the other hand, we performed cerebellar lesion on adults and juveniles zebra finches (at 30 and 60 dph) to quantify the impact of the cerebellum during song production and learning respectively. We found no or minor differences in adults song production features (duration, pitch) before and after cerebellar lesion. However, syllable duration, pitch and similarity to the tutor are impaired in juveniles.

Title: Understanding the role of glutamate in deep brain stimulation of the subthalamic nucleus using enzyme-based microelectrode amperometry in a transgenic mouse model

Authors: *E. S. ARVIDSSON, Å. KONRADSSON-GEUKEN, N. SCHWEIZER, S. PUPE, M. PAPATHANOU, Å. WALLÉN-MACKENZIE;
Uppsala University, Depratment of Comparative Phys, Uppsala, Sweden

Abstract: The underlying mechanisms of the clinical efficacy as well as the side effects of deep brain-stimulation (DBS) of the basal ganglia, more specifically, the stimulation of the subthalamic nucleus (STN), in patients suffering from severe Parkinson's disease, are still unknown. Despite both clinical and pre-clinical characterizations of the anatomical and electrophysiological properties of neurons within this structure, the identification of promoter-specific subgroups of neurons within this area itself has been somewhat neglected. As the STN is considered to be a homogenous structure, highly glutamatergic, we have characterized the expression of Vesicular Glutamate Transporters (VGLUTs) in this area of the mouse brain, to further increase the current understanding of the glutamatergic nature of the STN. In line with previous studies, we have confirmed VGLUT2 to be the predominant subtype. More notably, we have been able to identify a subpopulation within the STN, which is characterized by co-expression of VGLUT2 and the paired-like homeodomain transcription factor 2 (Pitx2). Based on this knowledge, we were able to create a conditional knockout (cKO) mouse line lacking expression of VGLUT2 in this STN subpopulation. These cKO mice displayed hyperlocomotion and decreased latency in the initiation of movement, while preserving normal gait and balance (*Schweizer, Pupe et al, PNAS, May, 2014*). No major cognitive deficits were observed. To investigate the importance of glutamate dynamics in target areas of the STN, the Entopeduncular nucleus (EP) and the substantia nigra pars reticulata (SNr), we are currently implementing enzyme-based microelectrode amperometry (MEA) with a second-by-second time resolution. Our preliminary results suggest that the cKO mice display a reduced glutamate release to the EP. These data correspond to the traditional view of the basal ganglia, where reduced glutamate release onto the EP and SNr will decrease the indirect pathway gated by the STN and hence, increase the action of the direct pathway, and could thus provide the explanation for the observed hyperlocomotion. By utilizing MEA in our cKO mice, we hope to be able to explain the importance of glutamate in the STN network involved in DBS and, hereby, suggest clinical improvement of this therapy.

Title: After effects of microstimulation in human globus pallidus

Authors: *F. LUO, D. CLARK, L. KIM, M. NOOR, Z. KISS;
Dept. of Clin. Neuroscience, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Deep brain stimulation (DBS) of the internal segment of the globus pallidus (GPi) is a highly effective therapy for movement disorders such as Parkinson disease and dystonia, yet how it does so remains controversial. The mechanisms of action are likely complex and may be different for different movement disorders. We previously reported cholinergic involvement in simulated DBS (sDBS) applied to entopeduncular nucleus (EP, rodent equivalent of GPi) neurons in brain slice. sDBS applied inside EP induced a prolonged afterdepolarization with increased spiking that was dependent on activation of cholinergic inputs and muscarinic receptors. However, evidence from humans is lacking; mainly inhibition, related to GABA release, has been identified in human GPi in response to microstimulation. Therefore, in order to validate our finding in EP, we sought evidence for increased spiking in patients undergoing dual-microelectrode (distance between 200 and 300 μm) mapping of the GPi. Preliminary data suggest that 10 seconds of high frequency microstimulation (similar to sDBS in brain slice) applied either from the recording electrode or adjacent non-recording electrode could increase post-stimulation spiking in 4 of 9 GPi neurons studied (3 patients). The post-stimulation spiking patterns of these GPi neurons were similar to those of EP neurons observed in brain slice (as well as those described in MPTP treated monkeys). This study provides new insights into the underlying mechanisms of clinical DBS in human.

Title: Acetylcholine evokes spontaneous muscarinic IPSCs in medium spiny neurons overexpressing GIRK channels

Authors: A. MAMALIGAS[1], *C. FORD[2];
[1]Neurosciences, [2]Physiol. and Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: Cholinergic interneurons (ChIs) provide the primary source of acetylcholine for the striatum. Firing of striatal ChIs is relevant in various movement and motivated behaviors. Previous studies have shown that ChI active zones do not directly appose MSN dendrites. Nonetheless, it is known that medium spiny neuron (MSN) excitability is modulated by activation of muscarinic receptors (mAChRs). However, the time course over which ChIs signal to MSNs is unclear because acetylcholine does not directly activate any endogenous ion channels on these neurons. Here, a G-protein coupled inwardly rectifying K+ channel (GIRK2) was virally overexpressed in striatal MSNs. The resulting K+ conductance was used to readout the activation of mAChRs using whole-cell voltage clamp recordings. Upon electrical stimulation of ChIs, robust M4-mAChR mediated IPSCs were evoked in GIRK2 expressing MSNs. The kinetics of the evoked M4-IPSCs were rapid relative to other metabotropic IPSCs that have been observed, with a 10-90% rise time of 72 +/- 3ms and a 20% width of 484 +/- 50ms. This suggests that a high concentration of acetylcholine likely activates mAChRs on MSNs. IPSCs evoked at minimal stimulation intensities exhibited successes and failures, suggesting that stimulation of a single ChI can elicit an IPSC. Subsequently, paired recordings of ChIs and MSNs were performed to determine if an action potential elicited in a ChI could evoke an M4-IPSC in a postsynaptic MSN. When an action potential occurred in a ChI, an IPSC was reliably observed in the synaptically paired MSN, indicating that mAChRs on MSNs reliably encode acetylcholine release resulting from the action potential of a single ChI. Finally, spontaneous M4-IPSCs, eliminated by TTX, were also observed in GIRK-expressing MSNs, suggesting that the 2-5 Hz tonic firing pattern of ChIs can be encoded by mAChRs. Thus despite the tonic background firing of cholinergic interneurons, the results suggest that release of acetylcholine may produce a local and phasic activation of muscarinic receptors in MSNs.

Title: Enkephalin disinhibits striatal patches via the delta opioid receptor

Authors: *S. NEUFELD[1], M. R. BANGHART[1], N. MULDER[1], B. SABATINIT[1,2];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Howard Hughes Med. Inst., Boston, MA

Abstract: Opioid peptides and their receptors are prominent in the dorsal striatum, a brain region critical for the generation of purposeful movements and goal-directed behavior. Mu-opioid receptors (MORs) are highly enriched in patch compartments (or striosomes), distinct limbic microcircuits embedded within the predominately sensorimotor dorsal striatum (known as the matrix). There is growing evidence that imbalances of patch-matrix activity in the striatum correlate with Huntington's disease, Parkinson's disease, and drug addiction. Previous work has revealed patch specific suppression of inhibition by the MOR agonist DAMGO. It is not known which populations of pre- and post-synaptic neurons within patches are targeted by DAMGO, and whether action of endogenous opioid peptides, which can activate multiple opioid receptors, shifts the balance of patch-matrix activity. Using a combination of transgenic mice, optogenetics, and pharmacology we identified the inhibitory synapses suppressed by opioid peptides, investigated the underlying receptors, and assayed the overall effect of opioid signaling on patch and matrix output. We validated a transgenic mouse line that allows simultaneous observation of patches and post-synaptic cell identity. Using these mice we confirmed that enkephalin (enk), the only endogenous ligand for MORs in striatum, suppresses local inhibition onto both direct and indirect pathway striatal projection neurons selectively in patches. By virally introducing cre-dependent ChR2 into mice expressing cre-recombinase under cell-type specific promoters, we identified local collaterals of indirect pathway striatal projections neurons as the major pre-synaptic target of enk. To our surprise, selective pharmacology revealed that delta-opioid receptors, not MORs, dominate the suppression of inhibition. Finally, we assayed the overall

effect of enk on the output of patch and matrix neurons by stimulating corticostriatal input. We found that enk increased spike frequency in the patches, but not in the matrix. Our data indicate that enk release could shift the balance of patch-matrix signaling by selectively disinhibiting patch neurons via delta-opioid receptors.

Title: VTA-AcbSh circuitry analysis and modulation of the response to novelty

Authors: ***H. LI**, M. CRANSTON, C. MACTUTUS, M. AKSENOVA, B. KANTOR, R. BOOZE;
Psychology, Univ. of South Carolina, Columbia, SC

Abstract: The mechanism of how stimulation of specific pathways modulates behaviors, such as the response to novelty, is still unknown; however, previous studies show that dopamine is critical for orientation and response to novel stimuli. To investigate the role of particular pathways in responses to novelty, pharmocogenetic techniques (retroDREADDs) were used to modulate the G protein-coupled receptor (GPCR) system during a novel experience. First, the selectivity and expression of the AAV-hM3D DREADD was confirmed in primary neuronal cell cultures. Second, we selectively expressed AAV-CAG-CRE-GFP in nucleus accumbens shell (AcbSh) and infused AAV-hSyn-DIO-hM3D (Gq)-mCherry (a presynaptic enhancer in the presence of its cognate ligand clozapine-N-oxide, CNO) in the posterior ventral tegmental area (VTA). We found AcbSh CRE-GFP was retrogradely transported to the pVTA, which then triggered hM3D-mCherry production in neurons of the VTA which had connectivity with the AchSb. Finally, activation of the DREADD *in vivo* by administration of CNO altered the

response to novelty (removal of background white noise) in an open-field task ($p \leq 0.05$), without altering locomotor activity levels. Immunohistological analysis confirmed production of hM3D in neurons of the posterior limb of the VTA; these AcbSh projection neurons were both dopaminergic and non-dopaminergic. Collectively, stimulation of the circuit connections from the pVTA to the AcbSh altered selective responses to novelty, without altering gross locomotor behavior. In sum, selective retroDREADD pathway analysis provides insights into the circuitry underlying particular behaviors (e.g., novelty) and provides a unique therapeutic approach.

Title: Task properties determine age-related differences in force control

Authors: *S. VIELUF[1], J.-J. TEMPRADO[1], R. SLEIMEN-MALKOUN[2];
[1]Fac. of sport science, Aix Marseille Univ., Marseille, France; [2]Inserm, Inst. de Neurosciences des Systèmes UMR_S 1106, Aix-Marseille Univ., Marseille, France

Abstract: Accuracy and stability of force control results from the temporary coalition of multiple subsystems (e.g. cognitive and muscular systems), as well as from central integration of different sensory feedback loops, which finally depends on task constraints. Age-related differences in rapid force production (RFP) and isometric force maintenance (IFM) tasks have been well described in the literature (Christou & Carlton, 2001; see Morrison & Newell, 2012 for an overview). However, an experimental paradigm is still lacking to investigate the combination of these processes. The present study addressed this issue by comparing how age-related changes manifest when RFP and IFM are performed in separation or combined in a Fitts-like paradigm. We expected age-related differences to be differently expressed in the combined than in the separated tasks. Young and old adults performed RFP and IFM tasks at various force levels (10, 20, 40, 60, 80% of MVC). Both tasks were combined by a Fitts-like paradigm in which both distance (D) and target width (W) were manipulated (ID 1, 2, 3, 4). For RFP the time to peak (equivalent to MT) was detected and Brinley plot slopes were analyzed. SD and multi-scale-

entropy area (MSE) were calculated for IFM. Brinley plots showed multiplicative slowing in all task conditions, with higher slopes for the separated (4.33) than the combined tasks (W: 1.40; D: 2.20). In the separated IFM task, no age-related differences were found. In the combined task older showed higher variability, W: $F(1,20) = 5.05$, $p = .04$, $\eta_p^2 = .202$; D: $F(1,20) = 20.76$, $p < .01$, $\eta_p^2 = .509$, and for MSE an age by ID interaction, W: $F(3,20) = 4.26$, $p = .01$, $\eta_p^2 = .176$; D: $F(3,20) = 3.34$, $p < .05$, $\eta_p^2 = .143$, indicating different evolutions of MSE over IDs. As predicted, the comparison of RFP and IFM showed different age effects in separated and combined tasks, respectively. This suggests that the combined task is more than the simple juxtaposition of RFP and IFM. It also indicates that the consequences of reorganizations occurring in the aging force control system are strongly sensitive to task properties. This should be taken into account in future studies References Christou, E. A., & Carlton, L. G. (2001). Old adults exhibit greater motor output variability than young adults only during rapid discrete isometric contractions. *J Gerontol A-Biol, 56*(12), B524-B532. S. Morrison and K. M. Newell. (2012). Title: The effects of dual tasking on bimanual grip force control in older adults

Authors: *H. HIBINO[1], R. CARLSON[2], S. H. BROWN[2];
[1]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan, Sch. of Kinesiology, Ann Arbor, MI

Abstract: Dexterity declines with age, due, in part, to difficulties maintaining submaximal forces (Marmon et al., 2011). While motor unit reorganization is thought to contribute to increased force variability in older adults (Galganski et al., 1993), age-related declines in attentional capacity may also play a role in difficulties maintaining static force (Voelcker-Rehage et al., 2006). Further, most studies have examined fine force control using unimanual tasks despite the need to simultaneously control force production in both hands during many activities of daily living (Kilbreath and Heard, 2005). Thus, the purpose of this study was to examine the

interplay between age, attentional demands, and grip force production under different force conditions. Ten healthy young (mean age 19.0 y) and 10 older (mean age 70.7 y) adults generated visually-guided unilateral (dominant, non-dominant) and bilateral grip forces at 5 or 20% of each individual's maximum voluntary contraction (MVC) using hand-held dynamometry. Tasks varied in difficulty by having participants increase force to either 5 or 20% of MVC from baseline or increase/decrease force from and to a controlled force level - i.e. increasing force from 5-20% or decreasing force from 20-5% of MVC (5% to 20%, 20% to 5%). All tasks were performed with and without a concurrent cognitive load involving counting backwards by seven. Following target acquisition, participants maintained force for 4 sec. Dependent measures included force maintenance variability and force initiation time. When increasing force from baseline, static force variability at 20% MVC did not significantly differ between age groups and was unaffected by hand, hand configuration (i.e. unimanual vs. bimanual), or cognitive load. In contrast, significant age differences in force variability were seen when maintaining very low submaximal forces (0-5% task) but only during the cognitive load condition ($p < .001$). In tasks requiring controlled decreases in force from 20% to 5%, variability did not differ between age groups when the task was performed unimanually and in the absence of any cognitive task. However, bimanual force tasks, coupled with increased attentional demands led to pronounced age-related differences in variability ($p<.001$). Force initiation time was consistently longer in tasks requiring a force increase in both age group ($p<.001$) with cognitive loading leading to longer initiation times in the older compared to the younger group ($p<.001$). These results extend the previous results demonstrating attentional demands in submaximal force control in older adults and underscore the importance assessing bimanual grip force control.

Title: Sensorimotor memory and sensorimotor integration abilities dissociate in a post MCA stroke population

Authors: *B. KC, K. FERCHO, L. A. BAUGH;
Biomed. sciences, Univ. of South Dakota, Vermillion, SD

Abstract: Current bedside diagnostics used for the assessment of the loss of hand function post-stroke examine limited aspects of motor performance. Further, they are not sensitive to subtle changes that can cause deficits in everyday object manipulation tasks. Efficiently lifting an object entails a prediction of required forces based on intrinsic features of the object (sensorimotor integration), and short-term updates in the forces required to lift objects that are poorly predicted (sensorimotor memory). Therefore, a successful object manipulation is a complex neurological event with multiple cortical areas involved. Unfortunately, this complexity is not represented by the existing assessment tools used in clinics for both diagnostic and rehabilitative purposes. The presented research examined the ability of two object lifting tasks designed to assess sensorimotor memory and sensorimotor integration to classify middle cerebral artery (MCA) stroke deficits relative to age-matched control participants. Age-matched control participants and MCA stroke participants completed two tasks. The first was designed to assess sensorimotor memory integration abilities. Participants were presented with large wood or brass blocks following trials of small and medium sized blocks from the same size-weight families. To accurately predict the weight of the larger cubes, sensorimotor integration of object size and apparent material is required during the first lifts of the large cubes. In the second task, participants were required to lift a series of size-weight blocks of different colors. One color signified an inverse size-weight relationship that required the modification of short-term sensorimotor memory to efficiently lift. In both tasks, lifting forces were examined and compared to age-matched control data. As predicted, individual stroke participants demonstrated dissociable errors in each of the lifting tasks. A small portion of stroke patients performed at control levels in both tasks. However, most stroke participants showed a deficit in sensorimotor memory, sensorimotor integration, or both lifting scenarios as revealed through a detailed analysis of lifting forces. The presented research demonstrates MCA stroke participants may have deficits in one or more components required for the successful manipulation of hand-held objects, and these deficits can be detected in an object lifting task. Further, by identifying specific deficits in lifting ability, targeted rehabilitation regimens may be possible.

Title: The influence of transcranial direct current stimulation timing on motor skill acquisition in older adults

Authors: ***B. J. POSTON**[1], A. JACKSON[1], Z. RILEY[2], E. L. HEISLER[3], R. R. WALSH[3], J. L. ALBERTS[3];
[1]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV; [2]Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [3]Cleveland Clin., Cleveland, OH

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation technique that has been shown to enhance motor performance in older adults. However, the optimal tDCS parameters for improving motor function in older adults have not been established. The purpose was to determine the influence of the timing of tDCS on motor skill acquisition in older adults. The study was a sham-controlled, crossover experimental design. Nine older adults (71 ± 6.9 yrs) participated in 3 experiments that were each separated by a 7 day washout period. Each experiment involved practice of a precision grip task (primary practice task; PPT) performed in association with 1 of 3 tDCS interventions (BEFORE, DURING, and SHAM) in counterbalanced order. The PPT involved matching a target sine wave (target force range: 5-25% of maximum) for 10 trials of 30 seconds each followed by a 90 s rest (total practice or stimulation time = 20 min). Thus, tDCS was applied either before or during motor practice for 20 minutes. tDCS was applied to the scalp area overlying the 1st dorsal interosseus muscle representation area of the primary motor cortex. The tDCS current strength was held constant at 1 mA in both of the treatment conditions. SHAM stimulation was applied in the same manner according to established blinding procedures. The force error (primary outcome measure) during the PPT was quantified as the average error in force relative to the target force. tDCS applied both before and during the PPT lead to better performance (21% and 25% lower force error, respectively) compared to SHAM stimulation. However, there was a non-significant (~4%) difference in force error between the BEFORE and DURING conditions. The findings indicate that a single application of tDCS applied either before or during motor practice can increase the rate of motor skill acquisition in older adults.

Title: Postnatal motor cortex stroke alters development of the rubrospinal system

Authors: *P. T. WILLIAMS, J. H. MARTIN;
Physiology, Pharmacol. and Neurosci., City Col. of the City Univ. of NY, New York, NY

Abstract: Motor cortex stroke during development is a leading cause of cerebral palsy (CP), a common developmental disorder affecting 2-3/1000 births. In unilateral CP the corticospinal system (CS) from the damaged cortex fails to develop strong contralateral connections with the spinal cord, and the CS from the less affected hemisphere develops bilateral spinal connections and leads to motor map impairments and behavioral deficits. The CS and the rubrospinal system (RS) are the two components of the lateral motor systems for skilled limb control. It is unknown if CS miswiring enhances or corrupts development of the RS. In this study, we addressed two questions: does M1 stroke alter development of the (1) red nucleus (RN) motor map, and (2) the pattern of rubrospinal tract (RST) terminations in the cervical spinal cord. We studied these questions in the cat, a species for which we have detailed information about the timing of development of both the corticospinal tract and RST. Our hypothesis is that the RS will show augmented growth of the RN motor map and RST from the ipsi-lesion side if there is compensation for the injured CS. To model CP, a unilateral stroke (photothrombotic: rose bengal, 20mg/Kg i.v.; 15 min activation with 530 nm LED light source) was induced in the forelimb region of motor cortex at postnatal week 5, which is a key period of CS and RS development in cats. We examined RST terminations labeled in C8-T1 with anterograde tracers (BDA or AF488DA) injected in the RN. In terminal experiments at weeks 7-8, the RN motor maps on the ipsilesional and contralesional sides were examined using microstimulation. We found low variability in stroke lesion size. All animals showed a placing deficit with the contralesional forelimb, consistent with forelimb motor cortex lesion. The RN map on the side in which M1 was ischemic appeared normal. Surprisingly, the map on the contralesional side was abnormally small with elevated thresholds compared with the ipsilesional side. Analyses of RST terminations are ongoing. These are the first results to link postnatal lesion of CS with altered development of RS function. The diminished RS from the contralesional side suggests the intact CS out competes the RS for access to spinal motor circuits. On the basis of changes in the RN motor map, we did not find evidence that the RS spontaneously compensates for the damaged CS during development.

Title: Neural correlates of passive forefinger kinematics: effects of amplitude, direction and velocity

Authors: *J. DUENAS[1], J. SULZER[2], P. STAEMPFLI[3], M.-C. HEPP-REYMOND[3], S. KOLLIAS[4], E. SEIFRITZ[3], R. GASSERT[1];

Abstract: While the differential neural responses to passive and active movements have been well-studied, there is little understanding as to the relationship between the degree of passive movement and brain activity. Afferent input includes receptors that are sensitive to both length and rate of length changes in the musculotendon unit. Thus, we hypothesized that these parameters are represented differently in the brain during passive forefinger movement. We measured whole brain blood oxygenation level dependent (BOLD) signal using functional magnetic resonance imaging (fMRI) in response to parametric changes in passively induced forefinger kinematics. Nineteen healthy participants were exposed to combinations of forefinger flexion and extension imposed by a MR-compatible robotic manipulandum, which also measured forefinger interaction forces. Each subject was exposed to passive forefinger movements at three different levels of amplitude and velocity, separately in flexion and extension. We used a parametric analysis and modeled forefinger interaction force as a regressor of no interest to account for variance due to different mechanoreceptor input. We found that contralateral primary and secondary somatosensory regions, as well as putamen and ipsilateral cerebellum were positively linearly correlated with increases in passive movement velocity. Increases in displacement amplitude showed a non-linear decrease in activity within bilateral secondary somatosensory regions, whereas increases in static forefinger position presented an increase in the aforementioned areas. These insights will provide a greater understanding of the neural representation of kinematic variables, which could lead to improve therapeutic strategies for severely impaired patients following brain injury.

Title: Correlated deficits in finger individuation following unilateral stroke in the affected and unaffected hand

Authors: *N. EJAZ[1], J. XU[2], B. HERTLER[5], M. BRANSCHEIDT[5], M. WIDMER[5], N. KIM[2], M. HARRAN[6], J. C. CORTES[6], A. V. FARIA[3], P. A. CELNIK[4], T. KITAGO[6], A. LUFT[5], J. W. KRAKAUER[2], J. DIEDRICHSEN[1];

Abstract: Following a stroke, the recovery of dexterous hand function (Xu et al. 2015) largely occurs within the first few months. This recovery is likely as a result of cortical reorganization in the affected hemisphere. However, the extent of reorganization in the unaffected hemisphere in this recovery process is currently unclear. Here we investigated cortical reorganization in both hemispheres by quantifying behavior deficits in both paretic and non-paretic hands following stroke. Patients with a unilateral stroke (N=48) and healthy age-matched controls (N=14) were asked to perform a finger individuation task and their behavioral performance was assessed longitudinally at 5 time points (between weeks 1-52 after stroke onset). Subjects made individuated force presses with an instructed finger at four different force levels (between 20-80% of maximum voluntary contraction), and the patterns of involuntary forces produced by the passive fingers of the instructed hand (enslaving), and by all fingers of the uninstructed hand (mirroring) were recorded. These enslaved movements are proposed to have - in part - a cortical origin (Zatsiorsky et al. 2000), and provide a window into cortical reorganization during recovery. We found increased enslaving of the fingers of the affected hand as well as increased mirrored movements in the unaffected hand when the affected hand moved. Both enslaving and mirrored movements reduced during recovery at roughly the same time-course. Apart from the overall enslaving, we also studied patterns of enslaving themselves - i.e. enslaving between pairs of fingers - after normalizing for severity. Stroke caused this pattern to become abnormal in comparison to the enslaving patterns for healthy controls. Strikingly, during weeks 1-4, the enslaving patterns in both affected and unaffected hands were equally deviated from the healthy enslaving pattern, with no significant difference between hands. Furthermore, during recovery

the enslaving patterns for both hands started to increasingly resemble the healthy enslaving patterns. This result suggests a shared bilateral representation for both hands across hemispheres that is disrupted through stroke, and subsequently recovers. Consistent with this idea, the enslaving and mirrored movement patterns were more correlated across the affected and unaffected hands within the same patient, than across hands across individuals. Together, these results argue that skilled finger movement representations are co-operatively organized across both hemispheres. Damage to even a single hemisphere potentially results in bi-hemispheric cortical reorganization to recover hand function over time.

Title: White matter changes in pianists with focal hand dystonia

Authors: *K. KITA[1], K. UEHARA[2], S. FURUYA[3], R. OSU[4], T. SAKAMOTO[5], T. HANAKAWA[2];
[1]Chiba Univ., Chiba, Japan; [2]Dept. of Advanced Neuroimaging, Integrative Brain Imaging Center, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]Sophia Univ., Tokyo, Japan; [4]ATR, Kyoto, Japan; [5]Natl. Ctr. of Neurol. and Psychiatry Hosp., Tokyo, Japan

Abstract: Musician's dystonia (MD) is a task-specific movement disorder characterized by abnormal posturing and loss of fine motor control. Typically in MD at the hand, the affected fingers become uncontrollable mostly during playing a specific musical instrument, and respond normally to other motor activities. For pianists, MD can be highly disabling and terminate their professional musical careers. Although the neurological origins of this disorder are not yet completely clarified, it is probable due to dysfunctional or maladaptive brain plasticity. For instance, gray matter reorganization in basal ganglia and abnormal brain activities in motor and premotor area were reported in previous studies. Recently, we also have revealed abnormal cerebellar activation of pianists with MD during continues finger-tapping task. In this study we focus on structural, especially white matter, abnormalities underlying pathophysiology of MD. The diffusion tensor imaging (DTI) was acquired from 14 experienced healthy pianists (EP), 14 non-experienced pianists (NP) and 18 pianists with MD by using 3T MRI scanner. All pianists with MD had dystonic symptom at either the right hand or both hands. EP are pianists who have majored the keyboard, whereas NP are healthy pianists who enjoy playing piano as a recreation. Functional anisotropy (FA) is one of the most popular parameter computed from DTI. FA represents size and density of axons and degrees of myelination and shows structural organization of white matter fibers. We performed a voxelwise statistical analysis of FA values using tract-based spatial statistics (TBSS, Oxford Centre for Functional MRI of the Brain's software library (FSL5.0.8)). A comparison of FA values across the groups found significantly greater FA values in corpus callosum, corticospinal tract, posterior and anterior thalamic radiation in EP compared to pianists with MD (the statistical threshold was set at $p < 0.05$, FWE corrected). Although the difference of FA values between NP and pianists with MD was not significant, it showed the same tendency with the comparison between EP and pianist with MD: FA values in the aforementioned areas tend to be greater in NP compared to pianists with MD. The present study suggests that abnormal structural organization in the white matter in cortical and sub cortical areas may be related to pathophysiology of MD.

Title: Effects of age and handedness effects on hand motor recovery after sensorimotor cortex lesions in Macaca mulatta

Authors: *W. G. DARLING[1], S. M. HYNES[1], M. A. PIZZIMENTI[2], D. L. ROTELLA[1], J. GE[3], K. S. MORECRAFT[3], R. J. MORECRAFT[3];
[1]Dept of Hlth. & Human Physiol, [2]Dept of Anat. & Cell Biol., Univ. Iowa, Iowa City, IA; [3]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Recovery of hand/digit function after unilateral damage to sensorimotor areas of the brain may be affected by age if potential for neuroplasticity decreases with increasing age. Strength of handedness may also affect recovery of hand function, especially after damage to the more dominant hemisphere, because reduced interhemispheric inhibition (IHI) to the non-lesioned hemisphere may improve skillful use of the ipsilesional hand and promote learned nonuse of the contralesional hand. Larger volume lesions to a strongly dominant hemisphere would be expected to decrease IHI to a greater extent and perhaps contribute to even poorer recovery of contralesional hand function. We examined effects of age and strength of hand preference on recovery of hand motor function in 18 adult rhesus monkeys with a wide range of: surgically placed lesion volumes to sensorimotor areas of the brain (112 - 1001 mm3), ages (3.8 - 20.7 years) and strengths of hand preference (1.1 - 96) as measured by handedness index (Nudo et al. 1992, J Neurosci 12:2918). Multiple linear regression was used to assess the effects of these variables on recovery of skill in reaching and manipulation. Performance of reaching and manipulation were quantified in modified dexterity board and modified movement assessment panel tasks as described previously (Darling et al. 2009, Exp Neurol 220:90). Overall, total white matter lesion volume was the strongest predictor of the deficits in upper limb motor function and recovery of reaching and fine hand/digit motor function. Gray matter lesion volume, age and strength of hand preference generally made rather small, if any, contribution to the prediction of post-lesion deficits and recovery of upper limb function. Also, effects of age and lesion volume on neuroplastic responses in the corticospinal projection (CSP) to C5-T1 from ipsilesional supplementary motor cortex (iM2) were studied in 8 monkeys (McNeal et al. 2010 J Comp Neurol 518:226; Morecraft et al., 2015 J Comp Neurol 523:669). Younger animals exhibited larger increases in estimated numbers of boutons in spinal laminae of C5-T1 relative to controls than older subjects after M1+LPMC lesions, suggesting age-related effects. In contrast, after M1+LPMC+anterior parietal lobe lesions there was a reduction in estimated number of iM2 CSP boutons relative to controls that depended primarily on lesion volume and was relatively unaffected by age. Overall, these data suggest that white matter lesion volume primarily affects hand motor recovery with little effect of age and handedness whereas age affects the M2 CSP neuroplastic response following frontal lobe lesion but not after frontoparietal injury.

Title: The effect of developmental dyslexia on grip and load force coordination while holding an object during cyclical arm movement

Authors: *P. B. DE FREITAS, JR[1], S. T. PEDÃO[2];
[1]Univ. Cruzeiro Do Sul, Sao Paulo, Brazil; [2]Inst. de Ciências da Atividade Física e Esporte, Univ. Cruzeiro do Sul, São Paulo, Brazil

Abstract: Developmental dyslexia is a common neurobiological syndrome that affects individuals' reading and writing ability but has no effect on their intelligence. Dyslexia is also associated with individuals' poor performance in sensorimotor tasks, such as postural control and gait. Recently, we found that dyslexic children have deficits in visuomotor processing during a visually guided isometric manipulation task (i.e., ramp up and hold), but have no changes in grip (GF) and load force (LF) coordination. However, the manipulation task performed could be considered very simple and could have concealed possible alteration in GF-LF coordination in this population. Hence, we compared indices of GF-LF coordination of dyslexic and normal reader children during vertical, continuous oscillation of a free-moving object. Nine dyslexic and 9 control children between 9 and 12 years-old were asked to hold an instrumented object using a tripod grasp and to move it continuously up and downward, with peak to peak amplitude of 20 cm, in two frequencies, 0.8 and 1.2 Hz, during 12 seconds, repeating it three times for each frequency. The GF scaling was assessed by GF to LF ratio (GF/LF), GF modulation was evaluated by GF gain and GF offset (respective slope and y-intercept of the linear best fit of GF-LF diagrams), and GF-LF directional and temporal coupling were estimated by the maximum coefficient of a cross-correlation function (rmax) and by its respective time-lag. For GF/LF and GF offset, results revealed no effect of group and no group*frequency interaction, but revealed higher GF/LF and GF offset at 1.2 than at 0.8 Hz. Time-lag was around zero and neither main effect of group and frequency nor group*frequency interaction were observed. Regarding rmax and GF gain results revealed that dyslexic presented lower rmax and GF gain than non-dyslexic children, mainly at 1.2 Hz oscillation task and that rmax was higher in 1.2 than at 0.8 Hz. These results indicate that dyslexic children are as good as non-dyslexic ones in scaling GF with the changes in LF. Also, dyslexics are able to predict the consequences of their arm motion in the digits-object interaction, adjusting GF with the changes in LF with virtually no delay. However,

the directional coupling between GF and LF is altered (lower directional coupling) and GF modulation is negatively affected in dyslexic children. These findings corroborate the idea that dyslexic children present deficits in sensorimotor coordination and that such deficits could be associated with structural changes in specific brain areas as the posterior parietal cortex and portions of the cerebellum which have been linked to GF-LF coordination.

Title: Changes in neural activity patterns during recovery of fine finger control after stroke

Authors: *J. XU[1], N. EJAZ[4], B. HERTLER[5], M. BRANSCHEIDT[5], M. WIDMER[5], N. KIM[1], M. HARRAN[6], J. C. CORTES[6], A. V. FARIA[2], P. A. CELNIK[3], T. KITAGO[6], A. LUFT[5], J. W. KRAKAUER[1], J. DIEDRICHSEN[4];
[1]Neurol., [2]Radiology, [3]Dept. of Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD; [4]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [5]Dept. of Neurol., Univ. of Zürich, Zürich, Switzerland; [6]Dept. of Neurol., Columbia Univ., New York, NY

Abstract: Fine finger control recovers maximally during the first months after a stroke, and is largely independent from recovery of strength (Xu et al. 2015, NCM). The neuronal changes that underlie this recovery in the human brain are largely unknown. Using fMRI, a number of previous studies have documented changes in the overall BOLD signal during hand movements. Recent studies from our lab indicate that the structure of digit representations in sensorimotor cortex, in the form of digit-specific pattern distances, is well-organized and consistent across time and individuals. Changes in these fine-grained patterns of neural activity are a more sensitive assay of neural plasticity. Patients with acute onset unilateral cortical or subcortical strokes and a moderate initial impairment in hand function (N=37) and age matched controls (N=11) were tested longitudinally at 5 different time points over one year (week 1, 4, 12, 24, and 52). In the scanner they produced individuated isometric force presses with one of 4 fingers of either the affected or the unaffected hand. Multivariate pattern analysis was used to analyze

fMRI activity in motor and premotor cortices, which was decomposed into a) overall BOLD activity for each hand, b) strength of digit representation, i.e. overall mean distance between finger-specific activity patterns, and c) digit representation structure, i.e. pattern of distances for all digit pairs. Our results showed a reduction of overall average activation in ipsilesional M1 and PMd initially after stroke, which normalized during recovery. The corresponding digit patterns were also disrupted, and recovered in the first 12 weeks, though never reached the level of healthy controls. Digit pattern strength was strongly correlated with a behavioral measure of individuation in the paretic hand, suggesting recovery-related structural change in the peri-infart and premotor areas in the lesioned hemisphere. Furthermore, compared to healthy controls, the overall digit representation structure in both lesioned and non-lesioned hemispheres, when either the paretic or non-paretic hand moved, also showed an initial disruption and subsequent recovery, approaching normal structure with a similar temporal course of behavioral recovery. This result coincides with recovery pattern of enslaving profiles in both paretic and non-paretic hands, suggesting a bi-lateral involvement in the recovery process. In summary, our results indicate that recovery of the ability to individuate fingers is associated with plastic changes in motor and premotor areas of the lesioned hemisphere, and a possible functional role of the contra-lesional hemisphere.

Title: Abnormal eeg oscillations in writer's cramp

Authors: *G. CISOTTO[1], K. KITA[2], K. UEHARA[3], Y. HASHIMOTO[5], T. SAKAMOTO[4], J. USHIBA[6], T. HANAKAWA[4];
[1]Univ. of Padua, Padova, Italy; [2]Ctr. for Frontier Med. Engin., Chiba Univ., Chiba, Japan; [3]Dept. of Advanced Neuroimaging, [4]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]Kitami Inst. of Technol., Kitami, Japan; [6]Dept. of Biosci. and Informatics, Keio Univ., Tokyo, Japan

Abstract: Writer's cramp (WC) is a type of focal dystonia involving the sensorimotor circuit, probably with a heterogeneous biological, environmental and psychological background. Many

kinds of intervention have been already attempted, with limited effectiveness and beneficial duration for the patients. EEG based Brain Computer Interface (BCI) has been recently shown to be a promising tool for the rehabilitation from this disease. Nevertheless, no exhaustive EEG study is yet available to determine which feature should drive the neurofeedback to achieve the most effective results. Therefore, the aim of the present study was to identify the most reliable EEG biomarker of WC. The EEG responses of seven WC patients (age 50±15, 4 males and 3 females, onset age 45±15) were examined and their neurophysiological behaviour was investigated during two different tasks: (1) the execution of a pinch grip movement performed with the right affected hand (ME) and (2) its kinesthetic imagination (MI). Time-frequency analysis over the 5-45 Hz frequency band was performed in terms of event-related spectral perturbation (ERSP) followed by a bootstrap analysis with significance at 95%. From the well-known literature on healthy subjects, a significant power decrease, i.e. negative ERSP, during both the tasks was expected in the μ band (around 10 Hz) and the β band (around 20 Hz) over the sensorimotor cortices, especially the contralateral, compared to a baseline period selected during the rest before the task. Moreover, a significant power increase, i.e. positive ERSP, in the β band was expected within one second from the termination of the task. Nevertheless, preliminary results in WC patients showed a significantly abnormal power increase in the high β band (above 25 Hz) during the ME (five patients) and the MI (seven patients) tasks, in line with the limited previous literature on EEG in WC. Additionally, a clear suppression of the negative ERSP in the μ band was seen during the ME and the MI tasks in six patients. Furthermore, an unexpected and significant power decrease in the μ as well as the low β band was observed at the end of the task period in five out of seven patients. Preliminary results showed that, besides the abnormality in the high β band previously suggested in the literature, other abnormal patterns - still far from the healthy case - could be identified in WC patients. Furthermore, the investigation on the relationship between the different frequency components and their behaviour during the occurrence of the dystonic symptoms could provide a support for these first interesting outcomes and clarify whether pathological or compensatory mechanisms led to the observed abnormal EEG patterns.

Title: Abnormalities of the finger movements in musician's dystonia

Authors: *S. FURUYA[1], K. TOMINAGA[2], F. MIYAZAKI[2], E. ALTENMÜLLER[3];
[1]Sophia Univ., Tokyo, Japan; [2]Osaka Univ., Osaka, Japan; [3]Inst. for Music Physiol. and Musician's Med., Hannover Univ. of Music, Drama and Media, Hannover, Germany

Abstract: Musician's dystonia (MD) manifests itself through repetitive and precise use of specific body portions, and causes involuntary movements and muscular cramping. Compared with other forms of dystonia such as writer's cramp and cervical dystonia, little has been addressed about neuronal and computational mechanisms underlying production of dystonic movements in MD. MD has therefore a high risk of misdiagnosis, possibly which occasionally causes injection of Botulinum Toxin into an intact finger. The present study addressed effects of MD on hand kinematics during musical performance. Using a dataglove, we recorded dynamic modulation of hand posture while healthy pianists and pianists with FD were playing the piano. The results demonstrated that the patients displayed limited finger extension and intact finger flexion compared with the healthy controls. Principal component (PC) analysis determined three patterns of fundamental joint coordination for both of the two groups. The overall patterns of the first two PCs described less individuated movements between the affected finger and a finger responsible for striking a key for the patients compared with the controls. The third PC that consisted of the individuated movements between the middle and ring fingers was evident during a sequence of strikes with these fingers for the healthy controls, which was however absent in the patients. Accordingly, the patients showed more pronounced rhythmic variability of keystrokes during this sequence of strikes than the controls. A stepwise multiple regression analysis identified less accurate keystrokes for individuals who moved the affected and striking fingers in a less individuated manner. Taken together, the current findings suggest that MD reorganizes joint coordination patterns so as to degrade independent control of movements across fingers and thereby impairs motor precision.

Title: Neural correlates of error processing in the elderly

Authors: *E. NIESSEN[1], G. R. FINK[1], P. H. WEISS[1], J. STAHL[2];
[1]Res. Ctr. Juelich, Juelich, Germany; [2]Dept. of Individual Differences and Psychological Assessment, Cologne, Germany

Abstract: With increasing age, cognitive control processes steadily decline. Prior research indicates that healthy elderly have a generally intact performance monitoring system, i.e., they perform accurately on tasks assessing motor inhibition, but show specific deficits in error awareness, i.e., the ability to detect committed errors. The electrophysiological correlates of the elderly's deficits in error processing and detection to date remain elusive. Here, we examine the neural processing of errors in healthy elderlies by analysing the error (-related) negativity (Ne/ERN) and the error positivity (Pe) using an adapted version of the Go/Nogo task. For detected errors, 20 elderly participants (mean age 57.0 ± 8.1 years) showed a significantly more negative peak amplitude of the Ne/ERN and a significantly more positive Pe peak amplitude when compared to correct responses. A subgroup analysis of those participants who committed a sufficient number of undetected errors revealed that compared to correct responses the Pe amplitude was similar, while the Ne/ERN peak amplitude was more negative for undetected errors. Data suggest that the neurophysiological patterns of error processing and error detection previously reported in young participants can also be observed in the elderly. Thus, the known electrophysiological correlates of committed errors are stable, irrespective of age. In addition, a sub-clinically depressed mood seems to have a detrimental impact on error detection performance and performance evaluation by depleting cognitive resources which are necessary for a good task performance.

Title: Effects of tactile feedback on manual function in patients with type II diabetes

Authors: *N. OCHOA[1,2], G. GOGOLA[3], S. L. GORNIAK[1,2];
[1]Univ. of Houston, Houston, TX; [2]Ctr. for Neuromotor and Biomechanics Res., Houston, TX;
[3]Shriner's Hosp. for Children, Houston, TX

Abstract: Control of manual function requires the optimal integration of sensory and motor systems. Pathology to either of these systems leads to suboptimal dexterity and manual object manipulation. Changes to sensory function is well documented in individuals with Type II Diabetes (T2D); however, the impact of the disease on motor function of the upper extremity has not been thoroughly investigated. The purpose of this study was to evaluate the effects of altered tactile feedback on manual function in patients with T2D (n = 10; 7 females, 3 males) compared to age- and sex- match control subjects (n = 10; 7 females, 3 males) (age = 58 ± 6 years).Tactile sensation, proprioception, and motor function of the dominant hand was assessed in both groups in three conditions: at baseline, after a 1mL injection of 2% lidocaine administered at the carpal tunnel (median nerve block at the wrist, WB), and after a 1mL injection of 2% lidocaine administered medially to the brachial artery at the antecubital fossa (median nerve block at the elbow, EB). The injections used allowed for well-controlled, safe, and effective temporary suspension of tactile sensation distal to the wrist and elbow. We hypothesized that if tactile sensation alone is responsible for motor dysfunction of the hand/fingers in T2D, motor function in the anesthetized states of the control group should correspond to motor function of the baseline state in the T2D group. Alternatively, if another physiological mechanism is responsible for motor dysfunction, it can be expected that the T2D group will display greater reductions in manual function than the control group across all three testing conditions. Monofilament testing confirmed that tactile function in both WB and EB conditions in the control group were comparable to baseline tactile function in the T2D group. Analysis of timed clinical evaluations indicated that baseline function of the T2D group was similar to that of the control group under both anesthesia conditions. Linear and non-linear analysis of force production features was also performed. The data suggest that manual performance in patients with T2D may stem from a combination of tactile deficits as well as proprioceptive deficits.

Title: Motor and sensory components of finger representations in the human brain

Authors: *J. DIEDRICHSEN[1,2], G. PRICHARD[1], J. O'REILLY[3];
[1]Univ. Col. London, London, United Kingdom; [2]Brain and Mind Inst., Western Univ., London, ON, Canada; [3]Oxford Univ., Oxford, United Kingdom

Abstract: We used high-resolution functional MRI and multivariate analysis techniques to study the structure of cortical and cerebellar digit representations. To determine the influence of motor efference and sensory afference, we let subjects either produce isometric finger presses against a keyboard, or we moved their fingers passively using a pneumatic device. The force profiles experienced at the fingertips were approximately matched across active and passive conditions. Functional imaging data were acquired on a 7T scanner, using an isometric resolution of 1.4mm, 47 slices, TR=3s, and 8 runs with 107 images each. Each finger was moved 4 times during each trial, which lasted a total of 8.8 s. Each trial type was repeated 3 times during each run. The primary sensory cortex (Brodman area [BA] 3, 1, and 2), primary motor cortex (BA 4) and caudal premotor cortex (BA 6), the supplementary motor area, and lobules V / VI of the ipsilateral cerebellum revealed significantly digit-specific patterns. In cortical areas, the finger-specific patterns in the active and passive conditions correlated on average with r=0.79 across voxels with each other. This suggests that sensory information from each finger is transmitted to the cortical circuits that are involved in controlling movement of the digit. Both passive and active maps exhibited an invariant representational structure across regions and subject. While the underlying activity patterns themselves were variable, the relative overlap between the patterns was invariant. In contralateral sensory-motor areas, the passive condition elicited overall less activity than the active condition, but led to more distinguishable activity patterns. The ipsilateral sensory-motor regions were partly suppressed below baseline. However, for the active conditions a clear digit representation was found even in suppressed areas. This representation was less pronounced in BA 1 and 3, but stronger in BA 2, 4 and 6. Furthermore, the ipsilateral representation was much weaker during passive than during movement. Similar observations were made for the cerebellar digit representations. These results suggest that, while the contralateral digit representations observable in fMRI reflect mainly sensory re-afferent information, the ipsilateral and cerebellar digit representations are driven to a larger degree by an efference copy of the motor command.

Title: Effects of absent somatosensory feedback on digital isometric force control

Authors: *W. ZHANG[1], B. FAULKNER[2], B. SHERMAN[2], M. ALCORN[2], M. MACINA[2], C. BENSON[3], B. HAHN[3];
[1]Physical Therapy, Col. of Staten Island/ CUNY, Staten Island, NY; [2]Col. of Staten Island / CUNY, Staten Island, NY; [3]Staten Island Univ. Hosp., Staten Island, NY

Abstract: Success skilled manipulation requires complex force coordination among the digits, which requires the CNS ability to integrate sensation feedback signals and descending motor commands (Gordon et al. 1993). Appropriate modulation of forces, either within- or across-digits, relies on responses triggered by tactile feedback (Macefield et al. 1996), as a result of perturbations (Hermsdorfer et al. 1999; Johansson et al. 1999) or when digit forces are erroneously planned (Edin et al. 1992; Flanagan and Wing 1997). Such short-latency force responses, however, are absent or delayed when the tactile sensation is blocked under digital anesthesia (Monzee et al. 2003). The present study was designed to examine how intact and absent somatosensory feedback modalities are integrated and contribute towards implementing digital force production, by selectively removing tactile feedback from the fingertips, and providing visual feedback of performance error during isometric finger force production tasks. Twelve (6 males, 6 female) healthy, right handed, young adults participated in this study. Four 6-dimentional force/torque sensors were installed horizontally on the table to measure individual finger force. All subjects were instructed to perform three isometric force production tasks: one maximal force task, and two template-tracing force production tasks (ramp-like and step-like). Force templates and individual's performance were displayed on a computer monitor during the experiment. All tasks were repeated before (Control group) and after a digital nerve block procedure (Anesthesia group) on subjects' index and middle fingers of right hand. We analyzed subjects' digital maximal force, force sharing patterns, enslaving effect, and task performance error in Anesthesia group vs. Control group. Our results showed that maximal force ability was reduced in anesthesia group not only at local digits (index, middle, and index-middle combination), but also at non-local digit (little finger). In addition, maximal force ability by all four fingers was maintained (significant interaction Group×Condition, $P < 0.05$) with individual force sharing pattern re-distributed, especially at non-local fingers (ring and little). However, no

group difference was found in either enslaving effect or root mean square error of force performance. These results suggest that sensory information from one digit is shared across other digits to attain and maintain task-specific performance stability, and thus absent tactile sensation feedback interrupts the maximal force ability and force sharing pattern not only at local but non-local fingers.

Title: 7T fMRI reveals preserved SI topography of phantom fingers decades post amputation

Authors: *S. KIKKERT[1,3], J. KOLASINSKI[1], S. JBABDI[1], I. TRACEY[1,2], C. F. BECKMANN[3], H. JOHANSEN-BERG[1], T. R. MAKIN[1];

Abstract: Sensory deprivation has been considered a major driving force for brain plasticity. However, both in human and animal studies this view is based on indirect evidence of emerging representations in the "deprived" cortex (e.g. studying representations of adjacent body parts in the cortical territory of the missing hand). This leaves a potentially latent topography of the deprived brain region unexplored. Recent research shows that lingering sensations of the missing hand ("phantom sensations") are associated with activity in the deprived hand region of amputees. It is unknown whether this reflects some preservation of functional representation, or rather reflects disorganized aberrant inputs. Here we studied organisation in the cortical territory

of the missing hand by taking advantage of the vivid phantom sensations individuals experience decades post arm amputation. We used ultra-high field 7T fMRI (1.2mm3 resolution) to investigate whether representation of the phantom hand is topographically organized. We asked two unilateral upper-limb (above and below elbow) amputees with exceptionally vivid kinaesthetic phantom sensations during phantom finger movements and twelve control participants to volitionally move individual phantom or intact hand fingers. Movements were executed in a phase-encoding paradigm and a block design. We identified a detailed topographic map of the phantom hand in both amputees, where neighbouring clusters showed selectivity for neighbouring phantom fingers in the primary somatosensory cortex (SI) contralateral to the amputation. This topographic representation was not significantly different from maps seen in matched control participants, as shown using a multivoxel pattern analysis, and was independent of the intact hand representation. No such representation emerged when the amputees imagined phantom finger movements (not resulting in vivid kinaesthetic sensations). To better investigate the relationship between the preserved finger maps and peripheral inputs, we also studied phantom finger topography in an amputee suffering from a brachial plexus avulsion (abolishing afferent inputs and efferent outputs to the residual limb) with good motor control over his phantom fingers. Using multiband 3T fMRI (2mm3 resolution), we identified preserved topography during phantom finger movements, suggesting that the observed SI topography does not reflect peripheral reorganisation. Our results reveal that organised use-related inputs are not necessary to preserve topographic mapping in the somatosensory cortex. Our results call for a reassessment of plasticity following cortical deprivation of input.

Title: Changes in neuronal ensemble activities in the motor cortex during motor learning

Authors: *Z. SHEN[1,2,3], Y. FENG[1,2,3], K. XIAO[1,2,3];
[1]Inst. of Neurosci., Shanghai, China; [2]CAS Ctr. for Excellence in Brain Sci., Shanghai, China; [3]Shanghai Inst. for Biol. Sciences, CAS, Shanghai, China

Abstract: *In vivo* two-photon imaging of a large ensemble of layer 2/3 pyramidal neurons of the mouse primary motor cortex, using viral transfection of GCaMP6, allowed us to monitor changes in neuronal ensemble activities during motor learning. Head-fixed mice were trained to respond to a sound cue by initiating a motor task of moving a bar laterally with one arm over a defined distance in order to receive a water reward, while imaging was made from the contralateral motor cortex. The same ensemble of neurons was monitored for their activities during the two-week period that the mouse learned to perform the task. For neurons that were active during the task (~100), we observed two types of changes for the learning period. First, firing pattern of each neuron became more temporally reproducible among trials. When aligned with the sound cue, these neurons were reliably firing at a defined time after learning (e.g., day 14). Furthermore, activities among most neurons were correlated with a temporal sequence and some neurons fired prior to the movement initiation. By contrast, this reproducible firing pattern was not observed in most neurons at the early period of learning (e.g., day 1-4). Second, in a minority of neurons, reproducible firing patterns were observed among trials at each day, but gradual forward shift of the pattern towards the sound cue was found with days of learning. These results indicate activity patterns of layer 2/3 motor neurons may reflect the process of learning motor sequence in the cortex and further studies of the mechanism underlying the temporal changes in firing patterns may help to dissect neural circuit basis of motor sequence learning.

Title: Do consolidation of motor memory and interlimb transfer of adaptation rely on common processes?

Authors: *H. LEFUMAT[1], P. MUTHA[2], J.-L. VERCHER[1], C. MIALL[3], F. SARLEGNA[1];
[1]CNRS & Aix-Marseille Univ., Marseille, France; [2]Indian Inst. of Technol. Gandhinagar, Ahmedabad, India; [3]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: When we perform a motor task, such as reaching for an object, under a novel condition, we first adapt slowly to perturbations. However, when exposed to the same perturbation after several hours or days, we adapt much faster. This “savings” phenomenon is thought to stem from the consolidation of motor memory. The amount of savings is predicted by a specific sub-component of adaptation known as the “slow process”. This process responds slowly to movement errors but retains information well from one trial to another. Its contribution also increases from the beginning to the end of the learning phase. Brain structures involved in the end of the learning phase were shown to characterize interlimb transfer of adaptation, i.e. when adaptation of one arm benefits to the opposite arm. We thus hypothesized that consolidation of motor memory and interlimb transfer of adaptation both rely on the slow process. To test this, we designed experiments in which subjects had to reach with their arm for visual targets in a rotating platform producing a velocity-dependent force field. Subjects were right-handed young adults. They had no visual, only proprioceptive feedback of hand movements. On the first 1, there were 3 experimental phases: pre-rotation (right/left hand), training (right hand) and post-rotation (left/right hand). We assessed interlimb transfer by comparing the baseline initial direction of the left hand with the first trial of the post-test. On the second day, we assessed consolidation of adaptation by testing again the right hand in the force-field. Preliminary results (N=5) indicate that there is a small but significant difference in initial movement direction (measured at peak velocity) between the pre- and post-rotation phase of the left hand, indicating interlimb transfer. Analyses of savings were not conclusive so far, but it is likely that testing more subjects will help determining whether there is a link between the amount of interlimb transfer and the amount of savings.

Title: Modulation of sensorimotor β-band activity by unilateral kinematic-errors in bimanual coordination tasks

Authors: J. ALAYRANGUES, F. TORRECILLOS, A. BROVELLI, *N. MALFAIT;
CNRS / INT, Marseille, France

Abstract: The functional significance of the EEG oscillations recorded over the sensorimotor cortex is still unclear. In a previous study, we examined the modulations in the β-band (15-30Hz) sensorimotor oscillatory activity in response to kinematic errors induced in unilateral reaching movements. We described the error-related attenuations of the post-movement β-ERS (β-rebound) at the end of perturbed reaches as well as the modulations in the β-activity during the preparation of the immediately following movements. The clearly distinct patterns of modulation that we observed for the pre- and the post-movement periods pointed to their different functional roles in behavioral monitoring and sensorimotor adaptation. While the error-related attenuation of the β-rebound may reflect salience-processing, independent of sensorimotor adaptation, the modulation of the pre-movement β-power might be related to motor-command adjustments activated after movement-execution errors are experienced. In the present experiment, we examine error-related modulations of β-activity in a bimanual reaching task. Our goal is to determine whether "high-level" information influences the patterns of interhemispheric asymmetry in pre- and post-movement β-activity. In this purpose, we use two tasks involving comparable bilateral reaching movements, but in which the mode of bimanual coordination differs critically: on the one side, a task of "parallel" coordination implicates the control of two independent cursors (each controlled by one hand) to reach two different targets, on the other side, a "cooperative" coordination task involves controlling a single cursor with both hands to hit a unique target. Unpredictable mechanical perturbations (force-field) are applied unilaterally, to one of the arm. As previously reported, in these two tasks different behavioral responses to unilateral perturbations are observed (Diedrichsen, 2007). In the task of parallel control, on-line motor correction and adaptive processes (visible in the movements executed directly after a perturbed trial) are manifest for the arm submitted to the perturbation solely. In contrast, in the cooperative condition in which a single cursor is controlled by both hands, correction during the perturbed movement and motor-command update in the subsequent trial are observed bilaterally. We assess how the error-related modulation of the sensorimotor pre- and post-movement β-activity (in particular the degree of interhemispheric asymmetry) is influenced by the nature of the bimanual coordination, parallel or cooperative.

Title: Gain alteration of feedback control and adaptation induced by acquisition of a novel visuomotor map of reaching movements

Authors: *T. HAYASHI[1], A. YOKOI[2], M. HIRASHIMA[3], D. NOZAKI[1];
[1]The Univ. of Tokyo, Grad Sch. Educ, Tokyo, Japan; [2]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [3]Ctr. for Information and Neural Networks, Osaka, Japan

Abstract: Human motor system has two kinds of mechanisms for reaching movement corrections: (1) online correction within a trial (feedback control) and (2) offline correction across trials (adaptation). These two mechanisms contributed to perform accurate and consistent movements in the presence of noises and/or uncertainties. However, these corrections could be achieved involuntarily or implicitly, raising a fundamental question of why and how the motor system can correct movements in an appropriate direction to reduce the movement error. We hypothesize that this ability is associated with feedforward control based on visuomotor map that accurately transforms the visual target direction into the movement direction. Without such visuomotor map, the motor system would be confused about in which direction the movement is corrected. To test the causal link of the visuomotor map with online and offline corrections, we examined how these corrections were influenced when the visuomotor map was distorted. We tried to distort the map using the method in our previous study (Hirashima & Nozaki, Curr Biol 2012). When participants reached to one of two targets located clockwise (CW) or counter-clockwise (CCW) from a straight-ahead direction, a gradually increasing visual rotation was implicitly applied to the cursor representing the position of the participant's hand. CW and CCW visual rotations for the CW and CCW targets, respectively, implicitly made the movement directions more inward. Thus, after the adaptation to a certain amount of rotations, the executed movement directions became smaller (i.e., inward) than the target directions. Despite such distortion of visuomotor map, the movement direction to the central target (located straight ahead) remained unchanged, guaranteeing that this movement could be used as probe trials. We examined how a reaching movement to the central target was corrected online when the target suddenly jumped to other locations and offline in the next trial after experiencing a visual rotation. We found that the inward visuomotor map distortion decreased the gain of online and offline corrections. We also observed that when the visuomotor map was distorted outward, the gains of corrections increased. These changes were consistent with the changes of the movement corrections predicted by each visuomotor map distortion. These results support our hypothesis that both online and offline corrections reflect the properties of the visuomotor map, and also

illustrate possible close links between feedforward control, feedback control, and how they are modified by adaptation.

Title: Decomposing motor memory decay into trial- and time-dependent components

Authors: ***A. SASAKI**, D. NOZAKI;
Physical and Educaton, Univ. of Tokyo, Tokyo, Japan

Abstract: Since a pioneering work of Ebbinghaus (1885), it has been repeatedly shown that declarative memory monotonically decays with passage of time. However, it has not been fully elucidated how the motor memory changes with the passage of time. Indeed, the current computational model for motor adaptation (state space model; e.g., Thoroughman & Shadmehr, Nature 2000) has succeeded in capturing the trial-dependent pattern of motor memory, but we have not yet known how the effect of passage of time should be included in this model. Here, we examined the time-dependent pattern of motor memory decay. Participants performed reaching movements in the presence of velocity-dependent rotational force field (FF) applied to the hand (Shadmehr & Mussa-Ivaldi, J. Neurosci. 1994). We used error-clamp (EC) method (Scheidt et al., J. Neurophysiol. 2000) in which the force exerted against a virtual channel was measured to quantify the level of motor adaptation (i.e., motor memory). After performing 100 FF training trials interleaved randomly with 25 EC trials, the participants repeated a test set 100 times. Each test set consisted of six FF trials followed by two consecutive EC trials. The inter-trial interval (ITI) between the two EC trials was changed variously (3, 4, 5, 6, 7, 8,1 9, 12, 18 or 24 sec) so that we could investigate how the motor memory decayed with the passage of time. It should be noted that the first EC trial could not be the FF trial: The FF trial would produce time-dependent learning effect (Huang & Shadmehr, J. Neurophysiol. 2007) and contaminate the motor memory decaying pattern. We observed a small amount of reduction of motor memory from 1st to 2nd EC trial when the ITI was 3 sec. This amount of motor memory was maintained until ITI became 8 sec before showing gradual reduction with longer ITI (> 8 sec). Thus, this decaying pattern was

different from a naive prediction that motor memory decayed monotonically with passage of time (e.g. exponential curve). These results suggest that motor memory decay can be separated into two different components: the component reducing the memory immediately after a performing a trial (trial-dependent component) and that decays with passage of time (time-dependent component).

Title: Neuroplasticity in primary somatosensory cortex supports motor learning by observing

Authors: *H. R. MCGREGOR, P. L. GRIBBLE;
The Univ. of Western Ontario, London, ON, Canada

Abstract: While many of our motor skills are acquired through physical practice, we can also learn how to make movements by observing others. A series of studies has demonstrated that individuals can learn how to reach in novel dynamical environments ('force fields', FF) by observing the movements of a tutor. Moreover, as has been shown in the literature on motor learning through physical practice, observational motor learning also brings about sensory-motor plasticity and performance changes in the somatosensory domain. Here we directly tested the involvement of primary somatosensory cortex (S1) in observational motor learning. Subjects grasped the handle of a robotic manipulandum and performed straight reaching movements to a visual target in a null field (no force applied). Subjects in a learning group (n=16) then watched a video of a tutor learning to perform straight reaches while the robot applied a leftward FF. Subjects in a control group (n=16) watched a video of a tutor reaching in an unlearnable randomly-varying FF. We examined S1 function immediately before and after observation through the measurement of somatosensory evoked potentials (SEPs). SEPs were elicited through electrical stimulation of the median nerve at the right wrist and were recorded over left S1. We quantified pre- to post-observation changes in the amplitude of the N20-P25 SEP

component, the first cortical component of the SEP which is generated by S1. Examination of the N20-P25 SEP component thus allowed us to assess changes in early, low-level S1 function associated with motor learning through observing. After acquiring SEPs, all subjects performed a behavioral motor learning test to assess the degree to which they had learned the observed FF. We show that subjects who observed motor learning exhibited increases in the N20-P25 SEP component measured over left S1 compared to the control group who observed a tutor performing curved reaching movements but not learning. Moreover, the increases in N20-P25 amplitude in the learning group were reliably correlated with the amount of motor learning subjects achieved through observation, as assessed behaviorally after SEP recordings. These results suggest that plasticity in primary somatosensory cortex supports motor learning by observing.

Abstract: When we interact with the external world, our brain integrates various sensory inputs and maintains an internal representation of world dynamics. Due to the different physical properties and neuronal processing pathways of the inputs, sensory inputs are processed at variable delays with respect to their external source. Thus, our perception of multisensory events as simultaneous must be the outcome of active reconstruction processes that account for these delays. Here, we examine how the magnitude of the delay and the schedule of its presentation affect the representation of state and time in the motor system. To study the effects of delayed feedback on the performance of reaching movements, we used a virtual game of pong in which

the movement of the controlled paddle is delayed with respect to the movement of the participant's hand. Previous results indicated that for delays smaller than 150 ms, adaptation to the delayed environment also causes an overshoot in subsequent reaching to targets without vision of the hand (blind reaching). We suggested that these results can be explained by a state-based model in which a representation is based on a perceived change in the impedance parameters of the arm, rather than by a time-based representation model. In the current study, we explore whether a state-based representation of the delayed pong environment is bounded to small values of delay, and whether it is affected by the schedule of presentation of delay. We hypothesize that for large values of delay, the representation of the perturbation is more likely to be time-based. To test this, we exposed participants to delays of up to 300 ms, either by gradually increasing or decreasing the delay, or by presenting the participants abruptly with a constant perturbation of different delay magnitudes. During the experiments, participants also performed several blocks of blind reaches that were presented at constant intervals throughout the experiment, enabling us to examine the way they generalize their adaptation to the delay to a task that requires an accurate proprioceptive spatial representation. If large delays were explicitly compensated by a temporal representation, this representation would abolish the errors in blind reaching movements. Understanding the way delay is represented in the motor system is important for understanding how forward models are formed. It may also help in understanding pathological conditions that are characterized by delayed information transmission, such as Multiple Sclerosis.

Title: Learning novel sensory-motor maps: learning to move to auditory targets

Authors: *F. T. VAN VUGT[1], D. J. OSTRY[2];
[1]Psychology, [2]McGill Univ., Montreal, QC, Canada

Abstract: Humans readily learn motor skills such as reaching to visual targets, learning to speak or learning to play a musical instrument. In such tasks, the brain faces a double challenge: it needs to learn which movement achieves a certain aim (e.g., which motor commands produce a given vowel; for feedforward control) and it needs to learn which motor corrections to generate for a given sensory error (for feedback control). We hypothesized that this knowledge is organised into two maps: a target and error map, respectively. Existing motor learning paradigms typically test participants who already have well learned, pre-existing maps that are perturbed experimentally, but it remains unclear how such maps are initially formed. We test human participants who hold a robot handle and make reaching movements to auditory targets. Movements elicit a combination of pure tones whose frequencies depend on the endpoint position of the handle in the horizontal plane. In experiment I, auditory targets are chosen quasi-randomly from a continuous distribution. In experiment II, targets are chosen from a set of five targets that are presented in random order. In experiment III, auditory targets are continuous but each target is presented 16 times in a row (batch). Presenting different targets on subsequent trials allowed us to probe the target map, whereas presenting the same target repeatedly tapped into the error map. that novel audiomotor maps can be readily acquired within a single session on a single day, as shown by decreased target-movement error. Performance on purely auditory and purely motor tests remained stable, showing that learning cannot be explained as a change in auditory or motor function but is attributable to the learning of the mapping between them. A very coarse target map of the sensorimotor space was acquired within a few trials and became progressively more fine-grained, allowing it to eventually encode at least five unique targets at the end of the session. When targets were presented in batches, participants improved their accuracy within a batch, and critically this within-batch convergence became faster in the course of the experiment, revealing that they learned an error map. These results show that novel sensorimotor maps can be acquired remarkably rapidly. Our paradigm allows monitoring the formation of two types of mapping: a mapping between motor commands and sensory outputs (target map), analogous to feed-forward control; and a mapping between sensory errors and motor corrections (error maps), analogous to feedback control. This experimental paradigm provides a unique window into the earliest stages of sensorimotor learning.

Title: Effective connectivity changes before and after sudden and gradual visual-motor adaptation

Authors: P. BÉDARD, *J. N. SANES;
Neurosci., Brown Univ., Providence, RI

Abstract: Environmental changes occur constantly to form and then retain new sensory-motor relationships. We previously examined differences in brain activation and effective connectivity (EC) during adaptation to and retention of sudden and gradual perturbations (Bédard and Sanes 2014). Here, we assessed whether adapting to varying visual-motor regimens differentially changed spontaneous brain states (Albert et al. 2009). We used functional MRI to measure brain activation from young adults who used a joystick to acquire visual targets. The visual cursor followed the joystick normally (null), was rotated 30° on all trials (Sudden), or rotated incrementally 0.25°/trial, starting at 0° (Gradual). No one in the Gradual group became aware of the perturbation. All participants performed six phases: Null (80 trials), Rest (8 min), Learning (160 rotation trials), Washout (80 null trials), Rest (8 min), Recall (80 rotation trials at 30°). We analyzed EC during the two Rest periods using Granger causality methods between 10 regions that exhibited common activation across the two groups late in Learning. Reaching error of the Sudden group steadily decreased during Learning, while error for the Gradual group steadily increased to approximate that of the Sudden group late in Learning. Both groups showed similar performance during Washout and Recall. For the EC analyses, we found more directed influence in the Gradual group by the left superior parietal lobule (SPL) on the right cerebellum (CB) and by left premotor cortex (PM) on the left occipital gyrus after compared to before Learning. By contrast, the Gradual group exhibited less influence by the right SPL on medial CB and also on the left middle occipital gyrus and also less influence by the left PM on the right CB after compared to before Learning. For the Sudden group, we found more influence by the left somatic sensory cortex (S1) on medial CB and also by the right SPL on the left S1 after compared to before Learning. When directly comparing the Sudden to the Gradual group before Learning, we found more influence from left SPL to the middle CB for the Sudden group. After Learning, we found more influence from right SPL to left S1 and from left S1 to the right CB for the Sudden group and finally, more directed influence from the left SPL to the right CB for the Gradual group. These results demonstrated short-term changes in network connectivity, independent of task performance and also independent of the apparent similarity in learning two different types of adaptation, as measured by performance during Washout and Recall for the two groups. Thus, it appears that motor memory consolidation uses different brain mechanisms for different tasks.

Title: Neural substrates of the initial stages of human motor learning

Authors: *A. SIDARTA, N. BERNARDI, S. VAHDAT, D. J. OSTRY;
McGill Univ., Montreal, QC, Canada

Abstract: The initial stages of motor learning are often characterized by uncertain sensory goals. In learning how to play tennis, for example, one has a distal visual target that helps constrain the movement. However, it is necessary to discover, in somatosensory terms, what makes a good serve in the absence of direct visual guidance. During this period, motor commands and associated sensory targets are acquired and refined through trial, error and exploration. Reinforcement-based feedback, both implicit and explicit, can serve as a means to shape motor behavior. In this study, we focus on the functional brain networks that are involved in the initial period of motor learning. We recruited 21 healthy right-handed subjects who performed active reaching movements to a horizontal bar that contained a unseen target zone. During training trials, subjects were given feedback if their movement was accurate, that is, if it landed inside the reward zone. The size of the reward zone was progressively reduced across the four training blocks (50 trials each). Multiband-accelerated fMRI recording (TR=1.69sec, voxel size: 2mm isomorphic) was used under resting-state conditions, immediately before and after movement training. Seed-based analyses were conducted using a set of region of interests (ROIs) from the task-based localizer. We included as regressors in a group-level GLM, the reduction in movement error and the number of reinforced movements, to test whether changes in functional connectivity were associated with behavioural measures of learning. We found a reliable improvement in movement accuracy after the reinforcement-based training. This improvement was reliably correlated with the amount of reinforcement received. We also found that there was an increase in functional connectivity strength within the sensorimotor networks. In particular, networks involving supplementary motor area (SMA), primary and second somatosensory cortices, and the ventromedial prefrontal cortex show reliable increases associated with accuracy improvement following learning. This suggests that early motor learning involves changes to somatosensory as well as motor networks which occur in conjunction with reinforcement.

Title: Plastic changes in dendritic spines of pyramidal neurons from prefrontal cortex underlie motor learning in rats

Authors: ***M. N. VÁZQUEZ HERNÁNDEZ**[1], D. GONZÁLEZ-TAPIA[2], N. I. MARTÍNEZ-TORRES[1], M. HERNÁNDEZ-GONZÁLEZ[3], I. GONZÁLEZ-BURGOS[1];

Abstract: The ability to develop new skills through practice is defined as motor learning. The prefrontal cortex is involved in the rectification of information related to the achievement of motor abilities to be learned. Particularly, pyramidal neurons of the layer V of prefrontal cortex receive excitatory information previously integrated in the cortical-striatum-thalamic pathway, for its rectification. Excitatory synaptic inputs of these neurons are mainly mediated by dendritic spines, which regulate the income of synaptic stimulation that arrives to these neurons. In the present study, numerical density of dendritic spines and spine type proportions of pyramidal neurons of prefrontal cortex were investigated to help to elucidate the plastic changes underlying synaptic information processing during the period in which motor skills are acquired. Six Spregue-Dawley adult male rats where assigned to one of six sub-groups of study, according to a six-day paradigm of motor training. 36 non-trained rats, and 6 intact rats where used as controls. The time elapsed to traverse the trail, and the number of errors committed per session (four trials per day), were used as indicators of motor learning. Then, the prefrontal cortex of experimental animals where dissected out for quantification of numerical density and spine type proportions by direct observation under a light microscope. Pyramidal neurons showed more dendritic spines on days 1 and 3, as well as more thin spines on day 1 and less mushroom spines on days 2, 5 and 6. The findings allow to suggest that the rectifying participation of prefrontal cortex during motor learning is predominant on the first days of training based on the elevated number of thin spines on these days. According with this, since thin spines have been associated whit the

acquisition of novel information whilst mushroom spines are rather related with its long-term storage, the greater number of thin spines observed could indicate that the rectifying processes leading to motor learning may imply a rapid processing of information in the prefrontal cortex.

Title: Representation of reaching movements in motor cortex: a modeling perspective

Authors: ***W. W. TEKA**[1], K. HAMADE[2], S. N. MARKIN[2], R. F. ROGERS[3], I. A. RYBAK[2], Y. I. MOLKOV[1];
[1]Indiana Univ. – Purdue Univ. Indianapolis, Indianapolis, IN; [2]Drexel Univ. Col. of Med., Philadelphia, PA; [3]CHDI Mgmt., Princeton, NJ

Abstract: The motor cortex plays a major role in controlling voluntary movements by sending signals to the muscles through the spinal cord. Because of mapping complexity, the cortical representation of movement, and the relationship between the cortical neuronal activity and the dynamics of movement are not fully understood. How different movements are coded and represented in the cortical activity is a central motor control problem. Previous studies were based on two competing hypotheses. One approach attempts to correlate activity of primary motor cortex neurons during reaching movements with movement parameters (e.g., direction). However, these correlations cannot prove causation, and the directional tuning of given neuron may depend on other factors. A different approach suggests a dynamical paradigm of motor control based on the suggestion that neural activity in the motor cortex represents motor programs corresponding to a particular motor task (e.g., moving an arm from one position to another to reach an object) rather than the parameters of the movement per se. We have developed a model of a neuronal controller which governs a two-joint arm actuated by six muscles. This model describes the dynamics of voluntary arm movement controlled by a spinal cord circuit with afferent feedbacks. A thalamo-cerebellar-cortical controller in the model provides the neuronal motor program necessary to perform reaching tasks based on a bell-shaped

velocity profile and a straight line trajectory. To do so the controller calculates the joint torques which are necessary to move the arm along the specified trajectory and then generates these torques with agonist and antagonist muscles via specific activation of the low-level spinal circuit. The model was used to evaluate the relationships between neuronal activity in primary motor cortex, muscle activity and arm dynamics and to compare them with those reported in the previous experimental studies. The model demonstrates that patterns of activity in the motor cortex may indeed strongly correlate with both dynamical and geometric parameters of the movement. However, the apparent moto-cortical "coding" of a particular parameter depends on the experimental context, which might not be taken into account or reported. On the other hand, afferent feedback signals from muscles during the movement include information about movement geometry, and these signals are factored into the calculation of the motor program. We conclude that the dynamical paradigm of cortical representation of movement implies coding of both dynamical movement parameters and its geometrical characteristics.

Title: Difficulty of visual transformation modulates the contributions of explicit and implicit learning with and without tDCS

Authors: *S.-L. LIEW[1], T. THOMPSON[2], J. RAMIREZ[2], P. BUTCHER[3], J. TAYLOR[3], P. CELNIK[2];
[1]USC, Los Angeles, CA; [2]Johns Hopkins Sch. of Med., Baltimore, MD; [3]Princeton Univ., Princeton, NJ

Abstract: Recent research has shown that both error-based and strategy-based learning play a role in visuomotor adaptation (Taylor et al., 2014). Error-based learning involves the implicit generation of an internal model to predict movement errors, while strategy-based learning engages explicit instructions or cognitive strategies to improve motor learning. In the present study, we examined the effects of task difficulty on the contributions of error-based and strategy-

based learning. To do so, we increased the amount of visual transformation by changing the feedback screen orientation from horizontal to vertical. We predicted that this would increase the task demand on participants by adding a new level of visuomotor transformation. We collected data in two groups of participants (n=10 per group) who performed the exact same task with either a horizontal or vertical screen. Using the same visuomotor adaptation paradigm as Taylor and colleagues (2014), participants directed a stylus towards a target on a circle, flanked by numbers, presented on a computer screen. Participants were asked to try to get their cursor on the target, and also to verbally report the number they were aiming at in order to get their cursor on the target. In this way, both explicit (aiming report) and implicit (movement trajectory) components of each movement were measured. Participants were unable to see their hand during the task. After 120 baseline trials, a 45-degree clockwise rotation was introduced for 160 trials, followed by a block of 40 trials without feedback and 40 trials with feedback. We found that the vertical group performed worse than those in the horizontal group, showing a slower rate of learning. While both groups used the same amount of error-based learning, the vertical group used less of an aiming strategy compared to horizontal group. That is, increasing the task difficulty through the screen orientation modulated the relative contribution of the explicit aiming component during the visuomotor adaptation task. With this version of the task, we also replicated findings from a previous study using transcranial direct current stimulation. We found that facilitation of the cerebellum by anodal tDCS greatly increased the error-based learning component, while facilitation of the dorsolateral prefrontal cortex greatly increased the strategy-based learning component, relative to sham. The effects of tDCS on these explicit and implicit components were increased when the task was more difficult (vertical screen). These findings suggest that task difficulty via visual transformations can affect the contributions of implicit and explicit components during visuomotor adaptation.

Title: Concurrent reach and tracking adaptations of moving and static targets

Authors: *M. N. AYALA, P. SHARMA, D. Y. P. HENRIQUES;
York Univ., North York, ON, Canada

Abstract: Given that the neural networks and behavioural parameters subserving saccadic and smooth pursuit eye movements are independent of one another, we wanted to explore whether a similar analogy exists for ballistic reaching and tracking arm movements. Does adaptation to perturbed tracking movements generalize to that of ballistic reaching movements? In the following experiments, we explored whether training by tracking a moving target with a perturbed hand-cursor produces motor aftereffects and if these aftereffects differ from those produced in a typical perturbed ballistic reaching task with a static target. We found that adaptation to perturbed tracking movements produce significant reach aftereffects although to a smaller extent; tracking aftereffects were about half the size (on average 9°) of those produced after ballistic reach training (on average 19°). Additionally, we looked at whether neural processing of adaptation to tracking and reaching paradigms are independent of one another and would thus allow for concurrent adaptation to opposing perturbations (i.e. dual adaptation). Tracking trials were associated with a 30° CCW rotation while reach trials were associated with a 30° CW rotation. The 'single' perturbation groups adapted to either a CW or CCW perturbation while the 'dual' group experienced both perturbations concurrently. We found significant reach aftereffects following dual training of about 7°, which was substantially smaller than that produced when reach training was not concurrent with tracking training. The size of reduction of aftereffects is consistent with the extent of the interference from tracking training as measured by the reach aftereffects produced when only that condition was performed. Additionally, tracking performance in response to a visuomotor rotation significantly improved across training for both single and dual tracking groups, both saturating at the same level but with different learning curves, with only the single group fully returning to baseline levels. Finally, reach errors for static targets in the dual group significantly decrease across training although to a lesser extent when compared to that of the single group. These findings suggest that adaptation of tracking movements which tend to produce small errors that can be adjusted on-line, are processed somewhat, although not completely independent of reaching movements which tend to produce larger errors that are adjusted on a trial-by-trial basis.

Title: Individual differences in TMS sensitivity influence the effect of tDCS in a motor adaptation task

Authors: *L. LABRUNA[1], M. J. DABIT[1], B. VANDERSCHELDEN[1], A. STARK-INBAR[1,2], M. NITSCHE[3,4,5], R. B. IVRY[1];

Neurophysiol., Georg-August-University, Goettingen, Germany; [4]Leibniz Res. Ctr. for Working Envrn. and Human Factors, Dortmund, Germany; [5]Dept. of Neurol., Ruhr-University Bochum, Bochum, Germany

Abstract: Transcranial direct current stimulation (tDCS) provides a non-invasive brain stimulation tool to induce change in cortical excitability and perturb or enhance motor and cognitive function. To date, tDCS researchers have employed a fixed stimulation level, ignoring the potential impact of individual anatomy and physiology on the efficacy of the stimulation. This fixed approach contrasts with the standard procedure for transcranial magnetic stimulation (TMS) where the stimulation level is usually tailored on an individual basis. Labruna et al. (submitted) reported a modest relationship between individual differences in sensitivity to TMS and the efficacy of anodal tDCS: Individuals with a lower threshold for TMS showed a larger change in corticospinal excitability following anodal tDCS, compared to individuals with a higher threshold. In the present study we examined the impact of this relationship on tDCS-induced effects on sensorimotor learning. As an operational measure of TMS sensitivity, we identified each participant's resting motor threshold, defined as the minimal TMS intensity required to evoke motor evoked potentials on 5 of 10 consecutive trials in the right index finger. Participants were then tested on a visuomotor adaptation task in which they had to reach to visual targets with the right hand. Following a baseline phase with veridical feedback, a 30-degree clockwise rotation was imposed for 200 trials. Retention and forgetting was tested in a final phase of 288 trials in which feedback was removed. Anodal or sham tDCS (1 mV) was applied over left M1 during the second half of the baseline phase and throughout the adaptation phase. Contrary to the results of Galea et al. (2011), acquisition was faster for participants receiving anodal tDCS compared to sham stimulation, whereas performance was similar for the two groups in the forgetting phase. Of greatest interest in the present study, the enhanced acquisition effect was larger in participants with lower TMS thresholds (higher sensitivity to TMS). These results suggest that TMS sensitivity can be used as predictive measure of tDCS efficacy. Moreover, customizing tDCS stimulation levels to account for individual differences in brain stimulation sensitivity may increase the reliability of this method.

Title: Distinct modulations in sensorimotor post- and pre-movement β-synchronization related to error salience processing and sensorimotor adaptation

Authors: *F. TORRECILLOS, J. ALAYRANGUES, B. E. KILAVIK, N. MALFAIT;
AMU & CNRS- Inst. De Neurosciences De La Timone, Marseille, France

Abstract: It is well known that β-band (15-30Hz) oscillations often dominate in sensorimotor cortex, however their functional roles remain uncertain. Prominent at rest, they were originally attributed to an "idling" state of the motor system. Along these lines, β oscillations within and beyond sensorimotor cortex were recently proposed as an active process that promotes the existing motor state and compromises neuronal processing of new movements. Recently, Tan et al. (J Neurosci 34:5678, 2014) examined sensorimotor β-band activity during a joystick task in which visual perturbations were introduced. They found that the β-rebound, an increase in β-power typically observed at the end of movement, was attenuated in trials with movement-execution errors. Furthermore, the effect was stronger when contextual information enhanced the behavioral salience of the error. Here, we investigated further the modulations in β-activity by movement errors, contrasting error salience and sensorimotor adaptation. In two complementary experiments, along with the post-movement β-rebound we examined the pre-movement β-band activity during preparation of reaches immediately following perturbed movements. In the first experiment, participants performed reaching movements in a force-field created by a robotic device, and kinematic errors of different sizes were produced by unpredictable changes in the strength of the applied force. In the second experiment, we contrasted two types of reach errors: movement-execution errors induced by mechanical or visual perturbations that trigger trial-to-trial adaptive mechanisms, and goal errors caused by unexpected displacements of the target that do not elicit sensorimotor adaptation. Consistent with Tan et al, we found that the post-movement β-rebound was parametrically attenuated by the sizes of movement-execution errors produced by mechanical perturbations independently of their corrections on-line (Exp1). Importantly, this error-related attenuation of the post-movement β-rebound appears insensitive to the nature of the reach errors, as it was present for both movement-execution and goal errors (Exp2). In comparison, the pre-movement β-activity presented a clearly contrasting pattern, only being modulated by kinematic errors that triggered trial-to-trial motor-command updates. Our findings suggest that the error-related modulation of the β-rebound may reflect salience-processing, independent of sensorimotor adaptation, whereas the attenuation of pre-movement β-

power might be related to motor-command adjustments activated after movement-execution errors are experienced.

Title: Effect of protein synthesis inhibition in monkey primary motor cortex on performance of sequential movements

Authors: *M. OHBAYASHI[1,2,3], P. L. STRICK[1,2,3,4];
[1]Univ. of Pittsburgh, Sch. of Medicine, Syst. Neurosci. Inst., Pittsburgh, PA; [2]CNBC, Pittsburgh, PA; [3]Dept. of Neurobio., Pittsburgh, PA; [4]Veterans Affairs Med. Ctr., Pittsburgh, PA

Abstract: Regular practice enables motor skills to be retained and improved. Recent studies in monkeys indicate that extended practice on a motor skill alters patterns of neural and functional activation in M1 (Matsuzaka et al., ; Picard et al.). These and other results have led to the notion that M1 is a site of storage for highly practiced skilled movements. Experiments in rodents support this conclusion and indicate that constitutive protein synthesis in M1 is required to maintain a learned motor skill (Kleim et al., 2003). Here we tested whether protein synthesis in M1 of monkeys is required for the maintenance of learned sequential movements. We trained 2 monkeys (Cebus Apella) to make sequential reaching movements in two task modes (Matsuzaka et al., 2007). In the Random mode movements were guided by vision and new targets were filled using a pseudo-random sequence. The new target in the sequence was filled 100 ms after contact of the prior target. In the Repeating mode movements were internally guided and new targets were filled according to a repeating 3 element sequence (e.g., 5-3-1-5-3-1 ...). A 400 ms delay

was inserted between contact of one target and the fill of the next target in the sequence. The longer delay promoted the occurrence of predictive responses and we allowed the animal to contact the next target in the sequence before the target was filled. With practice, monkeys could perform the Repeating mode of the task without any visual cues. After the monkeys were trained for more than 200 days on the Random and Repeating modes of the task, we injected the protein synthesis inhibitor anisomycin (ANI, 5 µl of 100 mg/ml) into 2 sites of the arm area of M1 (monkey 1, n = 5; Monkey 2, n = 1). One day later we tested the animals' performance on the two modes of the task. After the ANI injections, the number of errors increased significantly only during performance of the Repeating mode of the task. The error rate for the most affected movements increased by an average of 49.7% (range of 77-29%) after the ANI injections. Similar increases in errors were not observed during the Random mode of the task or after control injections of saline into M1 (n = 2). The errors during the Repeating mode can be categorized as two types: errors of accuracy and errors in direction. An accuracy error was considered to be a reach performed in the correct direction, but to an endpoint outside of the correct target. A direction error was considered to be a reach performed in the direction opposite to the correct target. Substantial number of the errors (an average of 57.3%, range of 97.6-8.3%) during the Repeating mode were direction errors. These results support the concept that M1 is a site of storage for highly practiced motor skills.

Title: Task intuitiveness and non-linear filtering of surface electromyography facilitate learning of proportional 3D position control of a myoelectrically-controlled robot

Authors: *A. FEINMAN, T. D. SANGER;
USC, Los Angeles, CA

Abstract: In previous work, our group has shown that subjects can more easily control stable surface electromyography (sEMG) signal amplitudes when using Bayesian-filtered sEMG. In this study, we have begun to examine the factors that affect Fitts'-Law movement times and error

rates when subjects are required to control trajectories to acquire targets. Subjects were given control of the endpoint of a robotic arm. Endpoint position in Cartesian space was proportional to sEMG amplitudes of the flexor carpi radialis (FCR) for lateral motion, brachioradialis (BR) for upward motion, and anterior deltoid (AD) for forward motion. In each trial, a pair of bars was presented on the surface of a table in front of the subject, and they were asked to repeatedly tap the robot endpoint back and forth between the two bars as quickly as possible without missing. The two bars were identical in shape in each trial, but the width of the bars and/or the distance between the bars varied across trials to generate six indices of difficulty in the range of 1-4 bits. Five blocks of trials were conducted: 1 = tapping while grasping the robot, 2 = controlled robot using Bayesian-filtered sEMG, 3 = linear filtering, 4 = Bayesian filtering with FCR and BR Electrodes swapped, 5 = identical to block 2. Differences in movement times (MTs) and error rates (ERs) were observed. In blocks 2 & 3, where the action directions of the muscles matched the movements of the robot, subjects were able to achieve the correct motions in a matter of seconds. MTs did not improve between blocks 2 and 3, but ERs were higher in block 3. Subjects were mostly able to achieve a cyclic tapping in a short period of time. In block 4, most subjects could not learn the task quickly. Subjects that could learn the flipped task required more time to minimize ER and still had high MTs than in the intuitive task of the other blocks. Comparison between blocks 2 and 5 showed reduced MT and ER in block 5, despite subjects' having been exposed to different filtering and control paradigms in blocks 3 and 4, This indicates that subjects may be learning something that applies to that paradigm despite the interference. Our results show that both task intuitiveness and the type of EMG filtering affect the ability to learn the task quickly (i.e., minimize ER) and to master it (i.e., minimize MT). Future work in this project will extend to examining which kinematic states (or combinations) are the ideal control paramters, as well as studying the effect of visual aids on facilitating learning.

Title: The role of dorsolateral prefrontal cortex in motor learning during force-field adaptation: A continuous theta-burst stimulation study

Authors: *K. TREWARTHA, J. P. GALLIVAN, J. FLANAGAN;
Queen's Univ., Kingston, ON, Canada

Abstract: Many studies have investigated motor learning by requiring participants to learn to adapt to either visual (visuomotor rotation) or mechanical (force-field adaptation) perturbations. Two learning processes have been identified that support such learning: a fast process that adapts quickly, but also decays quickly; and a slow process that adapts and decays more gradually. The neural mechanisms underlying the fast and slow processes remain unclear. However, recent evidence has linked the fast process for motor learning to working memory resources that may be supported by dorsolateral prefrontal cortex (dlPFC). The current study used transcranial magnetic stimulation (TMS) in a continuous theta burst stimulation (cTBS) protocol to test the prediction that dlPFC plays an important role in the fast process for motor learning during force-field adaptation. Forty-eight healthy participants (18-34 years old) were recruited and assigned to one of three groups: a group receiving cTBS over right dlPFC, a group receiving cTBS over the arm area of left motor cortex (M1), and a control group who received no TMS. For the two cTBS groups, a 40 second train of pulses at an intensity of 80% of each participant's own active motor threshold was administered 5 minutes before participants completed a force-field adaptation experiment. cTBS is known to temporarily disrupt the function of the targeted brain area. On the group level our results were consistent with the hypothesis that temporary disruption of dlPFC selectively impairs the fast process for motor learning, leaving the slow process relatively intact. Behaviorally, participants in the dlPFC group exhibited slower adaptation during early stages of adaptation compared to both the M1 and no-TMS control groups. No differences were observed during later stages of adaptation, during a subsequent counter-adaptation phase, or during an error-clamp phase that immediately followed the counter-adaptation phase. No differences were observed between M1 and no-TMS control participants. These results are consistent with previous functional MRI data showing increased right dlPFC activity during early, but not late stages of visuomotor adaptation. The current data add to this literature showing that similar cognitive mechanisms are involved during early stages of learning during force-field adaptation. These findings suggest that the fast process for motor learning is highly cognitive, involving working memory resources that are supported by right dlPFC.

Title: The feedback response to error is a teaching signal during motor adaptation

Authors: *S. T. ALBERT[1], R. SHADMEHR[2];
[1]Biomed. Engin., [2]Biomed. Engineering, Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: When performing a motor task, we update our feedforward (FF) motor commands on a trial-to-trial basis in order to correct for errors we experienced on the previous trial. Feedback (FB) motor commands generated on-line to correct for error may serve as a teaching signal which instructs this motor learning process. If error-based learning is truly instructed by FB motor commands, these commands should be correlated. We tested this hypothesis by measuring FB motor commands and isolating the learning that was induced by them in FF motor commands. To assay FF and FB motor commands, we used electromyography (EMG) to measure the motor output of various arm muscles during a center-out reaching task (n=57 subjects). Before and after each perturbation, the subject experienced an error-clamp trial. In error-clamp, the robot generates a stiff channel which compensates for forces produced perpendicular to the straight line path connecting the starting position and target. During error-clamp, we assume that the desired state of the limb exactly matches its actual state, thus eliminating FB updates. Under this assumption, the error-clamp EMG signal is a direct measure of the FF motor command. Therefore, the difference between the pre- and post-perturbation error-clamp EMG signals is a timecourse that represents learning. Our proxy for error-dependent feedback commands was the difference between the EMG signals measured during the perturbation and the preceding error-clamp trial. Under this framework, we computed mean learning and FB timecourses across subjects and noted that they were related by a temporal shift. Cross-correlation indicated that learning and FB commands were maximally correlated if the FB traces were shifted earlier in time by 140 ms, on average. To further investigate the correlation between learning and FB we artificially shifted the FB responses within-subject to align them with the learning traces, according to the cross-correlation. We determined temporal segments where shifted FB and learning were positively correlated by linearly regressing, across subjects, learning at a particular time point onto the shifted FB response. Using this analysis, we determined that learning and shifted FB were significantly correlated during at least 80% of movement duration. These data suggest that feedback motor commands serve as a template or teacher for the motor learning system. Trial-to-trial motor learning may be partly driven by the addition of time-shifted, reduced-amplitude FB responses to the previous FF motor command.

Title: Occlusion of LTP-like plasticity in the primary motor cortex following adaptive motor learning

Authors: *S. UEHARA[1,4,5], F. MAWASE[1], P. CELNIK[1,2,3];
[1]Dept. of Physical Med. and Rehabil., [2]Dept. of Neurol., [3]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [4]Ctr. for Information and Neural Network,, Natl. Inst. of Information and Communications and Technol., Osaka, Japan; [5]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: When we learn a new motor behavior, different mechanisms are engaged including error-based (i.e. due to prediction errors), use-dependent (i.e. bias from prior movements), reinforcement (i.e. bias toward movements resulting in rewards) and strategic learning (i.e. due to cognitive strategies). These mechanisms seem to depend on different neural substrates, and importantly all of them are likely to contribute when learning new motor behaviors, even though some might be more weighted than others. An approach to test this framework is to determine whether physiological markers of one brain region are present during learning of behaviors. For instance, occlusion of LTP-like plasticity in M1 can be used as a physiological signature of motor memory retention (Cantarero 2013). Here, we tested whether learning a visuomotor adaptation task, known to heavily but not exclusively rely on error-based learning (presumably dependent on the cerebellum), also engages occlusion of LTP-like mechanisms in M1. Twenty subjects performed a visuomotor adaptation task involving reaching with their right index finger. In two counterbalanced sessions, all subjects were exposed to a 30-deg constant visuomotor perturbation and in the other session they were exposed to random perturbations. Half of the subjects performed 56 perturbed trials (short training group), while the other half performed 208 perturbed trials (long training group). Excitability of M1 was evaluated using single pulses of TMS before and after applying anodal transcranial direct current stimulation (AtDCS) to the left M1 for 7 min. To explore the effect of training on occlusion of LTP-like plasticity, we assessed the tDCS effects in a baseline session (no training session) and immediately after training. We

found that the short training group experienced an increase in M1 excitability by AtDCS at baseline and after training of both constant and random perturbations. However, the long training group had no increase in M1 excitability by AtDCS only after exposure to the constant perturbation, a signature of occlusion of LTP-like plasticity, whereas this effect was not present at baseline and after the random perturbation. Additionally, the subjects who leaned more, as depicted by more errors during catch trials, were those who showed larger occlusion effects. These findings indicate that M1 is engaged during visumotor adaptation learning paradigms if enough exposure is allowed, suggesting the potential presence of reinforcement or use dependent learning mechanisms underlying this behavior.

Title: Reaching for a good aiming strategy in people with cerebellar degeneration

Authors: *R. MOREHEAD[1], J. A. TAYLOR[2], R. B. IVRY[1];
[1]Psychology, UC Berkeley, Berkeley, CA; [2]Psychology, Princeton Univ., Princeton, NJ

Abstract: In visuomotor adaptation tasks, a systematic discrepancy is introduced between visual feedback of the hand position and the actual position of the hand. Patients with ataxia from cerebellar degeneration show a marked deficit in their ability to compensate for these perturbations, an impairment attributed to an inability to utilize sensory prediction errors. However, it is increasingly recognized that behavior in visuomotor adaptation tasks reflects the contribution of other learning processes in addition to adaptation. We performed a several experiments to assess the impact of cerebellar ataxia on these different learning processes. Experiment 1 assessed aiming strategy use by associating an arbitrary color cue with a visuomotor rotation. Prior work has shown that internal models cannot be selectively retrieved by color cues, while different actions (where to point) are easily associated with such cues. For the latter, healthy controls can use the cue to retrieve and implement an appropriate aiming plan, flexibly changing this plan from trial to trial. We manipulated the color cue to assess how much of the performance change observed in an adaptation task is attributable to aiming. Patients with

cerebellar ataxia (n=25) performed this task with either one or four targets arrayed in 90° increments around the workspace. In the single target condition the patients performed the task remarkably well, showing a clear ability to develop and implement an aiming strategy to compensate for the perturbation. In contrast, in the four target condition, the patients were unable to develop and implement an aiming strategy. Experiment 2 employed a different manipulation thought to isolate error based adaptation. Here we used a visual error clamp in which the feedback was always offset from the target by 45°, independent of the direction of the hand movement. Participants (n=10) were tested with either one straight ahead target or four targets located around the workspace. Participants were told to move the unseen hand directly to the target location, ignoring the cursor. Despite these instructions, control participants deviate their hand path, suggestive of adaptation. Surprisingly, the patients showed similar changes in performance in the one target condition and, based on preliminary results, a modest attenuation in the four target condition. This discrepancy between the 1- and 4-target conditions in both experiments suggests that part of the performance deficit observed in patients with ataxia may extend beyond an impairment in adaptation.

Title: Contrasting roles of distinct LFP beta bands in motor cortex and their relation to spiking activity

Authors: *B. E. KILAVIK, A. RIEHLE;
INT, CNRS - Aix-Marseille Univ., Marseille, France

Abstract: Sensorimotor beta oscillations (~ 13-30 Hz) modulate rather heterogeneously across different sensorimotor behaviors. Many roles in cognition and motor control were therefore proposed, including postural maintenance, signal expectancy and sensorimotor integration (Kilavik et al. 2013, Exp Neurol 245:15). In the motor cortex, local field potential (LFP) beta oscillation amplitudes and neuronal firing rates change systematically in relation to behavior, but their direct amplitude inter-dependence was barely studied. Furthermore, spikes lock to beta oscillation phase, but it is unclear whether spikes of single neurons lock to multiple rhythms co-occurring in the LFP, and if the locking is dependent on the neuron's task selectivity. We studied motor cortical LFP beta oscillations and neuronal spiking activity in macaque monkeys performing delayed visuomotor reaching tasks. Beta oscillations modulated systematically in relation to the behavioral context, in particular when comparing visual cue anticipation, cue processing and movement preparation. Importantly, not only beta power, but also beta frequency changed systematically with behavioral context, and sometimes two bands were observed simultaneously (below and above 20 Hz). Along the behavioral trial LFP beta amplitudes and multi-unit activity levels were negatively correlated, but within specific task epochs, significant across-trial correlations were rare. Furthermore, individual neurons with distinct task-related firing rate profiles were differently co-modulated with beta amplitude. Phase locking of spikes of individual neurons to LFP oscillations was significant only for the beta range, increased with beta amplitude and was rather independent of the neuron's task-related properties. When two beta bands were simultaneously present in the LFP, half of locked neurons locked to both bands within the same task epoch. In the literature it is often simplistically stated that sensorimotor beta 'de-synchronization' reflects motor cortical activation. However, we find no stereotypical relationship between beta amplitude and the level of single or multi-unit activation, beyond co-modulations with behavior. Beta oscillation amplitude rather trivially reflects the level of rhythmic synchrony across neurons, relatively independent of the firing rate and task selectivity of individual, locked neurons. Moreover, our results may reconcile the disparate roles proposed for beta oscillations in cognition and motor control, demonstrating distinct and sometimes co-active beta bands, with contrasting modulations in relation to event expectancy and motor maintenance.

Title: Unimanual and bimanual reach to grasp movements in typically developing children and children with Autism Spectrum Disorder

Authors: R. RODGERS, G. BELLINGER, C. FREER, B. TRAVERS, *A. H. MASON; Kinesiology, Univ. of Wisconsin - Madison, Madison, WI

Abstract: Autism Spectrum Disorders (ASDs) are characterized by impairments in social communication and repetitive behaviors and/or restricted interests (APA, 2014). Differences in movement planning, preparation, and execution have been found in children with ASD compared to typically developing (TD) children (Mari, 2003). We examined coordination using unimanual and bimanual reach to grasp tasks and induced an unexpected target perturbation during ongoing bimanual movements. Fifteen children and adolescents with ASD (10.6 ± 2.5 years) and 15 children with TD (10.1 ± 2.6 years) participated in the study. Participants with ASD had a previous diagnosis of autism and met cutoffs on both the Social Communication Questionnaire and the Autism Diagnostic Observation Scale. In unimanual conditions participants were asked to reach out with the right or left hands to grasp and lift targets located at near (18 cm) or far (28 cm) distances. During bimanual conditions participants grasped two targets located at the same distance or at different distances. On 42% of bimanual trials, a perturbation occurred immediately after movement onset. Either one or both of the targets located at the far distance were extinguished and new targets were illuminated at the near distance. Participants performed a total of 88 trials. Kinematic data were obtained for the index finger, thumb and wrist of both hands using a VisualEyez (Phoenix Technologies) 3D motion capture system. Analysis of movement times in the unimanual conditions revealed a significant main effect of Group ($F_{1,28}$=3.98, p=.056) . Children with ASD were slower (1050.1 ± 64 ms) than typically developing children (869.5 ± 64 ms). A Hand X Group interaction was also found ($F_{1,28}$=4.4, p=.046) which indicated that typically developing children were significantly slower when reaching with their left hands (Left = 916 ± 66; right = 822 ± 63 ms), whereas children with ASD used the same movement time regardless of hand (Left = 1062 ± 66; Right = 1037 ± 63 ms). Main effects of condition were found for movement times in the unperturbed ($F_{1,84}$=10.6, p<.01) and perturbed ($F_{2,56}$=3.3,p=.04) bimanual trials. Children were faster when both objects were initially positioned at, or perturbed to, the near locations than when one or both objects were at the far location. Surprisingly, no main effects or interactions of Group were found for movement time in the bimanual conditions. These results may suggest that deficits in performance in children with ASD are task specific and will be interpreted with respect to coupling between the limbs in bimanual performance. Further analyses will also probe more detailed kinematic parameters for evidence of Group differences.

Title: Decoding movement goals from human reach-related areas in a pro-/anti-reach task

Authors: ***H. GERTZ**[1], A. LINGNAU[2], K. FIEHLER[1];
[1]Justus-Liebig Univ. Giessen, Exptl. Psychology, Giessen, Germany; [2]Ctr. for Mind/ Brain Sci., Trento, Italy

Abstract: In a recent human fMRI study we investigated movement planning in a delayed pro-/anti-reach task (Gertz & Fiehler, 2015). Participants planned and performed right arm reaches towards the position of a previously presented visual target (condition Pro) or to its mirrored location (condition Anti). In condition Pro, the position of the visual target and the movement goal thus coincided, while condition Anti allowed for dissociating the position of the visual target from the position of the movement goal. Visual targets were presented either in the left or right visual field while participants fixated at the center of the screen. Using univariate GLM analyses we found activation in areas related to reach planning in the dorsal premotor cortex, the anterior intraparietal sulcus and the superior parietal cortex (SPL) in both the Pro and Anti condition. Within this reaching network we showed that the left SPL, contralateral to the moving arm, encodes the inferred movement goal rather than the physically present visual target during reach planning. Here we used linear discriminant analysis (LDA)-based multivariate pattern (MVP) analysis to test whether we can predict the position of the upcoming movement goal and/or the position of the previously presented visual target within areas of the reaching network. To this end, we trained the classifier on conditions with the same movement goal, i.e. [condition Pro/left visual targets + condition Anti/right visual targets] and [condition Pro/right visual targets + condition Anti/left visual targets], and on conditions with the same visual target, i.e. [condition Pro/left visual targets + condition Anti/left visual targets] and [condition Pro/right visual targets + condition Anti/right visual targets]. We observed significant movement goal decoding in the SPL and in the anterior intraparietal sulcus. These results confirm our previous findings based on

whole brain GLM analyses and suggest that the movement goal rather than the visual target is encoded in human posterior parietal areas in a pro-/anti-reach task.

Title: Comparison of cognitive motor integration deficits associated with concussion and Alzheimer's disease risk

Authors: A. T. VAN WIJNGAARDEN[1], M. DALECKI[1], K. M. HAWKINS[1], *L. E. SERGIO[1,2];
[1]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto, ON, Canada; [2]Ctr. for Vision Res., Toronto, ON, Canada

Abstract: We compared cognitive-motor integration between individuals with a history of concussion versus those with increased Alzheimer's disease risk (through a diagnosis of mild cognitive impairment or a familial history of dementia). Our previous research has shown performance decrements with concussion and early-stage Alzheimer's disease patients when completing visually guided movements that rely on visual-spatial and rule-based transformations. Here we examined the ways in which performance of individuals affected by concussion versus Alzheimer's disease risk differed, accounting for age-related psychomotor changes. Children with history of concussion (n = 22; mean age 13.2 ± 1.4 years) and adults with increased Alzheimer's disease risk (n = 22, mean age 67.5 ± 11.4 years) made finger movements on a touch-screen in two separate spatial planes to displace a cursor from a central to peripheral target. In the standard condition, the finger slid over the viewed horizontal surface directly to the target. In the non-standard "decoupled" condition, targets were viewed on a vertical monitor, spatially dissociated from horizontal-plane finger motion. Also, visual feedback was reversed such that the direction of cursor movement was rotated 180° from that of finger movement. Upon task decoupling, adults at increased Alzheimer's disease risk were less efficient at making movement corrections, produced less direct path trajectories with reduced accuracy, but were better at controlling ballistic path length to correct for errors versus those in the concussion

group. Both groups experienced similar increases in reaction time. Finally, individuals with a history of concussion had more difficulty executing voluntary movements with precision when the visual input and motion were spatially incongruent. A discriminant analysis correctly differentiated individuals with a history of concussion from those at increased Alzheimer's disease risk with 91% accuracy, based on task performance. These data suggest that the brain networks responsible for cognitive-motor integration are differently affected by concussion and Alzheimer's disease risk. Cognitive-motor integration provides a sensitive means to detect long-term functional impairment in a way that can distinguish mild traumatic brain injury from dementia risk, and may serve as an improved means of monitoring Alzheimer's disease-related functional decline.

Title: Children show cognitive-motor integration deficits nearly two years after concussion

Authors: *M. DALECKI[1], D. ALBINES[1], A. MACPHERSON[2], L. E. SERGIO[3];
[1]Sch. of Kinesiology and Hlth. Sci., [2]Sch. of Kinesiology and Hlth. Science, York Univ. Sport Med. Team, [3]Sch. of Kinesiology and Hlth. Science, Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: In a previous study we observed cognitive-motor integration (CMI) deficits in asymptomatic adult athletes with a history of concussion, especially when the brain had to decouple vision from action. In the present study, we examine whether the same is true for children. Asymptomatic children with a history of concussion (n=50, 0.25-48 months post, mean 12.87; mean age 12.84 yr) and age-matched controls (n=49, mean age 11.63 yr) performed two tasks. They had to slide a cursor from a central to a peripheral target using their finger, using a dual-touch screen laptop. Participants performed one direct-interaction task where target location and motor action were aligned, and a CMI task where targets were in a different plane from hand motion, and visual feedback was reversed (i.e. decoupling between vision and action). We

analyzed multiple movement timing (e.g. reaction time, movement time) and trajectory (e.g. pathlength, reaching precision) parameter. We observed a significant impairment in both movement timing and trajectory formation for children with concussion history. Specifically, we found a main effect of group and condition on both timing and movement accuracy/precision measures. Importantly, we observed an interaction of concussion history and level of required CMI on a number of variables. We also observed a significant relationship between the length of time since concussion and movement timing in the CMI condition. Notably, not until nearly two years later did children with concussion history perform the CMI task at the same baseline level as children with no concussion history. We suggest that these performance deficits are due to concussion-induced disruptions in the fronto-parietal networks responsible for rule-based movement guidance. We previously observed only timing but not trajectory deficits in varsity athletes with concussion history, hence these networks may be more vulnerable in the developing brain. The observed prolonged deficits in CMI further suggest that current return to sport/school/work assessments that test thinking and movement separately, something crucial in sport and daily life, are not fully capturing functional abilities post-concussion. Moreover, the findings of the present study might also be important for a better understanding of negative long-term effects that can appear following concussion, and help explain why seemingly asymptomatic athletes are more vulnerable to further brain injury.

Title: Primed vs unprimed paired associative stimulation: A single-subject proof of principle exploration

Authors: ***K. FROST**, M. CHEN, J. CAREY;
Univ. of Minnesota, Minneapolis, MN

Abstract: Background/Purpose: Neuroplasticity governs mechanisms of cortical reorganization, adaptation and recovery following neural injury. Paired associative stimulation (PAS) induces a

long-lasting change in neuroplasticity by pairing a peripheral nerve stimulus with a cortical stimulus. However, preceding PAS treatment intended to induce neuroplastic change in one direction with a treatment intended to weight synaptic plasticity in the opposite direction may deploy homeostatic synaptic mechanisms that prime the motor cortex to better respond to the second treatment, resulting in a larger and more consistent change in cortical excitability. Exploring principles of homeostatic synaptic plasticity, this study aims to provide proof of principle for primed PAS to augment neuromodulation. Subject: Single healthy human (male, age 65). Methods: We applied five different PAS conditions 1) control, 2) N20+5ms unprimed, 3) N20-5ms unprimed, 4) N20+5ms priming followed by N20-5ms conditioning and 5) N20-5ms priming followed by N20+5ms conditioning in this subject with one-week washout periods between sessions. The N20 was determined using electroencephalography. Change in corticospinal excitability was assessed by comparing the peak-to-peak average of 30 motor evoked potentials elicited by single pulse transcranial magnetic stimulation before PAS treatment and 0, 10, 20, 30, 40, 50 and 60 minutes following treatment. Results: Preceding facilitatory PAS with inhibitory PAS significantly increased cortical excitability more than facilitatory PAS alone ($p<.05$). Preceding inhibitory PAS with facilitatory PAS compared to inhibitory PAS alone was equivocal. Conclusions: This study suggests proof of principle that priming of motor cortex, previously demonstrated with other methods of non-invasive brain stimulation to accomplish more robust neuromodulation, may also apply to PAS and invites larger confirmation studies and possible translation to rehabilitation following neural injury.

Title: Pre-articulatory activity in human sensory cortex

Authors: ***K. FORSETH**[1], E. BARTOLI[1], G. HICKOK[2], N. TANDON[1];
[1]UT Hlth. Sci. Ctr. In Houston, Houston, TX; [2]Univ. of California, Irvine, CA

Abstract: During volitional movements, motor plans are previewed in sensory regions, allowing the precise real time auditing of the expected sensory consequences. This process allows for the refinement of the control of movement by comparison between the predicted sensory consequences and the actual ones. Therefore, the comparison between this “efference copy” of

motor commands and the actual sensory feedback is crucial during the control of motor abilities. Speech production is a particularly interesting type of motor skill, since multiple articulators needs to be precisely tuned to accurately produce sounds used to communicate. The sensory-motor interplay during speech production, strongly predicted by the proposed role of the efference copy in motor control, is still lacking categorical neurophysiological evidence. Here, we sought to detect the neural signature of efference copy related to articulation using a simple word production task. To this end, we recorded intracranial EEG (icEEG) in a sample of patients undergoing preoperative assessment of epileptic activity with intracerebral and subdural electrodes. Electrodes in pre-central, post-central and superior temporal gyri were specifically selected for the analysis. icEEG recordings were aligned to articulation onset and power changes related to gamma (60-120 Hz) oscillations were calculated using a time window locked to articulation onset (-1000; -1000 ms). Preliminary analyses show that, somatosensory (post-central) electrodes exhibit significant activity in the gamma band starting at ~200 ms prior the onset of articulation, overlapping in time with motor (pre-central) activation. However activity in the superior temporal gyrus (STG) does not clearly precede articulation onset. This pre-articulatory activation of somato-sensory regions is suggestive of the processing of ongoing motor commands relative to the expected sensory feedback from periphery. The information exchanged between these regions might represent the signature of sensory-motor mapping during articulatory control.

Title: Motor planning for speech modulates auditory responses differently in stuttering vs. nonstuttering adults

Authors: A. DALIRI[1], *L. MAX[2];
[1]Boston Univ., Boston, MA; [2]Univ. Washington, Seattle, WA

Abstract: Sensorimotor integration involves a predictive priming of task-relevant sensory systems. Here, we investigated modulation of the auditory system during speech movement planning in adults with typical speech and adults who stutter. In Study 1, we recorded auditory evoked potentials (AEPs) in response to probe tones presented during speech movement planning in a speaking condition and control conditions without movement planning. Nonstuttering subjects showed a modulation of the auditory system (reduced N1 amplitude in the speaking condition) that was not observed for the stuttering group. These data suggest that speech movement planning involves anticipatory adjustments in the auditory feedback pathway, and that stuttering is associated with deficiencies in this modulation process. In Study 2, we investigated whether modulation of the auditory system occurs only when making predictions during movement planning. We recorded AEPs in response to probe tones delivered (a) while subjects anticipated hearing their self-produced speech (speaking condition), (b) while subjects anticipated hearing a played-back version of their pre-recorded speech (hearing condition), and (c) during a control condition without auditory input (silent reading condition). For the nonstuttering group, there was modulation of the N1 amplitude in both the speaking and hearing conditions vs. the silent reading condition. For the stuttering group, there was no N1 modulation in either condition with auditory input. Thus, stuttering individuals have difficulties with making auditory predictions in general. In Study 3, we investigated whether pre-speech auditory modulation relates to the extent of reliance on auditory feedback during speech production. Reliance on auditory feedback was estimated with a sensorimotor adaptation paradigm. Auditory modulation was examined by presenting probe tones (a) prior to speaking with normal auditory feedback (NAF), (b) prior to speaking with delayed auditory feedback (DAF), and (c) in a control condition (silent reading). Adaptation was limited for stuttering vs. nonstuttering subjects, and auditory modulation was again nonsignificant in the stuttering group. Interestingly, DAF tended to reduce auditory modulation for nonstuttering subjects but increase it for stuttering subjects. Overall, auditory-motor adaptation correlated with the extent of change in auditory modulation from NAF to DAF. Hence, auditory modulation during speech planning relates to the extent of reliance on auditory feedback during speech production, and stuttering individuals show less auditory modulation and a reduced reliance on auditory feedback.

Title: Perceptual context effects on auditory feedback processing in speech production

Authors: *N. BOURGUIGNON[1,2,3], S. R. BAUM[4,3], D. M. SHILLER[2,1,3];
[1]CHU Sainte-Justine, Montreal, QC, Canada; [2]École d'orthophonie et d'audiologie, Univ. de Montréal, Montreal, QC, Canada; [3]Ctr. for Res. on the Brain, Language and Music, Montreal, QC, Canada; [4]Sch. of Communication Sci. and Disorders, McGill Univ., Montreal, QC, Canada

Abstract: We investigated the effects of changes in formant structure of externally presented speech signals on participants' auditory perception of their own speech output during a word production task. The study involved a novel combination of two previously established research paradigms. The first involves sensorimotor adaptation to altered auditory feedback (AAF) during speech production. Evidence from this paradigm typically supports the notion of speech sounds as accurate, stable sensory targets that serve as the primary goals of speech movements. The second relates to extrinsic talker normalization of vowel perception through the presentation of carrier-phrases spoken with different formant patterns. In contrast to AAF, results from this paradigm illustrate the adaptive plasticity of speech sensory targets to external speech variability. These combined paradigms allowed us to understand the extent to which formant frequencies of a carrier-phrase presented immediately prior to word production could also serve as a frame of reference for the perception of self-generated speech outcomes, thereby influencing subsequent speech production targets. Subjects read aloud single words containing the vowel /Ɛ/ (e.g., "bet", "head") under conditions of normal or altered auditory feedback. Real-time feedback alteration involved a decrease in F1 frequency, resulting in a vowel perceived to be closer to /I/ (e.g., "bit", "hid"). Consistent with previous research, we expected this perturbation to yield opposite compensatory responses in subjects' output. Before each production, subjects heard a phrase spoken with one of three different formant patterns, simulating differences in vocal tract properties of three different talkers (nearly identical to carrier phrases previously shown to induce changes in the perception of an ambiguous vowel between /Ɛ/ and /I/). We predicted that

if the carrier phrase influenced subjects' perception of their own vowel formants during word production, the resulting change would impact the degree of motor adaptation to their F1-altered auditory feedback. Our results suggest that the formant frequencies of a carrier-phrase presented immediately prior to word production serve as a frame of reference for the perception of self-generated speech, thereby influencing subsequent speech targets. This finding extends recent evidence indicating that the auditory processing of speech sounds for speech production is highly adaptive under a range of different conditions. Altogether, this evidence has important implications in the modeling of speech sensory targets as stable, accurate representations at the core of speech movements.

Title: Asymmetrical specialization of cortical-striatal white matter connections for motor speech control

Authors: *J. J. SIDTIS[1], A. MUBEEN[1], B. ARDEKANI[2], D. SIDTIS[3];
[1]Geriatrics, [2]Ctr. for Biomed. Imaging and Neuromodulation, Nathan Kline Inst., Orangeburg, NY; [3]New York Univ., New York, NY

Abstract: The specialization of the left cerebral hemisphere for speech and language became a cornerstone of functional localization in the brain following the observations of Broca and Wernicke, but interest in the effects of focal brain damage waned with the growth of functional imaging. However, brain maps derived from imaging have not always been consistent with lesion studies. Specifically, the strong left-hemisphere lateralization of speech and language has not been reflected in the bilaterality of brain activation in functional imaging. We have previously shown that despite bilateral activation during speech tasks, performance can be predicted by a combination of an increase in blood flow in the left inferior frontal region and decrease in the right caudate. In the present study, we examined the structural connections between the inferior frontal regions and the caudate nuclei using diffusion tensor imaging in normal volunteer subjects (n = 25) and assessed the relationships between the measures of white

matter connections and speech characteristics obtained from acoustic analysis of speech samples obtained at a separate evaluation. Probabilistic tractography was used to estimate the strength of the connections between the head of the caudate nucleus (the seed) and the inferior frontal region (the target), both ipsilaterally and contralaterally. After the probabilistic connections were established for each subject, the fractional anisotrophy (FA) was measured for these tracts. The probabilistic tractography demonstrated that the majority of fiber connections were ipsilateral, but contralateral connections were present as well. The inter-subject variability in the relative number of connections between the right caudate and the left inferior frontal region was significantly associated with the inter-subject variability in the acoustic measures of stability for frequency (Spearman's coefficients for the repetition of the syllables /pa/ = 0.46; /ta/ = 0.5; /ka/ = 0.46; /pataka/ = 0.52) and amplitude (Spearman's coefficients for the repetition of the syllables /pa/ = 0.43; /ta/ = 0.5; /ka/ = 0.49; /pataka/ = 0.49) in the speech signals, echoing the significant relationship in blood flow in these regions during speech. A similar pattern was found for FA. No other cortical-striatal connections demonstrated these relationships with speech characteristics. These results suggest that white matter connections may share some degree of functional specialization with the structures that they connect.

Title: Voluntary imitation of fundamental frequency and vocal tract length in human speech: A multimodal investigation using functional and real-time anatomical MRI

Authors: *C. MCGETTIGAN[1,2], D. CAREY[1], V. CARTEI[3], M. MIQUEL[4];
[1]Royal Holloway, Univ. of London, Egham, United Kingdom; [2]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [3]Dept. of Psychology, Univ. of Sussex, Brighton, United Kingdom; [4]Queen Mary Univ. of London, London, United Kingdom

Abstract: The human voice is a highly flexible channel for the expression of linguistic, emotional and social information. Perceptually, fundamental frequency (F0; closely related to pitch) and formant spacing (an index of vocal tract length; VTL) are important cues for the extraction of indexical characteristics such as sex and individual identities. Behavioural research has further shown that talkers instinctively modulate these cues to emulate various physical and social attributes (e.g. masculinity/femininity: Cartei et al., 2012; attractiveness: Hughes et al., 2014). The current study forms the first combined acoustic, articulatory and neurobiological investigation of these paralinguistic aspects of vocal behavior. Recordings of monosyllables (e.g. "bead") from individual participants were used to create synthethic arrays of target voices varying in F0 and VTL along two axes: one biologically typical axis ranging from voices with lower F0s and longer VTLs to those with higher F0s and shorter VTLs (i.e. from adult males toward adult females and children), and one less typical axis ranging from voices with lower F0s and shorter VTLs to those with higher F0s and longer VTLs. Acoustic analyses of imitations from 22 adults (11 M) showed that talkers reproduced significant changes in F0 and VTL along both axes, but that F0 was better differentiated than VTL (particularly for atypical targets; Figure 1a). In a second study, real-time anatomical MRI (rtMRI) of the vocal tract allowed us to measure the dynamics (at 8 fps) of VTL modulation as well as the functional correlates of perception and imitation using fMRI. The rtMRI data showed voluntary raising and lowering of the larynx to imitate varying VTLs (Figure 1b) - in-scanner rtMRI and acoustic recordings were then used to probe individual differences in the functional correlates of voluntary vocal imitation within auditory and somatomotor networks of the brain.

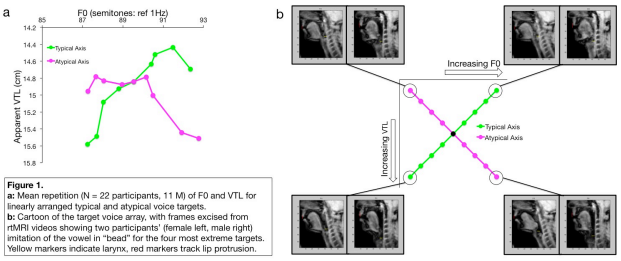

Figure 1.
a: Mean repetition (N = 22 participants, 11 M) of F0 and VTL for linearly arranged typical and atypical voice targets.
b: Cartoon of the target voice array, with frames excised from rtMRI videos showing two participants' (female left, male right) imitation of the vowel in "bead" for the four most extreme targets. Yellow markers indicate larynx, red markers track lip protrusion.

Title: Disrupted feedforward but spared feedback control during speech in patients with cerebellar degeneration

Authors: *B. PARRELL[1], J. HOUDE[2], S. NAGARAJAN[3], R. IVRY[1];
[1]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA; [2]Dept. of Otolaryngology, [3]Dept. of Radiology and Biomed. Imaging, Univ. of California, San Francisco, San Francisco, CA

Abstract: People with ataxia due to cerebellar degeneration exhibit a range of speech deficits referred to as ataxic dysarthria (AD). Symptoms include slow speech, excessively equal syllable durations, and (paradoxically) increased durational variability in syllable repetition tasks. These deficits reflect an inability to accurately plan the fast, precise movements of the speech articulators necessary for fluent speech—computations that are highly dependent on a feedforward control system. This impairment may cause people with AD to become overly reliant on feedback control when speaking, leading to temporal delays and instability inherent in any closed-loop feedback control system. These hypotheses are consistent with results from other motor domains (reaching, walking) that suggest the cerebellum is crucial to accurate feedforward control, with reduced involvement in feedback control. We compared feedforward and feedback control in two altered auditory feedback studies. Such studies—analogous to the methods used to study sensorimotor adaptation in reaching—involve real-time manipulation of the speech formants, with the end result that speakers hear a different vowel than that they actually produced (either slightly altered or categorically different, depending on the manipulation). Healthy speakers compensate for these manipulations, adapting the feedforward system across productions to consistent alterations and compensating within a vowel for unexpected perturbations via the feedback system. We tested the feedforward control system by measuring adaptation to consistent vowel perturbations, introduced gradually in one block of trials and abruptly in another. For dependent variables, we measured produced formants in words spoken during 1) maximum adaptation at the end of the perturbation phase and 2) probe trials in which the production was accompanied by loud noise to mask auditory feedback. People with AD adapted less than age-matched healthy controls in both measures to both the gradual and abrupt perturbations. To test the integrity of the feedback control system, we examined the response of the participants to unexpected vowel formant perturbations. In this case, people with AD were unimpaired in their compensatory behavior relative to control speakers. Combined, these results support the hypothesis that cerebellar degeneration selectively disrupts feedforward speech motor control.

Title: Cortical representation of articulatory gestures and phonemes during speech production

Authors: *E. M. MUGLER[1], M. GOLDRICK[2], R. D. FLINT[1], M. C. TATE[3], J. M. ROSENOW[3], M. W. SLUTZKY[1];

Abstract: Brain-machine interfaces (BMI) that decode speech could greatly improve the quality of life for people who are completely paralyzed, or "locked-in," due to a stroke or ALS, by restoring their ability to communicate. Despite recent successes in decoding certain aspects of speech production from cortical activity, the exact encoding of activity in motor and pre-motor cortices during speech production is unclear. Previous theoretical, acoustic, and fMRI work has suggested multiple levels of sound representation support speech production, from phonemes (whole speech sounds) to articulatory gestures (movements of individual articulators). A more complete, electrophysiological understanding of the cortical representation of these different levels of speech would aid BMI design. Using electrocorticography (ECoG), we evaluated the degree to which articulatory gestures and phonemes are functionally represented in speech motor and premotor cortices. We recorded ECoG in three subjects with brain tumors who required awake craniotomies to map speech and motor function. Electrode arrays (8x8, Integra Inc., 2.3 mm platinum electrodes, 4 mm inter-electrode spacing) were placed over the ventral motor (M1v), ventral premotor (PMv) and inferior frontal gyri. We sampled cortical activity at 2 kHz, after bandpass filtering from 0.3 to 500 Hz (Blackrock Microsystems). Concurrently, subjects read aloud single consonant-vowel-consonant (CVC) words presented on a monitor at a rate of 1 word every 2 seconds. We sampled audio at 48 kHz using a unidirectional lapel condenser microphone (Califone) and synchronized it with the cortical signal using BCI2000 software. We manually labelled the onset of each phoneme (speech sound). We obtained high-gamma power from ECoG by common-average referencing, bandpass filtering from 70-300 Hz, and applying a Hilbert transform. We then z-scored the high gamma bandpower for each ECoG channel. We separately decoded gestures and phonemes from the band power 200 ms before and after phoneme or gesture onset using linear discriminant analysis (LDA). By separately performing LDA using electrodes covering different anatomical areas, we could analyze changes in speech

representation in different areas of cortex. Gestures were better represented in the primary sensorimotor cortices, while phonemes were better represented in more anterior cortices.

Title: Cerebellar tdcs during speech perceptual learning dissociates the act of indicating perception from perceptual change

Authors: *D. R. LAMETTI, L. OOSTWOUD WIJDENES, J. BONAIUTO, S. BESTMANN, J. C. ROTHWELL;
Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Speech perception is remarkably malleable yet there have been few causal investigations of the brain regions involved in speech perceptual learning. Recent neuroimaging studies suggest that the cerebellum might play a role in perceptual learning. Here we test this idea using transcranial direct current stimulation (tDCS) in combination with a speech perceptual learning task. In the experiments, participants experienced a series of speech perceptual tests designed to measure and then manipulate their perception of the phonetic contrast between the words “head” and “had”. One group received cerebellar tDCS during speech perceptual learning and a different group received “sham” tDCS during the same task. Learning-related changes in speech perception were observed a week after training and the perceptual change transferred to a different phonetic contrast. Cerebellar tDCS did not have a significant impact on the rate of perceptual change or its subsequent retention and transfer. However, for both trained and untrained speech sounds, cerebellar tDCS significantly increased the time it took participants to indicate their perceptual decision with a keyboard press. Using the drift diffusion model, we provide evidence that cerebellar tDCS disrupted processes related to the act of indicating perception while sparing processes related to perceptual decision making. The results suggest that the cerebellum’s role in speech is restricted to the motor domain.

Title: Testing a new localizer task for the central control of vocalization using variations in voice onset for words

Authors: ***M. DIETRICH**[1], E. J. HUNTER[2], S. H. FREY[3];
[1]Communication Sci. and Disorders, Univ. of Missouri, Columbia, MO; [2]Michigan State Univ., East Lansing, MI; [3]Washington Univ., St. Louis, MO

Abstract: The study of the cortical control of vocalization for speech in humans has been facilitated by the development of event-related sparse-sampling fMRI experimental designs. We now have basic knowledge on the localization of the laryngeal motor cortex and primary and secondary vocal areas. However, knowledge on networks in the brain subserving vocalization under various task conditions remains scarce. Foundational studies on the central of vocalization focused on the production of isolated sounds and syllables without semantic meaning, that is, simple voluntary laryngeal motor behaviors (e.g., glottal stops). Learning more about the control of voice during speech, that is, complex voluntary laryngeal motor behaviors, will help to better understand functional voice disorders. Functional voice disorders, also known as primary muscle tension dysphonias, are characterized by excessive or disorganized activity of the intrinsic or extrinsic laryngeal muscles. Patients typically perceive increased vocal effort or strain. The objective of the current study is to test a new localizer task for complex laryngeal motor behavior. To that end, we focus on voice production at the word level. Twelve vocally healthy participants produce vowel-initial words in two manners: breathy vs. hard glottal onset. The manners differ in vocal fold adduction (closure) with greater vocal fold engagement for the hard glottal onset. Words chosen from the Psycholinguistic Database are monosyllabic, start with a vowel, and exclude verbs. Our word list shows a significant difference in mean airflow during voicing for words produced with a breathy vs. hard glottal onset (0.31 L/s vs. 0.18 L/s), which validates the differential vocal fold engagement. We predict that the subtraction of fMRI BOLD

activations will localize laryngeal motor cortical areas that are relevant for speech production (ventromedial area BA4p and dorsolateral area BA6) and that are viable as functional ROIs. We will also measure each participant's airflow for voicing and laryngeal airway resistance (subglottal air pressure divided by mean airflow for voicing). In the future, the new localizer task will be used with participants who report vocal effort and strain. Greater laryngeal airway resistance is often perceived as vocal strain. We predict that hard glottal onset will be characterized by greater activity in the laryngeal motor cortex, premotor cortex, and cerebellum (CB-VI, VIIIA) compared with a breathy voice onset. The overall goal of our research is to determine the pattern of brain activation underlying increased vocal effort to better understand individual differences in risk for voice disorders.

Title: Speech consists of simultaneous activation of the emotional and somatic motor system

Authors: *G. HOLSTEGE[1], H. H. SUBRAMANIAN[2];
[1]The Univ. of Queensland, Herston Qld 4006, Australia, Haren, Netherlands; [2]UQ Ctr. for Clin. Research, Asia-Pacific Ctr. for Neuromodulation, The Univ. of Queensland, Herston, Australia

Abstract: In animals and humans vocalization is generated by the emotional motor system, in which the mesencephalic periaqueductal gray (PAG) as well as the nucleus retroambiguus (NRA) play a central role. The caudal PAG has direct and strong access to the NRA, located in the caudal medullary ventrolateral tegmentum. Although the NRA is not mentioned in several recent review papers concerning vocalization and speech, it is the only cell group in the central nervous system that has direct and specific access to not only the motoneurons of pharynx and larynx, but also to the motoneurons innervating diaphragm, intercostal, abdominal and pelvic floor muscles.1 Together these muscles determine intra-abdominal-pelvic, intra-thoracic and subglottic pressure, necessary for generating vocalization. Lesions involving the caudal PAG

have been shown to result in mutism in animals as well as in humans. Only humans have the ability to modulate vocalization into words and sentences, resulting in speech. The descending pathways producing this modulation take part in the lateral component of the somatic or voluntary motor system, which in humans primarily originates in the primary motor cortex. These motor corticobulbar fibers have access to the motoneurons innervating face, mouth, tongue, larynx and pharynx and their premotor interneurons in the caudal pontine and medullary lateral tegmental field, but not to the nucleus retroambiguus.2 In order to generate speech, humans produce vocalization by activating the connection from the orbitofrontal cortex to the PAG-NRA-motoneuronal pathway, and modulate this vocalization by activating the primary motor cortex-motoneuronal pathway. It explains why patients with lesions in Broca's area (speech memory neurons in Brodmann's areas 44 and 45) are no longer able to produce speech (motor aphasia), but still can vocalize, while patients with lesions in the caudal PAG are mute. Title: Adaptation to altered auditory feedback in speech to assess transfer of learning in complex serial movements

Authors: T. CAUDRELIER[1], J.-L. SCHWARTZ[1], P. PERRIER[1], C. SAVARIAUX[1], *A. ROCHET-CAPELLAN[2];
[1]Univ. Grenoble Alpes, Gipsa-Lab, CNRS, Saint-Martin d'Hères, France; [2]DPC, Gipsa-Lab, Saint-Martin d'Hères, France

Abstract: Using bird song as a model to understand generalization in motor learning, Hoffman and Sober recently found that adaptation to pitch-shift of birds' vocal output transfered to the production of the same sounds embedded in a different serial context (J. Neurosc 2014). In

humans, speech learning has been found to transfer as a function of the acoustical similarity between the training and the testing utterances (Cai et al. 2010, Rochet-Capellan et al. 2011) but it is unclear if transfer of learning is sensitive to serial order. We investigate the effects of serial order on transfer of speech motor learning using non-words sequences of CV syllables. Three groups of native speakers of French were trained to produce the syllable /be/ repetitively while their auditory feedback was altered in real time toward /ba/. They were then tested for transfer toward /be/ (control), /bepe/ or /pebe/ under normal feedback conditions. The training utterance was then produced again to test for after-effects. The auditory shift was achieved in real time using Audapter software (Cai et al. 2008). Adaptation and transfer effects were quantified in terms of changes in formants frequencies of the vowel /e/, as a function of its position and the preceding consonant in the utterance. Changes in formant frequencies in a direction opposite to the shift were significant for ~80% of the participants. Adaptation was still significant for the three groups in the after-effect block. Transfer effects in the /bepe/ and /pebe/ groups were globally smaller than that of the control group, particularly when the vowel /e/ came after /p/ and/or was in second position in the utterance. Taken together, the results suggest that transfer of speech motor learning is not homogenous and as observed by Hoffman and Sober, depends on the serial context of a sound within the utterance. Title: Vocal motor development and coordination in wild type and Foxp2 heterozygous mutant mice

Authors: *G. A. CASTELLUCCI[1,2], D. A. MCCORMICK[1];
[1]Yale Univ., New Haven, CT; [2]Haskins Labs., New Haven, CT

Abstract: Deleterious mutations of the FOXP2 gene in humans is known to cause severe Developmental Verbal Dyspraxia (DVD; also called Childhood Dyspraxia of Speech). Interestingly, previous research from our lab has demonstrated that male Foxp2 heterozygous knock out (Foxp2 +/-) mice exhibit deficits in their ultrasonic courtship song. Most notably, while the song syllables of wild type (C57Bl/6J) male mice become significantly longer and less spectrally flat (more tone-like) with age, the syllables of their Foxp2 +/- littermates do not exhibit this developmental trajectory and instead are noisier and shorter at all ages tested (from weaning to adulthood, ~P23 to ~P70 respectively). Furthermore, it was also found that Foxp2 +/- mice produce approximately half the number of song syllables per bout (series of syllables produced in sequence separated by longer periods of silence) than their wild type littermates. While these findings show interesting cursory parallels to the articulatory and prosodic symptoms affecting the speech of individuals with DVD, the biological basis for mouse vocalization production - and therefore its relation to human speech - is not well understood. To better qualify mouse vocalization production, we are currently examining and will present the effects of experience on the vocal development trajectory observed in wild type mice in order to establish whether this trajectory is - like speech - dependent on experience. Additionally, simultaneous electromyography recordings from several muscles recruited during vocalization production (e.g. masseter, temporalis, anterior belly of the digastric, medial pterygoid) will be performed to examine the articulatory strategies employed during production and how they compare to those used for speech. By better understanding the mouse vocalization system, its utility as a limited model of human speech and language can be better evaluated.

Title: A temporal predictive code for voice motor control: evidence from neurophysiology and vocal behavior

Authors: *R. BEHROOZMAND[1], S. SANGTIAN[1], O. KORZYUKOV[2], C. LARSON[2]; [1]Communication Sci. and Disorders, Univ. of South Carolina, Columbia, SC; [2]Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: The predictive coding model suggests that voice motor control is regulated by the output of a comparative process in which the difference (error) between internally-predicted and sensory feedback stimulus is detected and used to correct motor commands during vocal production. Although motor-driven predictions (e.g. efference copies) are important for vocal error correction, predictions about sensory feedback stimuli can also play a key role in subsequent motor behavior during vocal production and control. In the present study, we studied how predictions about timing of feedback pitch perturbation stimuli can modulate vocal and ERP responses during vowel production. The experiment was carried out in six counterbalanced blocks in which a +100 cents pitch shift stimulus perturbed voice auditory feedback in the middle of vocalizing the vowel sound "a". In three blocks, there was a fixed delay (500, 750 or 1000 ms) between voice and stimulus onset (predictable), whereas in the other three blocks, stimulus onset delay was randomized between 500, 750 and 1000 ms (unpredictable). Analysis of behavioral data showed that for unpredictable stimuli, subjects compensated for feedback perturbations by changing their voice pitch in the opposite direction to stimuli. These compensatory vocal responses were initiated at latencies around 80 ms post-stimulus. However, for predictable stimuli, we found that subjects initiated vocal responses at about 20 ms prior to the onset of stimulus and followed the direction of pitch shifts in their voice feedback. Analysis of the ERPs showed that the amplitudes of the N100 and P200 components were significantly reduced in response to predictable compared with unpredictable stimuli. These findings indicate that predictions about temporal features of sensory feedback can modulate subsequent vocal motor behavior. In the context of the predictive coding model, reduction in the amplitude of the ERP components suggests that the brain may internally simulate and respond to predictable stimuli, and therefore, may assign fewer neural resources for processing auditory feedback during vocal production. This notion is corroborated by our findings showing that the vocal responses were initiated prior to the onset of predictable stimuli. These findings provide new insights into the neural mechanisms of vocal production and motor control.

Title: A representation of the larynx in macaque monkey M1

Authors: *C. M. CERKEVICH[1,2,3], P. L. STRICK[1,2,3,4,5];
[1]Systems Neurosci. Inst., [2]Neurobio., [3]Ctr. for the Neural Basis of Cognition, [4]Univ. of Pittsburgh Brain Inst., Univ. of Pittsburgh, Pittsburgh, PA; [5]Res. Service, Veterans Affairs Med. Ctr., Pittsburgh, PA

Abstract: Our understanding of the neural circuitry responsible for the cortical control of hand and arm movements has grown substantially in the last 25 years. In contrast, we know surprisingly little about the cortical areas involved in the control of vocalization in non-human primates. We know even less about the adaptations in these circuits that enable some monkeys to communicate using vocalization and to emit species specific calls on a voluntary basis. Some investigators contend that the voluntary control of vocalization is dependent on the development of direct connections from the primary motor cortex (M1) to motoneurons innervating laryngeal muscles. Others believe that vocalization has evolved through the addition of specialized, higher-order regions of cortex, comparable to Broca's area. As a first step toward resolving these questions, we used the retrograde transneuronal transport of rabies virus (RV) to define the cortical areas in the frontal lobe that control the cricothyroid muscle (CT). The CT is an intrinsic laryngeal muscle that is involved in vocalization. We injected 30µl of the N2C strain (9*10^8 pfu) of RV into the CT of two macaque monkeys. We allowed the animals to survive 90 or 115 hours. This time period was long enough to permit retrograde trans-synaptic transport of RV from the muscle through several synaptically connected neurons to the cerebral cortex. We observed RV-infected neurons in cortical layer V at multiple sites in the frontal lobe that are known to be involved in vocalization (Jurgens, 02; 09), including the anterior cingulate cortex and regions lateral to the ventral premotor area. In addition, we found a substantial number of RV-infected neurons in a far lateral region of primary motor cortex (M1) that includes the surface of the precentral gyrus and the anterior bank of the central sulcus. This region falls in the

presumptive face representation of M1 (e.g., McGuinness et al., 80). This observation provides evidence that a region of M1 in the macaque is the sire of descending input to a muscle involved in vocalization.

Title: Aerobic exercise modulates bilateral intracortical and interhemispheric primary motor cortex excitability

Authors: *J. L. NEVA[1], K. E. BROWN[2], C. S. MANG[2], L. A. BOYD[2];
[1]Dept. of Physical Therapy, [2]Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The potential for aerobic exercise to modulate neural plasticity, behaviour and cognition is becoming widely known. Recently, work from our lab and others have shown that the excitability of the primary motor cortex (M1) is modulated by a single session of aerobic exercise. Specifically, a single session of lower-limb aerobic exercise modulates unilateral M1 intracortical inhibitory and facilitatory circuitry in the lower-limb and upper-limb representations [1, 2] and facilitates methods of inducing cortical plasticity [3-5]. This suggests that aerobic exercise may alter widespread cortical excitability and inhibitory/facilitatory cortical circuits. However, there is a lack of fundamental understanding of the potential widespread modulation of various intracortical and interhemispheric neural mechanisms supporting the effects of aerobic exercise. The purpose of this study was to investigate the effects of a single bout of moderate aerobic exercise on bilateral intracortical and interhemispheric circuitry within M1. Single and paired pulse transcranial magnetic stimulation (TMS) was used to measure short-interval intracortical inhibition (SICI) and facilitation (SICF), intracortical facilitation (ICF), cortical silent period (CSP) and transcallosal inhibition (TCI) bilaterally in the M1 representation of the non-exercised abductor pollicis brevis (APB). Intracortical and interhemispheric circuitry was measured pre and two time-points post (immediately post and 30 min post) aerobic exercise. Moderate intensity aerobic exercise was performed for 20 min at 65-70% of age-predicated

maximum heart rate on a stationary cycle ergometer. Preliminary results suggest that SICF was enhanced predominantly during the early inter-stimulus intervals. Additionally, SICI decreased and CSP duration was shortened. These results suggest a decreased inhibition and increased facilitation in multiple circuits within M1 after a single session of aerobic exercise. Recruitment for this study is ongoing. Finally, further experiments on the modulation of interhemispheric inhibition of related motor areas are underway. [1] Singh et al. (2014) BMC Sports Sci, Med and Rehabil, 6:23. [2] Yamaguchi et al. Title: A single bout of aerobic exercise impacts excitability of cerebellar circuits for a non-exercised upper limb muscle

Authors: ***C. MANG**[1], N. J. SNOW[2], J. L. NEVA[1], K. E. BROWN[2], K. L. CAMPBELL[2], L. A. BOYD[2];
[2]Rehabil. Sci., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Background: A single bout of aerobic exercise impacts the excitability and plasticity of motor cortical (M1) circuits for a non-exercised upper limb muscle. These effects include: a decrease in short-interval intracortical inhibition [1], an increase in intracortical facilitation [1], and increased modulatory responses to inhibitory continuous theta burst stimulation [2] and excitatory M1 paired associative stimulation (PAS, 25 ms interstimulus interval [ISI]) [3]. The effects of a single bout of aerobic exercise on motor-related circuitry outside of M1 have been less studied. In this study, we evaluated the effects of a single bout of aerobic exercise on cerebellar circuits for a non-exercised hand muscle by way of two experiments. Methods: In Experiment 1, response to excitatory M1 PAS was evaluated in 32 young healthy individuals on two occasions: once preceded by 20 min of seated rest, and once preceded by 20 min of high-intensity (90% maximal oxygen uptake) cycling interval training. In 16 individuals PAS was

delivered with a 25 ms ISI (PAS25), and in the other 16 participants with a 21 ms ISI (PAS21). In Experiment 2, three individuals returned for evaluation of cerebellar inhibition on M1 (CBI) at ISIs ranging from 3-8 ms before and after 20 min of seated rest and 20 min of high-intensity interval cycling. Recruitment for Experiment 2 is ongoing. Results: In the first experiment, both PAS25 and PAS21 increased M1 excitability when preceded by exercise, but not rest (Condition x Time interaction: p=0.03). A secondary analysis indicated a greater increase in M1 excitability evoked by exercise and PAS25 (61.0%) compared to exercise and PAS21 (14.3%; p=0.03). Preliminary results from Experiment 2 suggest a release of CBI at ISIs of 6 ms and 7 ms, with an average inhibition of 29.1±18.8% prior to exercise, but facilitation by 22.2±26.9% at the same ISIs following exercise (p=0.02). Conclusion: Previous work has indicated that increases in M1 excitability following PAS25, but not PAS21, involve cerebellar circuits [4]. Thus, our finding that aerobic exercise facilitated response to PAS25 to a greater extent than PAS21 suggests that exercise effects on plasticity in M1 are likely dependent, in part, on cerebellar circuitry. Preliminary results from the second experiment provide further evidence for an effect of aerobic exercise on excitability of cerebellar circuits. [1] Singh et al. Title: Differential off-line effects of 10 Hz and 20 Hz transcranial alternating current stimulation on motor cortical excitability

Authors: *H. NAKAZONO, K. OGATA, S. TOBIMATSU;
Dept. of Clin. Neurophysiology, Neurolog. Institute,, Fac. of Med. Sciences, Kyushu Univ., Fukuoka-shi, Japan

Abstract: Background: Transcranial alternating current stimulation (tACS) has been considered to entrain the ongoing oscillatory activities in a frequency dependent manner. For the primary motor cortex (M1), 20 Hz tACS but not 10 Hz one increased the cortical excitability during tACS (online effect). However, it is unclear about the off-line effects of 10 and 20 Hz tACS on the M1 excitability. Thus, we investigated the plastic effects of these tACS over the M1. Methods: Twelve healthy subjects participated in this study. Alternating current of 1 mA was passed for 20 min between the left M1 and Pz electrodes. The frequency of tACS was set at 10 or 20 Hz, and the experiment of each frequency was conducted on separate days. M1 excitability was measured by the motor evoked potentials (MEPs) with single pulse transcranial magnetic stimulation (TMS). Two sessions of 12 MEPs were recorded before tACS as baseline. After tACS intervention, 12 MEPs were collected every 5 min up to 30 min. The mean amplitudes of MEPs after logarithmic transformation were compared before and after tACS. Results: MEPs were increased after 20 Hz tACS while they were decreased after 10 Hz one. These effects were short lasting, and returned to the baseline at 15-20 min after both interventions. Thus, the MEP trials of from 20 to 30 min after tACS were collapsed into 'over 20 min'. Statistical analysis showed that MEPs were significantly increased at 5-10 min after 20 Hz tACS while they were decreased at the same period after 10 Hz tACS. Discussion: We found not only the facilitation of the M1 excitability after 20 Hz tACS, but also inhibitory effect after 10 Hz tACS. These results suggested that both of 10 and 20 Hz tACS over M1 modulate the cortical excitability in the opposite direction, which last 5-10 min after intervention. The differential tACS effects of between 10 Hz and 20 Hz stimulation may results from the difference in the functional roles of alpha and beta oscillations in the human motor system.

Title: Modulation of cTBS after-effects following aerobic exercise

Authors: *A. M. SINGH, W. R. STAINES;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Previous research indicates that acute aerobic exercise has a facilitatory effect on motor cortical excitability. Specifically, exercise may enhance the induction of early long-term potentiation (LTP) in the primary motor cortex, possibly via an increase in neurotransmitter release. Thus, exercise may be useful to prime cortical regions for plasticity when followed by more targeted interventions. However, the role of exercise when performed after the induction of plasticity has not been investigated. In addition, despite the potential for enhanced LTP-type processes, it is unclear whether the same effects are seen with techniques that induce long-term depression (LTD). Continuous theta-burst stimulation (cTBS) can be used to temporarily suppress excitability in the target region for up to 60 minutes. It is thought that this suppression is due to LTD-type processes occurring in cortical output neurons. Thus, in this study, we investigated the contribution of exercise to the duration and intensity of cTBS after-effects. In particular, we performed lower-limb aerobic activity following cTBS delivered to an upper-limb muscle representation. It was hypothesized that when exercise was performed immediately following cTBS, the duration and intensity of the effects of cTBS would be reduced. Healthy participants were recruited and underwent two experimental sessions: a) cTBS followed by rest, and b) cTBS followed by exercise. Following the identification of the motor hotspot for the right first dorsal interosseous (FDI) muscle, baseline measurements were collected, including resting motor-evoked potential (MEP) amplitudes, short-interval intracortical inhibition (SICI) and intracortical facilitation (ICF). CTBS (600 pulses, 3-pulse bursts delivered at 5 Hz, 40 seconds) was then delivered over the FDI hotspot at 80% of the active motor threshold. Participants then underwent either 25 minutes of moderate-intensity stationary biking, or rested comfortably in a chair for 25 minutes. MEP amplitudes were measured at 3 timepoints following cTBS: 1 minute (just prior to exercise or rest), 30 minutes, and 60 minutes. SICI and ICF were also recorded at the 30-minute and 60-minute post-timepoints. Changes in MEP amplitude and the degree of SICI and ICF were quantified at each timepoint. Preliminary results indicate that exercise suppresses the effects of LTD-like plasticity when performed immediately following cTBS. This suggests that exercise may not necessarily enhance all types of plasticity induction, but rather favours the induction of excitability and may shift the balance of interneuronal network activity towards facilitation.

Title: The effect of aerobic exercise coupled with transcranial direct current stimulation on motor learning

Authors: *J. BAER, M. B. KOLAR, A. HARRISON, R. NEWMAN-NORLUND;
Univ. of South Carolina, Columbia, SC

Abstract: When treating a brain injury, such as during stroke recovery, traditional rehabilitation modalities typically involve periphery-driven increases in motor function that could be bolstered by central stimulation approaches. Transcranial direct current stimulation (tDCS) promotes motor learning by altering the excitability of cortical neurons. Anodal tDCS (AtDCS) increases the excitability of underlying neurons making them more likely to depolarize. Furthermore, a single bout of aerobic exercise can lead to increases in brain derived neurotrophic factor (BDNF). BDNF is a key player in CNS neuroplasticity with important roles in memory and learning that has been linked to benefits in motor learning. The purpose of the current study was to evaluate the effects of AtDCS and acute aerobic exercise on motor learning both in isolation, as well as in a combined approach where a single bout of aerobic exercise alters the level of BDNF which primes the neuronal environment creating the optimal conditions for subsequent AtDCS. We measured motor performance in the non-dominant upper extremity after healthy, young participants: (1) exercised for 20 minutes then received tDCS (combo), (2) exercised for 20 minutes then received sham stimulation (exercise), (3) rested for 20 minutes then received tDCS (stim), or (4) rested for 20 minutes and received sham stimulation (control). Our measures of motor performance included the Jebsen Taylor Hand Function test (JTHF), a series of 6 different locks (locks), and the Purdue Pegboard test (PPT). All three tests were administered at 3 different time points: baseline, immediately post treatment, and 30 minutes post treatment. We hypothesized that the greatest improvements in motor performance would be seen in individuals who performed 20 minutes of aerobic exercise followed by tDCS, and that participants in both the exercise and the stim groups would improve more than controls. A 3(time) x 4(group) mixed model ANOVA using JTHF times as the dependent variable was insignificant ($F_{3.96, 51.48} = .332$, $p > .05$). Similar ANOVAs using locks and PTT also failed to reach significance ($F_{4.28, 55.61} = .648$, $p > .05$; $F_{5.6, 72.78} = .938$, $p > .05$, respectively). Negative findings may be due to i) lack of sufficiently sensitive measures, or ii) individual variability regarding the influence of AtDCS. Carefully designed studies should include additional measures (serum BDNF, motor evoked potentials, BDNF genotyping) to clarify the exact effects of AtDCS, aerobic exercise, and possible interactions between the two. Additional research with measures more sensitive to motor learning may also help elucidate these effects further.

Title: Targeted human cortical and spinal neuroplasticity by transpinal stimulation

Authors: *M. KNIKOU, L. DIXON, D. SANTORA, M. M. IBRAHIM;
The Grad. Ctr., City Univ. of New York, Staten Island, NY

Abstract: In this study, we examined whether noninvasive cathodal or anodal transpinal constant current stimulation (c-tsCCS, a-tsCCS) can alter human cortical and spinal motor and reflex activity. Using noninvasive cortical, spinal, and peripheral nerve stimulation we examined the effects of 40-min of c-tsCCS and a-tsCCS on human motor evoked potentials (MEPs), sensory afferent-mediated MEP facilitation, transpinal evoked potentials (TEPs), flexor reflexes, cortical-mediated flexor reflex facilitation, and soleus H-reflex homosynaptic depression. We found that 40-min of c-tsCCS and a-tsCCS decrease the afferent-mediated facilitation of tibialis anterior MEPs. c-tsCCS increases and a-tsCCS decreases the cortical-mediated flexor reflex facilitation. Both c-tsCCS and a-tsCCS increased the cortical induced MEPs in the tibialis anterior muscle, but decreased the transpinal induced TEPs of hip flexors and increased the TEPs from ankle extesnors. c-tsCCS did not affect soleus H-reflex homosynaptic depression but decreased the flexor reflex size in the tibialis anterior muscle. Last, a-tsCCS decreased the flexor reflex size in the tibialis anterior muscle, and soleus H-reflex homosynaptic depression was not different from that observed after c-tsCCS. Our findings reveal that c-tsCCS and a-tsCCS have distinct effects on human cortical and spinal motoneuron activity.

Title: Effects of prior hand use on practice-dependent plasticity and ballistic motor skill learning

Authors: *S. J. HUSSAIN, K. J. COLE;
Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: The theory of homeostatic metaplasticity states that the history of postsynaptic activity shifts the threshold for induction of long-term potentiation and long-term depression, and these principles have been demonstrated in human motor cortex with respect to both exogenous (i.e., non-invasive brain stimulation) and endogenous (i.e., motor practice) activity. Some work has even shown that voluntary muscle contraction prior to brain stimulation can reverse the effects of the stimulation and increase the variability of responsiveness (Gentner et al. 2008; Goldsworthy et al. 2015). Further, the amount of hand use over 8 hours modulates the effectiveness of brain stimulation (Rosenkranz et al. 2014). Yet, the impact of prior hand use on motor learning and practice-dependent plasticity is unknown. Here, we aimed to replicate previous findings that decreasing hand use for 8 hours reduces corticospinal excitability and to also characterize the effects of reduced hand use on motor learning and practice-dependent plasticity. We recruited healthy adults for participation in a cross-over study. Testing sessions were divided into immobilization sessions and control sessions, and the order of sessions was counterbalanced. For immobilization sessions, subjects reported to the lab in the morning, completed a baseline assessment of ballistic thumb extension and were fit with a splint that restricted motion of the left thumb. Subjects were instructed to avoid left hand use while wearing the splint. 8 hours later, subjects returned to the lab, the splint was removed, and a recruitment curve for left opponens pollicis was collected. After baseline TMS, subjects repeatedly practiced the ballistic skill and another recruitment curve was collected after training. We also tested retention of the ballistic skill both 30 minutes and 24 hours after practice. During control sessions, all experimental procedures were identical except that subjects did not wear a splint at any time nor did they avoid left hand use. Preliminary results suggest that immobilization may impair acquisition of the skill but may also augment practice-dependent plasticity and retention. If these trends are maintained with further analysis, the results would suggest that short-term immobilization can selectively enhance retention of ballistic motor skills, potentially through an effect on practice-dependent plasticity.

Title: Effects of anodal tDCS on motor skill learning in the acute phase of stroke: mechanistic and therapeutic considerations

Authors: P. HAUFLER, M. ROCHA CURADO, B. FRITSCH, *J. REIS;
Univ. of Freiburg, Freiburg, Germany

Abstract: Objective: Stroke is the leading cause of disability in adults. New therapeutic approaches are needed to improve impaired motor function. Anodal transcranial direct current stimulation (tDCS) can enhance motor learning in healthy subjects and chronic stroke patients. However , it is unknown, if tDCS is advantageous for motor skill learning as well as motor recovery in general in the acute phase after stroke. Methods: This ongoing study includes patients with acute, unilateral, first-ever ischemic stroke causing a moderate hemiparesis. The speed-accuracy-tradeoff function (SAF) is assembled on day 1, day 5 and day 35 after stroke. On day 1-5 patients practice the sequential visual isometric pinch force task (SVIPT1) with their paretic hand. Training is combined with either anodal tDCS or sham tDCS for 20 minutes over M1 of the affected hemisphere on day 2-4. The change from the initial SAF (day 1 to day 5 to day 35), motor skill learning over the first 5 days and retention on day 35 are compared between the sham-stimulated and anodal tDCS-stimulated patients. Moreover, the Grooved Pegboard Test (GPT) as well as a tracing task2 is performed on day 5 and day 35 to test for overall enhancement of motor function. Clinical scores are taken into account to assess neurological recovery in general. Results: At the time of this interim analysis patients showed similar initial impairment (UEFMS 58 ±2, NIHSS 5±1). On the training task, motor skill increased in both groups and was preserved at the day 35 follow up. Anodal tDCS-stimulated patients outperformed sham-stimulated patients, suggesting a beneficial effect of tDCS on motor skill learning in the acute phase. After training, patients showed a significant shift in the SAF, i.e. lower target error rates at predefined speeds. This shift was greater in the anodal tDCS group compared to sham. The anodal tDCS group also showed better performance on the GPT and tracing task. There was no difference between groups in terms of their clinical scores. Conclusions: Our preliminary data suggest that motor learning ability in acute stroke patients is preserved and that anodal tDCS combined with repeated motor training can facilitate motor skill learning in these patients. General enhancements in fine hand motor function indicated by the SAF shift, GPT and tracing task performance was also greater in the anodal tDCS group. These findings could be directly transferable to neurorehabilitative treatments of acute stroke patients as a safe strategy to facilitate recovery of lost motor function the first days after admission to a stroke unit. 1.Reis et al., PNAS 2009;106(5):1590-5. 2.Prichard et al., Brain Stimul. 2014 Jul-Aug;7(4):532-40.

Title: Multimodal imaging to assess structural and functional changes associated with motor skill acquisition in healthy adults

Authors: ***B. LAKHANI**[1], M. R. BORICH[2], J. N. JACKSON[1], K. P. WADDEN[1], S. PETERS[1], A. VILLAMAYOR[1], A. MACKAY[1], I. VAVASOUR[1], A. RAUSCHER[1], L. A. BOYD[1]; [1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Emory Univ., Atlanta, GA

Abstract: Introduction: The brain undergoes numerous structural and functional changes when learning a motor skill. Multi-component T_2 relaxation imaging provides a validated marker of myelination (myelin water fraction or MWF). To date, no research has longitudinally quantified changes in myelin, cortical structure and functional connectivity in response to motor skill learning. Therefore, the objectives of the current study are to explore the relationship between changes in MWF and acquisition of an upper-limb motor task in healthy young adults and to identify concomitant changes in cortical volumetrics and functional connectivity. Methods: Seventeen healthy young adults (26 ± 4 years old; 10 female) underwent 3T magnetic resonance imaging before and after ten sessions of unimanual upper-limb training with their dominant right. MWF was extracted from the 32 echo T_2 relaxation MRI data using a non-negative least-squares with extended phase graph algorithm. Regions of interest for MWF analysis included the white matter underlying the intraparietal sulcus (IPS) and the parieto-occipital sulcus (POS). Cortical reconstructions and volumetric segmentation were performed using the FreeSurfer image analysis package. Resting-state fMRI (rsFMRI) analysis was conducted using independent component analysis with a spatial constraint seeded in the left IPS with the Group ICA function of the fMRI Toolbox. Skill acquisition was quantified by fitting an exponential curve to movement time. Results: The left IPS and left POS demonstrated significant MWF increases following training (8.30% and 6.28%, respectively). There was a significant correlation between the change in MWF in the left IPS and the change in cortical volume in the gray matter of the left IPS ($r=-0.697$, $p=0.003$). Consequently, there was a significant partial correlation between the percent difference in MWF in the left IPS and the rate of skill acquisition ($r=-0.607$, $p=0.016$),

when controlling for gray matter volume in the left IPS. In addition, rsFMRI contrast analysis identified one cluster located in the left middle frontal gyrus with a significant increase in activity following training (p=0.002). Discussion: This is the first demonstration of focal increases in MWF after skill training. Increases in MWF were observed only in ROIs contralateral to the trained limb, were correlated with indices of skill acquisition, and corresponded to regional decreases in cortical volume. Additionally, rsFMRI demonstrated changes in functional connectivity between the left IPS and the middle frontal gyrus, which is implicated in visuomotor attention.

Title: Influence of inter-train interval on the efficacy of repetitive transcranial magnetic stimulation

Authors: ***R. CASH**[1], A. DAR[2], J. HUI[1], L. DE RUITER[2], C. BURKE[2], J. DOWNAR[2], R. CHEN[1];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]MRI-Guided rTMS Clinic, Dept. of Psychiatry, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: INTRODUCTION: Previous studies indicate that incorporation of inter-train intervals (ITI) between trains of repetitive transcranial stimulation (rTMS) may be essential not only for participant safety, but also for inducing long term potentiation (LTP)- like increases in cortical excitability. We systematically investigated the influence of ITI duration on rTMS effects. METHODS: 10 participants were recruited thus far (aged 22 ± 1 years). rTMS (20Hz, 2 second train, 1200 pulses, 100% RMT) was delivered with 4 different ITIs (4, 8, 16, 32 seconds), in a randomised, cross-over design. The investigators performing the analysis were blinded to ITI used. Motor evoked potential (MEP) amplitude and short interval intracortical inhibition (SICI) were measured pre-and up to 75 minutes post-intervention. At baseline conditioning stimulus

intensity was adjusted such that SICI reduced MEP amplitude by ~50%. Electromyographic activity was recorded from four muscles including target muscle first dorsal interosseous (FDI). RESULTS: Preliminary results suggest that rTMS was most effective at ITI 4 sec, with the largest LTP-like effects, the lowest inter-individual variability, and the greatest muscle specificity. The average MEP increase over 75 minutes were: 4sec: 131 ± 11%, 8sec: 106 ± 9%, 16sec 110 ± 10% and 32sec 114 ± 13% compared to pre-rTMS baseline. SICI was maximally disinhibited at ITIs of 4 and 8sec ITI from a pre-rTMS level of ~50% inhibition to a post-rTMS level of ~30% inhibition. The effects on SICI was shorter lasting that the effects on corticospinal excitability. DISCUSSION: rTMS at ITI of 4 sec may be more effective at increasing cortical excitability than longer ITI. This preliminary result suggests that rTMS protocols used therapeutically may be shortened for greater efficacy and shorter session duration, leading to reduction in treatment cost and increase the number of patients that can be treated in a given time.

Title: Short-latency afferent inhibition differentially suppresses motor cortical networks depending upon visual attention load

Authors: *J. L. MIRDAMADI, L. Y. SUZUKI, T. R. ERICKSON, A. S. FEINGOLD, S. K. MEEHAN;
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Primary motor cortex works in association with different brain areas to support different types of learning. We recently demonstrated that attention influences motor cortical plasticity through somatosensory gating. However, the motor cortical substrates of this interaction are not known. Here, we examined the magnitude of short-latency afferent inhibition (SAI) under differing attention load upon motor cortical I-wave networks. SAI was elicited with electrical median nerve stimulation at the right wrist that preceded a single monophasic TMS stimulus over the left motor cortical representation of the first dorsal interosseous (FDI). To delineate the magnitude of SAI upon different I-wave networks, unconditioned and conditioned

motor evoked potentials (MEPs) were evoked using either posterior-anterior (PA) or anterior-to-posterior (AP) current. Motor evoked potentials (MEPs) evoked by each current direction were recorded while participants engaged in a visual detection task of varying attention load. The visual attention task consisted of colored crosses presented in different orientations. Under low visual attention load, participants were required to count all red crosses regardless of orientation. Under high visual attention load, participants were required to count only upright yellow and upside down green crosses. We hypothesized 1) that SAI would be greater for PA compared to AP current direction during low visual attention load and 2) that SAI would be significantly reduced for the AP current direction but not the PA current direction under high visual attention load. Preliminary data (n=5) support our hypotheses. SAI was greater for MEPs elicited using the PA current direction compared to AP current. SAI was reduced under high attention load compared to low attention load for AP but not PA current. These results suggest that attention specifically alters cortical excitability of motor cortical circuits mediating late I-waves. Decreased SAI possibly reflects reduced sensory projections to M1 as a result of attention-related sensory gating. Late I-wave cortical networks within M1 have been linked to model-based learning involving the cerebellum. Attentional modulation of these same motor cortical networks may serve as a point of convergence for implicit and explicit model-based learning. Understanding the interactions between cerebellar-mediated implicit and attention-related strategic mechanisms has important implications for skilled learning.

Title: Activation training alters corticomotor excitability of the gluteus maximus

Authors: *Y.-L. KUO[1], C. M. POWERS[1], A. C. SOUTHAM[1], Y.-Y. LEE[2], B. E. FISHER[1]; [1]Biokinesiology and Physical Therapy, USC, Los Angeles, CA; [2]Healthy Aging Ctr., Chang Gung Univ., Taoyuan, Taiwan

Abstract: Objectives: To determine whether a short term (6 hours) activation training program targeting gluteus maximus (GM) results in neuroplastic changes in the primary motor cortex (M1). Study Design: Within subject - repeated measures Background: It has been proposed that

strengthening and skill training of GM may be beneficial in treating various knee injuries. Given the redundancy of the hip musculature and the small representational area of GM in M1, learning to activate this muscle prior to prescribing strength exercises and modifying movement strategy would appear to be important. Methods: Using Transcranial magnetic stimulation (TMS), motor evoked potentials (MEPs) were obtained in 12 healthy individuals at 5 different stimulation intensities while subjects performed a double-leg bridge. Subjects then completed a home exercise program for approximately 1 hour/day for 6 days that consisted of a single exercise designed to selectively target GM. Baseline and post-training input-output curves (IOCs) were generated by graphing average MEP amplitudes and cortical silent period (CSP) durations against corresponding stimulation intensities. Linear slopes of the IOCs were compared pre and post training using a paired t-test. Results: Following GM activation training, the linear slope of the MEP IOC increased from 14.89 to 21.51 ($p = .01$). For CSP duration, the linear slope of the IOC increased from 14.89 to 21.51 ($p = .04$). Conclusion: Short term GM activation training resulted in a significant increase in corticomotor excitability as well as changes in inhibitory processes of GM. We propose that the observed corticomotor plasticity will allow for better utilization of GM in the more advanced stages of a rehabilitation/training program.

Title: From motor pathway to song system - functional brain specialization in birds

Authors: *A. SIMON, S. LETZNER, O. GÜNTÜRKÜN;
Biopsychology, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Sven Ebbesson (1980) proposed in his parcellation theory that distinct neural systems evolve by differentiation and parcellation. These processes involve an increased specialization within neural circuits that is accompanied by a loss of neuronal connections within system components. In order to investigate if specialization of a primordial avian sensorimotor system is accompanied by a change of connectivity, we compared the global motor system of the non-oscine brain with the specialized and well-studied oscine song system. The oscine song system comprises of several telencephalic nuclei which are part of two major interconnected pathways:

the anterior forebrain pathway (AFP) and the posterior motor pathway (PMP). HVC, located adjacent to NCL, receives input from the ascending auditory system and links both of these pathways. Therefore, the HVC plays a key role within the oscine songs system. Within the HVC different projection neurons either target the robust nucleus within arcopallium (PMP), or Area X within medial striatum (AFP). Since the only three avian taxa that are capable of vocal learning (songsbirds, hummingbirds and parrots), show a remarkably similar song system, it seems not very likely that their vocal learning and production systems evolved completely independently. Indeed, a connectivity pattern resembling the one discovered in oscines also exists in pigeons and participates in the control of sequential movement patterns. Here we address the question if this motor control system could serve as a preliminary form of the oscine song system. According to the parcellation theory, we might expect that the PMP- or AFP-like neurons in pigeons are less specialized such that single neurons subserve both projection streams. In order to examine whether functional specialization is accompanied by such a change of neuronal connectivity, we injected different retrograde tracers into arcopallium and MSt in pigeons. Subsequently we scanned the pigeon NCL for biprojecting neurons which project to both MSt and arcopallium. These neurons might constitute a preliminary stage of specialized nerve cells in the HVC of songbirds. However, no biprojecting neurons, but a remarkable differentiated projection pattern to both areas were detected. Additionally, we discovered a topical projection from NCL to the intermediate arcopallium and found out that NCL projects only to the somatic MSt. These findings might indicate that these NCL neurons are already specialized. Altogether these results deliver new insights into the complexity of brain organization.

Title: Influence of motor cortex stimulation plus motor training on neuroplasticity

Authors: *C. L. MASSIE[1], C. L. WHITE[2];
[1]Occup. Therapy, [2]Kinesiology, Indiana Univ., Indianapolis, IN

Abstract: Use-dependent neuroplasticity is an important factor for rehabilitation, yet the potential to influence neuroplasticity when combining with neuromodulatory techniques such as repetitive transcranial magnetic stimulation (rTMS) is not fully characterized. The objective of the study was to determine how engaging in motor practice during rTMS influences neuroplasticity. Ten young adults participated with a mean age of 24. Each participant completed three separate sessions in a random order: motor practice with sham-rTMS, motor practice with rTMS, and rTMS only. The motor practice protocol included 30 bouts of isometric contractions in a customized wrist device during rTMS or sham protocol. The rTMS/sham protocol was 30, 3 second trains at 10Hz with 70% resting motor threshold intensity. The intertrain interval was 30 seconds. Assessments included force steadiness and electromyography during a wrist extension task, the Box and Block Test (BBT), and transcranial magnetic stimulation (TMS) before and after the rTMS intervention. The force steadiness task was two trials of at least 10 seconds at 10% of the maximum voluntary contraction. The BBT is a measure of dexterity assessed as the number of small blocks moved in a minute. The TMS measures included 10 stimulations each at suprathreshold (116% of resting motor threshold), short-interval intracortical inhibition (SICI), and intracortical facilitation (ICF) with motor evoked potentials (MEP) recorded from the extensor carpi radialis (ECR) and extensor carpi ulnaris (ECU) muscles. Data were analyzed with a RMANOVA (time by condition) and change scores from baseline were used for correlation coefficients. The variability of force steadiness decreased after all three conditions ($p < 0.05$) and the amount of ECR activity significantly changed as well ($p < 0.05$). There was a significant time effect for the BBT ($p < 0.05$), with significant increases following the conditions with motor practice. The results from the MEP data were non-significant. There was a significant, negative correlation ($r = -0.61$, $p < 0.05$) between the variability of force with an increase in the BBT following the rTMS only condition, but not when motor practice was involved. These results suggest that a short intervention can influence motor control in young adults although these changes are modulated differently by motor practice plus sham-rTMS, motor practice plus rTMS, and rTMS alone. This demonstrates the importance of better understanding how possible rehabilitation interventions influence neuroplasticity and may need to be individually determined and prescribed in future contexts to maximize therapeutic potential.

Title: Paired stimulation induces spike-timing dependent plasticity of neural connections in primate sensorimotor cortex

Authors: *S. SEEMAN, B. J. MOGEN, E. E. FETZ, S. I. PERLMUTTER;
Univ. of Washington, Seattle, WA

Abstract: Classic studies have described spike-timing dependent plasticity (STDP) at synapses: the connection from neuron A to neuron B is strengthened (or weakened) when A fires before (or after) B within an optimal time window. Accordingly, spike-triggered stimulation between motor cortical sites in a behaving monkey resulted in changed motor output of the leading site. The ability to modify connections in cortex becomes useful in the context of injury when connectivity, and associated functionality, is compromised. To avoid the need for long-term, stable isolation of single units, one could control timed activation of two cortical sites with paired stimulation. We tested the hypothesis that STDP could be induced via prolonged paired stimulation as quantified by cortical evoked potentials (EPs). Two macaques were implanted with bipolar electrodes positioned in a grid over sensorimotor cortex bilaterally. At each site, one lead penetrated into cortex while the other rested on the surface. Bipolar stimulation at some sites evoked robust, short-latency EPs at other sites mediated by connections between the stimulation and recording sites. We performed conditioning sessions between interconnected sites (A and B) for 3 hours via a head-fixed device, the Neurochip, while the monkey engaged in free behavior in the cage. On different days we varied the delay between trains of 3 stimuli at A and B. Before and after conditioning, test pulses of various amplitudes were delivered to sites A, B, and a connected control site C that did not receive conditioning stimulation. The mean peak-to-trough amplitude of test EPs was quantified as a percent change in amplitude after conditioning compared to before. Previous STDP studies showed a 20 ms delay between activation of 2 sites is in the optimal range for inducing plasticity. Here, a 20 ms delay between stimulation at sites A and B produced a 78.1 ± 22.8% (mean ± SEM, n=3) increase in EP from A to B immediately after conditioning. This effect was site and direction specific: the EP from A to C (control) showed no effect (-4.2 ± 10.5%) and the EP from B to A (reverse direction) showed a slight depression (-14.3 ± 19.7%), as expected from STDP rules. Three hours after conditioning ended the EP from A to B remained larger by 54.2 ± 17.2% showing a lasting effect. Longer conditioning delays produced no effect (100 ms: -20.2% n=1, 200 ms: -10.4% n=1) indicating that paired stimulation follows STDP timing rules. Interestingly, paired stimulation did not induce plasticity between every pair of sites tested. Still, these results show promise for future

clinical applications to induce targeted plasticity in cortex, and elucidating connectivity of cortical networks

Title: Corticospinal population activity during motor learning

Authors: ***A. J. PETERS**, J. LEE, S. X. CHEN, T. KOMIYAMA;
UC San Diego, La Jolla, CA

Abstract: The motor cortex controls movement through direct projections to the spinal cord. Despite this primary connection, the relationship between motor cortex activity and movement has been difficult to decipher. Moreover, extensive evidence has shown that the motor cortex is capable of significant plasticity which is engaged during and necessary for motor learning, indicating that this relationship may be flexible. We are investigating how these changes are manifested in population activity of the motor cortex of mice using two-photon calcium imaging. We employ a head-fixed lever press task which mice can learn over the course of two weeks. The same set of neurons are simultaneously imaged during behavior every day. Previously, we focused on the superficial input layers of the motor cortex and found that learning induces an initial period of highly variable activity, which is followed by stabilization into a novel but

reliable set of activity patterns corresponding to individual movements. We are currently contrasting this input layer activity with output activity of layer 5b neurons that project directly to the spinal cord. By comparing the activity of the primary input and output layers of the motor cortex, we are able to describe plasticity as it pertains to laminar specificity. We are currently testing the hypothesis that layer 2/3 exhibits substantial changes in the relationship between activity and movement while layer 5b corticospinal neurons are less flexible in this regard. Such a scenario would support the model that plasticity in this area is effectively an interlaminar phenomenon where networks of layer 2/3 cells serve to drive layer 5b corticospinal neurons that act as stable drivers of movement. If on the other hand corticospinal neurons exhibit activity as flexible as layer 2/3 neurons, then it provides evidence that given movements do not rely on consistent output from the motor cortex.

Title: Plasticity of inhibitory effect on indirect cortico-motoneuonal pathways in humans

Authors: *T. NAKAJIMA[1], S. SUZUKI[1], G. FUTATSUBASHI[2], S. IRIE[1], T. KOMIYAMA[2], Y. OHKI[1];
[1]Kyorin Unversity Sch. of Med., Mitaka City/Tokyo, Japan; [2]Chiba Univ., Chiba, Japan

Abstract: We previously reported that repetitive combined stimulation (RCS) of pyramidal tract and peripheral nerve induces long-term potentiation (LTP) in indirect cortico-motoneuronal (C-M) excitations, which would be mediated via. cervical propriospinal neurons (PNs) in humans. In the current study, we examined plastic changes in inhibiotory systems in the spinal cord. Healthy volunteers, who all gave written informed consent, participated in the experiments.

Electromyograms were recorded from the right triceps brachii (TB) and extensor digitorum comunicis (EDC) muscles. RCS intervention (0.2 Hz) was performed for 10 min, during which transcranial magnetic stimulation (TMS) to the contralateral motor cortex was delivered in conjunction with the right superficial radial nerve stimulation (NERVE) at wrist, under weak contractions of the target muscles. Interstimulus interval (ISI) for the combined stimulation (CS) was set at 10 ms (TMS behind), which gave converging inputs in upper cervical segments. Under the ISI, stimulus strengths for CS were determined before RCS, at which TMS-induced motor evoked potentials (MEPs) were suppressed most by combined NERVE. MEP amplitudes in TB and EDC were significantly suppressed after RCS, which lasted for ~70 min. The suppression was observed in both MEPs evoked by TMS and transcranial electrical stimulation (TES). Furthermore, the NERVE-induced suppression on MEP was significantly enhanced after RCS than that before RCS. The suppression was not observed in the initial part of MEP. These results suggest that RCS can induce plastic changes in pyramidal inputs to spinal inhibitory systems, which receives peripheral nerve inputs and inhibits PN and/or motoneurons.

Title: Electrical cortical stimulation paired with volitional movement produces subsequent intra- and inter-hemispheric effects in the nonhuman primate

Authors: ***A. R. BOGAARD**[1,2], S. ZANOS[2], A. G. RICHARDSON[3], E. E. FETZ[2];
[1]Med. Scientist Training Program, [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [3]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Pairing cortical stimulation (CS) with volitional movement can have effects that last beyond the end of stimulation. Documented effects depended on the timing of stimulation

relative to movement and included changes in the motor output of sites ipsilateral to stimulation. In those studies, stimulation was delivered only to sites contralateral to movement and analysis primarily described effects on movement contralateral to stimulation. Interhemispheric effects and the underlying neurophysiological mechanisms need further review. Two male macaques were trained to perform a reaction time (RT) task using bilateral wrist movements. Each wrist controlled a cursor on a screen. For each trial, one cursor was randomly cued to be moved by rapid wrist extension into a "target" box, while the other cursor remained still in a "resting" box. Each session consisted of 3 epochs of about 500 trials each: preconditioning, conditioning and postconditioning. During the conditioning epoch, brief trains of suprathreshold electrical CS were delivered to a motor cortex electrode at a given latency relative to expected movement onset. The behavioral effects of conditioning were assessed by comparing RTs of movements contralateral and ipsilateral to the stimulated hemisphere during the preconditioning and the postconditioning epochs. Field potentials were recorded bilaterally during the task. At baseline, average RTs were similar between the two monkeys (monkey I: 244 ms; monkey K: 236 ms). When CS was triggered by contralateral movement (cont-CS; e.g. left movement triggers right motor cortex stimulation), RTs of both contralateral and ipsilateral movements decreased (I, contra: -22.3 ms, ipsi: -58.8ms; K, contra: -28.5ms n.s., ipsi: -20.0ms). When CS was triggered by ipsilateral movement (ipsi-CS), RTs increased for ipsilateral but not contralateral movements (K, contra: 18.8ms n.s., ipsi: 6.15 ms). In agreement with previous studies, cont-CS decreased RTs of contralateral movement. Here, we observed an even more robust decrease in the RTs of ipsilateral movement. Our results also demonstrate an increase in RT of contralateral movements during ipsi-CS. Assuming that RTs are indicative of underlying cortical activation, these effects can be explained by excitation of cortical activity in the movement-generating hemisphere by cont-CS, and by an increase in interhemispheric inhibition, known to arise from the unrecruited hemisphere, by ipsi-CS. Analysis of neural signals collected during performance of the task will allow us to explore physiological correlates of these behavioral effects.

Title: Tool-use learning in rats

Authors: *A. NAGANO[1], K. AOYAMA[2];
[1]Doshisha Univ., Kyoto / Kyoto, Japan; [2]Fac. of Psychology, Doshisha Univ., Kyotanabe, Japan

Abstract: Tool-use behavior has been observed in non-human animal species such as keas and common marmosets. Tool use has been observed in the wild and in experimental settings. Some primates and a species of rodent (degus) have been used as animal models to investigate the neural basis of the tool-use behavior. However, a more efficient animal model is needed. In the present study, we tested whether rats could be trained to use tools to obtain food in an experimental setting. We used eight experimentally naïve male Brown-Norway rats, approximately three months old at the start of the experiment. During the training and testing phase, all rats were maintained at approximately 85% of their initial free feeding weight. Each daily experimental session consisted of 36 trials in each phase. The rats were trained to use a hook-shaped tool to retrieve a food (one eighth of a chocolate flavored loop cereal) beyond the rats' reach. In the training phase, rats had to choose between an appropriately arranged hook and an inappropriately arranged hook. If the rat pulled the appropriate hook directly, rats could obtain the food because the food was placed inside the hook. On the other hand, if the rat pulled the inappropriate hook, rats could not obtain the food because the food was placed outside the hook. This training continued until the rats reached a criterion of 30 or more successful trials in two consecutive sessions. All rats reached this criterion after 15 to 41 sessions. After the rats reached the criterion in the training phase, one test session was run for each rat. In the test phase, rats had to choose between a functional rake-shaped tool and an unfunctional rake-shaped tool. If the rat pulled the functional rake, the rat could obtain the food. In contrast, if the rat pulled the unfunctional rake, the food passed through the rake blade. We analyzed their choice between the functional rake and the unfunctional rake in the test phase with a chi-square test. This analysis revealed that all rats could choose the functional rake, which was above chance levels. The results indicate that rats could select functional tools based on features of the tools in an experimental setting. This is the first time tool use has been reported for the rat. Thus, we offer the rat as an animal model that can be used to investigate the neural mechanism of higher cognitive functions in animals and, potentially, humans.

Title: 4-Aminopyridine strongly increases motor cortex and spinal stimulation responses at a clinically relevant dose

Authors: *A. SINDHURAKAR[1], A. MISHRA[1], T. BETHEA[1], J. IACI[2], T. PARRY[2], J. B. CARMEL[1,3];
[1]Burke Med. Res. Inst., White Plains, NY; [2]Acorda Therapeut., Ardsley, NY; [3]Dept. of Neurol. and Pediatrics, Brain and Mind Res. Inst., New York, NY

Abstract: The potassium channel blocker 4-Aminopyridine (4-AP) improves walking speed in people with multiple sclerosis (MS) and in people with stroke. The mechanism of action of 4-AP in MS may be through reversal of conduction block, but how 4-AP acts to improve sensorimotor deficits after stroke is not known. The current experiments test which circuits mediate 4-AP effects at clinically relevant serum concentrations. We hypothesize that 4-AP will increase excitability of both descending motor connections and spinal cord circuits. We first determined the proper dose of 4-AP required to achieve plasma levels which were effective in human trials-60-100 ng/ml-in adult female Sprague Dawley rats. A dose-finding study indicated that a 4-AP dose of 0.8 mg/kg would produce these levels, and we used this dose to investigate which neural circuits are affected by 4-AP. All experiments were performed on anesthetized and uninjured rats. The effects of 4-AP on descending motor pathways were studied by stimulating the motor cortex and recording the motor evoked potential (MEP) generated from the biceps muscle. In the same animals, spinal excitability was assessed by stimulating the dorsal spinal cord and recording MEPs from the bicep. Rats received either 4-AP or saline by intraperitoneal infusion and the experimenter was blinded to the group. Cortical MEPs and spinal excitability were then evaluated and blood samples were obtained prior to dosing of 4-AP or saline and 0.25, 0.5, 1, 2, 3, 4 and 5 h thereafter. The average maximum plasma level of 4-AP was 103.9 ± 22.3 ng/ml, and these levels fell to 39.7 ± 11.4 at 3 hours after infusion. Both cortical and spinal stimulation responses were markedly enhanced with 4-AP. The MEP response to cortical stimulation increased by 76 ± 19% from baseline and returned to baseline levels at four hours after injection. Spinal excitability increased 27 ± 6% above baseline, and it also returned to pre-infusion levels by 4 hours. Compared with saline controls, 4-AP significantly ($p<0.05$) increased MEPs evoked from both cortical and spinal cord stimulation in naïve rats. In rats, a 4-AP dose that produces therapeutically relevant plasma concentrations was found to increase the excitability of motor circuits, including spinal excitability, a finding not reported previously. Ongoing experiments in rats with stroke will test whether 4-AP affects motor function after stroke by strengthening spared neural circuits.

Title: Role of cAMP response element-binding protein and its target genes during motor skill learning

Authors: *B. OUIMET, G. BUREAU, M. CYR;
Dept. de biologie médicale, Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada

Abstract: In humans and animals, learning a skilled motor task requires integration of many signals from different parts of the brain especially the basal ganglia, motor cortex, and cerebellum. It is well known that once learned, a motor skilled task is performed automatically and never totally forgotten. However, the underlying molecular mechanisms of this learning process are not well-understood. Our recent studies suggest a contribution of protein kinase A (PKA), extracellular signal-related kinases (ERK) and striatal-enriched protein tyrosine phosphatase (STEP) in motor learning. It is well established that cAMP respond element binding protein (CREB) is regulated by many kinases notably ERK and PKA, and is very important in cognitive learning and long-term memory. However, the genes activated by CREB, as well as their specific roles in motor skill learning, are not identified. In order to study a skilled motor task in mice, we used the accelerating rotarod, which is well known to reproduce the slower and faster learning phases. To investigate the role of CREB in relation to learning phases, we have evaluated the protein levels of CREB by western blot after each day of rotarod training in the striatum. We observed that CREB expression levels were increased after each day of training. Next, we have searched for specific genes activated by CREB binding. We performed chromatin immunoprecipitation (ChIP) of CREB and verified the levels of CREB binding on various genes related to synaptic plasticity (GluR1, cFos, Arc, BDNF, NR2B, PSD95) in the striatum of untrained and trained mice on the rotarod. We observed a tendency to increase in the binding of

CREB on genes NR2B, BDNF and PSD95. Other experiments will be needed to conclude our results. These results will be useful to better understand the mechanisms of encoding of the memory of a skilled motor task.

Title: Probing the role of motor cortex in motor skill learning

Authors: *S. B. WOLFF, B. P. OLVECZKY;
Harvard Univ., Cambridge, MA

Abstract: One of the most fundamental functions of the brain is to learn and generate movements. Its remarkable capacity to acquire and improve motor skills depends on the intricate interplay between a number of distinct brain areas. Their specific roles and interactions and the overall implementation of the learning process in neuronal circuitry are still not well understood. Motor cortex (MC) is a central player in this distributed motor network. To dissect its involvement in the acquisition and execution of complex, learned motor skills, we train rats in a lever-pressing task which requires learning spatiotemporally precise movement patterns. Using chronic lesions, we have previously shown that MC is dispensable for executing these learned motor sequences. In contrast, we now show that transient optogenetic perturbations of MC activity acutely disrupt the execution of these motor skills. Together, these findings suggest that MC has the capacity to modulate complex, learned motor behaviors, but may refrain from exercising this capacity once a motor skill is consolidated. This is in line with our previous finding that MC is, in fact, necessary for the acquisition of the skills we train. Based on these results, we hypothesize that input from MC to downstream motor areas serves as a teaching signal during skill acquisition, guiding the acquisition and refinement of subcortically generated motor sequences. To test this hypothesis and to identify a subcortical target for MC's 'tutoring', we are using molecular and viral tools to gain selective access to distinct projection pathways from MC to different downstream motor areas. Preliminary results suggest that striatum may be a target of MC's 'tutoring'. While chronic silencing of corticostriatal projections affects motor skill acquisition, transient silencing acutely degrades execution of the learned behavior. To further dissect the role of specific projections from MC to different downstream areas, we are

combining projection-specific targeting with high-throughput behavioral training, single unit recordings, optogenetics and pharmacogenetics.

Title: Are changes in cerebellar excitability effector-specific?

Authors: *D. SPAMPINATO[1], P. A. CELNIK[2];
[1]Biomed. Engin., Johns Hopkins Unviersity Sch. of Med., Baltimore, MD; [2]Physical Med. and Rehabilitation; Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: One of the functions of the cerebellum in motor learning is to predict and account for systematic changes to the body or environment. This form of adaptive learning is mediated in part, by long-term depression of Purkinje cells in cerebellar cortex. We have previously shown in humans that changes in cerebellar-M1 connectivity, suggestive of cerebellar excitability, correlates with learning of a walking adaptation task. This was also found for a hand muscle (first dorsal interosseous or FDI) in association to visuomotor adaptation. However, the effector specificity of these findings is poorly understood. Using paired-pulse transcranial magnetic stimulation (TMS), we assessed inhibitory cerebellar-M1 connectivity (CBI) on healthy young adults, a measurement thought to represent the strength of cerebellar-to-cerebral pathways for a given muscle. In Experiment 1, we asked if learning a visuomotor rotation task with the right-hand elicit CBI changes to the right leg. We measured FDI and TA muscles before and after learning a visuomotor rotation with the hand. Additionally, we wanted to see if CBI changes were associated to the amount of learning that transferred to the right leg. In Experiment 2, we investigated whether simple movement execution (i.e. no learning) would produce effector specific CBI changes. To our knowledge, there are no studies that have investigated whether modulation of cerebellar-M1 connectivity occurs during the preparation of a voluntary movement. We assessed CBI for FDI muscle at five different time points during movement preparation of cued-simple reaction time (RT) task (Onset, 20, 40, 65, 90% of individual RT). The RT task was completed in two different sessions: (1) participants responded by moving the

FDI muscle and (2) participants moved the TA muscle while FDI muscle was kept relaxed. Our data shows that learning with the hand elicited changes in CBI for both FDI and TA muscles ($p<0.04$). This effect, associated to transfer of learned movements to the leg, cannot determine the somatotopic specificity of CBI. However, results from Experiment 2 revealed that CBI changes where only present prior to movement onset in the effector being moved (i.e. finger), but not the one at rest (leg). These results indicate that the cerebellar-M1 connectivity measure (CBI) is effector-specific. However, when the transfer of learning is present, CBI changes are also observed in the non-trained effector.

Title: Updating eye-hand coordination when manipulating objects with complex dynamics

Authors: *F. DANION[1], C. LANDELLE[1], A. MONTAGNINI[1], L. PERRINET[1], L. MADELAIN[2];
[1]CNRS, INT, Marseille, France; [2]URECA, University of Lille, France

Abstract: The ability to track with the eye a moving target is substantially improved when the target is self-moved in comparison to an externally-moved one. In particular it has been shown that when the target is moved by the subject's hand, eye tracking is characterized by a higher gain in smooth pursuit, fewer corrective saccades, and a smaller temporal lag between target and eye motion. However all those observations were obtained when the mapping between hand and target motion was kept linear. Here we investigate a situation in which the mapping between hand movement and target motion is altered so as to mimic an elastic link between hand and target, thereby simulating that a weighted target is attached to the hand by means of a damped spring. In order to remain efficient, these changes in target dynamics require the update between hand actions and their visual consequences. Our objective was to determine whether eye-hand coordination could accommodate these rather complex (non-linear) changes in hand-target dynamics. To fully appreciate the effects of this (visual) perturbation, we have compared eye-tracking performance when moving a rigid and a non-rigid target, as well as when the subject

faces target trajectories that he/she had previously generated when self-moving the rigid or non-rigid target. As in previous studies, we showed that eye tracking is more accurate when the target is self-moved. However, although this advantage was immediate when dealing with the rigid target, this was not the case when exposed to the non-rigid target. Still within a few minutes of practice with the non-rigid target, tracking performance improved substantially in the self-moved condition, up to a level that was similar to when self-moving the rigid target. In contrast performance did not improve much when tracking an externally-moved target, even though tracking was consistently better with the non-rigid target. At this stage it seems that the narrowing of the frequency bandwidth toward a resonant frequency could contribute to the advantage of the non-rigid target. Overall, despite the possible contribution of this resonant frequency, our results show that subjects can learn, within a few minutes, a complex mapping between their hand motion and their visual consequences. Title: Visuomotor coupling is necessary for the development of sensorimotor integration in mouse visual cortex

Authors: ***A. ATTINGER**, B. WANG, G. KELLER;
Friedrich Miescher Inst., Basel, Switzerland

Abstract: Neurons in primary visual cortex (V1) of the mouse not only respond to visual stimuli, but are also driven by motor-related signals. In mice navigating in a virtual reality environment layer 2/3 neurons strongly respond when the actual visual flow deviates from the visual flow that the animal expects as a consequence of its own locomotion. The detection of such mismatch events requires the integration of both visual and motor-related signals. It is still largely unknown how experience shapes this sensorimotor integration in V1. To assess this, we raised one group of mice in conditions of normal visuomotor coupling, in which forward locomotion

was coupled to backward visual flow in a virtual reality environment. A second group was raised in conditions of random visuomotor coupling, in which locomotion had no influence on visual flow. Both groups were raised in complete darkness when not in the virtual reality setup. After six two-hour training sessions on alternating days, we measured activity of defined populations of neurons in the superficial layers of V1 using *in vivo* two-photon imaging of a genetically encoded calcium indicator (GCaMP6f or GCaMP5) expressed in a Cre-dependent manner. Even though both groups of mice experienced identical visual input and exhibited indistinguishable locomotion behavior, we found profound differences in sensorimotor processing between the two groups. Selective responses to mismatch were only present in animals raised under coupled visuomotor conditions. These differences in processing were particularly prevalent in inhibitory neurons. Moreover, different classes of interneurons responded differently to mismatch events. Based on these data, we developed a circuit model of mismatch detection. Although absent initially in animals with random visuomotor coupling, selective responses to mismatch developed quickly with coupled visuomotor experience. These data indicate that normal development of V1 function critically depends on the experience of visual feedback coupled to movement.

Title: Effects of vagus nerve stimulation paired with motor training on contralesional cortical plasticity after brain injury

Authors: *D. PRUITT[1], A. SCHMID[2], K. FLANAGAN[2], B. BAKER[2], C. ABE[2], R. MORRISON[2], J. TRIEU[2], S. SHAH[2], M. P. KILGARD[2], R. L. RENNAKER, II[2];

Abstract: Traumatic Brain Injury (TBI) is one of the largest health problems in the United States. The effects of TBI can be debilitating and recovery of function is often incomplete. We previously demonstrated that vagus nerve stimulation (VNS) paired with forelimb use enhances motor recovery after TBI. Here we have investigated how varying the parameters of VNS affects

both functional motor recovery and contralesional cortical plasticity after TBI. Rats were trained to pull on a handle to receive a food reward, and then received a controlled-cortical impact (CCI) in motor cortex. After CCI, animals were assigned to experimental groups receiving VNS at differing levels of current (0.8 mA or 0.4 mA) either paired with motor training or delivered separate from motor training. Following six weeks of post-lesion training, we investigated contralesional cortical plasticity using intracortical microstimulation in the motor cortex. Our findings indicate that motor training alone enhances contralesional cortical plasticity, but no effect of VNS is observed in the contralesional hemisphere.

Title: Motor and limb performance assessment with OptiMan an operator-independent fully-automated multi-sensor system for forelimb strength, gait performance, motor coordination and motor learning assessment

Authors: ***Y. WINTER**[1], H. MUNAWAR[2], W. CLEMENT[3], C. JUNG[4], C. REIMERTZ[3], M. RIVALAN[2];

Abstract: Asssessing motor performance of animals by means of behavioral test is often influenced by operator-animal interaction and represents a stressful situation for the animal that may largely influence test results. In order to analyze motor phenotypes that are specific for a given disease/deficit we developed and validated a battery of automated behavioral tests that

allows the continuous assessment of motor function of rats in a fully operator-independent setup. Four to six RFID-tagged rats are group housed in a home cage environment. Their individual motor activity including locomotion distances and speeds is continuously monitored with a RFID-sensor array placed underneath the home cage. Rats can voluntarily leave their home cage by passing through an RFID-based electronic gating system and individually enter a course of four sequential units. First, a weighing cage to record body mass, secondly followed by a horizontal ladder task (1 meter) with electronically monitored rungs to evaluate limb stepping, placing, and coordination. Thirdly, an operant cage comprising a bilateral isometric pull task that evaluates forelimb function and strength while the animal learns to pull a retracted lever to obtain pellet reinforcement. The fourth and last unit before the animal enters back into its home cage is a walkway consisting of a high-density piezo force transducer array assessing gait kinematics and individual limb weight bearing. Motorized gates and unidirectional flaps guide the animal through the multiple-chamber system in a one-way direction. We used this system with rats from different experimental backgrounds and demonstrate that different types of motor impairment yield significant differences in multiple parameters that can be measured in the OptiMan system. This operator-independent, home cage based test-battery yields objective, stress free high-quality motor function data that is comparable to or better than conventional behavioral testing and unprecedented in terms of quantity of data gained per time in a quasi-continuous fashion.

Title: Betasort: A computation model of serial learning

Authors: ***G. G. JENSEN**[1], F. MUÑOZ[2], Y. ALKAN[2], V. P. FERRERA[2], H. S. TERRACE[1]; [1]Psychology, [2]Neurosci., Columbia Univ., New York, NY

Abstract: Do animals learn by purely associative mechanisms, or do they rely on representational structures? The success of “model-free” reinforcement learning (RL) in

explaining many complex tasks supports the former view. However, there are some tasks that seriously challenge RL models. A particularly salient example is the transitive inference (TI) task, which requires that subjects infer the ordering of a set of stimuli from incomplete information. TI is notable not only for the difficulty it poses for computational learning methods, but also for its ubiquity in comparative cognition: Every vertebrate species tested to date has demonstrated some aptitude for TI. Another cognitive task that is difficult to account for in associative terms is the simultaneous chain procedure (SimChain). We propose a novel computational model for serial learning, called betasort, which uses Bayesian updating to maintain a spatial representation of the stimulus order. Betasort readily and rapidly performs both TI and SimChain. We used betasort and Q-learning (a powerful RL algorithm) to fit behavioral data from 3 rhesus monkeys and 19 humans performing a 7-item TI task in which they were trained on adjacent pairs and tested on all pairs. Betasort demonstrated transfer of learning from adjacent to all pairs whereas Q-learning failed to learn during adjacent pair training. We also used betasort to fit data from 7 monkeys and 21 humans performing a 5-item simultaneous chain task; in this case, betasort yielded learning curves similar to those observed in subjects. In both of these tasks, betasort not only identifies correct responses, but also displays symbolic distance effects in its response errors, consistent with the hypothesis that serial learning makes use of a spatial continuum. Despite its representation of this continuum, betasort is efficient, able to simulate behavior at low computational cost. This sets it apart from Markov decision process (MDP) approaches, which often invoke intractable quantities that must be approximated numerically. Additionally, although reward prediction error (RPE) has long been assumed to play a pivotal role in neural networks, systems whose learning is determined by RPE signals, such as Q-learning, cannot approximate behavior in rigorous serial learning tasks. Betasort's success (when compared to RPE models) and its computational efficiency (when compared to MDP models) suggests that the debates over the "model-based vs. model free" dichotomy, borrowed from the machine learning literature, may have become a distraction from a central aim of modeling learning: To predict the behaviors that organisms display under controlled conditions.

Title: A novel test “Arenomat” for studying spatio-temporal integration

Authors: K. MALENINSKA[1], *A. STUCHLIK[2];
[1]Inst. of Physiology, Acad. of Sci. of the Czech Republic, Prague, Cyprus; [2]Inst. of Physiology, Acad. of Sci. of the Czech Republic, Prague, Czech Republic

Abstract: We would like to present an unique novel task developed in our laboratory for studying spatio-temporal integration in rats. As well as we are able to orientate in the space we also continually perceive time. For us it’s important to process the changes in this moving and diverse world and therefore we have to use these informations together. However yet this spatio-temporal integration hasn’t been studied extensively. For studying spatio-temporal integration, particularly integration of space and interval timing, we have developed a specialized tracking program called Arenomat. For our tasks we have applied classical behavioral apparatus - “Carousel” maze which is used to test animal’s spatial navigation and cognitive coordination. The apparatus consists of rotating arena with camera tracking animal’s movement. In original active allothetic place avoidance (AAPA) task is the animal trained to avoid aversive sector (usually 15 degrees wide) where a mild aversive stimuli is applied. Using Arenomat allows us to create novel and unique tasks which are analogs of AAPA task and allows us to test integration of spatio-temporal information. This include rotation of arena (different speeds and directions), precise timing of all processes, offering positive rewards (e.g. food pellet), negative stimuli (e.g. white noise, electric shock) and generating any kind of light or sonic stimuli. This novel test offers an insight into the cognition and behavior of rats during spatio-temporal integration and can be possibly a tool for studying neuronal mechanisms underlying this cognitive capacity. This work was supported by MSMT project LH14053 KONTAKT II.

Title: Cortical control of co-contraction and its use for the regulation of stiffness in brain-machine interfaces

Authors: *R. RUIZ-TORRES, L. E. MILLER;
Physiol., Northwestern Univ., Chicago, IL

Abstract: When interacting with different mechanical environments, humans regulate arm impedance in order to optimize stability and metabolic energy consumption. In 1982, Donald Humphrey described two distinct sets of neurons in the primary motor cortex (M1) of monkeys, one that was activated during reciprocal muscle activation, the other to control co-contraction. Brain-machine interfaces (BMI) have been successfully used to "decode" intended movement kinematics, and control robotic arms, but the users typically do not have control over impedance. We developed a BMI that controlled the activity of a virtual arm with a pair of simulated muscles spanning a single joint. The monkey learned to regulate the stiffness by co-contracting, but it did so using the same neurons involved in reciprocal contractions. We recorded neural activity from M1 and EMG activity from triceps and brachioradialis while a monkey generated isometric contractions of one or both muscles. We built a Wiener filter M1 to EMG decoder during a series of reciprocal muscle activations. During experiments, we fed the decoder outputs to the virtual dynamic arm. The torque applied to the joint was derived from the difference in activation between the two decoded muscles, with angular stiffness proportional to the co-contraction of the muscles. External forces could be applied to the endpoint of the virtual arm to displace it. When comparing neural activity between reciprocal and simultaneous muscle contractions, we were unable to find "co-contraction" neurons. Instead, we found a single population of neurons that was modulated during both reciprocal and simultaneous activation of the recorded muscles. The firing rate of single neurons did not modulate exclusively with the activation of any individual muscle. The monkey used the BMI to perform a task similar to Humphrey's, controlling the virtual arm as sinusoidal forces of different frequencies were applied to the endpoint. At a low frequency (0.25 Hz), the monkey was able to counter the perturbation by activating the simulated muscles reciprocally, with minimal co-contraction. At a high frequency (2 Hz), the monkey resorted to co-contracting, to increase the stiffness of the virtual arm. Implementing this approach to the control of a dynamic limb would allow BMI users to regulate the impedance of a robotic arm, making interactions with their environments safer and more natural.

Title: Concurrent independent brain-computer interface and movement control from the same cortical site

Authors: *L. BASHFORD[1,2], J. WU[3], D. SARMA[3], K. COLLINS[4], J. OJEMANN[4], C. MEHRING[2];
[1]Imperial Col. London, London, United Kingdom; [2]Bernstein Ctr. Freiburg and Biol. III, Univ. of Freiburg, Freiburg, Germany; [3]Dept. of Bioengineering, Ctr. for Sensorimotor Neural Engin., [4]Dept. of Neurolog. Surgery, Ctr. for Sensorimotor Neural Engin., Univ. of Washington, Seattle, WA

Abstract: Brain-Computer Interface (BCI) control can be disturbed by simultaneous movements that may be accompanied by neural activity in the same brain areas that are used for BCI control. Here we investigate whether it is possible to dissociate these competing activities and allow concurrent movements and BCI control. Furthermore we examine whether this concurrent control is accompanied by motor cortical reorganisation allowing for distinct cortical sites responding primarily to the BCI and less to movement behaviour. We present results from human ECoG studies where subjects perform concurrent BCI and movement control tasks, but where the same motor cortical region was used for both kinds of control. The channel over motor cortex most highly activated by finger movement in the contralateral hand was established in an initial screening. In the task this same finger movement controlled the horizontal movement of a computer cursor, whilst the mean power in the high gamma (70-90Hz) band from this same channel controlled the vertical movement of the cursor. Subjects had to move the cursor in a centre out paradigm to 8 targets spaced evenly on a circle. To reach the targets subjects had to learn to modulate the power in the band independently to the neural modulation that generated the finger movement. Subjects were able to gain this concurrent control indicating a dissociation of activity from the two behaviours at the control site. To examine if the BCI task caused any changes to the underlying activity at the control site subjects performed a force matching task by repeatedly gripping a force bulb in the fingers before any exposure to/and immediately after the BCI sessions. We compared the difference in activity for the force matching task pre and post BCI sessions and found differences in activity during the task after the BCI session compared to before the BCI session. This difference was confined to the control channel and occasionally

channels immediately around it also modulated during the task. The difference was most pronounced in the frequency band used for BCI control (70-90 Hz) while absent in many other bands also modulated during the task (e.g. beta 12-30Hz). Our preliminary findings demonstrate the potential for concurrent BCI and motor tasks and signs of motor cortex reorganization following this concurrent control, consistent with a re-assignment of activity from hand to BCI control, specific to the features used for BCI control. Future experiments aim to further refine this result.

Title: Neural responses to Activity-Dependent Stimulation (ADS) within different cortical areas

Authors: *A. AVERNA[1], D. GUGGENMOS[2], C. DUNHAM[3], S. BARBAY[3], G. VAN ACKER[4], M. CHIAPPALONE[1], R. NUDO[5];

Abstract: Behavior is driven by the complex interactions of neural activity within and between brain regions. Neurological disorders, such as stroke, disrupt this neural communication and presumably, nervous system reorganization is required in order to recover function. Facilitating functional recovery following stroke and other cortical lesions remains an ongoing clinical challenge. The post-injury synaptic plasticity related to the recovery process occurs spontaneously after a brain lesion and can be aided by electrical stimulation to modulate firing thresholds and promote neural activity. One technique, activity-dependent stimulation (ADS), utilizes the neural activity recorded from one site as a trigger for electrical stimulation at another site and has shown success in promoting behavioral recovery by re-establishing an artificial connection between somatosensory and pre-motor cortex following primary motor cortical injury. This technique is based upon Hebbian neural conditioning in which neurons that fire synchronously have an increased probability of enhancing connectivity through long term

potentiation (LTP) or long term depression (LTD) of existing synapses, and potentially, to create new connections through axodendritic sprouting. It remains unclear how pairing neuronal populations using ADS will impact their firing properties. The aim of the present work is to investigate whether or not ADS can be used to potentiate functional connectivity between distant cortical locations in healthy brain within a single four hour recording session in ketamine-sedated rats. Spontaneous and evoked activity within the rat pre-motor cortex was recorded using a sixteen-contact electrode and analyzed following either ADS or Gaussian (randomized) distributed stimulation approximating the frequency observed in ADS condition (trigger channel, ~7Hz). Based on known differences in anatomical connectivity, two cortical areas within S1 (forelimb responsive area or barrel field; FL or BF) were chosen for comparison of both spontaneous and stimulus-evoked firing. The results indicate that ADS was more effective than the randomized stimulation in modulating both spontaneous and evoked activity, further strengthening the idea that ADS could promote and potentiate cortico-cortical connectivity. Moreover this effect appears to be greater when the ADS stimulation occurs in BF rather than FL. These results are critical for understanding the electrophysiological effects of ADS, as well as providing information to optimize ADS for treatment following brain injury.

Title: Brain machine interface control through neurofeedback guided beta rhythm modulation

Authors: ***S. TORENE**[1], J. T. RITT[2], F. H. GUENTHER[3];
[2]Biomed. Engin., [3]Sargent Col., [1]Boston Univ., Boston, MA

Abstract: Brain-machine interfaces (BMIs) are an emerging medical treatment for many forms of motor impairments, including paralyzed and “locked-in” patients. Most BMI studies concentrate on decoding intended movement parameters within experimenter defined control

periods, when it is assumed the subject wants to move. However, the ability of the user to volitionally start and stop BMI control periods is also a critical requirement for BMI usability. Volitional control of the beta sensorimotor rhythm (SMR) could be used as a "brain switch" by the subject to indicate when the BMI decoder should start or stop decoding. We present a proof of concept that mice can use graded neurofeedback to increase beta SMR power in motor cortex. Freely moving mice in a neurofeedback task received water reward by controlling an auditory pitch cursor. The cursor was controlled through a modified beta LFP power measure from intracortical electrodes in vibrissal motor cortex. Beta power (13-30 Hz) was normalized by broadband activity to reduce motion artifacts. Bilateral EMG and slow speed video were used to confirm motor activity. Preliminary results show that: (1) behavioral performance improves over sessions; (2) post-hoc spectral analysis of the local field potential confirms that online beta power estimation is consistent with a true beta SMR; (3) beta activity is correlated to EMG activity, confirming the beta SMR's association with motor function; (4) mice are able to volitionally modulate beta power, shown by contrasting pre- and post-brain control sessions; and, (5) high beta activity predicts elevated EMG activity. This work illustrates the feasibility of using neurofeedback to create a beta SMR "brain switch" for motor BMIs.

Title: Semi-chronic chamber system for multi-scale electrophysiology in non-human primates

Authors: *A. L. ORSBORN[1], C. WANG[2], K. CHIANG[2], M. M. MAHARBIZ[3], J. VIVENTI[2], B. PESARAN[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Biomed. Engin., Duke Univ., Durham, NC; [3]Dept. of Electrical Engin. and Computer Sci., Univ. of California, Berkeley, Berkeley, CA

Abstract: Electrophysiology can monitor neural activity across many spatial scales_from highly localized firing of individual neurons to large-scale field potentials like electrocorticography (ECoG). Each signal may be useful for capturing different aspects of neural processing, but how measures at different spatial scales relate to one another is poorly understood. For instance, the sources of neural activity contributing to ECoG signals are unclear. Simultaneous multi-scale recordings will be critical for understanding relationships between individual neurons and larger-scale brain networks, and their links to behavior. Here, we present a technique for multi-scale electrophysiology and preliminary data exploring the relationships between spiking activity, local field potentials (LFPs), and ECoG in the cortex. We developed a semi-chronic chamber system to simultaneously record from subdural μECoG and a penetrating microdrive (Gray Matter Research) in non-human primates. The microdrive has independently-movable electrodes, providing 3D sampling of cortical volumes. The design is modular, scalable, and compatible with electrical and optical stimulation techniques. Our approach uses silicone artificial duras (ADs) for chronic subdural μECoG recordings and to align the ECoG and microdrive components within 250 μm tolerance. μECoG arrays are encapsulated within the AD. Impedance measurements show that this embedding procedure has minimal impact on recordings. The ADs (without an array) also provide optical access, transmitting 75-80% of 473nm light. We used this system to study the relationship between spike, LFP, and ECoG signals across cortical depths. We recorded from the post-central gyrus in an acute, anesthetized preparation from one non-human primate (macaca fascicularis). μECoG was recorded with a custom polyimide array with 5 μm thick Copper, 3 μm Nickel, and 150 μm Gold traces and contacts. The array had 124 contacts (200 μm in diameter; 0.75 - 1.5 mm spacing) and 32 holes (500 μm diameter) for the microdrive electrodes (glass-coated Tungsten micro-electrodes; 1.5mm spacing) to pass through. Spiking, LFP, μECoG signals were recorded as drive electrodes were lowered through the cortical tissue. Interestingly, coherence analyses of LFP and μECoG across depths suggest that μECoG may capture neural activity across multiple cortical depths in a frequency-dependent manner, rather than reflecting a single superficial source. Future work will focus on integrating optogenetic stimulation and increasing the scale of recordings to achieve large-scale multimodal, multi-scale recording and manipulation of neural circuits to study behavior.

Title: Stimulation in primate caudate nucleus modulates action selection in probabilistic reward task

Authors: *S. R. SUMMERSON[1,2], P. KHANNA[3], E. L. RICH[2,4], J. D. WALLIS[2,4], J. M. CARMENA[1,2,3];

Abstract: The mesolimbic and basal ganglia are crucial in arbitrating how sensory information, experience and motivation guide behavior. As such, the basal ganglia have been shown to play a role in decision-making and voluntary action. When this neural circuitry is operating in an aberrant manner, it can give rise to certain neuropsychiatric conditions, such as addiction and post-traumatic stress disorder. In this context, the reinforcement learning framework is useful for studying how decision policies are developed and, more importantly, how they can be biased. Deep brain stimulation is a potential therapy for altering decision policies and developing restorative and permanent treatments for those suffering from neuropsychiatric conditions. Here we ask how the value of alternative actions may be biased when electrical stimulation is administered in the caudate nucleus (Cd), part of the dorsal striatum. The striatum, is known to encode the value of alternative actions. In particular, Cd neurons encode action and decision values which are updated over time as more experience with the set of possible actions is gained. Using the nonhuman primate (NHP) animal model, we study how stimulation of the caudate in the time period preceding action selection influences subsequent decisions. Subjects are trained in a probabilistic reward task with both instructed and free-choice trials, where a trial consists of holding a computer cursor at a center target for a fixed length of time and then moving the cursor to a peripheral colored target. Each colored target has an associated probability of reward which is learned by the subject through exploration. During the center hold time, we expect that Cd encodes values of upcoming actions. Therefore, we delivered high-frequency stimulation during the hold time,on instructed trials to the lower value target. This stimulation is shown to significantly increase the likelihood of selecting the lower value target during subsequent free-choice trials relative to sham stimulation. Moreover, the effect is even greater if the action selected results in reward. We modeled the effects of temporally specific electrical stimulation in Cd with temporal difference learning models, and found that stimulation introduces a bias term in the model which results in a shifted action selection policy. This work supports further studies of the neural substrates of volition. Developing this vital understanding of decision making processing and how decision making can be mediated through stimulation will help inform novel closed-loop deep brain stimulation therapeutic approaches for treating people with neuropsychiatric conditions.

Title: Phase-dependent coding of decision information in posterior parietal cortex

Authors: ***D. J. HAWELLEK**[1], Y. T. WONG[1,3], N. D. DAW[1,2], B. PESARAN[1];
[1]Ctr. for Neural Sci., [2]Dept. of Psychology, New York Univ., New York, NY; [3]Electrical and Electronic Engin., The Univ. of Melbourne, Melbourne, Australia

Abstract: The posterior parietal cortex (PPC) plays a central role in integrating visual sensory information and upcoming actions. Firing rates of neurons in the PPC encode movement choices that animals make along with decision related variables such as expected value or confidence. Another hallmark of the PPC are rhythmic excitability fluctuations - the beta rhythm (~15Hz). Across the PPC and other sensory-motor structures neuronal spiking is robustly coupled to frequency specific phases of the local field potential (LFP). These two lines of observations have so far mostly been studied in separation, leaving a core question about PPC function unanswered: How do the encoding properties of neurons as seen in their spiking relate to the large-scale oscillatory network behavior? To address this we recorded single units and fields in the lateral and medial banks of the posterior intra-parietal sulcus while rhesus macaques engaged in a decision making task. More than 70 percent of all recorded neurons (74% monkey C, 71% monkey R, permutation test) contained significant mutual information (MI) about an upcoming movement choice in their firing rates. Likewise about 70 percent of all recorded neurons (69% monkey C, 68% monkey R, permutation test) showed significant spike-field coherence. Critically however we found that the MI neurons carried about an upcoming choice was modulated by the phase of the local field potential. We compared the MI about choice that

neurons contained in the firing rates at different phases of the beta oscillation to the MI obtained at random phases with identical sampling statistics. We found that MI is significantly non-uniformly distributed across LFP phases ($p<0.05$, permutation test). In addition, individual phase bins at around the trough of the beta oscillation showed significantly more MI (27.6% monkey C, 40.9% monkey R) than spiking at random phases ($p<0.05$, permutation tests FWER corrected). Interestingly, while spike count was symmetrically distributed around the spike-preferred phase, MI about choice was not and reached its peak slightly later (60°, monkey R). Our findings show that firing rate encoding properties of neurons in the PPC and large-scale circuit dynamics of sensory-motor structures are fundamentally linked. The encoding of sensory-motor decisions is temporally patterned by the beta rhythm. These findings have important implications for understanding the propagation of information in large-scale circuits. Furthermore, the design of brain-machine interfaces that target neural decision-making systems may benefit from incorporating neural time by closed-loop stimulation based on the LFP.

Title: Decoding arm movements using epidural ECoG in non-human primate

Authors: ***H. CHOI**[1], J. LEE[1], K. MIN[1], K. AHN[2], K. LEE[2], D. JANG[1];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The spatial resolution of electrocorticogram (ECoG) is known to be much higher than electroencephalogram. Recently, several studies have reported usability of epidural electrocorticogram (eECoG) for brain computer interface (BCI). eECoG is less invasive, and less inflammatory than traditional ECoG (subdural ECoG). However, the feasibility and performance of eECoG on BCI were not fully evaluated yet. In this study, we verified the usability of implanted eECoG in non-human primate by decoding the three dimensional arm trajectories using eECoG signals. Two micro electrode patches (32 channels) were inserted over duramater

on rhesus monkey's brain covering premotor cortex, primary motor cortex, and primary somatosensory cortex. Three motion sensors (IMU: Inertial Measurement Unit) were attached shoulder, upper arm, and lower arm. The monkey performed four directional arm movement tasks responding to target's location change (45, 135, 225, 315 degrees). We contemporary recording the arm movement signals and brain signals for 1hour, twice a week. The signal was analyzed off-line using MATLAB. To computing the correlation coefficient between the arm movement and brain signal, we used regression algorithm, time frequency power of the brain signals, and Cartesian (xyz) position of the movement signals. As results, some frequency bands of the brain signals were significantly correlated with the arm position and arm movement preparing. So we verified the eECoG's feasibility and showed significant and stable decoding performance over several months. This could support the efficacy of BCI using eECoG and the various neuro-prosthetics fields.

Title: Changes in functional connectivity due to brain-computer interface learning

Authors: K. CASIMO[1], *K. E. WEAVER[2], J. D. WANDER[3], A. KO[4], J. G. OJEMANN[4], F. DARVAS[4];

Abstract: Prior work on brain-computer interface (BCI) learning mechanisms has focused on changes in connectivity of the BCI-driving site during the task itself. Connectivity between a motor cortex BCI-driving site and distant sites has been observed. However, patterns between those distant sites have not been characterized, and the persistence of these changes after the BCI task has not been examined. We used phase coherence, also called phase locking value (PLV), to evaluate changes in resting state connectivity after BCI learning between functional anatomical

regions including and beyond the BCI site. Participants were trained to use a challenging two-dimensional BCI with electrocorticographic (ECoG) electrodes implanted directly on the surface of the cortex. Electrode position was controlled with modulation of high gamma (HG, 70-200Hz) power in hand motor cortex controlled vertical position of the electrode. After BCI learning, we found significant increase in beta (13-30Hz) PLV between sensorimotor (SM) cortex (location of the BCI control site) and lateral parietal lobe, within the parietal lobe, and between other known skill-learning network sites (Figure, A). There were significant increases in HG PLV within SM and within parietal cortex, but not between SM and parietal cortices. Notably, this is a broad HG range (70-200Hz), such that these effects would not be seen in traditional coherence measures. We also evaluated slow (<1 Hz) amplitude modulation of HG, a marker of stable cortical networks (Ko et al., 2013). We found significant increases in frontal-temporal and temporal-parietal PLV and significant decrease in SM-dlPFC PLV (Figure, B). Persistence of changes in connectivity after the task implies that the observed changes are due to robust skill learning and consolidation. Control site connectivity to learning-related regions and increases in connectivity between regions other than the BCI site further support the view that BCI skill acquisition depends on a widespread network of cortical regions that interact directly besides their interactions with the BCI control site.

Title: Towards a responsive deep brain stimulation system for essential tremor

Authors: *E. OPRI[1], J. B. SHUTE[1], R. MOLINA[2], K. FOOTE[3], M. S. OKUN[4], A. GUNDUZ[1]; [1]Biomed. Engin., [2]Electrical Engin., [3]Dept. of Neurosurg., [4]Dept. of Neurol., Univ. of Florida, Gainesville, FL

Abstract: Essential Tremor (ET) is one of the most common movement disorders defined as a rhythmical, involuntary oscillatory movement of the limbs. Intention tremor occurs in the hands and arms, typically with a slow oscillation (~5-10 Hz). It is experienced during the initiation and execution of goal-directed reaching motions, while it is absent at rest. Although the pathophysiological basis of ET remains unknown, a pathological synchronous oscillation in a neuronal network involving the thalamus, especially the ventral intermediate nucleus (Vim), the premotor (PM) and primary motor (M1) cortices, and the cerebellum has been suggested. It is assumed that deep brain stimulation (DBS) suppresses tremor by masking the "tremor cells" in the Vim. The aim of this study is to implement a responsive therapeutic stimulation that would activate only in the presence of specific biomarkers such as movement intention (mu rhythm on motor and premotor cortices), presence of tremor (accelerometer), coherence between electrocorticography (ECoG) and accelerometer. This approach would allow theoretically to deliver an equally effective treatment while avoiding most of the stimulation side effects such as balance and speech impairment, and slowing the battery depletion of the implant.

Title: Detection of tourette syndrome tics via centromedian thalamus lfp and acute trial of closed loop stimulation

Authors: *J. B. SHUTE[1], E. ORPI[2], R. MOLINA[2], J. ROSSI[3], M. OKUN[2], K. FOOTE[2], A. GUNDUZ[2];
[1]BioMedical Engin., UF, Gainesville, FL; [2]Univ. of Florida, Gainesville, FL; [3]Univ. of Florida, gainesville, FL

Abstract: Tourette Syndrome (TS) is a paroxysmal neuropsychiatric disorder characterized by involuntary movements or/or vocal outbursts known as tics. Deep brain stimulation (DBS) is an emerging therapy for cases of severe and intractable TS. DBS is an invasive neuromodulatory therapy in which depth electrodes are placed within deep subcortical structures of the brain and high frequency electrical stimulation is used to modulate pathological neural activity. Recent TS DBS studies have indicated that low frequency local field potentials between 1-15 Hz (lf-LFP) within the centromedian thalamus (CM) were observed during tics. We investigated the presence of lf-LFP in the CM. Two subjects, TS01 and TS02, suffering from severe and intractable TS were implanted with DBS. Both subjects were implanted with CM depth electrodes bilaterally and EcoG strips over the primary and premotor cortices (hand region). Subjects were asked to perform three conditions: Baseline (data containing no tics or movements), volitional movements (data containing no tics) and ticing (data containing tics but no volitional movements). LFP data was collected concurrently with accelerometers, EMG, and video. Data was collected from TS01 and TS02 during surgery and every month postoperatively for 6 months. A neurologist analyzed video data and tic times were determined. LFP data from the motor strip and CM was bandpassed into 10 Hz bins and rectified. The top 3 discriminated features (between baseline and tics) were used. A support vector machine was trained to detect tics. TS01 exhibited long duration tics that were dystonic in nature affecting primarily the right-sided arm, neck, and face. TS02 exhibited vocal tics, flicking the middle finger, and sustained mumbling tics. lfLFP were observed in both TS01 and TS02 at or around the time of tic. Tics of long duration (longer than 5 seconds) were detected with a high precision (85-100%) and recall (85-100%) across every month with TS01 and across the first 3 months with TS02. Short duration tics (less than 5 seconds) were detected with less than 70% recall and precision for every month. The top 3 features were low frequency CM (1-10Hz , 11-20Hz , 20-30Hz). No changes in CM LFP were observed during volitional movements or during baseline. lf-LFP were used to drive close loop stimulation in the acute setting. Stimulation was triggered off of positive detections and was verified with video and accelerometers.

Abstract: Objective: The use of brain-computer interfaces (BCIs), including those driven by electrocorticography (ECoG), allows for exploration of brain function exploration and rehabilitative applications. Commonly, BCIs are controlled by activity changes in primary motor cortex that occur when subjects perform motor imagery. The default mode network (DMN) comprises brain regions thought to be active during a resting state. During periods of attention, such as a BCI task, the neural activity in DMN regions *decreases*, which is referred to as task induced depression (TID). The goal of this study is to explore if TID can be used for BCI control. **Methods:** Subjects (n=3) implanted with ECoG grids performed a 2-target right justified box task (2-RJB) controlling the BCI with activity from an electrode over putative DMN regions. The electrode for control was picked as one showing high gamma (HG, 70-200 Hz) suppression during goal-oriented behavior. HG power increases drove the cursor down, and HG decreases the opposite. 2 subjects also attempted a 3-target RJB (3-RJB). **Results:** 1 of 3 subjects performed above chance for the 2-RJB. Neither of the 2 subjects performed above chance for the 3-RJB. Significant ($p<0.05$) differences in the HG power were seen between both up and down target presentation, when comparing neural activity during the task to a rest period for the above chance subject. For down targets, HG power increased relative to rest, while for up targets, HG power decreased. No significant difference was seen between the rest periods for up and down targets. **Conclusions:** Novel DMN BCI via ECoG derived signals was demonstrated in one subject. This subject modulated HG power both above and below baseline when completing the task, which is distinct from motor cortex-driven BCI, where modulation above baseline only is commonly observed. DMN electrode controlled BCI could be a viable alternative to motor

cortex control. However, as evidenced by the failure of 2 subjects to perform above chance, and the inability to execute the 3-RJB, DMN control may be more difficult and further development is necessary.

Title: Changes in post-synaptic efficacy of primate corticospinal cells is associated with compensatory changes in firing patterns

Authors: Y. NISHIMURA[1], S. I. PERLMUTTER[2], R. W. EATON[2], *E. E. FETZ[2];
[1]Dept. of Developmental Physiol., Natl. Inst. for Physiological Sci., Okazaki, Japan; [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: Motor learning and functional recovery from brain damage involve changes in the strength of synaptic connections between neurons as well as changes in neuronal activity. Whether changes in post-synaptic efficacy of a neuron are reflected in its activity pattern is largely unknown. We previously documented that the size of post-spike effects of primate corticomotoneuronal (CM) cells can be modified with a recurrent neural interface that delivers spike-triggered stimuli in the spinal cord during free behavior (Nishimura et al., 2013). These post-spike effects on muscle activity are a direct measure of the strength of the cells' synaptic connections and were modified for particular spike-stimulus delays according to a spike-timing dependent plasticity rule. We also documented the directional tuning of these cortical neurons in a 2D target-tracking task requiring isometric forces about the wrist. Here, we show that cells with strengthened CS connection exhibited decreases in the tuning depth, indicating that stronger post-synaptic efficacy was associated with lower firing rates. Significant decreases in cell tuning were produced after conditioning with spike-stimulus delays between 12 and 25 ms, but not 50 ms and longer, consistent with the effects on synaptic strength. For some cells, the decreased cell tuning lasted for days after the end of conditioning, but in most cases tuning eventually reverted to preconditioning levels. This relation between changes in synaptic efficacy and changes in firing patterns indicates that firing rates compensate for the changed output of CM cells and synchronized cells.

Title: Neural ensemble activity characterizes sleep states, active movement, and movement observation in motor cortex

Authors: *J. B. ZIMMERMANN[1,2], C. E. VARGAS-IRWIN[1,2], J. P. DONOGHUE[1,2,3,4]; [1]Dept. of Neurosci., [2]Inst. for Brain Sci., [3]Sch. of Engin., Brown Univ., Providence, RI; [4]Ctr. for Neurorestoration and Neurotechnology, Rehab. R&D Service, Dept. of VA Med. Ctr., Providence, RI

Abstract: Detection of behavioral states is an important feature of any brain-computer interface suitable for 24h operation. Periods of sleep can resemble rest in local field potentials or movement when comparing firing rates. Here we demonstrate distinct representations of action, action observation, rest, and sleep periods in a low dimensional neural state space. We recorded simultaneous ensemble neural activity from primary motor cortex, and dorsal and ventral premotor areas from the rhesus macaque while the monkey was engaged in a reach to grasp task, observed an experimenter perform the same task, and during sleep. In accordance with previous experiments, we found that overall neural activity is decreased during sleep compared to movement, observation, and rest in all three areas. Nevertheless, short periods of high neural activity occur during sleep, with firing rates comparable to movement periods. We used spike train similarity measures and dimensionality reduction techniques to project ensemble activity during movement, action observation, rest, and sleep into low-dimensional neural state spaces. In all areas, active movement trials cluster separately from observation trials during object contact. Rest in inter-trial periods constitutes another cluster. Periods of sleep again constitute a separate cluster, with some overlap with resting periods. Whereas both action observation and movement trials exhibit a distinct pattern of cycles in neural state space, such organization does not seem to occur in sleep periods. Transient increases in firing rates occur during all the behaviors investigated, yet we can distinguish between different behavioral states using unique signatures in neural dynamics. Automatic detection and classification of such states will be a valuable tool for calibration of closed-loop BCIs.

Title: Predicting decision outcomes from single realizations of lateral prefrontal cortex neuronal activity

Authors: *C. BOULAY[1,3], M. LEAVITT[4], F. PIEPER[5], J. MARTINEZ-TRUJILLO[6,4], A. SACHS[2,3];
[1]Neurosciences, [2]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada; [4]McGill Univ., Montreal, QC, Canada; [5]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [6]Univ. of Western Ontario, London, ON, Canada

Abstract: Neurons in the lateral prefrontal cortex (LPFC) encode sensory and cognitive signals, as well as commands for goal directed actions. Thus, this brain region might be a good signal source for a goal-selection brain-computer interface (BCI) that decodes the intended goal of a motor action previous to its execution. Toward the development of a goal-selection BCI, we set out to determine if we could decode saccade goals from single-trial LPFC neuronal activity. We recorded neuronal spiking activity from microelectrode arrays implanted in area 8A of the LPFC of two adult macaques while they made visually guided saccades. The rewarded target was indicated by a colour cue and we changed periodically the association between colour and rewarded direction. We extracted neuronal firing from single-trial LPFC activity in the pre-saccade period and predicted saccade targets using support vector machines with 10-fold cross-validation. Binary decision outcomes were decoded from pre-saccadic single-trial LPFC activity with better-than-chance accuracy. Decoder performance remained high when examining groups of trials with identical visual stimuli but different behaviour (>80%). Further, some LPFC activity was dependent on contextual information independent of visual information and saccade performance. These results provide further evidence that LPFC neurons encode decision processes and suggest that LPFC activity can be used as a signal source for a goal-selection cognitive BCI.

Title: Transfer of operantly conditioned firings between different neuron groups with BMI in rats

Authors: *K. SONG, S. TAKAHASHI, Y. SAKURAI;
Grad. school of brain science, Doshisha Univ., Kyoto-Hu, Japan

Abstract: It has been proved that controlling a neuroprosthesis is possible by selectively conditioned firings of a specific neuron group consisting of some neurons. It is also postulated that both a single neuron and a neuron group are able to be operantly conditioned to modulate their firings in isolation with neighboring neurons, which is called neural operant conditioning. However, it has not been clearly demonstrated if transfer of the operantly conditioned firings of a neurons group to other neuron groups is facilitated with neural operant conditioning. In this study, multiple neuron groups were recorded by multiple bundles of microwires implanted in the motor cortex of behaving rats. Experiment sessions started after firings of at least 2 neuron groups were identified in the rat's motor cortex. In pre-learning stage, the rats were trained to perform a behavioral free-operant task in which nose-poke behaviors were rewarded. During leaning stage, the rats were rewarded whenever firings of the neuron group 1 detected in real-time with a brain-machine interface (BMI) system satisfied preset criteria. After learning of the neural operant task with neuron group1 was completed, the rats conducted the identical neural operant task using firings of the neuron group 2. Data of each of the neuron groups were analyzed offline. Firing rates, reward rates and delays to reward delivery, were employed to examine the hypothesis that neuronal operant learning of neuron group 1 is transferred and facilitates the conditioned modulation of the neuron group 2. A preliminary results examining the hypothesis will be reported. It has been said that the most critical problem of neural operant conditioning using a small number of neurons is its limited life as sources of signals for

volitional motor outputs to control a neuroprosthesis. In this respect, transfer of operantly conditioned firings between different neuron groups is profitable to compensate the limited life of source signals. The result of this study is expected to contribute to advances in neurorehabilitation and neuroprosthesis.

Title: Supraoptic nucleus of hypothalamus modulates cardiovascular responses evoked by acute restraint stress in rats

Authors: *S. LOPES AZEVEDO, E. A. FORTALEZA, A. A. SCOPINHO, C. BUSNARDO, F. M. A. CORREA;
Pharmacol., Sch. of Med. of Ribeirao Preto/USP, Ribeirão Preto, Brazil

Abstract: Objective: The present work studied the possible involvement of supraoptic nucleus of hypothalamus (SON) neurotransmission in the mediation of restraint stress-induced autonomic changes. Methods: Guide cannulae were implanted bilaterally in the SON of rats for the microinjection of either drugs or vehicle, and a polyethylene catheter was implanted into the femoral artery for recording of mean arterial pressure (MAP) and heart rate (HR) using a computerized acquisition system. Tail temperature was evaluated using a thermal camera. Rats were subjected to restraint stress 10 min after the microinjection of drugs or vehicle into the SON and studied the effect of the bilateral microinjection of the nonspecific synaptic blocker cobalt chloride (CoCl2, 1mM/100nL) into the SON on hypertension, tachycardia and a reduction in tail temperature induced by restraint stress. Results: The CoCl2 pretreatment of the SON significantly reduced the restraint-evoked increase in MAP ($F_{1,600}= 252.0$, $P<0.0001$, $n= 6$) and potentiated the restraint-evoked increase in HR ($F_{1,600}= 188.5$, $P<0.01$, $n= 6$), when compared with ACSF-treated animals (vehicle, 100nL, $n= 5$). Conclusion: These results show that local SON neurotransmission participates in the neural pathway which is involved in the modulation of pressor and tachycardiac responses observed during acute restraint stress in rats, suggesting

facilitatory and inhibitory roles respectively on MAP and HR of this structure in this aversive situation.

Title: Heart-rate variability and power spectral densities as neurophysiological indices of post-traumatic stress disorder

Authors: ***R. T. CHANG**[1], S. J. SMITH[1], V. TAN[1], K. A. CORREA[1], M. CRYSTAL[2], R. JOHNSON[1], C. BERKA[1];
[1]Advanced Brain Monitoring, Carlsbad, CA; [2]BBN Raytheon, West Newton, MA

Abstract: The identification of the neurophysiological biomarkers for post-traumatic stress disorder (PTSD) has been an ongoing challenge for many researchers. Over the past decade, studies have examined the neurophysiology of PTSD using both electroencephalogram (EEG) and electrocardiogram (ECG) to investigate cognition and the autonomic nervous system (ANS). These studies have shown both EEG frequency bandwidths (BW) -particularly the Alpha and Theta range- and ANS activation, measured by low (LF) vs. high (HF) frequency ratio of heart rate variability (HRV), are altered in PTSD populations. Elevated LF:HF ratios are associated with greater sympathetic activation (and stress/anxiety states), while altered Alpha and Theta can be associated with arousal dysregulation. This study's objective was to further explore the neurophysiological biomarkers of stress by utilizing a tool that systematically elicits a genuine stress response while simultaneously recording EEG and ECG. A total of 96 participants from three different cohorts were recruited for the study: Healthy control, a high stress population measured by current level of major life stressors (MLS), and a population diagnosed with combat-related PTSD. A series of questionnaires and audio-visual stimuli were presented. The stimuli consisted of videos and images of generically negative content as well as negative content related to the participant's traumatic experience (e.g. autobiographical) indicated through their initial questionnaire. Initial results show that LF:HF ratios increased in all groups; with the

PTSD group showing a greater increase in sympathetic response from the baseline tasks (3CVT, A-PVT, and VPVT) to the audio-visual stimuli. In addition, there is an effect of task type (i.e. neutral vs. autobiographical content) for Theta (3-7Hz), Alpha (8-12Hz), Beta (21-30Hz), and Gamma (31-40Hz), indicating arousal changes throughout the protocol, across all conditions. These data suggest that those with PTSD are experiencing higher levels of arousal and stress that does not allow them to disengage from autobiographically reported stressors. Efforts to continue to build a foundation for the understanding of the biological basis and potential predispositions for PTSD may help enable the discovery of better interventions, training, and preventative solutions.

Title: Sigma-1 receptor mediates depressive behaviors induced by cardiovascular diseases

Authors: *K. FUKUNAGA, Y. SHINODA;
Tohoku Univ. Grad Sch. Pharm Sci., Sendai, Japan

Abstract: Cardiovascular diseases are risk factor to cause the depression in human. We recently defined that an impaired sigma-1 receptor (Sig-1R) function accounts for SSRI-resistant depressive behaviors in CaMKIV null mice (Mol Neurobiol DOI 10.1007/s12035-014-8923-2). We here hypothesized that 1) the impairment of Sig-1R in brain triggers the depressive behaviors in cardiovascular disease patients and 2) Sig-1R stimulation improves its depressive behaviors. To test our hypothesis, cardiac hypertrophy and heart failure were induced by transverse aortic constriction (TAC). Hyperfunction of hypothalamo-pituitary-adrenal axis was induced by

chronic corticosterone administration in mice. Oral administration of a specific Sig-1R agonist SA4503 (0.3-1.0mg/kg) significantly improved TAC-induced depressive behaviors with restoration of Sig-1R expression in both hippocampal CA1 and DG regions. Indeed, the plasma corticosterone levels were significantly elevated in 6 weeks after TAC concomitant with depression-like behavior expression. The chronic corticosterone administration for 3 weeks caused depressive behaviors with the reduction of Sig-1R expression in the hippocampus. Consistent with the improvement of depression behaviors, heart failure was also ameliorated by SA4503 (0.3-1.0mg/kg) administration. Taken together, Sig-1R stimulation with SA4503 is attractive therapy to improve not only depressive behaviors but also heart failure following cardiovascular diseases. Title: Anorexia induced stress involved changes in neurons morphology and neurotrophic factors in the serotonin 4 receptors knockout mice

Authors: *M. EL OUAHLI[1], F. CHIGR[1], M. NAJIMI[1], V. COMPAN[2];
[1]Life Sci., Fac. of Sci. and Techniques, Beni Mellal, Morocco; [2]institut de Génomique Fonctionnelle, Montpellier, France

Abstract: Adaptive decision-making to eat is crucial for survival but in neurodegenerative and mental diseases, the brain persistently supports persistent changes in food intake. How the brain persists in reducing or enhancing food intake to the point of death despite the evolution of multiple mechanisms to ensure survival by governing adaptive eating behaviors in front of stress remains mysterious. In order to study the functions of 5-HTR4, we previously engineered the 5-HTR4 knockout mice (KO4) and evidenced their critical role in anorexia-like and binge eating.

Here, we show an absence of increase in the production of the phosphorylated cAMP responsive element binding protein (CREB) in the hypothalamus in KO4 mice following acute stress. As pCREB is a transcription factor, we conducted transcriptom and RQ-PCR analyses. We evidenced that the 5-HTR4 control the expression of neurogenesis and DNA methylation factors suggesting that 5-HTR4 could induce persistent morphological changes of neurons and favor a persistent restrictive food intake. Consistently, we found that 5-HTR4 exert a positive control of the anorectic brain-derived neurotrophic factor in the medial prefrontal cortex, in which 5-HTR4 control stress-induced anorexia. The number of dendritic spines of pyramidal cells in the medial prefrontal cortex is reduced in the absence of 5-HTR4, which may support the abnormal resistance of KO4 mice to chronic stress-induced hypophagia. The present study shows that 5-HTR4 may contribute to implement neural networks by controlling gene expression of neural growth factors that are involved in adaptive behavior to stress.

Title: Stress, anorexia and neuroendocrine regulation of food intake

Authors: ***M. NAJIMI**[1], F. CHIGR[2];
[1]Life Sci., [2]Fac. of Sci. and Techniques, Beni Mellal, Morocco

Abstract: Food intake (FI) regulation in adult mammals is integrated mainly by 2 brain structures: the hypothalamus and the dorsal vagal complex (DVC). Short-term regulation, which consists in reflex arrest of FI under stomach filling or satiety reflex, is triggered by vagus nerve afferents to the DVC. Long-term regulation consists essentially in satiety reflex threshold which involve the hypothalamus and its reciprocal connections with the DVC Furthermore, numerous circulating peptides influence FI through their actions on the hypothalamus, the brainstem and the autonomic nervous system. The physiological importance of this homeostatic control system

is highlighted by FI deregulations causing eating disorders like anorexia and their associated complications. The relation between several stress paradigms and FI dysregulation is well evidenced. They may affect the central regulation, probably by interacting with factors involved in this regulation. Therefore, we decided to study the long-term effects of a single exposure to immobilization stress (IS)on the expression of anorexigenic and orexigenic factors such as neuropeptide Y (NPY), Agouti Related Peptide (AgRP), Pro-opiomelanocortin (POMC) and cocaine- and amphetamine- regulated transcript (CART)in different brain structures related to FI control. In order to investigate the involvement of the signaling of these peptides in the food control, notably in the context of FI alterations (anorexia caused by stress), we analyzed the hypothalamic and DVC expression of the mRNAs of these peptides. We showed, by using RT-PCR that the mRNAs of the peptides analyzed display significant increases in stressed rats compared to controls, although with differential peaks. In hypothalamus, NPY and CART transcript up-regulation is observed at the end of IS and persists until 48-72h after IS. In the DVC, expression of the 2 transcripts peaks significantly at 24h post-stress and decline afterwards; NPY mRNA remains then significantly higher than in controls, whereas CART mRNA is down-regulated after 48h post-stress. The comparison between the expression profiles of anorexigenic and orexigenic peptides investigated shows also the presence of a parallelism between that of POMC and AgRP. The persistence of alteration of the expression of anorexigenic and orexigenic factors during the post-stress period could be highly related to the slow recovery of the hypothalamo-hypophyseo-adrenal (HPA) axis in IS and points to stress-induced plasticity in both nervous centers of food intake regulation.

Title: Anti-inflammatory effects of PGRN on the temperature and food intake via suppressing the level of circulating cytokines

Authors: *T. MATSUWAKI, K. YAMANOUCHI, M. NISHIHARA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Progranulin (PGRN) is a multifunctional growth factor expressing widely in the whole body. We have previously identified PGRN as one of the genes that play important roles in masculinization of the brain during the perinatal period. On the other hand, it has recently reported that haploinsufficiency of PGRN is the major factor causing frontotemporal lobar degeneration. Subsequently, many other researches including ours have demonstrated the neuroprotective, neurotrophic functions of PGRN. We have also shown that PGRN is involved in voluntary exercise-induced neurogenesis and suppression of neuroinflammation after traumatic brain injury. As PGRN is expressed in the immune cells both in the peripheral and central tissues, the main purpose of the present study is to elucidate the role of PGRN in the inflammatory responses to immune challenge. In all the experiments, male C57BL/6J wild-type (WT) mice or PGRN-deficient (KO) mice of the same background were used. We intraperitoneally injected lipopolysaccharide (LPS, 120 μg/kg) to the animals and measured the body temperature for 9 hours in the daytime and food intake for 24 hours. Although LPS induced fever response and anorexia in the mice of both genotypes, the symptoms were much severer in the KO mice. LPS is known to induce the secretion of the inflammatory cytokines that transmit the immune signal from the peripheral to the central tissues. Thus, we subsequently determined the serum concentration of inflammatory cytokines i.e. IL-1β, IL-6 and TNF-α at 0, 1 and 3 hours after LPS injection. KO mice showed the significantly stronger induction of the IL-6 at 3 hours and TNF-α at both 1 and 3 hours after injection. IL-1β also had the tendency of stronger induction at 3 hours in KO mice although it did not reach statistic significance. These results suggested that PGRN suppresses excessive inflammatory responses by moderating secretion of inflammatory cytokines in the peripheral tissue.

Title: Erythropoietin and high fat diet-induced brain inflammation

Authors: S. DEY[1], J. ANHUT[1], M. GASSMANN[2], *C. T. NOGUCHI[1];
[1]Mol. Med. Branch, NIDDK, NIH, Bethesda, MD; [2]Univ. of Zurich, Zurich, Switzerland

Abstract: Erythropoietin (Epo), known for its hematopoietic role, inhibits obesity-induced white fat inflammation in mice, is also produced in brain by astrocytes, and its receptor (EpoR) is expressed in microglial cells. Microglial cells respond to saturated fatty acids present in high fat-diet (HFD) by producing inflammatory cytokines that disrupt the energy homeostatic regulation by the hypothalamus. We hypothesized that Epo signaling in brain could regulate HFD-induced microglial activation and thereby maintain metabolic homeostasis. Intracerebroventricular Epo (ICV-Epo) administration in HFD-fed wild-type mice for 4 weeks resulted in lower fasting glucose levels and lower weight gain compared to saline control (ICV-saline). Moreover, ICV-Epo and ICV-saline groups did not show any difference in hematocrit, indicating no peripheral hematopoietic effect, and showed equal food intake during that time period. ICV-Epo administration significantly reduced brain mRNA expression of inflammatory markers IL-1β, TNFα, and SOCS3 and increased mRNA levels of anti-inflammatory protein IL-10 compared to saline control. Chronic over-expression of human Epo transgene in brain (Tg21 mouse model) also prevented increase in fat mass after HFD-feeding for 3 weeks compared to wild-type (WT) control. We examined primary mouse microglial cells to assess direct Epo anti-inflammatory response using palmitic acid (PA) that activates inflammatory response. PA significantly increased TNF-α, IL-1β, and SOCS3 mRNA, while co-treatment with Epo significantly reduced TNF-α and IL-1β mRNA expression and showed an increased trend in IL-10 mRNA expression. In summary, these studies suggest an important extrahematopoietic and homeostatic function of Epo in brain inflammation and metabolism.

Title: T cells mediate behavioral, hormonal and cytokine responses in the learned helplessness paradigm

Authors: *S. M. CLARK[1,2], C. SONG[1], X. LI[1], L. H. TONELLI[1,2];
[1]Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Res. and Develop. Service, Dept. of Veterans Affairs, VA Maryland Hlth. Care Syst., Baltimore, MD

Abstract: Accumulating evidence supports a multifaceted role for T cells in behavioral responses to stress. Whether this role is protective against or potentiates the detrimental effects of stress appears to depend on the type of T cell studied, the mode and intensity of stressor employed, and the genetic background of the animal model utilized. In this study we examined the impact of naïve $CD4^+$ and $CD8^+$ T cells on several aspects of the stress response in immune deficient *Rag2*$^{-/-}$ and wild type (WT) C57BL/6 mice that underwent the learned helplessness (LH) paradigm. This protocol allows for the evaluation of these responses immediately following an initial, inescapable stress session and after repeated stress exposure. *Rag2*$^{-/-}$ mice in this study were more resilient in the LH paradigm, displaying reduced behavioral interference and a more rapid recovery to basal plasma corticosterone levels compared to WT mice. While reconstitution with T cells failed to completely recapitulate the WT behavioral phenotype there was a shift towards increased susceptibility and a significant increase in plasma corticosterone in the absence of overt T cell activation. Furthermore, the presence of T cells was sufficient to reduce levels of mature brain derived neurotrophic factor in the hippocampus after inescapable stress exposure, suggesting that T cell mediated regulation of neurotrophic factors may be an important link between the immune system and changes in neuronal function and subsequently, behavior. Our results indicate that T cells, are capable of affecting several facets of adaptive responses to stress, including behavioral, hormonal and cytokine responses.

Title: Early life stress activates microglial cells and induces an inflammatory response in the hippocampus of male rat pups

Authors: *L. TORNER[1], A. ROQUE GALICIA[1], A. OCHOA ZARZOSA[2];
[1]Inst. Mexicano Del Seguro Social, Morelia, Mexico; [2]Ctr. de Estudios Multidisciplinarios enBiotecnologia, Univ. Michoacana deSan Nicolas de Hidalgo, Morelia, Mexico

Abstract: Adult animals subjected to chronic stress show an inflammatory response in the hippocampus which has been related to cognitive dysfunction and psychopathology. However the immediate consequences of early life stress on hippocampal glial cells have not been studied. Here we analyzed the effects of maternal separation (MS) on astrocyte and microglial cell morphology in the hippocampal hilus, compared the expression of cytokines in the hippocampus and hypothalamus, and the peripheral response of cytokines, under basal conditions or stress exposure, on postnatal day (PD) 15. Male rat pups of MS (3h/day, PD1-PD14) and Control (undisturbed) groups showed similar cell densities of microglial cells in the hilus, but MS pups had significantly more activated microglia. The number of astrocytes was decreased and had fewer branches in the MS group compared to control group. Cytokine mRNA expression (qPCR) was analyzed in MS and Control groups, sacrificed i) under non-stressed, basal (B) conditions or ii) after a single stress event (SS) at PN15. Hippocampal extracts from MS pups showed an increase in IL-1β mRNA, under basal (B) and after a single stress (SS) event, compared to Controls. IL-6 was unchanged in both groups under B and SS conditions. TNF-α mRNA increased in control pups only under SS conditions. In MS pups, TNF-α mRNA increased in B but not after SS. In hypothalamic tissue, no differences were found in cytokine expression levels between both groups. In trunk blood, MS decreased IL-1β levels under B and SS conditions; IL-6 levels decreased in B but increased after SS in MS pups. TNF-α levels were unchanged in both groups. In conclusion MS activates microglial cells, decreases astrocyte number, and exacerbates the immediate inflammatory response to stress in the hippocampus, but triggers a differential response of peripheral cytokines. This indicates an independent response to stress of the brain immune system to that of the periphery. (Supported by CONACyT CB2014 No.243419 and FIS/IMSS/PROT/G14/1299)

Title: Differential effects of stress on microglial cell activation in male and female medial prefrontal cortex

Authors: *J. L. BOLLINGER[1,2,3], C. L. WELLMAN[1,2,3];
[1]Dept. of Psychological and Brain Sci., [2]Program in Neurosci., [3]Ctr. for the Integrative Study of Animal Behavior, Indiana Univ., Bloomington, IN

Abstract: Susceptibility to multiple stress-linked psychological disorders differs between men and women, with women nearly twice as likely to suffer from post-traumatic stress disorder and major depression. Various stress-linked structural and functional changes in medial prefrontal cortex have been implicated in these disorders, alongside numerous cognitive-behavioral deficits. Chronic stress affects medial prefrontal cortex in a sex-dependent manner, differentially remodeling neuronal morphology and disrupting prefrontally-mediated behaviors in males and females. Emerging evidence suggests that acute and chronic stress induce microglial cell-mediated inflammation in medial prefrontal cortex. In male rats, chronic restraint stress increases microglial cell density and activity, reflected in altered microglial morphology in medial prefrontal cortex. Unstressed female rats exhibit increased microglial cell density and ramification in several brain regions compared to males, suggesting both heightened basal activation and a potential for sex differences in the effects of stress on microglial cell morphology. Therefore, we assessed microglial cell density and morphology in the prelimbic region of medial prefrontal cortex in male and female rats following acute (3 h, 1 d) or chronic restraint stress (3 h/d, 10 d). Control animals were left unhandled except for weighing. On the final day of restraint, rats were euthanized and brains were processed for visualization of microglia via Iba-1 immunohistochemistry. Microglia in medial prefrontal cortex were classified as ramified, primed, reactive, or amoeboid, and counted stereologically. Unstressed females showed a greater proportion of primed microglia relative to males. Acute and chronic restraint stress reduced the proportion of primed to ramified microglia in females, but did not significantly alter microglial morphology in males. This sex difference in microglial activation could contribute to the differential effects of stress on medial prefrontal cortex structure and function in males versus females.

Title: Involvement of progranulin in regulating neurogenesis and microglial activation in the hippocampus under acute infectious stress conditions

Authors: *Y. MA, T. MATSUWAKI, K. YAMANOUCHI, M. NISHIHARA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Infectious stress stimuli have been shown to suppress adult neurogenesis and enhance microglial activation in the hippocampus. We have previously suggested that progranulin (PGRN), a multifunctional growth factor, mediates the stimulatory effect of voluntary exercise on adult neurogenesis. In addition, PGRN also plays a suppressive role in neuroinflammatory responses related to activated microglia after traumatic brain injury. Thus, in the present study, we investigated the possible involvement of PGRN in the suppression of hippocampal neurogenesis and microglial activation under infectious stress conditions, i.e., low- or high-dose challenge of lipopolysaccharide (LPS). Twenty-two hours after LPS treatment, mice were intraperitoneally injected with bromodeoxyuridine (BrdU) to label proliferating cells. Two hours after BrdU injection, their brains were processed for immunohistochemical staining for Ki67 as well as BrdU. The results showed that the expression of PGRN mRNA in the hippocampus was significantly increased 24 h after high-dose LPS injection, while low-dose LPS did not affect PGRN mRNA levels at any time point. Compared with the vehicle-injected animals, the numbers of Ki67- and BrdU-positive cells in the subgranular zone (SGZ) of the dentate gyrus (DG) were significantly decreased in both low- and high-dose LPS-injected animals. However, the numbers of Ki67- and BrdU-positive cells in the SGZ were not significantly different between wild-type (WT) and PGRN-deficient (KO) mice injected with either low- or high-dose of LPS. The Iba1- and CD68-positive areas in the DG in the low- and high-dose LPS-injected mice were significantly larger than those in the vehicle-injected animals. Although the Iba1-positive areas were not significantly different between WT and KO mice following either low- or high-dose LPS stimulus, high-dose LPS significantly enhanced the CD68-positive areas in the DG in KO mice. By contrast, low-dose LPS did not affect the CD68-positive areas between WT and KO mice. These results suggest that PGRN is strongly linked to the down-regulation of microglial activation, while PGRN may not be involved in protecting hippocampal neurogenesis, under acute infectious stress conditions.

Title: Gene network analysis of spinal cord in the model of chronic water avoidance stress

Authors: *S. BRADESI[1], I. KARAGIANNIDIS[2], K. BAKIRTZI[2], S. MAHURKAR JOSHI[3], D. ILIOPOULOS[3], C. POTHOULAKIS[2], E. A. MAYER[1];

Abstract: Certain types of stress can have harmful effects at the cellular level inducing damage to proteins, mRNA or DNA. In rats, chronic water avoidance stress (WAS) is associated with changes in the expression of specific glial markers in the spinal cord. We aimed to test the hypothesis that WAS induces change in protein encoding gene and microRNA (miRNA) expression, which may have a significant role in the neuroimmunomodulation of spinal nociception signaling. Methods: Male Wistar rats were exposed to a daily session of WAS for 10 days, or handled daily. At day 11, L6/S1 spinal segments were collected and processed immediately for mRNA and miRNA isolation followed by gene expression profiling using the Agilent SurePrint G3 Rat Exon Microarray and Rat miRNA Microarray platforms. Lists of differentially expressed genes were generated using the dChip software program. Microarray analysis was performed using the Ingenuity Pathways Analysis (IPA) tool from Ingenuity Systems. Quantitative real time RT-PCR was performed using a 7500 Fast Real-Time PCR sequence detection system. Results: IPA identified 70 genes affected by WAS (FDR<0.05) belonging to pathways which include IL-6 signaling, PI3K/AKT and acute phase response signaling. A list of 39 miRNAs, part of two networks with relevance to inflammatory processes, showed differential expression in WAS compared to control rats. An analysis of the miRNA predicted targets in our 70 gene list showed the following target genes: gp130, I kappa b kinase epsilon, and Hsp40 homolog, subfamily C, member 21 (DNAJC21) as potential targets for miR-148-3p, miR17-5p, miR181a-5p, miR19b-3p and miR24-3p. We verified increased expression of mir17-5p and miR19b-3p in stress using qPCR. In addition, we observed changes in the expression of gp130 (essential in signal transduction for the family of IL-6-type cytokines) and STAT3 (involved in intracellular signaling cascades in response to gp-130 activation), both

predicted targets for mir17-5p. A reduced GFAP gene expression was also found in stress. Conclusion: Using a high throughput method, we demonstrated the effect of WAS on several networks involved in inflammatory pathways, which are relevant to pain signaling modulation. Our findings, suggesting a link between mir17-5p upregulation and change in gene expression of gp130 and STAT3 (known to affect GFAP gene transcription), provide new insight into the possible mechanisms mediating the effect of chronic stress on neuroinflammation in the spinal cord.

Title: Structural and functional consequences of chronic psychosocial stress on the microbiota-gut-brain axis and immunity

Authors: *A. BHARWANI[1], J. BIENENSTOCK[1], J. FOSTER[2], M. SURETTE[3], P. FORSYTHE[3];
[1]Pathology & Mol. Med., [2]Psychology & Behavioural Neurosciences, [3]Med., McMaster Univ., Hamilton, ON, Canada

Abstract: The gut microbiota and the brain are engaged in persistent bidirectional interplay--a phenomenon that influences host neural function and behaviour. However, the functional relationship between the microbiota and stress-induced changes in brain and behaviour, and underlying pathways of communication, remain unknown. To elucidate this relationship, we profiled the intestinal microbiome, behaviour, and immune function of mice exposed to psychosocial stress. We also investigated the potential of microbe-based strategies to modulate such changes, through chronic administration of *Lactobacillus rhamnosus* (JB-1). Male C57BL/6 mice subjected to chronic social defeat for ten days were assessed for changes in social, anxiety-like, and exploratory behaviours. Genomic DNA was isolated from fecal samples to characterize

the microbiome profile. 16S rRNA-derived operational taxonomic units (OTUs) were used to predict the functional metagenomic content of the microbiota. To investigate gut-brain signaling, splenocytes were analyzed for changes in the immune cell population using flow cytometry. Serum and supernatant from stimulated splenocytes were assessed for functional changes in the release of soluble signals. In a preliminary study, mice were orally administered $1.67x10^9$ CFU of *L. rhamnosus* (JB-1) for 28 days, leading into the defeat procedure. Stress-exposure altered the overall microbiome composition, and reduced species richness and diversity. Predictive metagenomic analysis suggested functional changes in the microbiome following stress exposure, including reduced functional diversity as well as the down-regulation of pathways involved in the synthesis and metabolism of neurotransmitter precursors and fatty acids. Defeated mice exhibited reduced social and exploratory behaviours, and lasting changes in the immune profile, including increased dendritic cell maturation and activation, reduction in the population of CD4+ CD25+ IL-10+ regulatory T cells, and increased serum levels of IL-6, but not TNF α. Preliminary results suggest that *L. rhamnosus* administration attenuated stress-induced deficits in sociability and exploratory behaviour, but not aggressor interaction. These findings demonstrate an association between stress-induced behavioural deficits and structural and functional changes in the microbiome. The study also identifies immune changes as a potential cause or consequence of microbiota-gut-brain communication.

Abstract: We demonstrated that restraint stress increased the level of Galectin-1 (Gal-1) in the serum and the increase was regulated by the sympathetic nervous system but not the hypothalamic-pituitary-adrenal axis. Gal-1 is a widely expressed animal lectin with an affinity for β-galactoside and shows a variety of biological activities, such as immune-cell homeostasis, nerve regeneration after injury and the inflammatory response. These results suggest that the stress-induced serum Gal-1 may play an important role in preventing physiological and/or psychological stress through the sympathetic nervous system. In this study, we investigated the levels and the localization of Gal-1 in lymphoid organs, thymus and spleen, at 30min and 60 min after the restraint stress. Western analysis demonstrated the Gal-1 level in both organs of the stress group significantly increased compared to the controls. On the other hand, RT-PCR analysis indicated that the Gal-1 mRNA level did not increase after the stress. Immunohistochemical analysis showed that the immunoreactivity in the periarterial lymphatic sheath (PALS) of the thymus was stronger than in red and white pulp. In the spleen, Gal-1 staining was higher in the medulla than in the cortex. Furthermore, the Gal-1 co-localized with CD45+ lymphocytes in the PALS and the medulla. Thus, these results suggest that stress-induced Gal-1 in serum immediately accumulates in immune organs and may modulate the immune response through apoptosis by binding to CD45+ lymphocytes following physiological and/or psychological stress.

Abstract: In these days, the accelerated lifestyle of people has become one of the most important factors in the generation of mental disorders. Depression in young people can lead to the development of some serious problems like deficiency in school performance, substances abuse, violence, anxiety, eating disorders and suicidal ideation. There is evidence linking stress with the development of many psychiatric disorders. The body's response to a stressful stimulus is performed by the activation of the stress system, which causes changes in a large number of cells, increasing their metabolism, and free radicals production. When the generation of free radicals exceeds the antioxidant capacity of the organism, conduce to a harmful state, called oxidative stress, and begins damaging many vital structures for cell survival, such as DNA or cell membranes. This study aims to describe the relationship between oxidative stress and psychological stress caused by an academical test. For this, we analyzed the variation in the concentration of nitric oxide (NO) and Zinc (Zn), and the activity of the superoxide dismutase enzyme (SOD) in serum of 88 students from the Faculty of Chemistry Sciences of the Autonomous University of Puebla, with a range of ages from 19-24 years. The study was conducted in 3 groups of students taking classes with the same teacher (n1 = 32, n2 = 37, n3 = 19). The results show that there is indeed a variation in the concentrations of NO, Zn and SOD in serum samples taken one week before, during and one week after the test. The values of NO and SOD vary in proportion to the psychological demand caused by the stressor; however, serum Zn levels inversely changes due to the intracellular requirement during stress. The analysis of the variation in serum concentrations of NO and Zn, are good markers for determining the state of oxidative stress caused by an exam. The enzymatic activity of SOD however, doesn't show evident results with this stress level. (Supported by: CONACyT grants No. 138663 and 129303 to G Flores).

Title: Suggestion of the analysis method to extract the relationship between the brain activity and salivary metabolites during acute psychosocial stress

Authors: *T. OKAMURA, T. HIROYASU;
Doshisha Univ., Kyotanabe,Kyoto, Japan

Abstract: [Objective] In recent years, along with the development of the nerve imaging technology and the metabolome analysis technique, the kinds of data which are extracted from the living body increased, and the numbers became enormous. Therefore analysis method to extract the relationship of these data is required. In this study, suggestion of the method to extract the salivary metabolites related to a brain activity state is performed. As an evaluation experiment, brain activity and the salivary metabolites during acute psychosocial stress are measured, and a relationship between brain activity and the salivary metabolites are investigated using the proposed method. [Proposed method] The proposed method is summarized as follows. A target task is set, and the brain activity is measured using fMRI (functional Magnetic Resonance Imaging). Through the experiment, saliva samples are gathered to investigate metabolic information. Using brain activity information of plural subjects, the brain activity state is performed clustering and become the label. The brain activity information of each subject has each label. Saliva samples are analyzed using capillary electrophoresis-MS and density of salivary metabolites is acquired. The density of metabolites is the feature value. The discriminator which can classify the above-mentioned label is learned. SVM (Support Vector Machine) is employed to learning. Leave-one-out cross-validation is performed for all subjects, and a mean identification rate is obtained. The combination of analyzed metabolites which maximizes the mean identification rate is obtained using GA (genetic algorithm). It is found that the combination of metabolites provided in this way is metabolites related to the brain activity state for the target task. [Experimental method] A psychosocial stress experiment is carried out to verify the validity of the proposed method. Eight healthy young men (22±1 years old) took part in this study. Psychological stress was induced using the Montreal Imaging Stress Task (MIST), where subjects are exposed to challenging mental arithmetic presented on a computer screen. Eight saliva samples were acquired, starting 35 min before the onset of the MIST until 45 min after the MIST.

Title: Habituation of plasma corticosterone and neuroimmune alterations in response to repeated daily exposure to several distinct stress challenges in Sprague Dawley rats

Authors: *D. LOVELOCK, M. SAMMAKIA, T. DEAK;
Behavioral Neurosci. Program, Dept. of Psychology, Binghamton Univ., Binghamton, NY

Abstract: Exposure to stress involves activation of the HPA axis, synthesis of proinflammatory cytokines such as interleukin 1 (IL-1), interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF-α), and activation of microglia. These experiments explored how neuroimmune and neuroendocrine responses to an acute stress challenge (footshock) would be altered by prior exposure to daily chronic stress, termed chronic escalating stress (CES). This model utilized a combination of established procedures that involved exposure to predictable daily challenges, yet introduced a systematic escalation in both the intensity and length of daily stress challenges. Adult male Sprague-Dawley rats were exposed to an 11 day procedure, where days 1-5 consisted of 60 min of restraint, days 6-10 consisted of 60 min of restraint immediately followed by 30 min of forced swim, and on day 11 subjects were exposed to an 80 shock, 2 hour intermittent footshock challenge. Experiment 1 examined adaptation in the corticosterone (CORT) response at key points in the procedure. We found that habituation to restraint occurred by day 6, and that the escalation in stressors from day 6 to 10 partially disrupted the established habituation, suggesting that restraint likely became predictive of imminent swim stress. The response at the timepoint following swim increased across experiment days 6 and 10, and the response to 2 hours of intermittent footshock did not differ between controls and the CES group. Experiment 2 investigated the impact of this stress paradigm on the expression of several important cytokine (IL-1, IL-6, TNF-α) and cellular activation markers (c-Fos, CD14, CD200R) in key brain regions (paraventricular nucleus of the hypothalamus, hippocampus, & prefrontal cortex). As expected, acute footshock exposure led to expected increases in c-Fos in all brain regions, increased IL-1 in the PVN, and suppressed TNF-α in the HPC and PFC. These changes were largely unaffected by prior exposure to CES paradigm, with mildly increased c-Fos expression in the HPC and PFC being the only differences of note between the acute footshock and CES groups. Thus, recent stress history did not modulate cytokine gene expression, indicating that the key driver of cytokine changes was the final footshock challenge, not a history of chronic stress. Additionally, the CES model induced an interesting dissociation between adaptation in the HPA axis and the neuroimmune response, where it had clear effects on CORT habituation but the acute

neuroimmune response was unaffected. This CES model may serve as a highly tractable model for studying adaptation to chronic stress relative to previously established paradigms.

Title: Implications of stress and infection on neuroimmune function and behavior as potential risk factors for developing postpartum depression

Authors: *C. K. POSILLICO, J. M. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Drastic changes must take place in the function of the maternal immune system to foster the development of a growing fetus and to prevent it from being "attacked". Changes in immune function may also explain why women suffering from autoimmune diseases find improvement of their symptoms during pregnancy. Furthermore, it is well-known that neuroimmune changes have been linked to several psychiatric disorders including depression. Despite evidence of peripheral immune changes induced by pregnancy, no one has ever examined whether pregnancy or parturition induces changes in the central immune system simultaneously and whether this may be an underlying risk factor for postpartum depression. Therefore, we hypothesize that changes in immune function associated with pregnancy and parturition confounded with external stressors or infection may be linked to an increased risk for developing postpartum depression. Microglia are the immune cells of the brain, and they have both pro- and anti-inflammatory responses to various insults. Using real-time PCR, we identified significant changes in microglial activation markers and pro-inflammatory molecules within the medial prefrontal cortex (mPFC) and the hippocampus of pregnant and postpartum rats compared to non-pregnant controls. Females exposed to forced swimming stress during their last week of gestation showed a significant decrease in the expression of pro-inflammatory cytokine IL-1β in the mPFC as a result of the stress. Additionally, the experience of pregnancy or parturition in these animals further decreased IL-1β expression and increased IL-6 expression. Stress and pregnancy significantly decreased sucrose preference scores immediately postpartum;

however, the effects of both factors were not additive, and the effects were no longer seen one week postpartum. In a separate cohort of animals, females were given an injection of lipopolysaccharide (LPS, 100 μg/kg) one day prior to parturition. Similar to the previous experiment, pregnancy and immune activation increased the expression of IL-6 in the mPFC; however, the effects of both factors were not additive. Thus, these data indicate that pregnancy alone induces neuroimmune and behavioral changes. Additionally, stress or infection during late gestation interact with pregnancy resulting in unique neuroimmune gene expression and immediate depressive behavioral outcomes.

Title: Role of c-Src in oxidant-mediated Toll-like receptor 4 signaling

Authors: *O. J. IGWE, Y. ZHANG, R. KARKI;
Div. of Pharmacol. & Toxicology, Univ. Missouri- KC, Kansas City, MO

Abstract: Background: Oxidative stress is implicated in the initiation and progression of many diseases. ROS can act as second messengers in intracellular signaling to induce a dysregulated phenotype. But changes in cell signaling that may result in decreased or enhanced responsiveness after exposure to exogenous oxidants is not understood. Protein tyrosine kinases and phosphatases play a role in oxidant-induced cell signaling. As a leading member of the Src family of non-receptor tyrosine kinases, c-Src is involved in diverse signaling pathways. As most of c-Src is in a dormant state under basal conditions, regulation of its activation is crucial for its biological functions. c-Src is sensitive to cellular redox stress, but its role in oxidant-induced inflammation is not clear. Oxidants can activate NFB through stimulation of TLR4, which plays a critical role in innate and adaptive immunity. Here, we sought to establish a primary role for c-Src in oxidant-induced TLR4 signaling through the NFB activation. **Objective:** The purpose of the present study was to determine the role of c-Src in the molecular mechanisms that may underlie oxidant-induced NF-B activation through TLR4 signaling. **Methods:** We used HEK-Blue cells that are stably transfected with mouse TLR4 and that express secreted embryonic

alkaline phosphatase (SEAP) reporter gene under the control of a promoter inducible by NF-B. We used LPS and MPLA as TLR4 specific agonist and positive controls, and SIN-1 and PPC as sources of oxidants. The level of SEAP released due to TLR4 stimulation was a measure of NF-B activation. We used fluorescence imaging to measure the levels of intracellular ROS (iROS) after oxidant treatment. We quantified oxidant-induced lipid peroxidation as thiobarbituric acid reacting substances. We determined the activity of c-Src and the product of ROS-induced NF-B activation by ELISA and immunoprecipitation, respectively. **Results:** Treatment with either the oxidants or LPS-EK increased iROS with an enhanced production of nitric oxide and TBARS to confirm oxidative stress, SEAP release and TNF- production. Pretreatment with c-Src inhibitors, PP2 and CA-pY, which act by different mechanisms, decreased these parameters. Pretreatment with SSG, a c-Src activator, enhanced the effects promoted by LPS-EK and oxidants, and rescued cells from PP2- and Ca-pY-induced effects. Both oxidants and TLR4 agonist increased formation of c-Src complexes with TLR4 and IB- as coimmunoprecipitates. **Conclusion:** Prooxidant-induced activation of TLR4 through c-Src/NFB coupling provides a basis for a molecular understanding of the initiation and maintenance of "sterile inflammation".

Title: Psychological stress increases indices of neuroinflammation

Authors: M. WARWICK, K. KORNACKER, L. THAN, *D. Y. LO;
Coe Col., Cedar Rapids, IA

Abstract: Ample evidence has shown that intense psychological stressors can increase inflammation within the brain, and that stress-induced neuroinflammation contributes to the development of a host of central nervous system disorders. Despite the established relationship between stress and neuroinflammation, the mechanisms underlying the pathogenic effects of stress-induced neuroinflammation remain unclear. To elucidate the effects of stress on neuroinflammation, immunocytochemistry experiments were performed to characterize the expression of various inflammation-related proteins in the brains of acutely- and chronically-stressed animals. Experiments using glial fibrilary acidic protein (GFAP) to assess astrocyte reactivity revealed increased GFAP immunoreactivity in the brains of both acutely- and

chronically-stressed animals in several brain regions, including the striatum and corpus callosum, and surrounding blood vessels throughout the brain. While we observed a noticeable difference in GFAP immunoreactivity between control and stressed groups, we did not notice a difference between acutely-stressed and chronically-stressed animals. Experiments looking at the expression of inflammatory markers NF-kappaB (NF-kB) and cyclooxygenase-2 (cox-2) showed that stress increases NF-kappaB expression throughout the brain in cells consistent with glia, neurons, and perivascular cells, and it increases cox-2 expression in neurons throughout the cortex. Interestingly, we observed an increase in cox-2 expression in the brains of chronically-stressed compared to acutely-stressed animals, suggesting that repeated stressors act to exacerbate brain inflammation. Taken together, our results show that stress has widespread inflammatory effects on the brain by modulating glial activity and upregulating the expression of several pro-inflammatory genes.

Title: A pre-conditioning stress accelerates increases in mouse plasma inflammatory cytokines induced by stress

Authors: ***Y. CHENG**, R. JOPE, E. BEUREL;
Biochem., Univ. of Miami, Miami, FL

Abstract: Major depressive disorder is a prevalent disease that is inadequately treated with currently available interventions. Stress increases susceptibility to depression in patients and rodent models, which are also associated with aberrant activation of inflammation, specifically with increases in circulating IL-1β, IL-6, and TNFα. The two major goals were to measure changes in a broad panel of 19 cytokines, and to test if a pre-conditioning stress altered the inflammatory response to a subsequent stress. Administration of inescapable foot shocks

increased plasma levels of IL-1β, IL-6, TNF, IL-3, IL-10, IL-13, IL-17A, IL-5, GM-CSF, IL-12(p70), IFN-γ, MIP-1α, MIP-1β, IL-1α, IL-2, KC, RANTES and G-CSF, with peak levels occurring in the range of 6 to 12 hr after stress. Pre-conditioning the mice 24 hr prior with an equivalent stress resulted in similar magnitudes of increases in most cytokines as occurred after a single stress, but accelerated the increase, causing the levels of most cytokines to peak 1 hr after stress. These results demonstrate that a single stress induces the expression of many cytokines, and that sequential daily stresses accelerates the rate of cytokine production. Thus, stress broadly activates inflammation and the inflammatory response is more rapid following repeated stress, actions that may contribute to deleterious effects of stress on depression and other stress-linked diseases.

Title: Repeated, not single, stress induces persistent polyi:c-induced allodynia and depressive-like behavior in rats

Authors: ***T. OKA**, T. CHIJIWA;
Grad. Sch. of Med. Sciences, Kyushu Univ., Fukuoka, Japan

Abstract: Background: When animals suffer from viral infections, they develop sickness response. Recent studies suggest that psychological stress can modulate the sickness response. However, it remains uncertain whether acute and chronic psychosocial stress have the same effect on viral infection-induced sickness responses. Methods: To address this question, we compared changes in polyI:C-induced sickness responses, such as fever, mechanical allodynia, and depressive-like behavior in rats that had been pre-exposed to single and repeated social defeat stress. Results: PolyI:C-induced fever was attenuated by the pretreatment with either single or repeated social defeat stress. In contrast, only the repeated stress group showed late-onset and prolonged mechanical allodynia lasting until 35 days after injection in the von Frey test and prolonged immobility time in the forced swim test 9 days post-injection. To assess the involvement of glucocorticoids and microglia in the delayed and persistent development of these

sickness responses in rats exposed to repeated stress, we also investigated the effect of pretreatment with RU486, a glucocorticoid receptor antagonist, and minocycline, an inhibitor of microglial activation, on polyI:C-induced allodynia and depressive-like behavior. Pretreatment with either drug inhibited both the delayed allodynia and depressive-like behavior. Conclusions: The present study demonstrates that repeated, but not single, social defeat stress followed by systemic polyI:C administration induced prolonged allodynia and depressive-like behavior in rats. Stress-induced corticosterone and microglial activation may play a pivotal role in this phenomenon.

Title: Repeated stressor exposure differentially effects microglia and peripheral macrophages proinflammatory cytokine production and the regulation by norepinephrine

Authors: D. F. BARNARD, *J. D. JOHNSON;
Biol Sci. Dept, Kent State Univ., Kent, OH

Abstract: The elevation of proinflammatory cytokines have been implicated in a wide variety of physiological and behavioral diseases, such as depression and PTSD. Norepinephrine plays a critical role in the regulation of proinflammatory cytokines with studies demonstrating it has both stimulatory and inhibitory effects depending on the activation state of the immune cell. In fact, norepinephrine release during times of stress mediates the elevation of both central and peripheral cytokine production, which is critical for the onset of depression-like and anxiety-like symptoms in multiple animal models. Adrenergic receptor expression and signaling changes after stressor exposure, yet it remains unknown how the regulation of proinflammatory cytokines by norepinephrine might be altered following repeated stressor exposure. Studies here examine how stress influences norepinephrine's ability to regulate basal and LPS-induced cytokine production from both peripheral and central immune cells. Rats were exposed to a four-day stress protocol and sacrificed 24h following the last stressor. Microglia from the hippocampus as well as peritoneal phagocytes were isolated and plated. Cells were treated for 20h with media or

LPS with or without three doses of norepinephrine. Stressor exposure significantly suppressed LPS-induced IL-1 production in microglia while having no effect on TNF-alpha production. Interestingly, the highest dose of norepinephrine enhanced LPS-induced IL-1 production in microglia from both control and stressed animals but had no effect on TNF-alpha production. Alternatively, the effects of stress and norepinephrine's ability to regulate cytokine production in peripheral immune cells drastically differed from microglia. Stress enhanced LPS-induced IL-1 production from peritoneal cells and norepinephrine enhanced this production more pronouncedly in stressed animals compared to controls. Additionally, stress significantly enhanced LPS-induced TNF-alpha production from peritoneal phagocytes and this was inhibited by the high dose of norepinephrine in both control and stress groups. These results indicate that the ability of norepinephrine to regulate LPS-induced cytokine production is specific to both cell type (microglia or peripheral macrophage) as well as the cytokine type.

Title: Basal HPA axis activity is related with responses of inflammatory gene expression to acute stress

Authors: X. CHEN[1], C. M. MCINNIS[1], D. WANG[2], L. HANLIN[1], D. GIANFERANTE[1], M. V. THOMA[1], *N. ROHLEDER[1];
[1]Psychology, Brandeis Univ., Waltham, MA; [2]Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: Introduction: Diurnal hypothalamus-pituitary-adrenal (HPA) axis activity, which is characterized by an increase during the first hour after awaking (cortisol awakening response;

CAR), and a gradual decline afterwards, has been found to be altered in individuals with chronic stress or psychiatric disease, and to be predictive of health outcomes. The mechanism linking basal activity with health remains unclear. In the present study, we investigated whether basal HPA axis activity was related with response and habituation of inflammatory gene expression to acute stress in humans. **Methods:** We recruited n=36 healthy individuals from two age groups (Young adult group: 13 male/11 female, mean age 20.75 yrs. ± 3.66 SD, BMI 24.14 kg/m^2 ± 3.25 SD; Older adult group: 5 male/7 female, mean age 50.17 yrs. ± 9.46 SD; BMI 25.52 kg/m^2 ± 2.86 SD) and collected salivary cortisol at 6 points in two successive days: immediately and 0.5h, 1h, 4h, 9h and 13h post-awakening. Participants were further exposed to the laboratory stressor Trier Social Stress Test (TSST) on two consecutive days. On both stress days peripheral blood was taken before, 30 and 120 min post TSST, and gene expression of interleukin (IL)-6, IL-1β, nuclear factor (NF)-κB, and IκB was measured using qPCR. **Results:** As reported before, expression of all genes increased after TSST1 and habituated after TSST2. A steeper CAR was related with higher IL-6 expression on both days (F= 6.00, p=0.021). Steeper diurnal cortisol decline was a marginally significant predictor of higher IL-6 at 120 min post-TSST1 (β=0.36, p=0.06), and of higher NF-κB expression post stress on both days (F= 3.22, p=0.08). Higher total daily cortisol output was a significant predictor of lower IL-1β response at 30 min (β=-0.60, p=0.003) and 120 min (β=-0.38, p=0.07) post-TSST2, and stronger IL-1β habituation at 30 min post-TSST (β=0.49, p=0.015), and it also marginally predicted lower IκB at 30mins post-TSST2 (β=-0.35, p=0.09), all controlling for age and gender. **Conclusion:** Results show that basal HPA axis activity was related with inflammatory gene expression in response to acute stress. Considering the importance of peripheral inflammation for health, this might be an important step in bridging the gap in the current literature regarding health effects of acute stress reactivity and health outcomes of basal HPA axis activity. Future work will employ longitudinal studies to understand the direction of these relationships.

Title: Sphingosine-1-phosphate receptors are novel regulators of the hypothalamic-pituitary-adrenal (HPA) axis

Authors: *N. SOTUYO[1,2], S. LUZ[2], S. BHATNAGAR[2,1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Div. of Stress Neurobio., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: In the past decade, sphingolipid receptors (sphingosine-1-phosphate receptors 1-5; S1PR1-5) have become popular therapeutic targets for multiple sclerosis and other diseases due to their important roles in the cardiovascular and immune systems. However, the role of sphingolipid signaling in the central nervous system remains poorly understood. Fingolimod (FTY720) is an FDA-approved synthetic sphingolipid analog used to treat multiple sclerosis (MS) by acting as a functional S1PR1 antagonist on autoreactive T lymphocytes, leading to their sequestration in lymph nodes. Interestingly, patients treated with fingolimod also report less depression and anxiety than with other MS treatments (Montelban et al., 2011), which may be indicative of additional effects in the CNS. We were interested in whether fingolimod has any effects on the hypothalamic-pituitary-adrenal (HPA) axis, which has also been shown to be dysregulated in a subset of MS patients with major depressive disorder (e.g. increased cortisol levels, and abnormal cortisol awakening responses and dexamethasone suppression tests). In the current studies, we sought to characterize the effect of fingolimod on the HPA axis basally and in the context of various stressors. Specifically, we measured plasma levels of ACTH and corticosterone before, during, and after novel restraint stress and the social interaction test following either acute (single) or repeated intraperitoneal fingolimod administration. Interestingly, an acute injection of 2.5 mg/kg fingolimod increased basal HPA hormones, but no additional effect of restraint was observed. However, with repeated injections (3 days of 2.5mg/kg/day ip) restraint-induced ACTH was significantly increased. Furthermore, fingolimod increased the number of activated cells in the paraventricular nucleus of the hypothalamus (PVN) consistent with its role in regulating ACTH. Increased neuronal activity was also observed in the medial prefrontal cortex and basolateral amygdala, regions important in regulating the stress response. In sum, these results demonstrating fingolimod's time-dependent effects on the HPA axis may highlight a novel role for sphingolipid signaling as a central regulator of the HPA axis. Further elucidation of the mechanisms underlying this HPA activation by S1P receptors will be important for developing effective therapies for stress related psychiatric diseases, including but not limited to major depressive order seen in HPA-dysregulated MS patients.

Title: Stress response profiles in women during the active hormone and inactive no-hormone weeks of hormonal contraception

Authors: *A. E. YCAZA, S. E. NIELSEN, M. MATHER;
Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: Cortisol responses to stress vary across the menstrual cycle and with hormonal contraception (HC) use. For example, women on HC and in the low hormone phase of the menstrual cycle experience lower cortisol responses to stress compared with women during the high hormone phase of the menstrual cycle. This pattern suggests that the low ovarian output experienced during HC use may be related to the reduced cortisol response to stress. However, it is unknown whether this reduced cortisol response to stress persists when HC-induced ovarian suppression is removed during the no-hormone inactive days of HC. To examine the effect of HC phase (active vs. inactive) on the adrenal and sympathetic stress response, we tested 41 women during either the active (hormone days; n = 23) or inactive (n = 18) phases of their HC regimens. Women had been using HC (monophasic oral pill or vaginal ring) for at least 2 months. Stress was induced via the cold pressor task (holding one's hand in ice water) for up to 3 minutes. Saliva samples were collected immediately before stress onset (baseline), immediately after stress exposure (post-stress 1), and 15 minutes after stress onset (post-stress 2). Salivary alpha-amylase (sAA) and cortisol was measured in all 41 participants, and progesterone (P4) was measured in 40 participants (active: n = 22; inactive: n = 18). A series of chi-square analyses revealed a similar number of women in each HC phase experienced increases in cortisol and sAA in response to cold pressor stress. Conversely, more women experienced increases in P4 during the active phase of HC than during the inactive phase. Next, a series of 2 (HC phase) x 3 (salivary sample time point) mixed ANOVAs revealed a main effect of stress on cortisol, but not on P4 or sAA. There also was no main effect of HC phase on cortisol, P4, sAA, nor any interactions. To better characterize response differences, we then compared the change score in cortisol and P4 responses between HC phases. Independent t-tests revealed no difference in magnitude of cortisol change between HC phases. However, P4 response from baseline to post-stress 1 was significantly different between HC phases, with active women experiencing an increase and inactive women experiencing a decrease. Despite evidence that women not using HC experience greater stress responses than women using HC, the comparable cortisol and sAA response to stress in both HC phases suggests that the blunting effect of HC on the stress

response persists into the inactive, no hormone phase of a HC regimen. Surprisingly, however, the P4 response to stress is larger during the active phase of HC, which may relate to the anxiolytic properties of P4 and the ability of HC to stabilize mood.

Title: Pubertal activation of estrogen receptor α in the medial amygdala is necessary for the expression of male-type social behavior in adult mice

Authors: K. SANO[1], M. NAKATA[1], S. MUSATOV[2], S. TSUKAHARA[3], N. YAMAGUCHI[4], *T. SAKAMOTO[5], S. OGAWA[1];

Sch. of Sci. and Engin., Saitama Univ., Saitama, Japan; [4]Dept. of Pharmacol., Aich Med. Univ., Nagakute, Japan; [5]Kyoto Tachibana Univ., Kyoto, Japan

Abstract: Testosterone is known to play a central role in the facilitation of male-type social behavior, such as sexual and aggressive, and the development of their neural bases in male mice. Moreover, the action of testosterone via estrogen receptor (ER) α, after being aromatized to estradiol in the brain, is suggested to be crucial for the full expression of these behaviors. We previously reported that knocking down of ERα in adulthood with the use of virally mediated RNAi method in the medial amygdala (MeA) had no effect on either behavior (Sano et al. EJN, 2013). Recent studies have shown that testosterone stimulation in pubertal period may play a critical role for full expression of male social behavior in adulthood. However, it is still not known whether and in which brain region(s) ERα is involved in this developmental effect of testosterone. In the present study, we examined the effects of pre-pubertal knockdown of ERα in the MeA. At the age of 21 days, gonadally intact male mice (ICR/Jcl) were bilaterally injected either with adeno-associated viral vector silencing ERα or a control vector in the MeA. All mice

were then tested for their sexual and aggressive behaviors starting at 12 weeks old. We found that pre-pubertal knockdown of ERα in the MeA reduced both sexual and aggressive behaviors. Furthermore, the number of MeA neurons examined in adult was reduced to the level similar to that of female. These results collectively suggest that although it may not be required at the time of testing, ERα activation in the MeA by aromatized testosterone during pubertal period is necessary for the full masculinization of this region that is essential for the expression of male-type social behavior later in adulthood. In addition, we also examined the pre-pubertal knockdown effects of ERβ in the MeA on the male social behavior. Unlike that of ERα, knocking down of ERβ during pre-pubertal period did not affect the expression of either sexual or aggressive behavior in adulthood.

Title: Role of estrogen receptor β in the dorsal raphe nucleus in the regulation of female sexual behavior in mice

Authors: C. MORIMOTO[1], K. SANO[1], M. NAKATA[1], S. MUSATOV[2], N. YAMAGUCHI[3], T. SAKAMOTO[4], *S. OGAWA[1];
[1]Univ. of Tsukuba, Tsukuba, Japan; [2]Mol. Neurosurg., Weill Cornell Univ. Med. Col., New York, NY; [3]Dept. of Pharmacol., Aich Med. Univ., Nagakute, Japan; [4]Dept. of Psychology, Kyoto Tachibana Univ., Kyoto, Japan

Abstract: Estrogen regulates the expression of female sexual behavior by acting through estrogen receptors, ERα and ERβ. Both receptors are widely but somewhat differentially distributed in various brain regions. It is well known that ERα in the hypothalamic ventromedial nucleus plays a crucial role for the facilitation of female sexual behavior during the estrus phase. On the other hand, neuroendocrine mechanism to suppress sexual receptivity in non-estrous

females, particularly on the day after the behavioral estrus, still remains unclear. Our previous studies have shown that global ERβ knockout (βERKO) female mice maintained high levels of lordosis behavior on the day after behavioral estrus (Ogawa et al., PNAS, 1999). Therefore, it is hypothesized that ERβ may be involved in the inhibition of lordosis, but responsible brain regions have not been identified yet. In this study, we site-specifically knocked down the ERβ expression (βERKD) in the dorsal raphe nucleus (DRN) with adeno-associated viral (AAV) vector expressing a small hairpin RNA targeting ERβ. We examined the expression of sexual behavior in ovariectomized mice with steroid-priming which mimicked the hormonal conditions of the day of behavioral estrus (Day 1) and the day after behavioral estrus (Day 2). βERKD mice showed similarly high levels of lordosis quotient (LQ, number of lordosis / number of mounts and intromissions) and receptivity score (the average of 15 lordosis scores (rated as 0-3) on Day 1 as mice injected with control vectors. However, βERKD mice continuously showed high levels of LQ and receptivity score on Day 2, when control mice showed a great reduction in both measurements compared to Day 1. These results suggest that the expression of ERβ in the DRN may be involved in the inhibitory regulation of female sexual behavior on the day after behavioral estrus.

Title: Effect of site-specific knockdown of estrogen receptor α or β in the medial preoptic area on postpartum aggression in female mice

Authors: *K. NAGATA[1], Y. MIYATA[1], K. SANO[1], S. MUSATOV[2], S. OGAWA[1]; [1]Lab. of Behavioral Neuroendocrinology, Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Mol. Neurosurg., Weill Cornell Med. Col., New York, NY

Abstract: Estrogen plays a critical role not only in the induction of female sexual behavior but also in the regulation of various other social behaviors including maternal behavior. It is well known that postpartum lactating female mice show fierce aggressive behavior towards intruder male mice as part of their maternal caring behavior. However, neuroendocrine mechanism of postpartum aggression is not completely understood. In the present study, we aimed to determine whether two types of estrogen receptors (ER), ERα and ERβ, both highly expressed in the medial preoptic area (MPOA) that is known to play a critical role for maternal behavior, may also be involved in the regulation of postpartum aggression. We site-specifically knocked down ERα or ERβ in the MPOA by bilaterally injecting adeno-associated viral (AAV) vector expressing a small hairpin RNA targeting either ERα or ERβ in ICR/Jcl virgin female mice. All mice were then mated and individually housed once pregnancy was confirmed. On the day of parturition, defined as postpartum day (PPD) 0, litters were culled to as close to 10 pups as possible. Dams were tested against an olfactory bulbectomized male intruder mouse in a resident-intruder paradigm on PPD 1, 3, 5, 7, 9, 13, and 17. Control dams showed high levels of aggression during the early period of lactation (PPD 3, 5, and 7), and their levels of aggression declined thereafter. Dams of the ERα knockdown group exhibited similar levels of aggression as control mice throughout the postpartum period. In contrast, knockdown of ERβ greatly increased the levels of aggression compared to those of the control group. These results suggest that ERβ expressed in the MPOA may be involved in inhibitory modulation of the levels of aggression in postpartum female mice.

Title: The role of estrogen receptor β in adult medial amygdala in the regulation of male social behavior

Authors: *M. NAKATA[1], K. SANO[1], S. MUSATOV[2], N. YAMAGUCHI[3], T. SAKAMOTO[4], S. OGAWA[1];
[1]Lab. of Behavioral Neuroendocrinology, Univ. of Tsukuba, Tsukuba, Japan; [2]Mol. Neurosurg., Weill Cornell Univ. Med. Col., New York, NY; [3]Dept. of Pharmacol., Aichi Med. Univ., Nagakute, Japan; [4]Dept. of Psychology, Kyoto Tachibana Univ., Kyoto, Japan

Abstract: It is well known that testosterone plays an essential role in the regulation of male-type social behavior. Moreover, estrogen receptors (ERs) are known to mediate behavioral effect of testosterone, after aromatization of testosterone to estradiol in the brain. Previous studies using knockout mouse models suggested that two types of ERs, ERα and ERβ, play different roles in the regulation of male-type social behavior including sexual preference to receptive female, and sexual and aggressive behaviors. To identify brain site(s) responsible for ERα mediated action of testosterone, we previously conducted site-specific knockdown of ERα using virally mediated RNAi technique (Sano et al. EJN, 2013). However, it is still not known about brain site-specific role of ERβ in the regulation of male social behavior. In the present study, we examined the effects of site-specific knockdown ERβ in the medial amygdala (MeA), in which ERβ is abundantly expressed, and known to be responsible for processing of social cues. Gonadally intact adult male mice (ICR/Jcl) were bilaterally injected either with adeno-associated viral vector silencing ERβ (βERKD) or a control vector in the MeA. Three weeks after injection, animals were tested for preference between a receptive female (ovariectomized and primed with estradiol and progesterone) and a gonadally intact male (PTFM), and between a receptive female and a non-receptive (ovariectomized) female (PTFF). After preference tests, we conducted sexual and aggressive behavior tests. We found that ERβ knockdown in the MeA disrupt male-typical sexual preference. Unlike in control mice which showed preference to a receptive female over a non-receptive female, βERKD mice sniffed both females at a comparable level in the PTFF test. On the other hand, knockdown of ERβ did not affect preference during PTFM test and expression of sexual and aggressive behaviors. To further investigate functional significance of our finding, we additionally tested whether male mice preferentially mate with a receptive female when receptive and non-receptive females were simultaneously introduced to their home cage. As observed in the PTFF test, βERKD mice showed no preference to a receptive female in terms of mount and intromission frequency whereas control mice tended to show more sexual behavior toward a receptive female than to a non-receptive female. These results suggest that ERβ activation in the MeA at the time of testing in adult is essential for the expression of male-type sexual preference.

Title: Site-specific action of testosterone via estrogen receptor β, not α, in the medial preoptic area is required for the full expression of aggressive behavior in male mice

Authors: *N. YAMAGUCHI[1], K. SANO[2], M. NAKATA[2], S. MUSATOV[3], T. SAKAMOTO[4], S. OGAWA[2];
[1]Dept. of Pharmacol, Aichi Med. Univ., Nagakute, Aichi, Japan; [2]Lab. of Behavioral Neuroendocrinology, Univ. of Tsukuba, Tsukuba, Japan; [3]Mol. Neurosurg., Weill Cornell Univ. Med. Col., New York, NY; [4]Dept. of Psychology, Kyoto Tachibana Univ., Kyoto, Japan

Abstract: The expression of male-type social behavior such as sexual and aggressive, are highly dependent on the action of testosterone. Testosterone is known to activate not only androgen receptors but also estrogen receptors (ER), ERα and ERβ, after being aromatized to estradiol in the brain. A series of our recent studies revealed that two types of ERs in different brain regions might be involved to regulate each of sexual and aggressive behaviors differently. Among them, we have reported that activation of ERα in the medial preoptic area (MPOA) at the time of testing in adult is necessary for the facilitation of male sexual, but not aggressive, behavior (Sano et al. EJN, 2013). However, mechanisms of testosterone action in the MPOA for the expression of male aggressive behavior still remain unclear. Since we have found that activation of ERα during pubertal period in the medial amygdala may be crucial for full expression of sexual and aggressive behaviors (Sano et al., SfN abstract, 2015), it is possible that pre-pubertal knockdown of ERα in the MPOA may also affect aggressive behavior in adulthood. Furthermore, ERβ highly expressed in the MPOA might be involved in the regulation of aggressive behavior by aromatized testosterone. Thus in this study, we site-specifically knocked down ERα or β in the MPOA during pre-pubertal period and examined the effect on the expression of male aggressive behavior. At the age of 21 days, gonadally intact male mice (ICR/Jcl) were bilaterally injected either with adeno-associated viral vectors silencing ERα or ERβ, or a control vector in the MPOA. Starting at the age of 12 weeks, all mice were tested for their aggressive behavior. Surprisingly, knockdown of ERβ reduced the levels of aggression while the knockdown of ERα had no effect on the expression of aggressive behavior. These results indicate that testosterone action via ERβ, but not ERα, in the MPOA is required for the full expression of male aggressive behavior. Taken together with our previous studies, it is suggested that ERα and ERβ in the

MPOA may be responsible for the differential regulation of male sexual and aggressive behaviors by testosterone.

Abstract: Estradiol can rapidly (within 1 hr) modulate social and reproductive behaviors in both mammalian and non-mammalian species, potentially through actions on neuroendocrine cell populations in the hypothalamus and preoptic area. For example, recent studies have shown that estradiol can stimulate central and peripheral release of the neuropeptides oxytocin (the mammalian homologue of isotocin, IT) and vasopressin (the mammalian homologue of vasotocin, VT), which are potent modulators of social behaviors in all species thus far examined. The mechanism by which these rapid neuroendocrine effects occur is, however, unclear. One possibility is that estradiol stimulates rapid neuropeptide release via a non-genomic mechanism through receptors such as GPR30 (also known as GPER), a G protein-coupled membrane estrogen receptor. To address this issue, we first localized GPR30 in the brain of male goldfish via immunohistochemistry. We found that GPR30 is robustly expressed throughout the preoptic area (POA), a highly conserved node in the social brain network. Using an anti-oxytocin antibody to label neurons that produce isotocin, we then asked whether GPR30 was expressed specifically in isotocin-producing cell populations. We found that virtually all GPR30-positive cells and fibers in the POA were also IT-positive. Some POA neurons had double-labeled fibers with varicosities, suggesting that GPR30 may be co-localized with the neuropeptide's axonal secretory vesicles. Preadsorption of the anti-oxytocin antibody with excess VT did not block

GPR30 or IT immunoreactivity or co-immunolabeling, however, preadsorption of the anti-oxytocin antibody with excess IT eliminated IT immunoreactivity but not GPR30 immunoreactivity. We observed similar patterns of GPR30/isotocin co-localization in males sacrificed both during and outside of the breeding season. Together, these observations suggest that GPR30 has the potential to mediate the rapid neuroendocrine effects of estradiol in the preoptic area, including the rapid release of isotocin, to influence vertebrate sociality.

Title: Recurrent clusters of gene expression characterize the impact of the estrous cycle in the rat brain

Authors: A. KACPURA[1], R. SCHMIDT[2], L. WELCH[2], *S. DE LACALLE[1];
[1]Biomed. Sci., Heritage Col. of Osteo. Med., Athens, OH; [2]Electrical Engin., Russ Col. of Engin., Athens, OH

Abstract: The roles of hormonal and genetic factors in the emergence of sex differences in susceptibility to mental disorders, mood and cognitive disturbances are far from understood. While it is not known why major depressive disorder affects twice as many women as men over the course of a lifetime, fluctuating reproductive hormones are a potential factor (Joffe & Cohen, 1998), perhaps through changes in neurotransmitters involved in mood regulation (Freeman et al., 2006; Daly et al., 2003). We set out to identify patterns of gene expression across the estrous cycle, with the goal of obtaining a point of reference to understand the connection between hormonal cyclicity and mental health in aging. We processed the basal forebrain, dorsal hippocampus and frontal cortex regions of female rats at 10 am and 6 pm on proestrus, and at 10 am on estrus (n=4 in each group), using Affimetrix Rat Genome 230 2.0 Array. A comparison of the three time points across all brain regions revealed 198 probes and 106 genes differentially expressed with a nominal p-value under the 0.05 threshold. Applying the Bayesian estimation of temporal regulation (BETR) algorithm we identified 465 probes and 273 genes differentially expressed, with probability greater than 0.99, across the three time points in all brain regions. Compared to this overall brain expression, each brain region exhibited larger number of differentially expressed probes and genes: 693 probes and 422 genes in the frontal cortex; 798

probes and 529 genes in the basal forebrain, and 1642 probes and 1054 genes in the hippocampus. The hippocampus contained the most differentially expressed probes and genes when using a BETR probability threshold of 0.99. Fuzzy clustering of differentially expressed probes identified by the BETR algorithm was conducted using the Bioconductor package Mfuzz 2.18.0, resulting in the identification of nine expression patterns for each of the specific areas of the brain and across the brain as a whole. Clearly, the impact of the estrous cycle on gene expression in the central nervous system appears to follow a tightly regulated pattern with unique features in the different brain regions analyzed, and it also seems to be more extensive than anticipated.

Title: Changes in socio-sexual interactions during transition from non-estrus to estrus in devocalized as well as vocalizing hormone-treated, ovariectomized rats housed in a semi-natural environment

Authors: ***O. LE MOENE**[1], E. SNOEREN[2], X. CHU[2], A. AGMO[2];

Abstract: Previous studies in intact females revealed a sudden change in behavior immediately preceding the first lordosis displayed during estrus. The purpose of the present study was to determine whether this sudden change occurs also in ovariectomized females after sequential estrogen - progesterone treatment. Five groups of 7 rats (3 males and 4 females) were housed in a semi-natural environment for 8 days. Some of the individuals were devocalized prior to experiment. Females were injected with 18 µg/kg of estradiol benzoate 48 h prior to observation and with 1 mg/rat of progesterone 4 h before observations. Socio-sexual behaviors during the 8 minutes preceding the first lordosis of each female and the 8 minutes following it were recorded. Females demonstrated more paracopulatory behaviors during the estrus than before it, but also more nose-off and more flight. In parallel, males performed more pursuits, more mounts and more nose-off during estrus. Further analysis revealed that most of the behavioral changes happened between the last minute of the pre-estrus period and the first minute of the estrus; and

for some of them even between the last 30 sec of the pre-estrus and the first 30 sec of the estrus. For the first 8 minutes of the estrus period, the lordosis quotient was 97±16%. This demonstrates that once a female had displayed the first lordosis, she responded with lordosis to almost all mounts. Thus, the transition from non-estrus to estrus occurred in less than one minute, and females achieved instantaneously maximum receptivity. During the estrus, the number of agonistic behaviors was correlated to the number of sexual behaviors performed by the females. One explanation may be that the females in estrus attracted more males, then by rejecting unpreferred males, they increased their agonistic behaviors. This relationship was not observed among the male behaviors, which suggests that the rise in female agonistic behaviors is indeed due to male sexual solicitation. No effect of devocalization was found on socio-sexual behaviors during the transition period. Moreover, males did not show any preference for vocalizing females compared to devocalized ones. Conversely to what has been observed in most studies conducted in small cages and with forced sexual interactions, the behavioral transition from non-estrus to estrus is instantaneous rather than gradual in a semi-natural environment in which female herself determines whether to copulate or not. Because this pattern exists both in intact females and in females with induced estrus, we can conclude that the behavioral changes observed are not directly related to momentaneous changes in hormones levels.

Title: Differences in oxytocin, vasopressin, dopamine and estrogen receptor expression in female and male oxytocin knockout (OTKO) mice

Authors: ***A. B. LUCION**[1], V. LAZZARI[3], J. ZIMMERMANN-PERUZATTO[2], R. O. BECKER[3], S. ALMEIDA[4], M. GIOVENARDI[3];

[2]Physiol., [1]Univ. Federal do Rio Grande Sul UFRGS, Porto Alegre, Brazil; [3]Physiol., [4]Mol. Biol., Univ. Federal de Ciencias da Saude de Porto Alegre, Porto Alegre, Brazil

Abstract: Previous studies showed reduced sexual behavior in oxytocin knockout (OTKO) female mice, but not males. Present study aimed to analyze the expression of oxytocin (OXTR), vasopressin 1A (AVPR1a), dopamine D2 (D2R), alpha estrogen (ERα), and beta estrogen (ERβ) receptors in the prefrontal cortex (PFC), hippocampus (HPC), hypothalamus (HPT), and olfactory bulb (OB) of C57BL/6 mice. The animals (n=7/group) were genotyped (WT and OTKO groups); decapitated; and brain areas were collected. Total RNA was extracted and cDNA was produced. Amplification was performed by real-time quantitative polymerase chain reaction. Data are presented as mean ± SE; Mann-Whitney test was used for statistical analysis. Male mice results: OTKO group had increased OXTR expression in the HPC (WT: 9.96±6.35; OTKO: 69.84±40.09); in the other areas OXTR expression was not different between groups. D2R decreased expression in HPC (WT: 6.26±3.95; OTKO: 0.28±0.12); no differences were detected in other areas. OTKO group had increased ERβ expression in PFC (WT: 1.23±0.30; OTKO: 4.73±1.05); no differences were detected in the other areas. AVPR1a and ERα showed no differences between groups in all areas. Female mice results: OTKO group had decreased OXTR expression in HPC (WT: 1.56±0.51; OTKO: 0.52±0.08), while other areas had no differences. OTKO group had increased expression of AVPR1a in HPC (WT: 1.36±0.36; OTKO: 3.97±0.77) and decreased in HPT (WT: 1.35±0.36; OTKO: 0.26±0.09), no differences in other areas. In the PFC, OTKO group had decreased ERα (WT: 1.24±0.30; OTKO: 0.43±0.21) and ERβ expression (WT: 1.40±0.39; OTKO: 0.40±0.132); no differences in other areas. No differences in the expression of D2R were shown. The lack of oxytocin in the OTKO mice affects differently male and females: while OXTR is increased in males HPC, it is decreased in females HPC; while ERβ is increased in males PFC, it is decreased in females PFC. These opposite results can be an interesting way of behavioral modulation of sexual behavior. The dopamine receptors in the HPC were affected only in OTKO males. Differences in AVPR1a and ERα expression were detected only in females. The lack of oxytocin induces sex specific changes in receptors in specific brain areas that could be related to the behavioral changes observed in OTKO animals.

Title: A comparison of maternal hormonal influences in two animal models of autism

Authors: *H. GARMAN[1,2], A. LEE[5,2], J. KASS[5,3], P. WHITAKER-AZMITIA[5,4]; [2]Integrative Neurosci. in Psychology, [1]Stony Brook Univ., Stony Brook, NY; [3]Integrative Neurosci. in Psychology, Stony Brook Univ., Stony Brook University, NY; [4]Integrative Neurosci. in Psychology, Psychiatry, Stony Brook Univ., Stony Brook, NY; [5]Stony Brook Unversity, Stony Brook, NY

Abstract: The maternal environment associated with the neuroendocrine system has been proposed to play a role in the etiology of Autism Spectrum Disorders (ASD). Characteristics that typify ASD are heterogeneous with an increased incidence in males and several etiological elements are likely to be involved. Progesterone and testosterone are sex hormones involved in brain development which have been implicated in ASD. Specifically, low maternal progesterone (as evidence by increased obstetrical complications) or high testosterone (as proposed in the extreme male hypothesis) have been proposed as possible causes of ASD. Here, we compared a model of low progesterone (lowP), using the progesterone antagonist, RU-486 (5 mg/kg) or high testosterone (T) using 17β-estradiol (5µg/ kg), which masculinizes rodents, in order to test the hypothesis that these could be contributing factors to ASD. Litters from six Sprague-Dawley rats were cross-fostered and divided into three equal groups of 20 pups each: and injected subcutaneously on postnatal days 1, 2 and 5 (equivalent to human third trimester). We observed their physical, social, and motor development using an array of behavioral testing relevant to ASD. Both lowP and T showed deficits in social bonding characteristic of animal models of ASD, including huddling and return to dam. Importantly, females in the lowP group showed less bonding than the males; this was not seen in the T group nor the control group. Both groups showed increased stereotypy on PND 27 compared to the control group. Results showed body weight differences across groups. The lowP group showed increased body weight, whereas the T group showed decreased body weight compared to the control group. Using negative geotaxis at PND's 7, 8 and 11 as a test for motor development, T showed accelerated motor development compared to control while lowP showed a delayed motor development compared to both groups. Our results show that hormones in the maternal environment may contribute to the social behavioral changes which are hallmark features of ASD. However, there are also differences which could explain the spectrum nature of ASD. Specifically, these behavioral results suggest that low progesterone may serve as a model for characterizing behaviors specific to females with ASD. On the other hand, high testosterone may model early increased brain development, seen in certain cases of ASD. These results suggest a disruption in the neuroendocrine system leading to changes in physical development, motor skills, and social behavior. Further investigation into these animal models may be a step forward in understanding the significance of maternal environment and risk of ASD.

Title: Estradiol-G protein-coupled estrogen receptor 1 facilitation of sexual receptivity via direct regulation of the orphanin FQ/N-ORL-1 system in the arcuate nucleus of the hypothalamus

Authors: ***D. N. TRAN**, N. LONG, C. SEREY, K. SINCHAK;
California State Univ. Long Beach, Long Beach, CA

Abstract: In the ovariectomized (OVX) rat primed with 2 μg estradiol benzoate (EB), sexual receptivity (lordosis) can be facilitated within 30 minutes by infusing non-esterified 17β-estradiol (E2) into the arcuate nucleus of the hypothalamus (ARH). Infusion of the G protein-coupled estrogen receptor 1 (GPER; aka GPR30) agonist, G1, mimicked E2 facilitation of lordosis and was blocked by pretreatment with a GPER antagonist G15 (Long, et al., 2014 Horm Behav 66:663). EB-priming initially inhibits lordosis through rapidly activating ARH β-endorphin (β-END) neurons to activate μ-opioid receptors (MOP) in the medial preoptic nucleus (MPN). Forty-eight hours later, E2 infused into the ARH acts through GPER to inhibit ARH β-END neurons facilitating lordosis. A single high dose of EB (5-50 μg) also facilitates lordosis via orphanin FQ (OFQ/N; aka nociception) activating opioid receptor-like receptor 1 (ORL-1) that inhibits ARH β-END neurons. We therefore hypothesized that E2-GPER facilitation of lordosis is also mediated via OFQ/N activation of ORL-1 in the ARH. EB-primed (2 μg) OVX rats received sequential ARH infusions 47.25 (DMSO or UFP-101 (ORL-1 antagonist)) and 47.5 (DMSO, G1, or E2) hours later and then tested 30 minutes later for sexual receptivity. G1 and E2 ARH infusions facilitated lordosis and reduced MPN MOP activation. Pretreatment with UFP-101 prevented G1 and E2 MPN MOP deactivation and facilitation of lordosis, indicating the OFQ/N-ORL-1 system mediates E2-GPER facilitation of lordosis. The E2-GPER induced OFQ/N-ORL-1 inhibition of the β-END neurons is independent of progesterone receptor (PR) activation since RU486 (PR antagonist) did not block deactivation of MPN MOP and facilitation of lordosis by ARH infusion of OFQ/N. We confirmed that E2-GPER may act directly on ARH

OFQ/N neurons using double-label immunohistochemistry for GPER (Novus Biologicals) and OFQ/N (Neuromics), as well as GPER and ERα (Millipore), and ERα and OFQ/N. Subpopulations of ARH neurons were immunofluorescently double labeled for OFQ/N and GPER, OFQ/N and ERα, and GPER and ERα. These results indicate that E2 acts through GPER in OFQ/N neurons in the ARH to activate ORL-1 reducing β-END neuronal activity and facilitating lordosis. The colocalization of GPER and ERα indicate that estradiol can act through multiple ER mediated signaling pathways to regulate the activity of ARH neurons.

Title: Protein-protein interactions underly the interdependence of progesterone receptor-B, dopamine D1 receptor and Src family kinase signaling in the plasma membrane of the arcuate nucleus of the hypothalamus of female rats

Authors: *J. PHAN, D. LE, T. CHUON, K. SINCHAK;
Biol. Sci., California State University, Long Beach, Long Beach, CA

Abstract: Estradiol upregulation of classical progesterone receptor-B (PR-B) is necessary for progesterone facilitation of sexual receptivity (lordosis). Progesterone infused into the arcuate nucleus of the hypothalamus (ARH) facilitates lordosis within thirty minutes in ovariectomized (OVX) rats primed with 2μg of estradiol benzoate (EB). However, these rapid actions of progesterone indicate that it is signaling through extranuclear receptors to inhibit ARH β-endorphin neurons to induce lordosis. Although PR-B is a classical nuclear transcription factor, it is found in the cytoplasm and plasma membrane. We have shown PR-B to form complexes with Src family kinase (Src) in the cytoplasm and membrane cellular fractions from the ARH and that progesterone facilitation of lordosis requires Src activation. Progesterone facilitation of sexual receptivity is also mediated by the dopamine D1 receptor (D1). D1 has been hypothesized to

activate PR via a ligand independent mechanism (Mani et al., 1994; Mani et al., 1996). However, D1 can signal through multiple G protein signaling cascades as well as Src. We observed that PR, D1, and Src signaling pathways that facilitates sexual receptivity are interdependent. Antagonizing one, blocks facilitation of lordosis by the other two. This indicates that PR, D1, and Src signaling converge and are interdependent to facilitating sexual receptivity. We hypothesized that these PR-Src-D1 interactions are in ARH β-endorphin neurons. To test this, we performed double label immunohistochemistry in tissue from EB-primed female rats. Subpopulations of ARH β-endorphin immunopositive neurons also contained PR and D1 immunostaining. We showed previously PR and D1 colocalization in the ARH. Together, these results studies indicate the potential for expression of PR and D1 in β-endorphin neurons. Previously, we demonstrated that PR-B and D1 in ARH do not form complexes. Therefore, we tested the hypothesis that D1 and Src form complexes in the ARH. OVX rats were treated with EB or EB + progesterone and plasma membrane and cytosolic fractions were extracted from ARH block dissections. Western blot analysis revealed Src and D1 were present in the ARH, and co-immunoprecipitation experiments indicated the potential for D1 and Src to form complexes. Our results suggests that PR and D1 in the plasma membrane are capable of complexing with and signaling through Src in neurons of the ARH. These direct Src interactions with PR and D1 may explain the interdependence of these signaling proteins in the ARH to facilitate sexual receptivity.

Title: Estradiol-GPER facilitation of lordosis in the female rat is via direct regulation of the orphanin FQ-ORL-1 system in the arcuate nucleus

Authors: *N. P. LONG, S. M. CHOKR, K. SINCHAK;
Biol. Sci., California State Univ. Long Beach, Long Beach, CA

Abstract: In the female rat, sexual receptivity (lordosis) can be facilitated by sequential activation of estrogen receptor (ER) α and G protein-coupled estrogen receptor 1 (GPER) by estradiol (Long et al., 2014, Horm Behav 66:63). Estradiol initially binds to ERα in the plasma membrane that complexes with and signals through metabotropic glutamate receptor 1a (mGluR1a) to rapidly activate β-endorphin (β-END) neurons in the arcuate nucleus of the hypothalamus (ARH) that project to the medial preoptic nucleus (MPN). This activates MPN μ-opioid receptors (MOP) to inhibit lordosis. Facilitation of lordosis is dependent on the subsequent deactivation of MPN MOP. In a 2 μg estradiol benzoate (EB) primed ovariectomized (OVX) rat, infusion of non-esterified 17β-estradiol (E2) 47.5 hours later reduces MPN MOP activation and facilitates lordosis in 30 minutes through activation of the orphanin FQ-opioid receptor-like-receptor-1 (ORL-1) system that reduces β-END neuronal activity. We previously demonstrated that lordosis can be facilitated by treating EB-primed OVX rats with selective estrogen receptor modulators (SERMs) tamoxifen (TAM) or ICI 182, 780 (ICI). Although TAM and ICI are classical estrogen receptor antagonists, they have also been reported to activate GPER. Therefore, we hypothesized that infusion of either TAM or ICI into the ARH of a 2 μg EB-primed rat will rapidly deactivate MPN MOP and facilitate lordosis through a GPER dependent pathway. Infusion of either TAM or ICI into the ARH 47.5 hours after EB priming facilitated sexual receptivity within 30 minutes and reduced MPN MOP activation compared to vehicle controls. Further, both the deactivation of MPN MOP and the facilitation of lordosis through infusion of TAM or ICI were significantly decreased when animals were pretreated with the GPER selective antagonist, G15. Our findings indicate that TAM and ICI act through GPER to deactivate MPN MOP and facilitate lordosis. Thus, these SERMs can activate GPER in the CNS to produce estrogenic actions in neural circuits that affect physiology and behavior.

Title: Oxytocin receptors in the insular cortex mediate social affective behavior in rat

Authors: *M. M. ROGERS[1], A. F. PIERCE[2], J. P. CHRISTIANSON[2];
[1]Dept. of Psychology, [2]Boston Col., Chestnut Hill, MA

Abstract: Aberrant social behavior characterizes numerous psychiatric conditions like autism and schizophrenia. Impairments in the processing of affective information may account for deficits in empathy, perspective-taking and other social cognitions. The ability to detect the emotional state of an individual, or social affect, is a prerequisite for these sophisticated social behaviors. The insular cortex (IC) has rich sensory inputs and has been implicated in healthy and disordered social affect. Moreover, oxytocin (OT) modulates social behaviors and rich OT receptor (OTR) binding is found in the IC. To explore the contribution of insular OTR in social affect we introduced an affective manipulation to a rat social interaction test. In the Social Affective Preference (SAP) test an adult male rat is presented two unfamiliar male juvenile conspecifics, one exposed to stress (2x 5 s, 1mA footshocks) and the other naïve to treatment. In the SAP test adult male rats preferred to interact with the stressed juvenile ($p<0.01$). Bilateral infusion of OTR antagonist (10μg/side) to the IC prior to SAP testing abolished the preference for the stressed juvenile. The OTR is coupled to the extracellular signal-regulated kinases (ERK). Immunohistochemical analysis revealed that after a social interaction with a stressed juvenile, the number of phosphorylated ERK immunoreactive cells in the IC of adult male rats tended to correlate with time spent in interaction, but did not reach significance. Consistently, intra-insula inhibition of the ERK signaling cascade by U0126 (500ng/side) also prevented social affective preference. Together these data suggest that OTR and, possibly, ERK in the insular cortex are necessary for this form of social affect in rat.

Title: Effects of repeated presentation of social stimuli on social investigatory behavior in oxytocin receptor knockout male mice

Authors: *S. SAGOSHI[1], K. NISHIMORI[2], T. SAKAMOTO[3], S. OGAWA[1];
[1]Lab. of Behavioral Neuroendocrinology, Univ. of Tsukuba, Tsukuba, Japan; [2]Dept. of Mol. and Cell Biology, Grad. Sch. of Agr. Science,, Tohoku Univ., Miyagi, Japan; [3]Dept. of Psychology, Kyoto Tachibana Univ., Kyoto, Japan

Abstract: It is well established that oxytocin (OT) and oxytocin receptors (OTR) may play a primary role in the regulation of social recognition. However, it is still largely unknown about details in 'social amnesia' phenomenon (i.e., failure of discrimination between familiar and unfamiliar opponents) reported in OT and OTR knockout mice. In the present study, we aimed to determine whether repeated exposure to social stimuli might influence social investigatory behavior toward familiar and unfamiliar opponent mice in OTR knockout (OTRKO) male mice. Using social interaction test paradigm developed in our laboratory (SOSI Type1), we examined social investigatory (SI) behavior. Male OTRKO and their wild-type littermate (WT) mice were singly housed. Each mouse was tested for 4 days against a same male stimulus mouse presented in a transparent acrylic cylinder with holes placed at the center of his home cage for 4min per trial, 4 trials a day with 17min intervals. On Day 5, mice were tested similarly toward a novel male stimulus mouse. In each test, cumulative duration of sniffing toward stimulus mice was recorded as SI duration. We found WT mice showed a within-day decrease of SI duration toward the same stimulus starting on Day 1 whereas OTRKO mice failed to do so. However, staring on Day 3, OTRKO mice also showed a within-day decrease of SI duration. Moreover, on Day 5 when a novel stimulus was presented, both WT and OTRKO mice showed a clear within-day decrease of SI duration. These results suggest that repeated exposure to a stimulus mouse might be able to modify behavioral responses in social context in OTRKO mice and these effects of social experience might be generalized to their responses to a novel social stimulus. On the other hand, there was no spatial memory dysfunction in OTRKO mice in the Barnes maze task, suggesting that disruption of OTR gene affected behavioral responses specifically in social context.

Title: Effects of vasopressin V1a receptor in the bed nucleus of the stria terminalis on social withdrawal in males and females

Authors: *N. DUQUE, M. Q. STEINMAN, R. HAO, S. YOKOYAMA, B. C. TRAINOR; UC Davis, Davis, CA

Abstract: Oxytocin (OT) has important effects on social behaviors and coping responses to stress, with most studies indicating an anxiolytic effect of OT. However, in several cases OT has been reported to have anxiogenic effects. We recently discovered that social defeat stress induces hyperactivity in oxytocin neurons in the bed nucleus of the stria terminalis (BNST) and paraventricular nucleus, and that this effect is primarily observed in females but not males. These studies used the monogamous California mouse, which is one of the few species in which social defeat stress can be studied in both males and females. We found that intranasal infusions of OT reduced social interaction behavior in females but not males, which closely mirrors the effects of social defeat stress on this behavior in females. We also used autoradiography to quantify oxytocin receptor (OTR) and vasopressin V1a receptor (V1aR) expression. In the BNST, V1aR but not OTR was negatively correlated with social interaction behavior in females, and positively correlated in males. We used a pharmacological approach to test whether activation of V1aR in the BNST plays a role in stress-induced social withdrawal. Control and stressed males and females were randomly assigned to be infused with either artificial cerebrospinal fluid (CSF) or the selective V1aR antagonist β-Mercapto-β,β-cyclopentamethylenepropionyl1, O-me-Tyr2, Arg8]-Vasopressin). Stress reduced social interaction behavior in females and males. Intriguingly, V1A antagonist significantly reduced social interaction not only in naïve males, but also females, and had no effect on stressed animals. Thus, if hyperactivity of OT neurons contributes to social withdrawal in females, it appears that V1aR in the BNST are not an essential mechanism. Ongoing experiments are investigating whether other receptor populations contribute to stress-induced social withdrawal.

Title: Examination of oxytocin and vasopressin on the three chamber sociability test in male or female mice injected flutamide or letrozole

Authors: *Y. MOMOTA[1], T. AMANO[3], H. KAWABATA[2], H. SAITOH[2];

Abstract: Oxytocin (OT) and Vasopressin (AVP) are participated in various neuronal activity like sexual behavior and social recognition. Estradiol (Est) and testosterone (T) are reported to regulate the expression of OT and AVP in the CNS. The present study examined the effect of OT and AVP on sociability to partner in the male and female mice administered flutamide (Flu) or letrozole (Let). Both male and female mice (ddy strain) were equally divided into 3 groups, that is, male or female vehicle mice (MV or FV), accordingly, flutamide administrated mice (MF or FF) and letrozole administrated mice (ML or FL). Let or Flu was administered po per day at the dose of 15mg/kg or 20mg /kg, respectively. Mice were examined the partner preference test which was assessed with three camber sociability test according to method by A.C. Felix-Ortiz and K. M.Tye. The apparatus was divided 3 chambers. Mini cages were placed in end chambers. In each session, test mouse selected from vehicle mice and drug administered mice was placed in center camber first. Then an unfamiliar different sex mouse (1st presenter) was in a mini cage in one of end chambers. Likewise, next another mouse (2nd presenter) was placed in another end chamber. Sociability to different sex was evaluated in staying time of test mouse in each end chambers located different sex mouse in last 10 min (ST). After initial test, effect of OXY (0.2 n mole per 10g bw, intranasal administraion) was examined in test mouse. One week later, the effect of AVP (0.2 n mole per 10 g b.w.) was estimated. Male mouse: Without OXY and VAP treatment, VM and MF mouse indicated significantly longer ST in 2nd presenter camber, however, the ST of ML mouse was not significantly different. OXY treatment to male 3 groups indicated longer ST in 2nd mouse chamber. VAP treatment to VM mouse showed as same as OXY treatment, however, MF and ML mouse showed significantly longer ST in 1st mouse chamber. Female mouse: Without OXY and VAP treatment, all test mouse showed significantly longer ST in t 2nd mouse chamber. OXY treatment to all female test mice showed no significantly different ST (that is, equally stayed in each end chamber). AVP treatment to VF and FL mouse did not show significantly difference in ST, however, FF mouse showed significantly longer ST in 2nd mouse chamber. From present results, female mice indicate high sociability to 2nd mouse, which is not affected by Est and T level. However, oxytocin treatment decreases the sociability. Form the result of VF mouse, AVP and OXY shows cross- reactivity in the sociability. The effect of OXY and AVP is roughly different between female and male mice. Male sociability to female mouse might be strongly influenced by action of estradiol and AVP.

Title: Oxytocin receptor in the periphery of the perinatal mouse

Authors: R. VAIDYANATHAN[1], C. N. CARLTON[2], E. KIDWAI[2], T. A. MERRITT[2], I. SAKINAH[2], J. R. QUINTANA[2], G. G. HOFFMAN[1], *E. A. HAMMOCK[1];

Abstract: Oxytocin (OXT) and the OXT receptor (OXTR) influence adult species-typical social behaviors. Peripheral OXT exposure during development leads to long term changes in the brain and in social behavior, but by unknown mechanisms that may involve OXT signaling through OXTR in the periphery. We previously observed OXTR ligand binding in peripheral tissues of the perinatal C57BL/6J mouse, including the mouth, nasal cavity, dermis, brown adipose tissue, adrenal gland, kidney, and anogenital area. This distribution of OXTR protein indicates that some of these peripheral OXT receptors are poised to detect maternal sources of OXT in milk, saliva, and amniotic fluid. To begin to refine our hypothesis of the potential role of maternal sources of OXT acting on peripheral OXTR, we have investigated the distribution of Oxtr mRNA by colorimetric *in situ* hybridization in the whole perinatal mouse with a probe specific to the 3'UTR of Oxtr mRNA. We observed abundant and widespread mRNA expression in the brain and the face. We detected modest levels of Oxtr mRNA in brown adipose tissue, adrenal glands, and kidneys. In all of these areas, most of the colorimetric detection was diffuse and did not have the characteristic appearance of mRNA in the cell body. In addition, we also observed significant Oxtr mRNA expression in the dorsal root ganglia and in the trigeminal nucleus. The staining in these ganglia was a characteristic mRNA profile localized in the cell body. This suggests an intriguing hypothesis that Oxtr mRNA is expressed by visceral sensory afferents (the dorsal root ganglia) and touch and pain afferents of the face (the trigeminal) and that those cells transport Oxtr mRNA to distal locations where we detected diffuse extra-somal pattern of mRNA. Trafficked mRNA may be locally translated into the observed OXTR protein in these peripheral tissues. These findings are consistent with our hypothesis that exogenous sources of OXT may modulate afferent sensory signals, and provide a hardwired circuit for maternal OXT to shape the experience-dependent development of the infant brain.

Title: Prolactin decreases social avoidance and is required for short-term social memory

Authors: *M. DONHOFFNER[1], R. I. WOOD[2];
[1]USC, Los Angeles, CA; [2]Cell and Neurobio., Keck Sch. of Med. of the Univ. of Southern California, Los Angeles, CA

Abstract: Prolactin (PRL) is an anterior pituitary hormone essential for milk production during lactation. Oxytocin (OT) is a posterior pituitary hormone essential for milk-let down during lactation, but also functions as a neuromodulator to promote affiliative behaviors such as social memory, and approach. Since PRL and OT have complementary peripheral functions in lactation it is reasonable to expect that they share similar central functions to promote social behavior. Accordingly, we hypothesized that PRL increases social approach and social memory. To test this hypothesis, we determined if PRL restores approach behavior following acute social defeat. We also tested whether PRL increases discrimination of a familiar vs a novel rat. Male Long-Evans rats were injected ip with ovine PRL (2 mg/kg), the PRL antagonist bromocriptine (3 mg/kg) or saline vehicle 20 mins prior to behavioral testing. For social defeat, the test rat was placed in the home cage of a larger, aggressive male for 30 mins; non-defeated controls were placed in an empty cage. 2 hours later, rats were tested for 4 mins for approach (within 4 cm) towards an empty cage, followed by approach towards an identical cage containing the defeater rat. Compared to non-defeated controls, defeated rats avoided the defeater, but there was no difference in approach towards the empty cage. PRL administration, either before or after social defeat, restored approach towards the defeater rat (PRL before: 167.9±6.5 sec/4mins, PRL after: 154.4±11.1, defeated vehicle 107.3±6.6, $p<0.005$). In non-defeated rats, treatment with PRL or bromocriptine had no effect. These results suggest that PRL increases social approach in defeated rats. To determine whether PRL increases social memory, we tested rats with a social discrimination task. The test rat was housed with an unfamiliar stimulus rat for 4 mins. After 45 mins (short-term memory) or 2 hr (long-term memory), the test rat was exposed to both the familiar rat and a novel stimulus rat for 4 mins, and the time spent investigating each rat was measured. Rats prefer a novel rat over a familiar stimulus animal, and this discrimination persists for ca. 1 hr. After a 45-min delay, rats treated with bromocriptine to reduce PRL failed to show a

preference for the novel rat (familiar: 57.5±9.9sec vs novel: 61.4±8.2, p>0.05). However, PRL treatment did not enhance preference for the novel rat after a 2 hr delay (familiar: 56.1±6.3sec vs novel: 54.3±9.3, p>0.05), similar to saline-treated controls. These results suggest that PRL is required for short-term social memory. Therefore, this study suggests that PRL promotes affiliative social behaviors, similar to OT.

Abstract: Oxytocin is a nine amino acid neuropeptide associated with prosocial behaviour in healthy subjects. It has been suggested that oxytocin's ability to increase sociability is through a reduction in stress reactivity. In light of its prosocial effects, oxytocin is increasingly being recognized as a novel therapeutic target for psychiatric disorders characterized by social dysfunction including social anxiety, schizophrenia and autism. Owing to poor blood brain permeability, oxytocin is usually administered intranasally in humans as this route is thought to provide direct access to the brain. There are however, surprisingly few preclinical studies investigating effects of intranasal oxytocin in rodents which should be pursued given that intranasal oxytocin is increasingly being prescribed by health practitioners. With this in mind, in the present study, we assessed the effects of intranasal oxytocin on social interaction and release of corticosterone (a measure of stress reactivity) in rats and compare these effects with those elicited by the more traditional intraperitoneal route of administration. Intranasal and systemic administration of 20 but not 5 μg of oxytocin elicited a significant increase in social interaction. In addition, while intranasal oxytocin (20 μg) had no effect on blood corticosterone levels, a

marked increase in blood corticosterone levels was observed following systemic oxytocin administration. These findings in rodents are consistent with those observed in humans in that intranasal oxytocin increases prosocial behaviours. However, these behavioural effects appear unrelated to corticosterone levels refuting suggestions that the prosocial effects of oxytocin stem from reduced stress reactivity.

Title: Arginine vasopressin influences the social behavior of free-living Richardson's ground squirrels (Urocitellus richardsonii)

Authors: A. R. FREEMAN[1], J. F. HARE[2], G. ANDERSON[2], *H. K. CALDWELL[1];

Abstract: In many vertebrate taxa arginine vasopressin (Avp) and its homologues are important to the neural regulation of social behaviors. In rodents, Avp is best known for its modulation of affiliative behaviors such as grooming, sniffing, and the formation of social bonds and memories. Avp is also important for species-specific vocalizations, as demonstrated through work on birds, fish, and amphibians. More recently, Avp has been found to influence social communication in laboratory rodents (i.e. rat and mouse) by altering pup ultrasonic vocalizations. However, this work has not been extended to other rodent species or to free-living individuals of any species. Richardson's ground squirrels (*Urocitellus richardsonii*) are free-living social rodents, in which alarm calling serves as a proximate manifestation of sociality. In order to determine how Avp effects social communication in the wild, we implanted osmotic minipumps into Richardson's ground squirrels and administered Avp or saline intracerebroventricularly. We then examined behavior before and after Avp or saline administration using three assays: 1) a general behavior survey, 2) a predator model presentation, and 3) a social challenge experiment. While saline had no effect, Avp reduced aggression and increased antipredator vigilance and escape behavior in

males, but had no effect on the propensity to emit alarm calls in response to a predator model. However, during the social challenge, Avp-treated males increased chirp-type vocalizations during social interactions. These context-specific effects (i.e. predator versus conspecific) on communication are interesting and mirror effects seen in olfaction experiments with laboratory rodents. This work is significant as it is the first of its kind to examine the effects of Avp on social communication in the wild. Further, our discovery of Avp's effects on vigilance in a social setting is particularly exciting and highlights Avp's extensive influence on social behavior.

Title: Sex-specific influence of vasotocin cell groups on behavioral phenotype and phasic response to social contact in a gregarious finch

Authors: *C. L. PETERSEN, S. E. SCHROCK, M. A. KINGSBURY, J. L. GOODSON; Evolution, Ecology and Behavior, Indiana Univ., Bloomington, IN

Abstract: Sociality (grouping behavior) is but one aspect of an animal's social-behavioral repertoire. In estrildid finches, species-specific diversity in sociality is mediated by the nonapeptides arginine vasotocin (VT; Ile^3-Vasopressin) and mesotocin (MT; Ile^8-Oxytocin). Likewise, how individual finches respond to social or stressful conditions i.e., their behavioral phenotype or "personality" is significantly related to variation in constitutive expression of VT and MT in multiple brain regions. Less is known, however, about the relationship between measures of "personality" and how these nonapeptide groups respond to social contact, a metric of sociality. Here we test the hypothesis that behavioral phenotype will influence patterns of neural activation in response to social contact within multiple VT populations in a sex-specific manner. Male and female zebra finches (*Taeniopygia guttata*) were behaviorally phenotyped to determine individual levels of social contact time (sociality) and anxiety-like behaviors. Next, finches were housed overnight in sound attenuation booths in visual isolation from conspecifics. The next morning, focal birds had 2 novel same-sex conspecifics placed in their cages. Control

birds were left in social isolation. After 90 minutes, birds were sacrificed and brains were processed for multi-fluorescent immunocytochemistry (ICC). We investigated labeling of the immediate early gene product FOS within VT neurons in the medial bed nucleus of the stria terminalis (BSTm) in the amygdala, and the paraventricular nucleus (PVN) and supraoptic nucleus (SON) of the hypothalamus. We find that males exposed to same-sex conspecifics have a significantly higher percentage of VT-FOS colabled neurons in the BSTm than do control males. While there is no difference in VT-FOS colocalization in the BSTm of females, there is a significant correlation between social contact time (during personality assessment) and VT-FOS co-labeled cells in BSTm in both sexes. We find no difference in VT-FOS colocalization in the PVN for either sex or social treatment condition. Within the SON as a whole, there was no difference in VT-FOS colabeling in males or females regardless of condition; however, females had higher levels of VT-FOS colabeled neurons in the medial SON than males regardless of treatment group. Finally, total number of VT SON neurons correlated positively with social contact time in males, but not in females. To our knowledge, these data are the first to demonstrate how constitutive levels of VT in SON can relate to measures of an animal's "personality", and they offer a more complete picture of VT activation during social contact.

Title: Experience-induced facilitation of mouse empathetic behavior

Authors: *T. SAKAGUCHI, S. IWASAKI, K. OKAMOTO, Y. IKEGAYA;
Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Empathy, a high-level cognitive process, is believed to exist exclusively in humans; however, recent evidence has demonstrated empathy-like behaviors in rodents. The rodent models provide experimental platforms to investigate the neural basis that brings about empathy. We developed a fear observational system in which a mouse (observer) exhibits freezing

behavior through observation of another freezing mouse (demonstrator) that receives repetitive foot shocks. We found that observers showed higher freezing responses when they had received a priming foot shock. The priming shock could not be replaced with other aversive experiences, such as forced swimming and tail pinch, which suggests that empathy is facilitated by a common, shared experience. Moreover, the priming shock-induced increase in freezing time was abolished by systemic injection of MK801, an NMDA receptor antagonist. Thus, the priming effect is likely to emerge through NMDA receptor-dependent neuronal plasticity. We then focused on oxytocin, which is known to have broad effects on social behaviors in humans as well as rodents. Intraperitoneal injection of L-368,899, an oxytocin receptor antagonist, 30 min prior to fear observation attenuated the freezing response. Thus, oxytocin is likely to mediate the experience-dependent modulation of empathetic behaviors of fear-observing mice. Next, we investigated whether the priming shock leads to a reorganization of neuronal ensembles in the neocortices. To identify neurons that were active during the priming shock and/or the fear observation, we used temporal activity mapping with cellular resolution by detecting *Arc* mRNA (i.e., catFISH). We revealed that the neuronal ensembles that were active during the priming shock were significantly overlapped with those that were active during the fear observation, suggesting that the same neuron subpopulation was recruited in firsthand and vicarious pain representation. Thus, empathy may be a vicarious experience of what another person feels at the neuron level.

Title: Molecular mechanisms underlying sex differences in the brain oxytocin system

Authors: *N. B. WORLEY;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The neuropeptide oxytocin (OT) has been shown to modulate social behaviors, and often does this in sex-specific ways. This may be due to sex differences in the brain OT system. In support, our lab has recently demonstrated that adult male rats have higher OT receptor (OTR) binding densities than females in various forebrain regions, particularly in the posterior bed nucleus of the stria terminalis (BNSTp) and the ventromedial hypothalamus (VMH). Here, we

have started to explore the molecular mechanisms underlying the sex differences in OTR binding. We show that the sex difference in OTR binding density is present before and after puberty in the BNSTp, but only after puberty in the VMH. These sex differences, or lack thereof, correspond with a sex difference in OTR mRNA expression. From this, we hypothesized that the sex difference in OTR mRNA expression in the pBNST, but not the VMH, is the result of gonadal steroid hormone-dependent chromatin remodeling during early postnatal life. Specifically, we predicted that histone deactylation in early postnatal life plays a role in sexual differentiation of OTR mRNA expression in the BNSTp. However, we find that neonatal treatment with a histone deacetylase inhibitor did not alter OTR binding density in the BNSTp or VMH in either sex. Overall, these findings suggest that (1) the sex differences in OTR binding density in the BNSTp and VMH are due to a sex difference in OT mRNA expression, (2) the age of onset of sex differences in OTR is brain region-specific, suggesting separate, or at least temporally disjointed, underlying mechanisms, and (3) the sex difference in OTR binding in the BNSTp may not be the result of a sex difference in histone deacetylase activity in the neonatal rat.

Title: Sub region-specific distribution of μ-opioid receptors in the striatum of juvenile rats: Implications for social novelty preference

Authors: *C. J. SMITH, A. M. RATNASEELAN, M. L. POEHLMANN, A. H. VEENEMA; Boston Col., Chestnut Hill, MA

Abstract: The drive to approach and explore novel conspecifics is inherent to social animals and may promote optimal social functioning. Juvenile animals seek out interactions with novel peers more frequently and find these interactions to be more rewarding than their adult counterparts. We have previously shown that male and female juvenile rats spend more time interacting with a

novel conspecific than a cage mate. However, the neural systems regulating this social novelty preference have yet to be elucidated. We hypothesized that brain systems subserving social information processing and social motivation/reward, i.e., the opioid, dopamine, oxytocin, vasopressin systems, might support social novelty preference. To test this, we used intracerebroventricular antagonist administration to block receptors of each of these systems prior to social novelty preference testing. Central blockade of μ-opioid receptors (MORs) reduced both the duration and frequency of novel social interaction while leaving interaction with the cage mate unaffected. In contrast, central blockade of dopamine D2, oxytocin, or vasopressin V1a receptors failed to alter social novelty preference. Given these results, we next asked where in the brain MORs act to support social novelty interaction, and to that end, where in the brain MOR binding densities are highest in juvenile rats. Based on MOR binding patterns, we analyzed MOR binding density in six subregions of the striatum, namely the anterior caudate putamen (CP), posterior CP, nucleus accumbens (NAc) core, and anterior, dorsomedial, and ventral NAc shell. MOR binding density was the highest in the anterior CP compared to all other subregions. Additionally, MOR binding density within NAc subregions was the highest in the dorsomedial NAc shell. We are currently investigating the role of MORs in these two striatal subregions in the regulation of juvenile social novelty preference. Previous studies suggest a role for the NAc but not the CP in regulating the rewarding aspects of social novelty interaction. Therefore, we will test the hypothesis that MORs in the dorsomedial NAc shell, but not in the anterior CP, facilitate social novelty preference. Understanding the role of the MOR system in social novelty seeking may help to elucidate the neural mechanisms underlying abnormalities in this behavior, as seen in autism and substance abuse disorders. Title: Vasopressin regulates social play in sex-specific ways through glutamate modulation in the lateral septum

Authors: *R. BREDEWOLD, J. K. SCHIAVO, M. VERREIJ, G. RO, A. H. VEENEMA; Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: Social play is an affiliative and rewarding behavior displayed by nearly all mammals and peaks during the juvenile period. We recently showed that arginine vasopressin (AVP) acting via the V1a receptor (V1aR) within the lateral septum (LS) regulates social play in opposite directions in male and female juvenile rats. Specifically, administration of the specific V1aR antagonist (CH2)5Tyr(Me2)AVP into the LS decreased social play in females and increased social play in males . Because previous *in vitro* studies suggest that AVP modulates glutamate and GABA responses in the LS, we hypothesized that AVP may regulate social play differently in males and females by sex-specific modulation of glutamate and/or GABA neurotransmission. Using retrodialysis combined with microdialysis in awake and freely moving juvenile rats, we found that V1aR blockade in the LS increased the release of glutamate within the LS in females but not in males, while GABA release was increased in both sexes. We next determined whether the increase in glutamate release in females underlies the V1aR-induced decrease in social play. Administration of the glutamate receptor agonist, L-glutamic acid, prior to the social play test, decreased social play in females thereby mimicking the behavioral effects of V1aR blockade. This decrease in social play could also be induced in males by injecting L-glutamic acid in the LS. Moreover, L-glutamic acid prevented the V1aR antagonist-induced increase in social play behavior in males. In conclusion, an increase in glutamate in the LS, prior to the play test, has an inhibitory effect on social play in both males and females. These findings further suggest that the sex-specific regulation of social play by AVP involves differential glutamate neurotransmission in the LS of male and female juvenile rats.

Title: Dynamic vasopressin release in the lateral septum during social recognition in adult and juvenile male and female rats

Authors: *B. DIBENEDICTIS, R. BREDEWOLD, A. H. VEENEMA;
Psychology Dept., Boston Col., Chestnut Hill, MA

Abstract: Vasopressin (VP) is a neuropeptide implicated in the regulation of a myriad of social behaviors. VP signaling transpires within a circuit of interconnected limbic structures known collectively as the 'social behavior neural network.' In both rodents and humans, VP signaling has been associated with the regulation of social recognition (the ability to discriminate between familiar and unfamiliar individuals), a behavior critical for appropriate and adaptive social interactions. The lateral septum (LS) receives sexually dimorphic (more in adult males) VP fiber innervation. However, the extent to which sex differences in static LS-VP fiber density correlate with dynamic changes in VP release during social interactions remain unknown. Previous work from our laboratory demonstrated that VP signaling within the LS differentially regulates social recognition in adult versus juvenile rats and in males versus females. We hypothesized that differential LS-VP release in juvenile and adult males and females underlies sex and age-specific regulation of social recognition by VP and that increased VP release is positively correlated with a greater density of VP fibers in the LS. To test this, we are utilizing intracerebral microdialysis in the LS to measure VP release during social recognition in adult and juvenile rats of both sexes. Additionally, we are employing VP immunohistochemistry to determine the relationship between VP fiber density and VP release within the LS. Preliminary results indicate that while adults possess a greater density of LS VP-IR fibers than juveniles, all groups show similar levels of baseline VP release. This work will reveal for the first time how sex and age differences in LS-VP innervation relate to dynamic VP release patterns during social behavior.

Title: Vasopressin modulates lateral septum neuronal activity in sex-specific ways in juvenile rats

Authors: *A. H. VEENEMA, R. BREDEWOLD, J. VARELA, J. P. CHRISTIANSON; Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: We recently showed that arginine vasopressin (AVP) regulates social play behavior in sex-specific ways in juvenile rats. Specifically, blockade of the AVP V1a receptor (V1aR) within the lateral septum (LS) enhanced social play in males, but reduced social play in females. Here, we sought to reveal the underlying mechanisms. Because *in vitro* studies suggest that AVP modulates glutamate and GABA responses in the LS, we determined whether AVP administration into the LS modulates the *in vivo* release of glutamate and GABA and the *in vitro* frequency of spontaneous excitatory post synaptic currents (sEPSC) differently in male and female juvenile rats. By combining retrodialysis with microdialysis in awake and freely moving rats, we found that AVP increased extracellular LS-glutamate in females, while decreasing it in males. AVP did not alter extracellular LS-GABA in either sex. Moreover, baseline extracellular glutamate, but not GABA, was higher in males than in females, a sex difference that was abolished after AVP administration. In whole-cell voltage clamp recordings from acute LS slices from either male or female juveniles, AVP appeared to reduce the number of sEPSCs in males (greater inter-event-interval, 4 of 6 cells) whereas AVP did not appear to alter sEPSCs in females (no changes observed in 3 of 4 cells) indicating sex differences in the modulation of glutamatergic synaptic transmission in the LS; data collection is ongoing. Together, these findings suggest that the sex-specific regulation of social play by AVP may involve differential glutamate signaling in the LS of male and female juvenile rats.

Title: Emotion reading with eye tracker

Authors: *S. PARK, S. NAM, H. CHOI, D.-S. KIM;
KAIST, Daejeon, Korea, Republic of

Abstract: Spontaneous recognition of user emotion with passive sensors which measure the user's physical state or behavior has been widely studied. For example, Pupil response, heart rate, galvanic skin response or skin temperature are some of the most highly captured physical data to determine user emotional state. In addition, gaze trajectory, facial expression or body posture are also the most useful user behavior data obtained from video camera to determine emotion. In the current study, we proposed a simple emotion reading system using eye-tracking glasses which has one infrared camera to record pupil diameter and position while the other camera record user view point in order to estimate user pupil response on the certain gaze trajectory point. Seven healthy volunteers (seven males, age 24±3) participated in the study. Each participant was presented totally 60 pleasant & excited, 60 pleasant & calm, 60 unpleasant & excited, and 60 unpleasant & calm during whole experiment while wearing eye-tracking glasses. The pictures were selected from the International Affective Picture System (IAPS) database (Lang et al., 2008) based on the IAPS's valence (1 is unpleasant and 9 is pleasant) and arousal (1 is calm and 9 is excited) standard scores of male. Therefore, only male subjects were selected due to expected sex differences in certain images. All images were adjusted to be a gray-scale and the mean luminance of 107. The experiment consisted of four sessions, and one session consisted of 60 trials. Cross fixation of 3 sec, picture stimuli of 6 sec, response and rest for 6 sec were sequentially presented in each trial. The subjects were asked to experience any feelings which the pictures might arouse in them, and rate each picture in a 2-point valence scale and a 2-point arousal scale using a keyboard during response time. All subjects were also asked not to move during a session and not to blink during cross fixation and picture stimuli. The time series of pupil diameter changes while the subject gazed at a picture were considered to classify valence or arousal, which mean pleasant vs unpleasant or calm vs excited, respectively. Certain time points which reject the null hypothesis from a paired t-test were selected for the features to classify. The valence classification in the session 3 of subject 6 showed the highest score of 76.9% accuracy while the best true positive result was 87.5% and the best true negative result was 100%. The arousal classification in the session 4 of subject 6 showed the highest score of 80.0% accuracy while the best true positive or true negative was 100%. This result showed the possibility of emotion reading system using eye-tracking glasses.

Title: Analysis of neural/molecular mechanisms of mate-guarding behavior in small fish, medaka

Authors: *S. YOKOI[1,2], T. OKUYAMA[1], Y. KAMEI[2], K. NARUSE[2], Y. TANIGUCHI[3], S. ANSAI[4], M. KINOSHITA[4], L. J. YOUNG[5], N. TAKEMORI[6], T. KUBO[1], H. TAKEUCHI[1,7]; [1]Univ. of Tokyo, Tokyo, Japan; [2]Natl. Inst. for Basic Biol., Okazaki, Japan; [3]Kyorin Univ., Tokyo, Japan; [4]Kyoto Univ., Kyoto, Japan; [5]Emory Univ., Atlanta, GA; [6]Ehime Univ., Toon, Japan; [7]Okayama Univ., Okayama, Japan

Abstract: In various animal species from insects to vertebrates, males exhibit mate-guarding behavior to prevent other males from mating a potential or former mate, which is one of the forms of male-male competition for mates. Although the mate-guarding behavior has been studied extensively in behavioral ecology and phylogeny, its neural/ molecular basis is unknown. We previously demonstrated that medaka (Oryzias latipes) fish, which is a model animal for molecular genetics, exhibited mate-guarding behavior. In addition, we also showed that vasotocin (non-mammalian homolog of vasopressin) might have a role of enhancing this behavior by using pharmacologic methods. In the present study, we report that we generated mutants of vasotocin and its receptors (V1a1 and V1a2) genes by TILLING methods and revealed that two genes, vasotocin and V1a2, are required for normal mate-guarding behavior. In addition, behavioral analysis of courtship behaviors in a dyadic relationship and aggressive behaviors within a male group revealed that vasotocin mutant males displayed decreased sexual motivation but showed normal aggression. In contrast, heterozygote V1a2 mutant males displayed decreased aggression, but normal mate-guarding and courtship behavior. Therefore, impaired mate-guarding in vasotocin homozygote mutants may be due to the loss of sexual motivation toward the opposite sex, and not to the loss of competitive motivation toward rival males. The different behavioral phenotypes between avt, V1a2 heterozygote, and V1a2 homozygote mutants suggest that there are redundant systems to activate V1a2 and that endogenous ligands activating the receptor may differ according to the social context.

Title: Generation of Oxtr cDNAHA-Ires-Cre mice for gene expression with oxytocin receptor specific manner

Authors: *S. HIDEMA[1], Y. HIRAOKA[1], H. MIZUKAMI[3], T. FUKUDA[2], S. SUZUKI[1], A. OTSUKA[1], S. MIYAZAKI[1], K. NISHIMORI[1];
[1]Mol. Biol., [2]Animal Breeding and Genet., Grad. Sch. of Agr. Sciences/Tohoku Un, Sendai-Shi, Japan; [3]Ctr. for Mol. Med., Jichi Med. University,, Shimotsuke, Japan

Abstract: The neurohypophysial hormone oxytocin (OXT) and its receptor (oxytocin receptor, OXTR) have a critical role in the regulation of pro-social behaviors, defined as voluntary behaviors intended to benefit another, such as social recognition, pair bonding or parental behaviors (Neumann, 2008). We previously generated knockout mice for Oxt (Nishimori 1996) and Oxtr (Takayanagi, 2005). The OXT ligand and Oxtr deficient mice showed abnormalities in various pro-social actions, such as social, maternal behaviors and social buffering (Smith and Wang, 2014). In order to visualize the distribution of OXTR in the central nervous system (CNS) in mice, we established an OXTR-Venus knock-in mice (Yoshida, 2009). Our established Oxtr-Venus knock-in mice allowed us to identify the detailed distribution of the OXTR. These knock-in mice express enhanced yellow-fluorescent protein (EYFP; Venus) in various types of cells and tissues in the CNS, indicating the endogenous expression of OXTR in the positive tissues and cells. Interestingly, we detected nuclei-restricted expression of Venus in various regions of the brain, including the amygdaloid body, medial preoptic area, and raphe nucleus, among others. These areas are potentially associated with the regulation of social and sexual behaviors through OXT and OXTR signaling. In the present study, we established Oxtr cDNAHA-Ires-Cre knock-in mice expressing both the OXTR and Cre recombinase under the control of the endogenous Oxtr gene promoter. We demonstrate that these mice allow specific gene expression in a Cre recombinase dependent manner in OXTR-expressing neurons, with infection of recombinant adeno-associated virus including flip-excision switch (AAV-FLEX) vector that carried irreversible type loxP sequences. The social behavior of Oxtr cDNAHA-Ires-Cre knock-in mice

was found to be the same as that of wild-type animals. In addition, the distribution of Cre expression was the same as that observed in Oxtr-Venus mice. Furthermore, we showed restricted expression of the tracing molecule wheat-germ agglutinin with the fluorescent protein mCherry in OXTR-expressing neurons by nuclei-specific infection of recombinant AAV-FLEX including inverted WGA-2A-mCherry sequence in these knock-in mice. This study could contribute toward monosynaptic analysis of neural circuits and optogenetic analysis of neurons expressing OXTR. Our established knock-in mouse would be a powerful tool for the functional analysis of oxytocin-positive neurons in social behaviors.

Title: Intranasal oxytocin enhances socially transmitted fear behavior in mice

Authors: ***M. T. PISANSKY**[1], J. C. GEWIRTZ[2];
[1]Neurosci., [2]Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Oxytocin is an evolutionarily conserved neuropeptide implicated in social cognition processes. The oxytocin system is dysregulated in psychiatric diseases characterized by impaired social cognition, and intranasal oxytocin enhances emotional recognition (a component of "empathy") in both normal and psychiatric populations. In order to investigate the neurobiological effects of oxytocin on social cognition, we have developed a measure of socially transmitted fear, in which an observer mouse views a demonstrator mouse undergoing Pavlovian fear conditioning. Observer mice exhibit freezing, and - importantly - this effect occurs more robustly when the observer-demonstrator pair are familiar (i.e., siblings) with one another. We hypothesized that oxytocin would enhance socially transmitted fear. Therefore we administered oxytocin intranasally (20ug/kg) to non-sibling observer mice using a sub-chronic regimen (5 days). Compared to saline controls, oxytocin-treated observer mice exhibited significantly more freezing during the conditioning of demonstrator mice. Observer freezing behavior also correlated with demonstrator distress vocalizations recorded during conditioning, but only for

sibling and oxytocin-treated non-sibling observer mice. Interestingly, the enhanced freezing effect was not seen if oxytocin was administered using a single dose 30mins prior to testing. This suggests that sub-chronic intranasal oxytocin produced changes in endogenous oxytocin signaling mechanisms. To test this hypothesis, we are conducting immunohistochemical and quantitative PCR analyses of oxytocin receptor expression in observer mouse brain tissue. These experiments promise to elucidate the neurobiological effects of oxytocin on social cognition processes and contribute to our understanding of psychiatric diseases in which these processes are compromised.

Title: A history of enrichment alters the outcome of a social preference task in adolescent rats

Authors: *K. L. PATTERSON, H. L. JOHNSON, E. A. ARTZ, O. W. FIELDS, R. GUCWA, D. I. ALEWEL, M. C. ZRULL;
Appalachian State Univ., Boone, NC

Abstract: The physical, social, and cognitive development of adolescents is often accompanied by behavior changes including increased interest in novelty and risk taking. For rats, the changes involve not only how adolescents explore objects in the environment but also how they interact with conspecifics. Social preference (SP) offers a measure of novelty seeking behavior relevant for study in adolescent animals. Environmental enrichment (EE), exposing an animal to a novel and enhanced environment on a regular basis, can modulate these behaviors. Over time, EE can allow rats to exhibit more flexible behaviors when placed in novel situations. We investigated the impact of EE on SP in adolescent rats. Long Evans rats (n = 12) were exposed to enrichment cages in same-sex groups for 1.5-h 18 times between postnatal days (pnd) 21 and 49. Age matched controls (n = 13) were left alone, aside from being briefly held 18 times. On pnd 35 and pnd 49, rats performed a SP task, which involved placing a rat into a small cage with additional small cages on either side of the experimental rat that each contained a stimulus rat. The time the experimental rat spent contacting the wire mesh wall between it and each stimulus rat as well as nose pokes at stimulus rats were measured during a 3-min trial. Then, after a 30-min delay, one stimulus rat was replaced with a novel stimulus rat and another trial was completed. After

testing, brain tissue was processed to examine levels of neural activity in amygdala evoked by the SP task using immunohistochemistry for c-fos. At pnd 35, the proportion of the 180-s Trial 2 time spent socializing with either stimulus rat by EE and control rats was similar; however, at pnd 49, the proportion decreased by 43% for EE and only by 10% for control rats ($p < .01$). Across pnd 35 and 49 test sessions on the delay trial, EE rats spent a similar proportion of time near the known and novel stimulus rat ($M = 0.53$, $SD = 0.13$) while control rats spent a greater proportion of time near the novel stimulus rat ($M = 0.65$, $SD = 0.15$) ($p < .02$). While EE rats decreased Trial 2 nose pokes at the novel stimulus rat between tests at pnd 35 and 49 (-12%), controls rats increased nose pokes at the novel conspecific by 12% ($p < .05$). Behavioral data suggest that periodic exposure to enriched environments throughout adolescence promotes fluent adaptation to social novelty with EE rats exhibiting more balanced attempts at contact with known and novel conspecifics than rats without EE history. If preference for an unknown over a known conspecific can be considered risky, then EE seems to suppress this type of risk taking behavior in our rat model.

Title: The effects of a hyperandrogenic prenatal environment on early and later-life social behaviour

Authors: *C. S. WASSON[1], C. HOWES[1], M. CASTRO[2], A. SMART[2], A. J. GIUGA[2], N. J. MACLUSKY[3], E. CHOLERIS[1];
[1]Psychology and Collaborative Neurosci. Program, [3]Biomed. Sci., [2]Univ. of Guelph, Guelph, ON, Canada

Abstract: Testosterone drives the organization and development of the typical male phenotype, including sexually dimorphic behaviors. The developmental effects occur during the pre- and post-natal period to preadolescence. Subsequently, hormones have activational effects on sexually dimorphic behaviors throughout adult life. Most behavioral research has focused on

activational effects, leaving the developmental effects less understood. In particular, the developmental effects of testosterone on social behaviors, such as social approach, recognition and interactions, are not well elucidated. A female advantage in estrogen-dependent social behaviors is typically observed. In turn, “maleness” is often associated with aggression and asociability, with both testosterone and its metabolites being involved. Here we treated pregnant CD1 mice with 10μg of testosterone propionate systemically during embryonic days 12, 14 and 16, the periods critical for the development of sexual dimorphism. To assess for any developmental abnormalities, we measured the birth-weights, developmental weights, and litter sizes. Analysis showed no differences between groups, indicating normal development. However, we found an effect of treatment on the size of the prostate glands of male mice in adulthood, where testosterone treated mice exhibited smaller prostate weights. This demonstrates that our treatment was effective as early excess testosterone has been shown to down-regulate androgenic-feedback in the prostate. We then tested social motivation during preadolescence using the social approach/avoidance paradigm. Each mouse received a choice between a novel same-sex conspecific and an unfamiliar scent (vanilla). Results show that there was no significant effect of prenatal testosterone exposure in this test, suggesting that treatment did not affect motivation to approach social stimuli. Hence, the same dosage that was effective on peripheral tissues (prostate) did not affect a fundamental test of social motivation. Follow up investigations assessing other social behaviors such as social recognition and agonistic behavior will determine whether cognitively more complex social behaviors are influenced by the prenatal hormonal environment. We will also investigate interactions between the prenatal developmental and adulthood activational effects of the sex hormones on social behaviors. Our findings will help elucidate how hormones mediate sociability and will allow for better insight into developmental disorders, such as Autism Spectrum Disorder, where an abnormal social phenotype is apparent. Supported by the Ontario Mental Health Foundation.

Title: The effects of hyperandrogenic prenatal environment on later life social learning and gonadal hormone sensitivity

Authors: *C. HOWES, C. S. WASSON, M. CASTRO, A. SMART, A. J. GIUGA, N. J. MACLUSKY, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Colin Howes, Cameron S Wasson, Anastasia Smart, Marian Castro, Anthony Giuga, Neil J MacLusky, and Elena Choleris Department of Psychology and Neuroscience Program Department of Biomedical Sciences University of Guelph Gonadal hormones and their downstream effectors are involved in the regulation of a number of social cognitive behaviours, such as social learning, social recognition, and social motivation in adult animals. In addition, testosterone has been shown to exert lasting developmental effects on sexual and affiliative behaviours. This indicates that the action of testosterone during development may be also be involved in the mediation of social cognition in later life. In the present study, we examined the developmental effects of testosterone on social learning in mice. Injections of 10 g testosterone propionate or sesame oil control were administered to pregnant CD1 mice on embryonic days 12, 14, and 16. This time period corresponds with critical periods for sexual differentiation and the development of socially relevant brain regions. Mice were tested on a number of social tasks prior to the onset of puberty. Social learning was assessed using the social transmission of food preferences task, in which experimental "observer" animals were allowed to interact with a "demonstrator" conspecific that had recently consumed one of two novel flavoured diets. Following this interaction, the observers were given access to both the demonstrated and non-demonstrated foods, and consumption was compared in order to discern whether or not they exhibited a socially acquired preference for the demonstrated food flavour. Preliminary data suggest that prenatal testosterone treatment had an impairing effect on social learning in male, but not in female mice. This suggests that testosterone may exert sexually dimorphic effects on social cognitive behaviour during development, which is in line with findings from human studies of autistic populations. Animals will undergo further testing to assess the effects of gonadal hormones in adulthood. In addition, we will correlate a number of physiological and brain measures with behavioural data in order to elucidate the possible mechanisms by which gonadal hormones act in development and later life to mediate social behaviour. This study will further illuminate how interplay between the developmental and activational effects of hormones produces a social behaviour phenotype. Supported by the Ontario Mental Health Foundation.

Title: Investigation of neural activity during social eavesdropping in male golden hamsters using c-Fos immunohistochemistry and local field potential recording

Authors: *C.-Y. LIU, W.-C. YU, C.-Y. CHANG, T.-R. HUANG, W.-S. LAI;
Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Social eavesdropping is a special type of social learning and it is defined as the act of extracting information about the relative or absolute quality of signalers from social interactions between conspecifics. Social eavesdropping has advantage in information gathering and has attracted increasing attention. However, this behavioral phenomenon and its underlying neural mechanisms remain much unclear. Taking advantage of agonistic behaviors in male golden hamsters and using the established social eavesdropping model in golden hamsters, we investigated brain areas and related neural activity underlying social eavesdropping in hamsters with a single defeated experience. Three groups of hamsters that were exposed to either a fighting interaction, a neutral encounter, or an empty arena were tested. In experiment 1, using c-Fos immunohistochemistry to map neuronal activities in the brain, males in the fighting interaction group had more c-Fos labeled neurons in the piriform cortex and sub-regions of cingulate cortex (especially anterior mid-cingulate cortex, aMCC) compared with males in the other two groups. But no significant difference was found in the hippocampus and amygdala. Based on the findings in experiment 1, local field potential was recorded in the aMCC of behaving hamsters to reveal neural activity during social eavesdropping in experiment 2. Neuronal tracing technique was further applied to identify neuronal pathways and projection areas of the aMCC in experiment 3. Our preliminary results reveal that the neurons of the aMCC seem to oscillate faster during fighting interactions compared with neutral interactions. Data collection and analyses are still in progress. Collectively, our data suggest that hamsters are capable of social eavesdropping and the aMCC might play an important role in the information gathering and extracting process during social eavesdropping.

Title: GABA neurons in the BNST and MA respond to social stimuli

Authors: *N. RIGNEY, K. MCDANIEL, A. PETRULIS;
Georgia State Univ., Atlanta, GA

Abstract: The medial amygdala (MA), bed nucleus of the stria terminalis (BNST) and the medial preoptic area (MPOA) are all critical brain regions for the regulation of social behavior. However, the chemical nature of socially responsive neurons in these areas is generally unknown. This study examines the co-localization of glutamic acid decarboxylase (GAD-67), the rate-limiting enzyme for GABA synthesis, with c-Fos gene activity (a marker for neuronal activation) in neurons of male mice following exposure to male and female stimuli. We use a mouse strain in which green fluorescent protein (GFP) is linked to an allele of the GAD-67 gene, thus allowing us to visualize GABAergic neurons, and c-Fos co-localization, across sub-regions of MA, BNST, and MPOA in response to male, female or control stimuli. However, we observed that these transgenic mice have both low levels of c-Fos expression and social deficits, likely due to decreases in GABA synthesis. GAD67-GFP mice investigated social stimuli less and produced less ultrasonic vocalizations than controls. Consequently, we are examining social behavior and c-Fos/GABAergic neuron co-localization in male offspring of vesicular GABA transporter (VGAT)-Cre mice crossed with lox-GFP reporter mice. Furthermore, using Cre-dependent viral-vector mediated delivery of inhibitory designer receptors exclusively activated by designer drugs (DREADD) to the BNST we are testing the necessity of GABAergic BNST neuron activity on production (ultrasonic vocalizations, urine marking) and reception (investigation, approach) of communication signals. These experiments provide critical information about the chemical identity of social-responsive neurons in the limbic brain and will greatly increase our understanding of social brain organization.

Title: Rapid formation of social memories in songbirds

Authors: *D. C. TOCCALINO[1], H. SUN[2], J. T. SAKATA[3];
[1]McGill University, IPN, Montreal, QC, Canada; [2]Neurosci., [3]Biol., McGill Univ., Montreal, QC, Canada

Abstract: Individual recognition is a form of social memory that shapes the expression of social behavior. To reveal behavioral indices of individual recognition and factors that influence the formation of social memories, we assessed how brief (<30 sec) and repeated exposures to females affected the expression of courtship behavior in male Bengalese finches, *Lonchura striata* var. *domestica* . Using a habituation-dishabituation paradigm, we analyzed the degree to which the prevalence and structure of courtship songs changed with repeated exposures to an individual female. Courtship behavior toward individual females rapidly changed following a single exposure. For example, males were significantly less likely to produce courtship song to an individual female upon their second exposure to that female. In addition, males produced progressively shorter songs to an individual female with repeated exposures. In contrast to song duration, other features of song that are affected by social interactions with females (e.g., stereotypy of syllable structure and sequencing, song tempo) did not change across repeated exposures to an individual female. Exposure to a different female increased the probability of courtship behavior and the duration of courtship songs. To assess the persistence of social memory, we also investigated the degree to which males differentially courted novel vs. familiar females two days after initial exposures. We observed that males preferentially courted novel females over females they were exposed to at least three times, suggesting that repeated exposures result in the formation of a persistent social memory. Single exposures, however, failed to induce the formation of persistent social memories for individual females. Taken together, these experiments demonstrate that interactions with females rapidly induce the formation of social memories and that multiple exposures are required for more persistent memory formation. In addition, these studies reveal that some features of courtship behavior are more sensitive indicators of social memory than others.

Title: Rats demonstrate helping behavior toward a soaked cagemate

Authors: ***N. SATO**, L. TAN, K. TATE, M. OAKADA;
Kwansei Gakuin Univ., Nishinomiya, Hyogo, Japan

Abstract: Helping behavior is a prosocial behavior whereby an individual helps another irrespective of disadvantages to him or herself. To examine helping behavior in rats, we used a pool of water to create distress. We examined whether rats would help distressed, conspecific rats that had been soaked with water. To help a distressed cagemate, helper rats were required to open a circle-shaped door. The rats quickly learned to rescue a soaked cagemate from the water area by opening the door to allow the trapped rat into a safe area. We also examined the rats' preference regarding water and confirmed that the rats dislike soaking. Additional tests showed that the presentation of a distressed cagemate was necessary to induce rapid door-opening behavior. In addition, it was shown that rats that had previously experienced a soaking were quicker to learn how to help a cagemate than those that had never been soaked. The results using another rats indicated that they did not open the door to a cagemate that was not distressed. We also tested rats' behavior when they were forced to choose between opening the door to help a distressed cagemate and opening a different door to obtain a food reward. In half of the helper rats, the door-opening behavior was shaped by helping the cagemate. In the remaining half of rats, the door-opening behavior was shaped by food reward. Irrespective of how they learned to open the door, in most test trials, rats chose to help the cagemate before obtaining a food reward, suggesting that the relative value of helping others is greater than the value of a food reward. These results suggest that rats can behave prosocially and that helper rats may be motivated by empathy-like feelings towards their distressed cagemate. The paradigm in the present study can be a useful tool for understanding the underlying neural basis of prosocial behavior.

Title: Early post-natal sleep fragmentation prevents normal social development in male, but not female, prairie voles

Authors: E. A. D. HAMMOCK[1], D. L. COCKING[2], *M. M. LIM[2];
[1]Psychology, Florida State Univ., Tallahassee, FL; [2]Sleep Med., Portland VA / Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Consolidated sleep periods during development are critical for synaptic plasticity and pruning in basic brain circuits (such as the visual system). However, it is unknown whether sleep plays a role in the maturation of more complex circuits, such as those involved in species-typical social behavior. Prairie voles (Microtus ochrogaster) are a highly social rodent species and form lifelong pair bonds with other individuals, thus providing an ideal model organism to study the role of sleep in shaping social function. We sought to establish an animal model to directly investigate the effects of sleep on the development of neural systems involved in social behavior. We applied a unique method of chronic sleep fragmentation, which preserves total sleep times and is relatively stress-free, to prairie vole pups during a sensitive post-natal period of development. Following developmental sleep fragmentation, voles underwent tests for social behavior as juveniles, and again as adults. At 5 weeks of age, juvenile male prairie voles showed increased aggression towards age-matched stranger voles, regardless of sleep intervention. At 11 weeks of age, adult male prairie voles subjected to sleep fragmentation in the post-natal period showed persistence of aggressive behavior towards juvenile voles, in contrast to non-sleep-fragmented male prairie voles. Furthermore, adult male prairie voles sleep-fragmented during the post-natal period showed profoundly impaired pair bond formation as assessed by the partner preference test. Sleep fragmentation during post-natal development did not significantly affect olfactory memory function, nor did it affect social behavior in female prairie voles. This sex-specific effect of sleep fragmentation on partner preference is reminiscent of human disorders of social behavior showing a male-biased prevalence, including autism spectrum disorders. Our data suggest that sleep fragmentation during the pre-weaning post-natal period may halt the

normal developmental trajectory of social behaviors, including persistence of aggression and an inability to form pair bonds. Future studies will examine markers of synaptic plasticity and neuronal activity, oxytocin receptors, vasopressin receptors, and GABA interneurons. Studies utilizing this unique animal model will enhance our understanding of modifiable risk factors, such as sleep, that may contribute to atypical development of the brain and social behavior.

Title: Neural architecture of a pair bond: calcium imaging of the nucleus accumbens in awake-behaving prairie voles

Authors: E. CARAZO[1], A. M. CUNNINGHAM[1], R. HEN[1,2], M. A. KHEIRBEK[1,2], *Z. R. DONALDSON[1,2];
[1]Columbia Univ., New York, NY; [2]New York State Psychiatric Inst., New York, NY

Abstract: Despite the strong evidence that social bonds impact numerous aspects of human health, the neural basis for bonding remains poorly understood. This is in part due to the relative shortage of appropriate animal models; biomedical research relies heavily on rats and mice, but these animals do not form strong, selective bonds with other adult conspecifics. However, laboratory-amenable prairie voles offer further opportunities to understand how social bonds are formed and maintained because, as a monogamous species, they form intense bonds between mated partners. Multiple lines of converging evidence suggest that the nucleus accumbens (NAcc) plays a critical role in pair bonding. Monogamous prairie voles exhibit high levels of oxytocin receptors in the NAcc. Local antagonists or reduction of oxytocin receptors in the NAcc inhibits bond formation, while increasing levels of these receptors can enhance bond formation. In addition, both dopamine D2 and μ-opioid receptor signaling within the shell of the NAcc are required for bonding. Further, plasticity in gene expression within this brain region has been observed following pair bond formation. This suggests that coordinated action of multiple

neuromodulatory systems converge in the NAcc during pair bond formation and that neuroplastic changes within this region may help to maintain social bonds. However, despite the clear importance of the NAcc in pair bonding, very little is known about the local circuit within the NAcc that mediates this behavior, and how this circuit changes upon bond formation and over time. In order to understand the neural circuits that underlie the formation of social bonds, we have used calcium imaging *in vivo* to monitor activity of large populations of NAcc neurons in prairie voles during epochs of social interaction. This allowed us to observe population activity in response to different social and non-social stimuli before and after bond formation. Analysis of NAcc neuron firing rate reveal that these neurons code for both the type of stimulus (social versus non-social) and the type of the social interaction. Our ongoing efforts are aimed at identifying how this population code within the NAcc is related to interactions with a bonded partner versus a novel conspecific and how this changes with time after bonding.

Abstract: The African Naked Mole-Rat (H. Glaber), a fossorial rodent, is one of only two mammalian species identified to have a eusocial organization and cooperative breeding system. This unique social hierarchy, along with the extreme longevity of this species, allows for the measurement of individual and group behaviors under laboratory conditions, in large groups (>

30 animals) over a long time span (> 1 year). This study analyzed the stability of individual and group measures within a single colony at two or more timepoints over a 1 year period. Measures included individual characteristics (weight, sex, cortisol levels, hierarchy position, activity, and diurnal rhythm), social behaviors (animal proximity) and prosocial colony behaviors (nest-building, pup-carrying, tunnel excavating, and threat response). Measurement of these behaviors involved Radio Frequency Identification (RFID) and computational approaches to complement observational data. Results supported a "division of labor" model of task performance, and demonstrated a significant correlation over time for the contribution of each animal to nest building and tunnel excavating, suggesting stability of these roles. Measures of pup-carrying and animal proximity (degree centrality of colony social network) were less stable. The demonstrated stability of some colony roles will allow for measures of epigenetic factors that determine social hierarchy. -The first two authors contributed equally to this work.

Title: Understanding heterogeneity in social behavior using QTL mapping in BXD mouse strains

Authors: *A. T. KNOLL[1], N. FOX[2], P. LEVITT[1];
[1]Inst. for the Developing Mind, Children's Hosp. Los Angeles, Los Angeles, CA; [2]Dept. of Human Develop., Univ. of Maryland, College Park, MD

Abstract: Humans exhibit broad heterogeneity in affiliative social behavior. Twin and family studies demonstrate that individual differences in core dimensions of social behavior are heritable, yet there are knowledge gaps in understanding the underlying genetic and neurobiological mechanisms. In neurodevelopmental disorders, there is also remarkable heterogeneity in social dysfunction, even in individuals with the same causal mutation, and this

often negatively impacts the efficacy of clinical treatments. We hypothesize that the genes that cause variation in typical social behavior act in concert with disorder-related genes to influence clinical heterogeneity. Here, we report initial studies using the BXD genetic reference panel of mice to address the heritable nature of heterogeneity in social behaviors. The BXD panel is comprised of >100 recombinant inbred strains derived from the C57BL/6 (B6) and DBA/2 (D2) parental strains. The B6 and D2 parental strains show high levels of sequence variation (~2 million informative single nucleotide polymorphisms (SNPs)), and all BXD strains have been sequenced at >7000 informative SNPs, enabling rapid quantitative trait locus (QTL) mapping. We examined four domains of affiliative social behavior: social approach motivation, social recognition, direct social interaction motivation, and communication. Using a large subset of BXD strains, multiple measures were obtained, including data collected from the 3-chamber social interaction task and a direct social interaction (DSI) task with synchronous ultrasonic vocalization (USV) recording. There was a several hundred-fold range in quantitative traits, with moderate to high heritability (h2) of USV count (h2 = 0.33) and the percentage of time spent sniffing a social partner in DSI (h2 = 0.50). Continuous measures collected for each task were used for QTL mapping, with several novel QTLs identified for social approach, direct social interaction, and USV communication. Bioinformatics tools were used to identify functional polymorphisms within candidate quantitative trait genes (QTGs), and brain regions and biological networks in which they might function to influence social behavior, resulting in a prioritized list of 10 candidate QTGs. These data will guide next step opportunities for determining gene by environment factors that influence social behavior heterogeneity, which is essential for understanding typical social development and addressing disorder risk in children and families.

Title: MUPET - A novel software tool for high-throughput analysis of mouse ultrasonic vocalizations

Authors: M. VAN SEGBROECK[1], A. T. KNOLL[2], *P. R. LEVITT[2], S. NARAYANAN[1]; [1]Dept. of Electrical Engin., USC, Los Angeles, CA; [2]Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: Social communication across species includes the use of different forms of vocalizations. Analysis in animal models typically has utilized a limited number of spectro-temporal measures to compare vocalizations generated in different environmental contexts or following genetic manipulation. A few in depth analyses have revealed a level of communication complexity that will likely require new analytical tools that enable higher throughput processing of hundreds of hours of vocalizations. Measures must also be sufficiently sensitive to detect subtle variations in vocal production and syllable repertoires. Here, we report the development of MUPET (Mouse Ultrasonic Profile ExTraction) software, an open access MATLAB® tool with graphical user interface that provides a data-driven, high-throughput analysis of mouse ultrasonic vocalizations (USVs). Using a fully automated and unsupervised algorithmic approach, MUPET has five core capabilities that enable it to detect, learn, and compare syllable patterns and repertoires: 1) syllable detection--the isolation and measurement of basic spectro-temporal call parameters, 2) acoustical dataset analysis--statistical analysis of overall vocalization features, such as number of syllables, syllable rate, syllable duration, and frequency bandwidth, 3) repertoire learning--the extraction of up to several hundred of the most highly represented syllable patterns ("repertoire units") in individual datasets, 4) syllable category counts--a categorical cluster analysis of syllable-like patterns across different dataset repertoires to measure the frequency of use of different syllable types, and 5) measures of repertoire similarity--rank order comparisons of the similarity of spectral shapes of individual repertoire units across datasets. MUPET allows the user to rapidly analyze thousands of calls, facilitating the comparison of fine details of vocal production and repertoire use across large numbers of mouse lines and experimental conditions. Proof of principle was accomplished using USV data collected from mice in the BXD genetic reference panel, which we have shown exhibits wide-ranging social communication competencies. MUPET analysis revealed genetic control of USV counts, vocal production and repertoire sampling, which are at least partially independent of the social context. MUPET is a powerful new tool for the automated analysis of mouse USVs and has the flexibility to be applied to USV datasets collected from different species. MUPET is also open to the scientific community for the incorporation of additional analytical features.

Title: Mapping of genetic factors for intermale aggressive behavior on mouse chromosome 15

Authors: *A. TAKAHASHI[1,2], H. SUGIMOTO[4], S. KATO[5], T. SHIROISHI[3], T. KOIDE[2]; [1]Univ. of Tsukuba, Tsukuba, Ibaraki, Japan; [2]Mouse Genomics Resource Lab., [3]Mammalian Genet. Lab., Natl. Inst. of Genet., Mishima, Japan; [4]Ctr. for Mol. Med., Jichi Med. Univ., Shimotsuke, Japan; [5]The Inst. of Statistical Mathematics, Tachikawa, Japan

Abstract: Aggression has large individual difference, as well as wide-range of conservation among animal kingdom. Despite high level of heritability estimates for aggressive trait, genetic basis for individual difference of aggression is still unclear. Japanese wild-derived mouse strain MSM/Ms (MSM) has intensively high level of aggressive behaviors compared to standard laboratory strain C57BL/6J (B6). Almost all males of MSM showed high frequency of attack bites and pursuit in the resident-intruder test, while only a few males of B6 showed aggressive behavior with low frequency. In addition, MSM showed killing behavior of his littermates, or sometimes female pair-mates, in his home cage after the sexual maturation. We identified that chromosome 15 (Chr 15) has one of the genetic factors of escalated aggression observed in MSM by using a panel of consomic strains of MSM on B6 background. To narrow down the genetic loci involved in the enhancement of aggressive behavior on Chr 15, we established a panel of subconsomic strains of MSM Chr 15. Analysis of the subconsomic strains suggested the existence of multiple genes that enhance and suppress aggressive behavior even within Chr 15, and those loci have complex interactions. The least squares linear regression analysis successfully identified four genetic loci involved in aggressive behavior on the Chr 15, and one of the genetic loci, which partially enhances aggressive behaviors, was narrowed down into a 4.1 Mbp region of the Chr 15.

Title: Differential methylation as a function of social status in a cichlid fish, Astatotilapia burtoni

Authors: *A. T. HILLIARD[1], D. XIE[2], Z. MA[2], M. SNYDER[2], R. D. FERNALD[1];
[1]Dept. of Biol., [2]Dept. of Genet., Stanford Univ., Stanford, CA

Abstract: Social status is an important feature of all social systems and the effects of low status have well-known negative health consequences. However, the molecular systems underlying social behavior are complex and not well understood. While some specific genes have been linked to social behavior (e.g. hormone receptors), the nature of their regulation in social contexts remains unclear. DNA methylation is a promising candidate regulatory mechanism, as it has recently been linked to social behavior in multiple species. In addition, unpublished work in our lab has shown that methylation can influence social rank in Astatotilapia burtoni, a cichlid fish with a dynamic social system based on male status. Dominant (D) A. burtoni males defend territories, are reproductively capable, display bright colors, and perform a number of aggressive and courtship behaviors. In contrast, non-dominant (ND) males cannot establish territories or reproduce, are drably colored, and display a limited behavioral repertoire. Here, our aim was to broadly characterize the molecular pathways and functions that are differentially affected by DNA methylation in the brains of D and ND males. To ensure that our samples were representative of distinct D and ND physiological states, we placed size-matched males in dyads where a stable D-ND relationship was established and maintained for weeks. Since multiple hypothalamic sub-regions are members of a conserved set of neural circuits that regulate vertebrate social behavior, we collected hypothalamus tissue from two D and two ND males in stable D-ND dyads. To establish status-related methylation patterns in an unbiased manner we isolated DNA and performed whole-genome bisulfite sequencing, a method that allows quantification of methylation levels at single base-pair resolution across the entire genome. To assess whether potential methylation differences affected gene expression we also sequenced RNA from the same samples. We used the BSmooth algorithm to generate smoothed methylation profiles for each fish and identified genomic regions that were differentially methylated in D vs ND fish (DMRs). Some of the most significant DMRs were directly upstream of, or within, genes differentially expressed in a manner consistent with the DMR, including genes involved in transcriptional regulation, protein degradation and trafficking, cell growth, and calcium ion activity. Deeper analysis of these results will allow us to optimize the design of future necessity/sufficiency studies by highlighting the most promising candidate genes and pathways,

especially when combined with findings from other large-scale gene expression studies in our lab.

Abstract: Organisms that share the same genotype can develop into different phenotypes depending on perceived environmental condition cues (aka phenotypic plasticity). Although not without its costs, phenotypic plasticity has been considered to facilitate adaptive evolution by allowing organisms to exploit a wider spectrum of resources when their fitness is reduced. Particularly in species with discrete variation in reproductive behavior, different life-history trajectories are observed that can either be fixed (e.g. genetic polymorphism), or plastic and therefore responsive to environmental factors (e.g. time of birth, resource availability) that will ultimately influence developmental processes. In the peacock blenny Salaria pavo males can follow either of two developmental pathways, grow directly into dominant nest-holder males or mimic the females' morphology and courtship displays in order to approach the nests of larger males to sneak fertilizations. These alternative reproductive tactics (ARTs) are sequential and consistent with body size (i.e. size at sexual maturity), such that sneaker males in the follow

breeding season switch to nest-holder males, going through a phase in which they are reproductively inactive (i.e. transitional males). In this work, we explored at the neurogenomic level how gene expression profiles differed between male morphs (i.e. nest-holder, sneaker and transitional males) and females. For this, RNA was isolated from whole brain tissue for each one of the four phenotypes, sequenced using Illumina HiSeq 2000 and de novo assembled. We found that at the brain level, expression of the plastic male tactic was accompanied by broader and divergent gene expression when compared to either females or nest-holder-males, both more similar between themselves. Overall, sneaker males differed from the other phenotypes in the expression of 643 unique transcripts (78.38% annotated), followed by transitional males (597 transcripts; 75.71% annotated), females (562 transcripts; 76.51% annotated) and finally nest-holder males (517 transcripts; 78.92% annotated). Given the unique dichotomy present in sneaker males of the peacock blenny, behaviorally female-mimics but mature reproductive males, the lack of convergence between brain gene expression and behavior in sneakers to either females or nest-holders points to a differential modulation of underlying proximate mechanisms of sexual behavior in sneakers.

Title: The neurogenomic substrate of and extended phenotype in Lake Malawi cichlid fish

Authors: *R. YORK[1], H. FRASER[2], R. D. FERNALD[2], J. T. STREELMAN[3];
[1]Biol., Stanford Univ., LA Honda, CA; [2]Biol., Stanford Univ., Stanford, CA; [3]Georgia Inst. of Technol., Atlanta, GA

Abstract: Identifying the proximate and ultimate causes behind behavioral evolution is one of biology's central challenges. To do so requires integrating methods from multiple disciplines in

order to analyze animal clades that show substantial variation in tractable behaviors. To this end we studied two species from the bower (mating nest) building clade of Lake Malawi cichlid fish: Copadichromis virginalis ("CV"; pit-digger) and Mchenga conophoros ("MC"; castle-builder). We tested for cis-regulatory divergence between CV and MC by analyzing allele-specific expression (ASE) in whole brain RNA-seq data from CVxMC F1 hybrids. We identified over 150 genes with significant allele-specific regulatory changes driven by bower-building through the comparison of differential ASE in behaving and isolated F1 hybrids. We found evidence for lineage-specific selection at the expression level for several sets of genes in known pathways involved in neurophysiological processes such as ion transport. Because our RNA-seq results lack information about the spatial context in which these genes are functioning we next performed *in situ* hybridization targeting immediate early genes (IEGs) indicative of recent neural activity. These experiments identified several neural loci associated with bower building including the vagal lobe of the dorsal medulla. Finally we compared the brain expression patterns of candidate genes from the differential ASE analysis with these behaviorally associated brain regions. Our results suggest that the cis-regulatory divergence of genes involved in adult neural function may play an important role in the evolution of cichlid fish behavior.

Title: Creatine transporter knockout mice show increased anxiety, increased depressive-like behaviors, and reductions in sociability

Authors: *A. N. KOKENGE[1,2], M. R. SKELTON[1,2];
[1]Cincinnati Children's Res. Fndn., Cincinnati, OH; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Creatine deficiency syndromes are a family of disorders characterized by intellectual disability, aphasia, and epilepsy. The most common cause of Cr deficiency is Creatine Transporter Deficiency (CTD) which is the second leading cause of X-linked intellectual disability (XLID). We have developed a high-fidelity model for CTD, the creatine transporter (CrT) knockout ($CrT^{-/y}$) mouse. While the primary goal of the work to date has focused on the cognitive deficits, it is important to evaluate affective behaviors in these animals. Cr has been implicated in depressive-like behaviors in the mouse and rat; therefore, we set out to determine if

$CrT^{-/y}$ mice showed changes in anxiety and depressive-like behaviors. $CrT^{-/y}$ mice appeared to be more anxious than $CrT^{+/y}$ mice, spending less time in the open arms and committing fewer head dips in the elevated zero maze compared to $CrT^{+/y}$ mice. When tested in the tail-suspension test, $CrT^{-/y}$ mice had a decreased latency to immobility compared with $CrT^{+/y}$ mice, suggesting moderate depression-like behavior. Finally, sociability was reduced in the $CrT^{-/y}$ mice with $CrT^{-/y}$ mice spending less time with the novel stranger compared with $CrT^{+/y}$. These results suggest that Cr plays an important role in affective behaviors. Further, these results suggest that patients with Cr deficiencies need to be monitored for changes in these behaviors during treatment.

Title: Altered DNA methylation pattern in the amygdala of rats genetically prone to high versus low anxiety

Authors: *C. R. MCCOY, N. L. JACKSON, T. PTACEK, E. J. LEFKOWITZ, J. J. DAY, S. M. CLINTON;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Individual differences in emotionality contribute to vulnerability for mood disorders such as depression and anxiety. Understanding molecular mechanisms that drive these temperamental differences is crucial for generating improved treatments. To study neurobiological factors that influence emotionality, we use model rats that were bred based on a high versus low behavioral response to novelty. Rats bred for low novelty response (bLR) exhibit a high anxiety-/depressive-like phenotype compared to high novelty responder rats (bHRs), which vigorously explore novelty and exhibit high impulsivity, aggression, and risk taking. We previously found dramatic bHR/bLR gene expression differences and global DNA methylation differences in the early postnatal and adult amygdala. These data led us to hypothesize that individual differences in neural DNA methylation patterns contribute to the disparate bHR/bLR phenotypes. To obtain a more detailed understanding of DNA methylation differences in the adult bHR/bLR amygdala, the current study used next-generation sequencing

to map the methylation landscapes of adult bHR/bLR amygdala. Methylated DNA was immunoprecipitated and prepared for high-throughput sequencing on Illumina HiSeq2000. We examined DNA methylation at CpG sites using MEDIPS, a R Bioconductor program that compared methylation patterns across CpG islands, intragenic and other regulatory regions in bHR/bLR samples. We cross-referenced our methyome sequencing results with prior bHR/bLR amygdala transcriptome data to identify genes that were differentially expressed and also showed methylation differences in the gene promoter or gene body. To examine functional implications of bHR/bLR DNA methylation differences, another study manipulated methylation levels in bLR rats through diet, feeding them either a methyl donor-depleted, methyl donor-supplemented, or control diet for 4 weeks. Rats then embarked on a behavioral test battery that included the Elevated Plus Maze (EPM), Open Field test, and Forced Swim Test (FST). Methyl donor supplementation improved bLRs' anxiety- and depression-like behavior, leading to greater EPM open arm exploration and a trend for diminished FST immobility. Methyl donor depletion, on the other hand, exacerbated bLRs' depression-like behavior, with methyl-depleted bLRs showing greater FST immobility than bLR controls. Overall these data suggest that inborn DNA methylation differences contribute to disparate bHR/bLR behavioral phenotypes and point to novel therapeutic strategies for individuals that exhibit high levels of anxiety- and depression-like behavior.

Title: Early-life exposure to the SSRI paroxetine disrupts DNA methylation in the early postnatal hippocampus

Authors: *M. E. GLOVER, C. R. MCCOY, N. L. JACKSON, S. M. CLINTON;
Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Selective serotonin reuptake inhibitors (SSRIs) are the most common pharmacological treatment for major depression in pregnancy. The long-term effects of early-life SSRI exposure on human emotional health are largely unknown owing to insufficient study; however, in rodents, perinatal SSRI exposure can cause life-long adverse outcomes, elevating adult anxiety- and depression-like behavior. Furthermore, certain individuals appear to be more susceptible to adverse effects of perinatal SSRI exposure, but the mechanisms driving this differential vulnerability are completely unknown. We recently showed that rats selectively bred for low behavioral response to novelty (bLRs), which also exhibit high levels of spontaneous anxiety- and depression-like behavior, are vulnerable to the adverse effects of perinatal SSRIs. Perinatal SSRI exposure exacerbated bLRs' already high levels of depression-like behavior (Forced Swim Test (FST) immobility), while High Novelty Responder rats (bHRs) were unaffected by the treatment. We also conducted a transcriptome study that revealed widespread gene expression alterations in the early postnatal hippocampus (HPC) of perinatal SSRI-exposed bLR offspring, with striking SSRI-induced down regulation of several DNA methylation-related genes. Our new experiments tested the working hypothesis that the adverse behavioral consequences of perinatal SSRI exposure are mediated by perturbed DNA methylation in the early postnatal HPC. Our first study examined global DNA methylation (5-methylcytosine) levels in the postnatal day 15 HPC of bHR/bLR pups whose mothers were being treated with the SSRI paroxetine (10 mg/kg/day in drinking water) or vehicle (n=6/condition). Perinatal SSRI exposure led to decreased hippocampal DNA methylation levels specifically in bLR offspring relative to vehicle-exposed bLR controls; notably no changes were observed in other limbic brain regions. Interestingly, bHR offspring were not affected by SSRI exposure, with both SSRI- and vehicle-exposed bHR groups showing similar DNA methylation levels. Next generation sequencing analyses are currently underway to assess perinatal SSRI-induced gene-specific methylation changes in bLR offspring. Since we hypothesize that perinatal SSRI-induced suppression of DNA methylation leads to long-term behavioral effects such as increased FST immobility, our second study aims to suppress DNA methylation in early postnatal bLR rats using a methyl donor-depleted diet and then examining their adult behavior. The results of these studies will identify novel mechanisms in the etiology of depressive traits in a rodent model of SSRI susceptibility.

Title: A2 noradrenergic neurons regulate forced swim test immobility

Authors: *H. NAM, I. KERMAN;
Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The Wistar-Kyoto rat (WKY) is a well-established animal model of depression- and anxiety-like behavior, characterized by high immobility during the forced swim test (FST) along with a generally inhibited phenotype on related tests of emotional behaviors. Extensive literature indicates that deficits in noradrenergic neurotransmission may contribute to these behavioral traits. Previously, we have reported that the WKY rats are more immobile compared to other rat strains from the beginning of their training phase of the FST, and that they become even more immobile during the testing phase on the next day. We hypothesized that higher immobility during the FST and the greater increase in immobility throughout different phases of the FST are two separate components of rats' behavior likely mediated by different central mechanisms. We sought to identify the central circuits responsible for these behavioral components by studying activation of neurons within central noradrenergic cell groups during different phases of the FST. The WKY rats along with its parent strain, Wistar rats that experienced either the: 1) 5 minutes training phase (D1), or 2) entire FST (D1 and D2) were compared. Using double-immunocytochemistry for tyrosine hydroxylase and for c-Fos, we determined that within the A2 cell group significantly more noradrenergic neurons were activated in the Wistar than in WKY rats at D1. At D2 WKYs increased their activation of the A2 noradrenergic neurons, and this activation was equivalent to that of the Wistar group. Based on these results, we further investigated the role of A2 cell group during the FST using anti-DBH conjugated saporin (DSAP) to selectively destroy noradrenergic neurons within the area. The Wistar rats treated with DSAP were more immobile during both D1 and D2 of the FST as compared to the rats treated with the vehicle only. Together these data indicate that the A2 noradrenergic cell group regulates FST immobility in rats, and that its activation may contribute to the unique behavioral phenotype of WKY rats. Future experiments aimed at selective activation of A2 noradrenergic neurons will be required to fully elucidate the role of these neurons in mediating behavioral despair and learned helplessness.

Abstract: Memory function often declines with age and is disrupted in a variety of neurological disorders, but effective interventions are limited. Here we used targeted electrical stimulation of the human medial temporal lobe in an attempt to influence memory function in patients with epilepsy. In an initial passive recording session, patients undergoing intracranial monitoring performed a verbal free recall memory task while we recorded electrical activity from depth and cortical surface electrodes. We used the spectral decomposition of the electrode recordings to train a logistic regression classification model to discriminate brain-wide activity associated with successful and unsuccessful memory encoding. Within each patient, we analyzed recall performance according to the classifier's estimate of the probability that each trial would later be remembered. Recall performance was significantly higher in the top classifier quartile, compared to the bottom classifier quartile, validating the classifier's ability to discriminate remembered from forgotten trials. In a subsequent session, we then applied bipolar electrical stimulation while patients again performed the free recall task. We used the previously trained classifier model to estimate the probability that neural activity recorded after stimulation events was reflective of successful vs. unsuccessful memory encoding. Behaviorally, stimulation tended to impair memory performance on average, with memory improvements in some patients and impairments in others. Importantly, the behavioral effect of stimulation was predicted by the electrophysiological effects of stimulation, as estimated by the trained classifier's prediction of the probability of recall. These data demonstrate that machine learning classification can be used to decode neural activity to predict later memory, and that such decoding can be used to predict the behavioral effects of electrical stimulation. The findings suggest that such a process could be used to tune the parameters of stimulation or other neurological interventions intended to ameliorate memory dysfunction.

Title: Human hippocampal theta and its relationship to speed, memory, and voluntary movement

Authors: *J. MILLER[1], M. SPERLING[2], A. SHARAN[2], K. DAVIS[3], J. JACOBS[4]; [1]Drexel Univ., Philadelphia, PA; [2]Thomas Jefferson Univ. Hosp., Philadelphia, PA; [3]Hosp. of the Univ. of Pennsylvania, Philadelphia, PA; [4]Columbia Univ., New York, NY

Abstract: In rodents, the power and frequency of the hippocampal theta rhythm (4-8 Hz) is strongly modulated by ongoing behavior, particularly running speed. In contrast, human hippocampal theta is less prominent, and its relationship to movement is not well characterized. Electrocorticographic (ECoG) recordings from human hippocampus have shown increases in low frequency power associated with periods of virtual movement compared to periods of stillness, yet these previous tasks were not designed to explicitly examine the effects of movement speed. We designed a virtual spatial navigation and memory task well suited to elicit low frequency activity while systematically modulating speed of movement. Using data from neurosurgical patients with hippocampal depth electrodes, we provide evidence that movement related theta oscillations in human hippocampus reliably appear at lower (between 1-4 Hz) frequencies than in rodents and increase in power as movement speed increases. In addition, we use multivariate statistics to untangle the relative contributions of movement speed, memory performance, and voluntary vs involuntary movement to the overall spectral signal.

Abstract: Intracranial recordings in humans have shown that induced high frequency power (30-150Hz) can be used as biomarker for mapping and stimulation of memory circuits (Johnson and Knight 2015, Curr Opin Neurobiol 31), but their physiological origins and function in the mechanisms of cognition remain elusive. Although animal studies provide evidence for synchronous oscillations generated by coordinated firing of neuronal assemblies, broadband asynchronous neural activities were also proposed to underpin high frequency power changes in human intracranial recordings (Burke et al. 2015, Curr Opin Neurobiol 31). Here we used a large dataset of intracranial recordings and stimulation in epilepsy patients (DARPA 'Restore Active Memories' project) to investigate the relative contribution of brain oscillations and asynchronous power increases to high frequency responses induced in two verbal short-term memory tasks. High frequency power changes were detected on a trial-by-trial basis and classified into low gamma (30-60 Hz), high gamma (60-100 Hz) or ripple (100-150 Hz) band based on its peak power frequency. In total, over 6000 electrodes recording field potential from cortical and subcortical structures in over 30 patients were used in this study. On average, 4.2% of electrodes in any one patient showed induced responses in low gamma band, 11.1% in the high gamma, and 13.6% in the ripple band during word presentation. Cluster analysis revealed two distinct populations detected on these active electrodes: majority of them (72.4 - 81.6 %) had discrete characteristic narrowband frequency with maximum bandwidth less than 40 Hz (14.0 - 26.6 Hz mean cluster centroid). In contrast, the remaining detections showed broad bandwidth above 40 Hz (52.8 - 78.5 Hz mean cluster centroid) characteristic of asynchronous power increases. The broadband power increases had significantly shorter duration and higher amplitude than the narrowband oscillations. Relative contribution of the two high frequency activities to subsequent

memory effect and to the physiological response to 50 Hz stimulation were also assessed. Our results show that the induced high frequency responses recorded during memory tasks are comprised of two distinct types of brain activity. These show qualitative and quantitative differences, suggesting specific physiological origins and contributions to cognitive processing. We propose that the broadband power increases reflect asynchronous neural activities, whereas the induced oscillations are generated by coordinated neuronal assemblies, which present viable targets for the development of novel neuromodulation technologies.

Abstract: The medial temporal lobe has been jointly implicated in both spatial and episodic memory function, largely on the basis of separate studies with different sets of participants. Here we analyse the brain signals that predict accurate encoding of spatial and episodic memories in a unified dataset, allowing us to directly compare the neural basis of these functions for the first time. Our studies examine the behavior and electrophysiology of neurosurgical patients with

intractable epilepsy using intracranial electrodes. In our spatial memory task, patients performed a virtual navigation task in which they had to remember the locations of hidden objects. We found statistically significant changes in the time-frequency spectra related to good memory in individual subjects across brain regions and frequency bands. In the hippocampus, successful memory encoding was marked by significant increases in power for the low-theta (1-3Hz) and high theta (3-9) Hz bands and reduction in power in the HFA (70-200Hz) band. Separately analyzing memory for easy and hard trials, we found distinct memory biomarkers for hard and easy memory trials in the low and high theta bands, as well as in the HFA range. We compared these findings with the memory signals identified in an episodic memory task, which revealed significant differences between the brain signals that underlie spatial and episodic memory. Overall, these results demonstrate that medial temporal structures support both spatial and non-spatial memory, but with different electrophysiological patterns underlying each of these behaviors.

Title: Characterization of neural dynamics in response to electrical stimulation for designing a closed-loop control architecture for memory enhancement

Authors: *B. MAHMOUDI[1], R. GROSS[1], M. KAHANA[2];
[1]Emory Univ., Atlanta, GA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The optimal control of neurostimulation is a joint optimization problem in the neural state- stimulation action space to maximize the probability of recall over a certain time horizon. The state vector is a representation of direct measurements of multi-channel Local Field Potential (LFP) time series. Our goal is to design an adaptive learning control system for automatic optimization of the spatio temporal distribution of the neurostimulation. One of the

key steps in designing the architecture of the control system is characterizing the effect of stimulation on the dynamics of LFP signals (controllability) during memory tasks. Towards analyzing the controllability of the state vector using electrical stimulation and eventually improving the objective function, we analyzed the transient effect of stimulation on the dynamics of the LFP signals. The LFP time series were partitioned into three different segments, with reference to the stimulation epochs, namely inter-stim, post-stim and stim segments. The inter-stim refers to a segment of the LFP signal that is temporally between two consecutive stimulation epochs. The post-stim refers to a segment of the signal that was recorded immediately after the stimulation. Finally, the stim segment refers to the recording during the stimulation. We analyzed the effect of stimulation on the duration of the post-stim segment. This duration corresponded to the settling time for the neural states to return back to base-line after stimulation. A moving window with variable length was used to detect the state transition to base-line after stimulation. The separability between the inter-stim and post-stim segments was measured probabilistically using a Support Vector Machine (SVM) classifier. By changing the length and the offset of the post-stim window, the SVM was trained to discriminate between the post-stim and the inter-stim states. The offset of the stimulation was detected automatically and was assigned as the reference point in time to define the starting point of the post-stim window. The results of classification between the post-stim and inter-stim groups suggested that electrical stimulation at 50 Hz induced a transient pattern in the LFP that distinguished the post-stim state from the baseline inter-stim state. The classification results using a window in time that progressively grew by 100 ms was relatively uniform across multiple window sizes, therefore, we selected the window size of 500 ms to study the effect of offset. A transition point around 1 sec was detected beyond which the statistics of the LFP signal returned back to the baseline, however, the decline point was not uniform across multiple recording sites.

Abstract: The hippocampus and entorhinal cortex have long been implicated in memory encoding processes from lesions and neuroimaging studies. Here we used electrical stimulation to directly test the role of these structures in memory encoding. Neurosurgical patients with implanted electrodes performed a version of Morris's water maze experiment, which we customized to include electrical stimulation at 50 Hz in deep brain structures during the period when they encoded each item's location. We assessed the effect of stimulation on memory encoding efficiency by comparing navigation accuracy between items where the patients received stimulation during encoding compared to non-stimulated items. Across- and within-subject analyses revealed that stimulation significantly impaired the accuracy of memory encoding. These findings establish the hippocampus and entorhinal cortex as playing a critical causal role in memory encoding by showing that stimulation in these regions affects memory performance. Going forward, they suggest that the goal of using electrical stimulation to improve memory will require more advanced stimulation protocols.

Ctr., Lebanon, NH; [4]Thomas Jefferson Univ., Philadelphia, PA; [5]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The medial temporal lobe (MTL) structures, including the hippocampus and surrounding cortical regions, play an essential functional role during the encoding of episodic memories. Evidence from electrophysiological studies of rodents, non-human primates, and human patients suggest that memory formation is accomplished through coordinated activity between MTL structures, like the hippocampus, and neocortical regions. However, the physiological, network-level mechanisms underlying these MTL-cortical interactions during episodic memory encoding are not yet clear. Large-scale functional network analysis using graph theory in human intracranial EEG (iEEG) data can help reveal the central network-level role the hippocampus and other MTL regions play during episodic memory encoding. We measured local field potentials in 9 patients undergoing iEEG monitoring for treatment-resistant epilepsy while patients encoded a series of word lists. We constructed field-field coherence matrixes between all pairs of electrodes in the recorded network for each patient across multiple frequency bands between 1 and 100 Hz for words that were later recalled or not recalled. We then analyzed all electrodes (nodes) in each patient's coherence matrixes with two network measures of node centrality. Specifically, we estimated the global node centrality for each electrode with the measure "node betweenness" and the local centrality with "node degree." Higher centrality for a specific region is indicative of the region's role in facilitating functional integration in the network. Both centrality metrics were normalized for different electrode counts per participant. Finally, we tested whether the node centrality for hippocampal electrodes within each patient's coherence network predicted subsequent free recall. We found that hippocampal electrodes showed both higher node betweenness and node degree centrality in each patient's recorded network when encoding a word that would be later recalled than not recalled ($p<0.05$) for coherence networks specific to gamma activity (50-100 Hz), but not other oscillatory frequencies. This finding provides further evidence that the hippocampus is a hub of the episodic memory encoding network and may support binding of encoded features into an enduring long-term memory. This large-scale network characterization of the role MTL structures play in encoding may be useful in guiding the selection of sites for stimulation to modulate network activity and episodic encoding. Future analyses will explore these network-level subsequent memory effects in sub-regions of the hippocampus and other hypothetical encoding network nodes.

Title: Modulation of macaque hippocampal activity with entorhinal and septal stimulation

Authors: *A. G. RICHARDSON[1], P. K. WEIGAND[1], D. S. RIZZUTO[2], M. J. KAHANA[2], T. H. LUCAS[1];
[1]Neurosurg., [2]Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Deep-brain stimulation (DBS) has been proposed as a treatment for impaired hippocampal-dependent memory formation. However, little is known about how DBS affects hippocampal activity in primates, including humans. Here, we sought to modulate oscillations in the macaque hippocampus with stimulation of two major upstream areas: the entorhinal cortex (EC) and the medial septum (MS). Two rhesus macaques were chronically implanted with three clinical DBS arrays (Ad-Tech Medical) targeting the hippocampus, EC, and MS. Experiments were conducted with the animals lightly sedated with ketamine. A subset of the experiments was subsequently repeated with the second animal awake and freely behaving. The main finding of EC stimulation experiments was that evoked hippocampal responses were strongly dependent on ongoing hippocampal gamma activity. Single EC stimulus pulses evoked a short-latency potential in the hippocampus only 15-35% of the time. The 30-90 Hz power in the 50 ms prior to the stimulus was significantly higher in trials with evoked potentials versus without (t test, $p < 1e-6$). Closed-loop, gamma-triggered EC stimulation increased the evoked potential rate to 60-95%. The state-dependence of hippocampal activation was a prominent feature only of EC stimulation, not MS stimulation. The main finding of MS stimulation experiments was that gamma-frequency stimulus trains initiated gamma-frequency oscillations in the hippocampus. Entrainment occurred only over the low-gamma frequency range, 30-60 Hz. Entrained hippocampal oscillations typically started on the 3-4 pulse of the train and continued for 2-3 cycles after the end of the stimulus train. The post-stimulus amplitude of the evoked hippocampal oscillations was 4-6 times bigger than the size of the single-pulse evoked potential. Thus the MS-driven hippocampal response exhibited both entrainment and resonance. In contrast, entrainment and resonance were not features of the hippocampal response to EC stimulus trains. The hippocampal response frequency was independent of EC train frequency. And the post-stimulus response amplitude was approximately the same for trains and single

pulses. Gamma oscillations are thought to be critical to information flow in the hippocampus and to memory formation and retrieval. The present work demonstrates in primates with clinical DBS electrodes how to initiate hippocampal gamma rhythms with MS stimulation and how to time EC stimulation to those rhythms to maximize the hippocampal response.

Abstract: There are several known predictors of recall success in freerecall tasks, i.e., serial position, context retrieval, semantic clustering,and lexical frequency. Less is known, however, about the inherent memorablenessthat can be predicted based on a word's meaning. Given a list of mundane itemslike “table”, “rock”, and “dog” with more attention grabbing words like“knife”, “bullet”, or “shark”, we predict that the latter sort will be morereadily remembered. This semantic saliency hypothesis proposes that recallprobability for words can be predicted based on a semantic model. We analyzeddata from a large free-recall database (pyFR). Using Google' s semantic model(word2vec), we fit a regression model to predict recall probability for wordsin pyFR based on model vectors. A regression model was fit based on vectorsfrom all words but one, then recall probability of the left-out word waspredicted based on its vector. Correlation between the actual and predictedrecall probabilities was strong (r = .53), controlling

for other factorsincluding word frequency. Cluster analysis based on model vectors suggests asemantic dichotomy segregating animate from inanimate nouns; furthermore,recall probability of animate nouns was significantly greater than forinanimate nouns, suggesting factors related to animacy may predict recall. Weinvestigated neural correlates of animacy using invasive electrocorticography(ECoG) during a free recall task in a new group of patients (RAM_FR1: record only, andRAM_FR2: during which medial temporal lobe structures were electricallystimulated, N = 19). We coded nouns as animate or inanimate. Using patterns ofECoG magnitude across electrodes, we trained pattern classifiers for animateversus inanimate. We were able to decode animacy above chance in thenon-stimulated group, but not for the stimulated group, but the differencebetween groups was not significant. Accuracy across all subjects wassignificantly better than chance. Our findings suggest (1) semantics of wordsin a free recall task can contribute to the likelihood of recall, (2) theanimacy of nouns may be related to recall, and (3) the biomarkers of semanticrepresentations for animacy can be reliably measured using ECoG.

Title: Examining biomarkers of memory encoding and effects of electrical stimulation in human subjects performing paired associates learning

Authors: *J. H. WITTIG, JR[1], R. YAFFE[1,2], S. INATI[1], G. WORRELL[3], T. LUCAS[4], A. SHARAN[5], D. RIZZUTO[4], K. ZAGHLOUL[1,4];

Abstract: We have examined the electrophysiological biomarkers of recall performance during paired associates learning in a cohort of patients that have subdural electrodes placed for seizure monitoring. Participants were asked to memorize (encode) a list of 6 pairs of words, and approximately 45 seconds later they were prompted to recall each pair when one of the words from the pair was displayed on a computer monitor. Each testing session consisted of 25 such lists, and participants often completed 2 or more sessions while intracranial EEG signals were recorded from each subdural electrode. For each electrode, we compared the spectral power of correctly remembered versus forgotten word-pairs by evaluating (1) mean power differences during encoding, (2) mean power differences during recall, and (3) trial-by-trial similarity, or reinstatement, between encoding and recall. A subset of the cohort of patients (3 participants) performed additional paired associates learning sessions while they received subdural electrical stimulation time locked to the encoding period (10 of 25 lists) or the recall period (10 of 25lists). Electrical stimulation during encoding and/or recall caused no change in the percentage of correctly recalled word-pairs for any of the 3 participants; the only behavioral changes we observed were an increase in response time in 1 participant during recall stimulation, and an increase in the percentage of intrusion errors in another participant during recall stimulation. In this preliminary report, we assess the predictive power of biomarkers identified during non-stimulation sessions on the existence or absence of any behavioral effect of electrical stimulation.

Abstract: Cognitive deficits, particularly related to memory loss, are one of the most crippling side-effects of epilepsy, sometimes causing patients as much hardship as the seizures themselves. There is a pressing need to understand memory loss in epilepsy in order to identify better interventions. Characterizing the factors behind memory loss, such as seizures or interictal epileptiform discharges (IEDs), is a crucial step in this direction. Past studies have demonstrated that hippocampal IEDs may interfere with memory maintenance and retrieval in humans. In the present study, we use an automated detector to facilitate marking and analyzing IEDs in a larger set of brain regions and memory tasks. We analyzed electrocorticography data from 21 subjects in two tasks that were administered as part of the Restoring Active Memory project (RAM). In the first experiment, subjects studied a list of words and later recalled them. In the second experiment, subjects tried to remember the spatial location of objects in a virtual environment. For each paradigm, we analyzed the relationship between memory performance and IEDs in the hippocampus, parahippocampal gyrus, entorhinal cortex, and middle temporal gyrus. We found no significant effect of IEDs on performance in the spatial task. Meanwhile, IEDs that occurred in the middle temporal or parahippocampal gyrus during the study portion of the free recall task showed a significant association with words that were later forgotten ($p<0.0001$ and $p<0.05$ respectively). These results suggest that middle temporal IEDs may hinder mental processes specific to word encoding in the free recall task. This would be consistent with existing research that implicates the region in semantic processing and perception.

Abstract: In the free recall task, participants recall as many words as they can from a list in the order the words come to their mind. Subsequent memory effect (SME) analyses contrast the neural biomarkers during encoding of words that are later recalled to the biomarkers during encoding of words that are not recalled. However, in free recall there are many reasons why a particular word might be successfully recalled. For instance, the word might be particularly easy to recall due to its position in the list, or because it is semantically related to other words in the list. In order to separate the effect of these exogenous variables on the SME, we used a detailed computational model to identify the likelihood that each study word would be free recalled. Power at several frequency bands at three time points was measured from ECoG electrodes at a variety of locations in patients. We then regressed power onto the likelihoods provided by the behavioral model and compared the results to a multivariate SME. This enabled us to subdivide the SME into a part that aligns with the likelihood of a word being recalled, and a residual that is orthogonal to the likelihoods. The former component is the part of the SME attributable to all the exogenous variables incorporated into the behavioral model (serial position, semantics, etc.); the latter presumably includes biomarkers of endogenous variables that predict good memory encoding. The general strategy of using detailed computational models of memory to inform neurophysiological data analyses could yield dramatic insights into the processes of memory retrieval.

Title: Decoding episodic retrieval processes: frontoparietal and medial temporal lobe contributions to free recall

Authors: *J. E. KRAGEL, S. M. POLYN;
Vanderbilt Univ., Nashville, TN

Abstract: Neuroimaging studies of recognition memory have identified distinct patterns of cortical activity associated with two sets of cognitive processes: Recollective processes supporting retrieval of information specifying a probe item's original source are associated with activation of the hippocampus, ventral posterior parietal cortex, and medial prefrontal cortex. Familiarity processes supporting the correct identification of previously studied probes (in the absence of a recollective response) are associated with activity in anterior medial temporal lobe (MTL), and lateral prefrontal and dorsal posterior parietal regions. Here, we address an open question in the cognitive neuroscientific literature: To what extent are these same neurocognitive processes engaged during an internally directed memory search task like free recall? We recorded functional magnetic resonance imaging (fMRI) activity while participants performed a series of free recall and source recognition trials, and used a combination of univariate and multivariate analysis techniques to compare neural activation profiles across the two tasks. Univariate analyses showed that posterior MTL regions were commonly associated with recollective processes during source recognition, and with free-recall responses. Prefrontal and posterior parietal regions were commonly associated with familiarity processes and free-recall responses, whereas anterior MTL regions were only associated with familiarity processes during recognition. In contrast with the univariate results, free-recall activity patterns characterized using multivariate pattern analysis did not reliably match the neural patterns associated with recollective processes. However, these free-recall patterns did reliably match patterns associated with familiarity processes, supporting theories of memory in which common cognitive mechanisms support both item recognition and free recall.

Title: Oscillatory correlates of enhanced memorability following a shift in the perceptual modality of studied material

Authors: *J. D. MCCLUEY, S. M. POLYN;
Psychology, Vanderbilt Univ., Nashville, TN

Abstract: The human memory system interacts with an ever-changing perceptual environment, and the perceptual properties of new information can shape that information's mnemonic fate. Experimentally, shifts in perception to a salient stimulus have been shown to enhance memorability for post-shift items (Murdock & Walker, 1969). Despite this work, the neural signals that reflect this enhanced memorability at perceptual boundaries remain to be characterized. Sederberg et al. (2006) described global shifts in the oscillatory topography elicited by studied items at early vs. late serial positions, and showed distinct subsequent memory responses for items of each type. One interpretation of this oscillatory shift is that the presentation of the first few list items reflects a perceptual shift relative to experiences prior to the start of the current list, which enhances the memorability of the first few items. In a scalp EEG experiment, we manipulated the presentation modality (auditory vs. visual) of studied material to elicit a mid-list perceptual shift that enhances the memorability of the post-shift item. These post-shift items elicited an oscillatory response which showed enhanced delta activity (2-4 Hz) and diminished alpha and beta activity (10-26 Hz) relative to non-shift items. We examined how these signals changed with the subsequent memory status of the post-shift item, and contrast these effects with list position effects described by Sederberg et al. (2006). In addition, we used a retrieved-context model of memory search to investigate the potential cognitive mechanisms underlying the oscillatory signatures characterized by this study.

Title: The effects of exercise on the neural correlates of pattern separation

Authors: *B. KIRWAN[1], S. SPENCER[2], M. I. NASH[3];
[1]Psychology, [2]Neurosci., [3]Brigham Young Univ., Provo, UT

Abstract: While there are many known benefits of regular physical activity (PA), including lower rates of mortality and morbidity, the majority of individuals in the United States do not engage in the recommended levels of fitness. Furthermore, there have been a limited number of studies evaluating the effect PA may have on cognitive abilities and neurological components and none have evaluated what effect the recommended levels of fitness may have on these areas. The current study evaluated differences between individuals with varying levels of PA using functional magnetic resonance imaging (fMRI) during the performance of a mnemonic discrimination task meant to tax pattern separation processes. Differences in diffusion tensor imaging (DTI) were also examined. Individuals were separated into three groups based on established PA patterns. These groups consisted of sedentary individuals, individuals who did not meet American Heart Association (AHA) recommendations of PA, and individuals who met or exceeded AHA recommendations. Twenty individuals (10 men and 10 women) were recruited for each group. The mnemonic discrimination task consisted of a series of color photographs of everyday objects shown one at a time. For each image, participants indicated whether the object was “new” (objects shown once_foils), “old” (objects shown twice_repeats), or “similar” (objects consisting of paired images that were visually and conceptually similar_lures). It was hypothesized that participants with self-reported higher levels of PA would have a greater bias toward pattern separation both behaviorally and in the fMRI activation of the CA3/dentate gyrus subregions of the hippocampus than those with lower fitness levels and sedentary individuals. Furthermore, it was predicted that those with higher levels of PA would have increased white matter integrity in the cingulum, uncinate fasciculus, and temporal lobe pathways. Significant differences were found in white matter integrity (axial diffusivity or AD) in bilateral cingulum, the left temporal middle gyrus, and the right uncinate fasciculus. Surprisingly, no behavioral or functional differences were found across groups, which may have been influenced by the task demands and small group differences in recorded activity level.

Title: An fMRI investigation on how testing format affects performance on a pattern separation task

Authors: *M. ANDERSON, C. DOXEY, B. KIRWAN, M. NASH;
Brigham Young Univ., Provo, UT

Abstract: Many published studies aimed at investigating memory specificity or mnemonic discrimination use a recognition memory paradigm meant to tax pattern separation processes. These tasks require participants to view images of everyday objects, one at a time, and classify them as "new" if it is the first time the participant is viewing the image in the study (New), "old" if the image is an exact duplicate of an image already seen (Repeat), or "similar" if the image is similar to a previously viewed image but not exactly the same (Lure). Participant responses to Lure stimuli are used to evaluate memory specificity. Lures classified as "similar" (Lure Correct Rejection) indicate a higher degree of memory specificity compared to Lures classified as "old" (Lure False Alarm). This memory specificity paradigm has been used by researchers in mainly two different formats: a study-test design and a continuous recognition design. In the study-test design, participants complete a study phase, in which they view the stimuli and classify them as belonging indoors or outdoors, followed by a test phase. Only during the test phase are the participants asked to classify the images as "new", "similar", or "old". In the continuous recognition design participants view the stimuli and classify them as "new", "old", or "similar" without any previous exposure (i.e. there is no study phase, only a testing phase). In this study, we evaluated the behavioral differences of these two paradigms and used functional magnetic resonance imaging (fMRI) to assess the neurological correlates. The study-test condition consisted of 49 participants and the continuous condition consists of 52 participants. Using a pattern separation score (calculated by subtracting the proportion of "similar" responses to New stimuli from the proportion of "similar" responses to Lures to correct for possible response bias), the continuous recognition group preformed significantly better ($p < .001$) compared to the study-test group in correctly identifying Lures (similar images), indicating a higher degree of memory specificity. However, the overall pattern of fMRI activation in the hippocampus and in the cortex was similar between the two groups.

Title: An fmri investigation of the impact of sleep on pattern separation

Authors: *C. DOXEY[1], B. KIRWAN[2];
[2]Neuroscience/Psychology, [1]Brigham Young Univ., Provo, UT

Abstract: The unique anatomy of the hippocampus, and particularly the hippocampal subfields, makes it especially suited for performing complex computations while forming and retrieving long-term declarative memory representations. One such computational process, known as pattern separation, establishes orthogonal or non-overlapping memory representations in order to discriminate between similar memories. In pattern separation, memory representations are established to allow individuals to successfully recall specific details of previously viewed stimuli and discriminate between similar memory representations. Pattern completion is a complementary process that allows for previously stored memory representations to be reactivated from degraded or noisy cues, resulting in generalization from similar memory representations. The processes of pattern separation and pattern completion have been widely studied in a variety of contexts and models. Human studies have relied on memory specificity paradigms that tax pattern separation, but the effects of sleep on memory specificity have yet to be elucidated. Studies have implicated that consolidation that occurs during sleep improves declarative recognition memory, so we hypothesized that sleep would have a similar effect on memory specificity. We scanned 50 participants using fMRI who were assigned to either a sleep or a wake condition. Participants in both groups studied pictures of random, everyday objects and were then tested immediately on their memory for half of the stimuli while undergoing fMRI scanning. During the testing portion, participants were shown exact repeats, similar lures, and completely new stimuli, and were asked whether each object seen was “old”, “similar”, or “new”. They were brought back to the scanner 12 hours later where they were tested on the remaining objects. Participants in the wake group performed the study and immediate test in the morning and the delayed test in the evening with no sleep between. Participants in the sleep group performed the study and immediate test in the evening and the delayed test in the morning following a night’s sleep. Participants in the sleep group were better at labeling lure stimuli as “similar” compared to participants in the wake group. Interestingly, this sleep effect was not found when analyzing recognition memory in broad terms. Behavioral results were correlated with the simultaneous fMRI data in which differences were found between groups. The implications of hippocampal subfield activity on memory specificity processing will be discussed.

Title: Neural correlates of repetitive versus randomly sequenced learning of context-dependent associations

Authors: ***D. R. O'YOUNG**, J. L. VOSS;
Northwestern Univ., Chicago, IL

Abstract: Associative learning occurs within specific contexts that govern the appropriate behavioral expression of memory (e.g. mixing sucrose into buffer solution in lab, but into coffee at home). Human and animal research suggests that hippocampal and prefrontal regions are especially involved in flexible, rule-based learning rather than inflexible, stimulus-response learning. Here, we investigated neural correlates of context-dependent association learning under conditions designed modulate the involvement of flexible, rule-based learning. Trials were presented in one of four quadrants (e.g. contexts). Given a Cue object, subjects indicated if a subsequent Target object was associated or not. Cue-Target associations were varied by context such that Targets could be classified as Associated-Match (AM, associated with cue and context), Associated-Nonmatch (AN, associated with cue in other contexts), or Unassociated (UA, never associated with cue). Each subject (N=20) performed the task during two sessions, including either (i) randomized trial sequences to promote learning all associations concurrently and the use of rule-based retrieval of associations or (ii) repetitive trial sequences to promote learning each association individually and the use of stimulus-response associations. During memory testing, accuracy was high and did not differ for randomized versus repetitive learning sequences, indicating successful learning and expression of memory for both conditions. ERPs in response to cues included positive potentials from 250-600 ms at frontal sites with greater amplitudes for repetitive learning, suggesting greater preparatory recall in response to cues (rather than to targets) in this condition. In contrast, relative to repetitive learning, randomized learning led to enhanced positive potentials (250-500 ms) for AN targets versus UA targets,

suggesting utilization of contextual information to resolve ambiguities in associative recall in response to targets rather than cues. For both repetitive and randomized conditions, AM targets resulted in enhanced positive potentials (250-600 ms) relative to AN and UA targets, suggesting no nonspecific differences in neural correlates of successful memory retrieval for these conditions. These results suggest that different modes of learning, distinguished only by trial order, engage different brain systems during subsequent expression of memory. Results are interpreted regarding distinctions between human and animal memory research, which often differ in consistency and predictability of trial order during training, potentially promoting involvement of different brain systems.

Title: Targeted enhancement of hippocampal-cortical networks alters neural correlates of object-location association memory

Authors: *A. NILAKANTAN, D. BRIDGE, E. GAGNON, J. WANG, J. VOSS;
Med. Social Sci., Northwestern Univ., Chicago, IL

Abstract: We have previously shown that multi-day repetitive transcranial magnetic stimulation applied to fMRI-defined sites of hippocampal-cortical resting-state networks enhances network connectivity and associative memory. Here, we aimed to extend these findings by examining neural correlates of changes in associative memory retrieval following hippocampal-cortical network-targeted stimulation. In a counter-balanced design over two separate weeks, participants (n=8) completed five consecutive days of network-targeted stimulation (using individualized parietal locations within resting-state fMRI connectivity networks of the hippocampus) versus five consecutive days of sham stimulation (applied to vertex). EEG was recorded during an object-location memory task 24 hours prior to the first stimulation session and 24 hours

following the final stimulation session. Participants studied objects in distinct locations and later recalled object locations during the memory test. Effects of stimulation were assessed for a continuous measure of spatial recall (low precision to high precision placement). High-precision memories selectively improved following network-targeted stimulation relative to sham, suggesting that memory improvements were specific to hippocampal-mediated recollective processing. Furthermore, event-related neural correlates of high-precision recall changed due to stimulation, with greater amplitudes of late-positive activity for parietal electrodes that are normally observed for recollection (associated with oscillatory power increases in the delta and theta bands). These findings demonstrate that the enhancement of hippocampal resting-state fMRI networks caused by targeted noninvasive stimulation translates into enhanced neural correlates of successful memory retrieval.

Title: Dominance provides structure to episodic memories

Authors: ***D. J. BRIDGE**, J. L. VOSS;
Med. Social Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Of the many elements that comprise an episode, are any particularly important for coherent memory binding? It is possible that all episode elements are bound equally and recriprocally, and therefore equally support memory retrieval. However, we reasoned that there is structure to memory representations, such that binding is unequally distributed among event elements based on dominance. We hypothesized that active retrieval causes select elements to attain dominance, which enables these elements to be disproportionately bound with other less-dominant elements. We tested this hypothesis using a multi-element episodic memory task. Subjects (N=16) studied three objects at specific locations. After a brief delay, subjects selected

one object and recalled its associated location. Memory was later tested for the other, less-dominant objects. When high-dominance objects served as reminder cues, retrieval of less-dominant objects was significantly more accurate than when less-dominant objects were reminder cues. Specifically, memory of the episode configuration was enhanced when a dominant cue was used as a reminder cue relative to a less-dominant cue. Binding of all objects was therefore strongest to the high-dominance object. Further, dominance binding was associated with enhanced fMRI activity in the hippocampus, suggesting that the hippocampus is involved in disproportionately binding dominant elements to less-dominant elements. Eye movements recorded during the study phase provided mechanistic evidence for disproportionate binding with the dominant objects. A control condition involving passive manipulation of objects rather than active retrieval established the specificity of these dominance effects on behavior and fMRI correlates. Active retrieval therefore selectively increases dominance of specific episode elements and thereby organizes episodic memory. Binding is not equipotent, but rather dominant elements have disproportionately strong binding and therefore serve as effective retrieval cues for coherent episodes.

Title: Memory awareness modulation due to theta-burst stimulation of distinct prefrontal cortical networks

Authors: *A. J. RYALS, J. L. VOSS;
Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: Evidence from neuroimaging and lesion studies suggests that subjective memory awareness may involve anterior prefrontal cortical regions acting in concert with the hippocampus. We used theta-burst transcranial magnetic stimulation (TBS) to temporarily

modulate dorsolateral versus frontopolar prefrontal cortex to test for distinct causal roles in memory awareness in healthy individuals. TBS targets were identified in frontopolar cortex (FPC), dorsolateral prefrontal cortex (DLPFC), and sham (vertex) locations, and were stimulated bilaterally in each of three distinct experimental sessions over the course of one week using a within-subjects design (N=18). FPC locations were found to have greater resting-state fMRI connectivity with hippocampus relative to DLPFC locations, further suggesting that these locations might have critical importance for memory awareness. Associative recognition accuracy did not differ based on stimulation location. In contrast, frontopolar stimulation significantly influenced several measures of memory awareness. During study, judgment of learning accuracy increased, such that lower ratings were given to items that were subsequently forgotten selectively following frontopolar TBS. Confidence ratings during test were also higher for correct trials following frontopolar TBS. Finally, the trial-by-trial correspondence (i.e., gamma correlation) between overt performance and subjective awareness during study demonstrated a linear increase across control, dorsolateral, and frontopolar TBS locations, supporting a proposed rostrocaudal hierarchy of prefrontal contributions to memory awareness. These findings indicate that frontopolar cortex contributes causally to memory awareness, which was selectively enhanced by anatomically targeted TBS. Effects of TBS on FPC versus DLPFC functional connectivity networks will be discussed in relation to the effects of TBS on memory awareness.

Title: Refresh my memory: Context information from episodic memory affects working memory maintenance

Authors: ***A. NOVICK**, A. M. BORNSTEIN, J. D. COHEN;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Humans rely on many kinds of memory to make decisions. Some memory processes, such as working memory (WM) and episodic memory (EM), have distinct neural substrates and

can be subject to distinct disruptions. For instance, when WM maintenance is hindered in simple short-term memory tasks- e.g., when one's ability to rely on a "phonological loop" is disrupted - EM is used to guide behavior. Here, we investigated whether we might see evidence of EM's effect on behavior even when WM is not disrupted. Episodic memory is known to carry information about the associative and temporal context at the time of encoding that is not present in working memory (Howard & Kahana 2002). Therefore, we sought signatures of the influence of encoding context on behavior. 55 subjects studied four word lists, each in a different "context" - a picture of a face or a natural scene. In addition to studying the words, subjects were asked to provide verbal descriptions of the pictures accompanying each list. After training, subjects completed a delayed match (or nonmatch) to sample task. On each trial, they viewed a target set, four words drawn from one of the previously learned lists. After an 18 second delay, subjects were shown a probe word, and asked whether that word was among the target set. Three kinds of probes were used: a word in the target set itself, a word from the same list as the target set, or a word from a different list. These tasks have previously been shown to rely on sustained WM representations. We aimed to test whether WM representations are supported by occasional refreshes from EM. We reasoned that, if EM were used to refresh those representations, we would see effects of the reinstated context from the time of learning. Specifically, we hypothesized that if context information were recalled from EM and present in WM, then the process of comparing the item on screen to those in working memory would be slowed if the probe was from the same list (context) as the targets. Alternatively, if WM representations were entirely self-sustaining, then no context information would be present, and same-list probes would be responded to equally as quickly as different-list probes. Our results matched the former pattern, with same-list probes significantly slowing responses relative to different-list or targets. Critically, the effect depended on how strongly a subject encoded the context: A more vivid verbal description of the context at encoding lead to a slower RT for same-list probes. This result is strongly supportive of the presence of episodic context content in working memory, and thus for a role for episodic memory in sustaining working memory representations.

Title: Developing a neurocognitive model of memory integration

Authors: *N. W. MORTON, A. R. PRESTON;
The Ctr. for Learning & Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Memories are not formed in isolation, but rather are learned in the context of a vast store of existing knowledge. As a result, one of the central problems faced by the memory system is resolving interference between similar memories. Recent research demonstrates that the brain can integrate new information with existing memories in a way that not only reduces interference, but also facilitates new learning. The hippocampus and areas of the prefrontal cortex (PFC) are critically involved in this process of memory integration; however, many questions remain about how these regions work together to combine information across related memories. We developed a modeling framework based on the temporal context model (TCM), describing how the processes of associative binding, memory reactivation, and integration with reactivated memories determine how new events are encoded. Within this framework, we tested a set of competing neurocognitive models that linked brain regions implicated in memory integration (hippocampus, medial PFC, and ventrolateral PFC) to cognitive processes specified by the model. We used a recently developed model-based fMRI technique that we term predictive model analysis (PMA) that uses trial-level measurements of brain activation to estimate the degree of engagement of each process involved in memory integration. The neurally informed models were then used to predict subsequent memory for overlapping experiences. Specifically, we used PMA to examine hippocampal and PFC contributions to a task in which participants learned pairs of images that overlapped with pairs learned previously. We found that ventrolateral PFC engagement could be used to estimate trial-level fluctuations in a model parameter reflecting encoding of individual associations, allowing better prediction of behavior compared to a model not informed by neural data. In contrast, activity in ventral temporal cortex allowed us to estimate the strength of reactivation of overlapping memories. Hippocampus and medial PFC activation was linked to a model parameter formalizing integration of temporal context across overlapping events, consistent with the idea that these regions play a specialized role in memory integration. Our results demonstrate the potential of using PMA to test hypotheses about links between cognitive processes and their neural substrates. Here, this novel method allowed us to disentangle the interrelated mechanisms through which hippocampus and PFC contribute to memory integration during new learning.

Title: The effect of task demands on activity in hippocampal subfields and MTL cortices in a pattern separation task

Authors: S. M. STARK[1], *C. E. STARK[2];
[1]Neurobio. & Behavior, Univ. of CA, Irvine, Irvine, CA; [2]Univ. CA, Irvine, Irvine, CA

Abstract: Several studies have reported activity in the combined dentate gyrus and CA3 (DG/CA3) subfields of the hippocampus that is consistent with pattern separation, or the orthogonalization of highly similar patterns of input. In CA1, a contrasting pattern of activity has been observed that is less sensitive to small changes and may track the degree of change. Here, we extend these findings by directly comparing the use of an incidental task with an intentional recognition memory task to evaluate the potential impact of the over memory task demands on activity. In a between-subjects design, participants either incidentally encoded everyday objects with an indoor/outdoor judgment or performed a continuous recognition task with old, similar, or new responses (the Mnemonic Similarity Task). Trials of interest included first presentations, exact repetitions, and similar lure items that were visually similar to a previously viewed item, but not exactly the same. We also included a perceptual discrimination baseline task. Throughout, signals consistent with pattern separation were observed in the DG/CA3, replicating prior results. In addition, both in the hippocampal subfields and in the MTL cortical regions, results were similar across intentional and incidental tasks. However, two caveats should be noted. First, the intentional task typically yielded more robust activity suggesting that task demands can be relevant. Second, pattern-separation related activity in the subfields and the MTL cortices differed as a function of how pattern separation was operationalized (using the recognition memory responses vs. using repetition suppression). These data highlight the importance of how one operationalizes computational concepts like pattern separation when it cannot be directly observed (e.g., using imaging techniques) and stresses the need for relating findings such as these that can be observed in humans with more direct evidence from animal models.

Title: Propranolol influences reference-dependence in intertemporal choice

Authors: *K. M. LEMPERT[1], S. F. LACKOVIC[1], R. H. TOBE[3], P. W. GLIMCHER[2], E. A. PHELPS[1,3,2];
[1]Dept. of Psychology, [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Nathan Kline Inst., Orangeburg, NY

Abstract: Many decisions involve weighing immediate gratification against future consequences. In such intertemporal choices, people often choose smaller, immediate rewards over larger delayed rewards. Although it has been suggested that emotion underlies impulsivity and the tendency to favor immediate rewards, we have previously shown that emotional arousal (specifically, pupil dilation responses), as well as choices, in intertemporal choice tasks are reference-dependent (Lempert et al., 2015). Arousal increases when less predictable rewards are better than expected, whether those rewards are immediate or delayed. Furthermore, when immediate rewards are more variable than delayed rewards (Immediate Vary condition), participants tend to be patient. When delayed rewards are more variable (Delay Vary condition), people are more impulsive. We tested whether emotional arousal causes this reference-dependence in intertemporal choice by pharmacologically blunting arousal responses using propranolol, a beta-adrenergic receptor antagonist. We administered propranolol and placebo in a two-day, double-blind within-subjects design, hypothesizing that propranolol would reduce the difference in impulsivity between the Immediate Vary and Delay Vary conditions in an intertemporal choice paradigm. Replicating our previous study, in the placebo condition, participants were significantly more impulsive in the Delay Vary than the Immediate Vary condition. This effect was weaker when individuals were given propranolol. This suggests that emotional arousal underlies sensitivity to the choice context during intertemporal choice.

Title: The role of reward immediacy in temporal discounting

Authors: *U. BROMBERG[1], C. BÜCHEL[2], J. PETERS[1];
[1]Dept. of Systemic Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Univ. Med. Ctr. Hamburg Eppendorf, Hamburg, Germany

Abstract: Temporal discounting choices which include an immediate reward (now-trials = NT), might give rise to more impulsive behavior than choices which do not (not-now-trials = NNT) (McClure et al., 2007). Exerting self-control during temporal discounting (i.e. choosing the larger later (LL) option) has been associated with the LPFC (Cohen & Lieberman, 2010; Hare et al., 2014, Figner et al., 2010). Here we investigate neuronal correlates of decision-making in relation to reward immediacy in a sample of young adults (n=81, age 18-20 years). We hypothesized that choice-dependent modulation of value-processing would be stronger during NT as compared to NNT, because the tempting option of an immediate reward in NT is expected to require stronger self-control than only delayed options in NNT (Figner et al., 2010). While we did find a main effect of lPFC-correlates when choosing the LL across all trials, contrary to our hypothesis, no neural correlates of choice where bigger in NT as compared to NNT. Furthermore the main effect of choice seemed to be driven by NNT, proving both dorsal and ventral PFC areas to be correlated with choosing the LL in NNT but not in NT. To further investigate the role of lPFC also in NT, we hypothesized that a stronger lPFC regulation during NT may only be required in high-discounting subjects, who are likely to be particularly tempted by the immediate reward option. Confirming this hypothesis only the high-discounters showed significant lPFC activation (both dorsal and ventral) also in the NT, when choosing the LL. While our results confirm a role of lPFC in self-control processes during discounting, they partly reveal a specific relevance for those who discount rewards more steeply. This result suggests an important role for individual differences in neural correlates in discounting behavior, in particular with respect to involvement of prefrontal regions implicated in self-control.

Title: Treating impulsivity: temporal discounting in heroin users undergoing treatment

Authors: *S. LOPEZ-GUZMAN[1], A. B. KONOVA[1], J. ROTROSEN[2], S. ROSS[3], P. W. GLIMCHER[1];
[1]Ctr. for Neural Sci., NYU, New York, NY; [2]Psychiatry, NYU Sch. of Med., New York Univ., New York, NY; [3]Div. of Alcoholism and Drug Abuse, Bellevue Hosp. Ctr., New York, NY

Abstract: Objective: Impulsive decision-making is a hallmark of addiction and, in the case of opioids like heroin, seems to be modified with treatment consisting of standard counseling and pharmacological maintenance therapy. Previous studies have used intertemporal choice procedures to measure the discount rate as a quantitative means for estimating impulsivity. However, whether discount rates can be used to predict and accurately track opioid use disorder patients' path through treatment remains a pressing open question. Its usefulness as a predictor of relapse or recovery is of critical importance. Opioid use is skyrocketing and opioid use disorder has one of the highest rates of relapse across substances of abuse. We conducted a longitudinal within-subjects study with repeated measures of temporal discount rates in a cohort of patients starting treatment for mild to severe opioid use disorder. Methods: Repeated measures (weekly and bi-weekly) of both an intertemporal choice task and a risk attitude task were made in a group of patients starting their treatment at Bellevue Hospital's Methadone Treatment Program. Both tasks were fully incentive compatible. A group of matched healthy controls performed the same tasks. The Time Line Follow Back questionnaire was used to track drug use between sessions, including use of patients' prescribed maintenance medication. Urine testing confirmed these reports. Subjects' choices in the behavioral tasks were fitted with a standard hyperbolic discount model and a second hyperbolic discount model, which incorporated a risk parameter to account for nonlinearities in the utility function. Results and conclusions: As previously reported, opioid use disorder patients have significantly higher discount rates compared to healthy controls. Preliminary results from our pilot study indicate discount rates follow each patient's clinical state through recovery, decreasing progressively with abstinence. Interestingly, discount rates also correlate with relapse events, peaking when these events occur. Data collection in a larger sample is ongoing. We conclude that temporal discounting, when assessed repeatedly over the course of treatment, could be used as a behavioral signature of patients' evolution and potentially serve as a useful predictor of prognosis and treatment adherence for opioid use disorder.

Title: The interaction of episodic future thinking and temporal discounting in pathological gambling

Authors: *A. WIEHLER, J. PETERS;
Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Delayed rewards are devalued by human and non-human agents, a phenomenon know as temporal discounting (TD). Similar to many addiction disorders, pathological gambling (PG) is associated with steep devaluation of delayed rewards (Petry, 2001, J abnorm psychol). Recent studies reported that the ability to imagine future events (episodic future thinking, EFT) can interact with TD such that increased EFT leads to more foresighted decisions and attenuated discounting (Lin et al., 2014, Behav neurosci; Palombo et al., 2014, Hippocampus; Peters et al., 2010, Neuron). This interaction is of high clinical relevance for highly impulsive populations such as PGs or addiction patients in general. PGs do not show an overall impairment of EFT (Wiehler et al., 2015, submitted), but the interaction of EFT and TD and the neuronal underpinnings have not yet been studied in PG. We investigated a sample of n=24 pathological gamblers fulfilling the DSM-5 criteria and n=24 matched healthy controls (HCs) with fMRI during a TD task. The identical task was performed by n=6 (respectively n=7) behavioral pilots. The TD task consisted of two conditions: in the control condition, offers about delayed rewards were presented with a numerical amount and delay. In the episodic condition, rewards were presented in the same way, but enriched by participant-specific personal future event cues (based on a pre-scan interview, Peters et al., 2010, Neuron). We modeled participants decisions using the hyperbolic discounting model by Mazur (1989, J exp anal behav). k parameters (representing the degree of discounting) were significantly higher in the PGs than in healthy controls (main effect of group: $p < 0.01$). TD tended to be attenuated during the presence of episodic cues (main effect of condition: $p = 0.09$). This effect does not differ between groups (group x condition interaction: $p = 0.44$). On the neuronal level, both groups showed a robust activation of the EFT network (PCC, vmPFC) in the episodic condition (conjunction analysis: FWE corrected $p <$

0.05). We replicated previous findings of increased temporal discounting in pathological gamblers. However, similar to HCs, PGs tended to benefit from the presence of episodic cues by showing attenuated discounting. This finding might provide an interesting avenue for novel therapeutic interventions in pathological gambling and addiction more generally.

Title: Tracking the neural dynamics of hypothesis evaluation with model-based fMRI

Authors: *N. MARINSEK, B. O. TURNER, M. B. MILLER;
Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: In this study, we aimed to 1) model the component processes of hypothesis evaluation during the receipt of new evidence and 2) identify brain regions that support these processes. We used fMRI data from a previous experiment in which participants attempted to generate appropriate category labels for a series of word sets that were designed to either elicit repeated cycles of hypothesis formation and evaluation ("hard" word sets) or minimize these processes ("easy" word sets). We modeled participants' hypothesis certainty over the course of each trial as a Bayesian process and then conducted a model-based analysis of the fMRI data to identify brain regions with activity profiles that correspond to the predictions of our Bayesian model, such as absolute hypothesis certainty, changes in hypothesis certainty, and expectancy. We found that the left ventrolateral prefronal cortex (vlPFC) and left occipital cortex were more active when hypotheses were uncertain and the brain regions in the canonical default mode network (DMN) were more active when hypotheses were certain. These results are in line with previous research and suggest that the left vlPFC may play a role in forming hypotheses. We also found that activity in the left primary motor cortex increased when hypothesis certainty increased, even though we controlled for motor activity and motor preparation in the model. We propose that this activity reflects the motor preparation that results from discovering (or honing in on) the correct category. The results of this study provide insight into the psychological and neural processes of hypothesis evaluation, as well as the validity of Bayes' theorem as a model of belief updating in

humans. This research was supported by the Institute for Collaborative Biotechnologies under grant W911NF-09-D-0001.

Title: Neural manifestations of decision making are insensitive to confidence among pathological gamblers

Authors: *M. E. HUDGENS-HANEY[1], J. P. HAMM[2], E. A. KRUSEMARK[3], A. S. GOODIE[2], J. E. MCDOWELL[2], B. A. CLEMENTZ[2];
[1]Dept of Psychology, [2]Depts of Psychology & Neurosci., Univ. of Georgia, Athens, GA; [3]Dept. of Psychology, Univ. of Wisconsin, Madison, WI

Abstract: Pathological gambling disorder, classified in DSM-5 as an addictive disorder, is associated with severely maladaptive gambling behavior, often with dire economic and personal consequences. Pathological gamblers (PG) display both more confidence and more overconfidence on gambling tasks compared to frequent but non-pathological gamblers (NPG) and also fail to modulate bet acceptance according to their confidence level (Goodie, 2003). In addition, PG accept bets as if they have control over a betting situation even when the relevant control does not exist (Hudgens-Haney et al., 2013). Describing the neural circuits associated with confidence and control assessment, as well as aspects of this circuitry which are aberrant in PG, could lend critical information for understanding the neurophysiology of pathological gambling. In the current study, 34 PG and 34 NPG completed the Georgia Gambling Task, which begins with a standard confidence assessment task using 180 pairwise comparisons of US state populations. In a subsequent magnetoencephalography session, participants in the "Knowledge" condition viewed the same comparisons (Choice; 2000 ms), followed by the number of points that could be lost during trial (Cost; 1500 ms), and then accepted or rejected the bet that their previous answer was correct with a button press. After bet acceptance or rejection,

participants received feedback on whether they won or lost. The "Random" condition was similar in stimulus sequence except that, rather than state pairs, participants were presented matched uncontrollable probabilities of winning that bet on each trial. Oscillatory power was used to assess manifestations of stimulus and decision making processing at different frequencies. Main effects of gambling pathology, task control (Knowledge vs Random), and confidence level, as well as interactions, were found at various frequencies throughout the trial duration. Prior to the Choice, NPG showed a greater beta desynchronization than PG in occipital cortex. In addition, NPG showed greater beta activity in left visual regions during LC than HC, while PG did not modulate based on confidence level. A number of 3-way interactions were also found in bilateral visual regions. In response to the Choice, NPG, but not PG, modulate high gamma-band activity according to their confidence level, and only during the Random condition trials. These findings provide neurophysiological evidence that PG suffer from deviant confidence and control assessment and suggest that manifestations of top-down bias signals in early sensory processing are dysregulated in PG.

Title: Does temporal discounting predict future drug use? Structural mri and behavioral assessment at 14 and 18 years old

Authors: *S. MACKEY[1], B. CHAARANI[1], P. SPECHLER[1], K.-J. KAN[1], K. HUDSON[1], C. ORR[1], R. R. ALTHOFF[1], H. GARAVAN[1], T. HE IMAGEN CONSORTIUM[2];
[1]Psychiatry, Univ. of Vermont, Burlington, VT; [2]EU Framework 6, London, Dublin, Berlin, Paris, Germany

Abstract: Greater temporal discounting has been associated with a range of problematic impulsive behaviors including substance abuse, obesity, pathological gambling, as well as poor health and financial decision-making. Here, we examined the neural correlates of temporal discounting in a large group (N=1830) of 14 year old adolescents. Temporal discounting and drug use was assessed again at 18 years old to determine the stability of the measure across time and the relation of temporal discounting at age 14 to subsequent substance use. Methods Kirby's Monetary Choice Questionnaire (MCQ) was administered to a large sample of adolescents at 14 and again at 18 years old. The MCQ contains 27 items probing the subjects' preference for a range of small immediate rewards versus larger delayed rewards, e.g. item 5 asks: "Would you prefer €14 today, or €25 in 19 days?" Drug use history was assessed with the European School Survey Project on Alcohol and Drugs (ESPAD) questionnaire. T1-weighted magnetization prepared gradient echo sequence (MPRAGE) structural MR-images were obtained at age 14 years old and processed with the optimized voxel-based morphometry (VBM) method. Results The VBM analysis indicated that three cortical clusters (i.e. bilateral insula and frontomedial cortex) and one subcortical cluster including the anterior thalamus and ventral striatum were significantly related to temporal discounting, $p<0.05$ after correcting for multiple comparisons. Temporal discounting was positively correlated with the combined lifetime frequency of alcohol, nicotine, and illicit drug use ($r = 0.115$, $p<0.001$) and a composite measure of anti-social behavior ($r = 0.129$, $p<0.001$) at age 14. The overall rate of temporal discounting declined slightly from the age of 14 to 18 but the change was not statistically significant ($t(1312) = -1.65$, $p = 0.24$). The correlation between temporal discounting at 14 and 18 years old was $r = 0.29$, $p < 0.001$. Among the adolescents who had not been exposed to alcohol, nicotine, or illicit substance at age 14, individuals who endorsed greater temporal discounting had consumed more alcohol and drugs by the time they reached the age of 18 ($r = 0.146$, $p < 0.01$) Conclusions We found that temporal discounting is associated with a specific set of brain regions which have previously been associated with reward processing (e.g. the ventral striatum and frontomedial cortex) and the representation of the physiological state of the body (i.e. the insula). The stability of temporal discounting across time and its ability to predict future alcohol and drug use support the use of temporal discounting as a marker of addiction processes.

Title: The genetic and neural correlates of risky decision making in young adults with antisocial substance disorder

Authors: *H. YARDLEY[1], M. DALWANI[2], J. SAKAI[2], S. MIKULICH-GILBERTSON[2], T. CROWLEY[2], M. MCQUEEN[1];
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Univ. of Colorado Denver, Denver, CO

Abstract: Background: Behavioral disinhibition (BD), an underlying vulnerability and a highly heritable trait, encapsulates separate behavioral manifestations including impulsivity, conduct disorder, substance dependence, and other externalizing behaviors. We aim to uncover the common pathways associated with this behavior by combining functional magnetic resonance imaging (fMRI) and analysis of genomic pathways to shed light upon the genetic and neural determinants of these behaviors. Methods: We recruited 43 young adults scoring high for BD and antisocial substance disorder, aged 24-32 years from the Colorado Longitudinal Twin Study, as well as 41 age matched controls. Functional scans were acquired using a risk-taking fMRI paradigm called the Colorado Balloon Game (CBG). A genome-wide association study (GWAS) pathway analysis of BD was conducted on a larger sample from which these subjects were recruited. We will then test for associations between brain activation during risky and cautious decisions in the BD subjects with the genetic summary score after adjusting for age and IQ. Results: Hi-BD subjects (n = 43, 21 males, mean age = 28.18 ± 1.53) in comparison with average BD subjects (n = 41, 19 males, mean age = 27.96 ± 1.71) made significantly higher risky button presses on the CBG (Hi-BD: mean 53.05 ± 15.78, Avg-BD: mean 46.39 ± 13.39, $p < 0.05$). We are awaiting results on BD vs. genetic score association and brain activation association with genetic score after adjusting for covariates. Conclusion: This study provides a unique opportunity to study individuals with high BD and understand if severity of BD is associated with genetic underpinnings, and to understand to what extent brain activation during risky and cautious decision-making is associated with their genetic profile. Such an analysis would be the first step to understand the contribution of genetics to biological brain vulnerability during decision making in BD individuals.

Title: Do we need to treat risk? Attitudes toward risk and ambiguity in opioid addiction

Authors: *A. B. KONOVA[1], S. LOPEZ-GUZMAN[1], J. ROTROSEN[2], S. ROSS[2,3], P. W. GLIMCHER[1];
[1]New York Univ., New York, NY; [2]New York Univ. Med. Ctr., New York, NY; [3]Div. of Alcoholism and Drug Abuse, Bellevue Hosp. Ctr., New York, NY

Abstract: Objective: Drug addicted individuals are thought to be excessively reckless and risky, but the relevant factors that drive these behaviors are poorly understood. Economics provides a set of tools to quantify at least three factors that distinctly contribute to an individual's propensity for risk taking: their tolerance of known risk (technical risk attitude), their tolerance of ambiguous or unknown risk (ambiguity attitude), and the randomness in their decision process (stochasticity). Therefore, to more fully understand the behavior of opioid users in risky situations, in the present study we focused on these three factors, which have not been the subject of previous experimental decomposition in addiction - although such a decomposition may have important implications for understanding and potentially treating this disorder. Method: Individuals seeking treatment for an opioid use disorder at a large urban hospital completed a task in which they chose between a certain $5 and a lottery offering a chance to win more than $5 or nothing. Across trials, we varied the magnitude of the potential win, the probability of winning, and the level of ambiguity (how much was known about the probability of winning). The task was incentive compatible meaning that subjects were paid according to their actual choices. Results & Conclusions: Preliminary data suggest opioid users are more risk tolerant than they are ambiguity tolerant, as has been observed in health. We find good fits of a modified power utility model that treats ambiguity as a subtrahend term to probability, suggesting the assumptions of this model hold for the behavior of this group. Analyses that do not assume a specific model also support this claim: users are more likely to choose the lotteries when the amount and probability associated with these lotteries is higher, and the ambiguity lower. Data collection in an age and wealth matched community sample of non-drug users is ongoing. However comparison with parameters obtained in two independent published healthy adult data sets suggests opioid users may deviate more from health in their tolerance of ambiguity (~24-25% more tolerant) than of risk (~0-16% more tolerant). No apparent differences are observed for stochasticity, suggesting that a diminished "quality" of decision making is not driving these differences from health. These initial data raise the possibility that there may be ordering in the

relative contribution of these individual factors to the behavior seen in addicts (ambiguity attitude > technical risk attitude > stochasticity). Our ongoing work seeks to validate this hypothesis.

Title: Cortical activity underlying risk and reward decision-making

Authors: *I. SAEZ[1], J. J. LIN[2], E. CHANG[3], J. PARVIZI[4], G. SCHALK[5], P. BRUNNER[5], R. T. KNIGHT[1], M. HSU[1];

Abstract: Generation of adaptive behavioral responses is not a passive process solely reliant on sensory evaluation. Rather, it requires active integration of sensory input with internally stored information such as generalized knowledge, previous experience, and goals. For example, variation in individual behavioral preferences, such as an individual's degree of aversion to risk, likely reflect underlying differences in internally generated neural activity. This active

combination of external information and internal activity is a fundamental, but understudied aspect of human decision-making. Brain oscillations have been proposed as a fundamental mechanism whereby activity within and across multiple brain areas is coordinated in the service of adaptive behavior. We recorded local field potentials from the brain of neurosurgical patients who underwent surgery for the treatment of intractable epilepsy using electrocorticography (ECoG) (n=7). ECoG signals reflect the coordinated activity of ensembles of hundreds of thousands of neurons, and are uniquely poised to reveal fast, circuit-level computations in the human brain. ECoG data was recorded from prefrontal cortical areas engaged in goal-oriented decision-making tasks, including orbitofrontal cortex (OFC) and lateral prefrontal cortex (LPFC) while patients engaged in a gambling game. We found that different aspects of the gambling game generated event-related changes in oscillatory activity across multiple areas and frequency bands. Specifically, we observed that in electrodes located in a variety of prefrontal locations there was a significant increase in high gamma (HG; 70-200Hz) power prior to choice in trials in which patients chose a safe prize over a gamble. A different set of electrodes showed differential HG activation at the time of gamble outcome reveal for behaviorally relevant aspects of the task (e.g. wins vs. losses), indicating that prefrontal regions carry out computations related to different aspects of the task. Cross-frequency coupling analyses revealed that the amplitude of HG was often related to the phase on slower oscillations on the theta frequency band (4-8Hz), suggesting a role for theta oscillations in coordinating local activity over multiple brain areas. These findings provide evidence that neural activity in lateral and orbital prefrontal regions may support cognitive processes underlying value-based decision-making such as cognitive control and reward-related learning, and highlight the role of ECoG recordings in advancing our understanding of the neural basis of risk and reward-related decision making in humans.

Title: Individual differences in risk-taking: The role of executive functions and anxiety in predicting ambiguous events

Authors: *Á. TAKÁCS[1], A. KÓBOR[2], K. JANACSEK[4,3], F. HONBOLYGÓ[4,2], D. NEMETH[4,3];
[1]Inst. of Psychology, Eotvos Lorand Univ., Budapest, Hungary; [2]Brain Imaging Centre, Res. Ctr. for Natural Sci., [3]Inst. of Cognitive Neurosci. and Psychology, Res. Ctr. for Natural Sci., Hungarian Acad. of Sci., Budapest, Hungary; [4]Inst. of Psychology, Eötvös Loránd Univ., Budapest, Hungary

Abstract: Decision making is affected by several internal and external factors, including social effects, information availability, processing capacity, and personality traits. In our studies we aimed to investigate the contribution of individual differences in executive functions (EFs) and trait anxiety to the neural background of risky decision-making. The first study investigated the role of executive functions (EFs) in different strategies underlying risky decision making. Healthy adults participated in a Balloon Analogue Risk Task (BART) while ERPs were recorded. Participants were assigned to low EFs and high EFs groups based on their performance on a neuropsychological test battery measuring shifting, updating, and inhibition. In the experiment, each balloon pump was associated with either a reward or a balloon pop with unknown probability. The feedback-related negativity (FRN) associated with undesirable outcomes was larger in the high EFs group than in the low EFs group. As the FRN has been found to reflect salience prediction error, we suggest that the high EFs group formed internal models that were violated by the outcomes. The second study investigated whether nonclinical adults with high trait anxiety show smaller FRN for negative feedback than those with low trait anxiety in the BART. Participants were assigned to low and high trait anxiety groups by a median split on the State-Trait Anxiety Inventory trait score. Our results showed that the FRN for negative outcome was decreased in the high trait anxiety group compared to the low trait anxiety group. We propose that pessimistic expectations triggered by the ambiguity in the BART decreased outcome expectation errors in the high trait anxiety group indicated by the smaller FRN. In sum, our studies showed that expectations and prediction errors are modulated by EFs and trait anxiety at the neural level during risky decision-making.

Title: Modulation of feedback-related negativity amplitude on the balloon analogue risk task

Authors: *A. W. MCCOY, M. E. YOUNG;
Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: When making decisions, the probability and magnitude of errors can play a major role in changing preferences. Electroencephalography (EEG) research examining the error-related negativity (ERN) and the associated feedback-related negativity (FRN) has indicated that the amplitude of each component may predict subsequent behavioral change. The current study used a version of the Balloon Analogue Risk Task (BART) that involves outcomes that are dynamically changing over time. As the balloon grows, more points are available but the probability of the balloon popping (netting zero points) is higher; the participant decides when to stop the balloon's expansion to maximize points. The BART was adapted to facilitate the study of the FRN in dynamic environments. The purpose of Experiment 1 was to determine the effect of error magnitude on FRN amplitude during popped (incorrect) trials, whereas Experiment 2 was aimed at determining the effect of error magnitude on FRN amplitude during cashed-in (correct) trials. It was hypothesized that larger errors (i.e., the balloon popping after waiting a long time to cash-in) would result in a larger FRN than smaller errors. In Experiment 1, error magnitude did not contribute to the amplitude of the FRN. In Experiment 2, the masked points possible condition was a replication of Experiment 1. In the unmasked points possible condition, the number of points that could have been earned for each balloon was presented before participants found out how many points were earned. It was expected that there would be a larger FRN magnitude after cashed-in trials in the unmasked points possible condition compared to the masked points possible condition based on the magnitude of the error. In Experiment 2, the amplitude of the FRN was affected by the magnitude of the error on cashed-in trials in the unmasked condition, but not the masked condition. These results are seemingly at odds, and cannot be assimilated into any currently extant model of the FRN. An explanation relying on the motivational importance of errors is discussed.

Title: Performance and ERP in the Iowa Gambling task is related to body weight and daily eating behavior in Japanese healthy young females

Authors: F. ISHIKAWA, *K. YAMANAKA;
Showa Women's Univ., Tokyo, Japan

Abstract: An impaired performance on Iowa gambling task (IGT) comes from decision-making that preferred a high immediate gain despite higher future losses. Previous studies demonstrated that obese individuals and patients with eating disorder, who are characterized by a preference for high immediate reward (excessive food intake) despite higher future punishment (weight gain), showed deficits on the IGT. Therefore, we hypothesized that, even in healthy participants, performance on IGT is correlated with their body weight, daily eating behavior, and ERP components related uncertain decision-making during the task. In this study, 10 Japanese healthy young female volunteers (height: 159.1±4.8, weight: 54.5±6.3, BMI: 21.5±2.1) conducted two sessions of the computerized IGT task, each containing 100 trials. In the IGT task, participants chooses from among four decks of cards, some of which yield higher immediate gain but larger future losses (disadvantageous decks) and others that yield lower immediate gain but smaller future losses (advantageous decks). They are asked to make choices that maximize their total gains. Task performance was assessed by (1) total number of choice for the advantageous decks minus total number of choice for the disadvantageous decks (net score), and (2) total number of choice for the largest loss cards (number of worst choice). Surface electroencephalography was recorded during the IGT task and analyzed by a traditional event-related potential (ERP) after the feedback onset. We addressed the relationships between a performance on IGT and body weight, daily eating behavior (Dutch Eating Behavior Questionnaire: DEBQ), and 2 ERP components, feedback-related negativity (FRN) and P300. Consequently, there was a significant negative correlation between body weight and net score. Also there was a significant positive correlation between body weight and number of worst choice. These results indicate that a participant whose weight is light can learn to make advantageous choices on the IGT. Next, amplitude of FRN in loss trials was negatively correlated with number of worst choice, while amplitude of P300 in loss trials was positively correlated with net score. Moreover, a participant whose score on restrained eating is high tended to be large FRN and P300 amplitudes. Overall results suggest that prefrontal function revealed by ERP components is related to not only IGT performance but also body weight and daily eating behavior even in healthy participants.

Title: Moral transgressions and dirty bodies: Embodiment of the Macbeth effect is mapped topographically onto the somatosensory cortex

Authors: *M. SCHAEFER[1,2], M. ROTTE[2], H.-J. HEINZE[2], C. DENKE[3];
[1]Psychology Dept., Med. Sch. Berlin, Berlin, Germany; [2]Univ. of Magdeburg, Magdeburg, Germany; [3]Charite Universitätsmedizin Berlin, Berlin, Germany

Abstract: The theory of embodied cognition claims that cognitive representations are structured by metaphorical mappings from sensory experience. According to this theory knowledge is represented in modal systems derived from perception. Recent behavioral studies found evidence for this hypothesis, for example by linking moral purity with physical cleansing (the Macbeth effect). Neurophysiological approaches provided further support by showing an involvement of sensorimotor cortices for embodied metaphors. However, the exact role of this brain region for embodied cognitions remains to be cleared. Here we demonstrate that the involvement of the sensorimotor cortex for the embodied metaphor of moral-purity is somatotopically organized. Participants were asked to enact scenarios where they had to perform immoral (lying) or moral acts either with their mouths (leaving a message on a voice mail) or their hands (writing a note). Subsequently participants had to evaluate different products. Behavioral results showed that mouthwash products were particularly desirable after lying in a voice mail and hand wash products were particularly desirable after writing a lie, thus demonstrating that the moral-purity metaphor is specific to the sensorimotor modality involved in earlier immoral behavior. FMRI results of this interaction demonstrated associated activation in sensorimotor cortices during the evaluation phase that was somatotopically organized with respect to preceding lying on a voice mail (mouth-area) and preceding lying in a written note (hand-area). Thus, the results demonstrate a central role of the sensorimotor cortices for embodied metaphors.

Title: The effects of gratitude expression on neural activity and plasticity

Authors: *J. W. BROWN[1], P. KINI[1], S. MCINNIS[1], N. GABANA[1], J. WONG[2];
[2]Sch. of Educ., [1]Indiana Univ., Bloomington, IN

Abstract: Gratitude is a common aspect of social interaction, yet relatively little is known about the neural bases of gratitude expression, nor how gratitude expression may lead to neural plasticity. To address these twin issues, we recruited subjects entering psychotherapy for depression and/or anxiety. One group was given psychotherapy plus a gratitude writing intervention, which required them to write a letter expressing gratitude. The control group was given psychotherapy only. After three months, subjects performed a "Pay it forward" task, similar to a trust game, in the fMRI scanner. In the task, subjects were repeatedly endowed with a monetary gift and then asked to pass it on to a charitable cause if they felt gratitude for the gift. We measured brain activity and found regions where activity correlated with self-reported gratitude during the task, even controlling for related constructs such as guilt motivation and desire to help. These were distinct from brain regions signaling empathy or theory of mind. We found other regions that correlated with trait gratitude measures. Finally, we found that a simple gratitude writing intervention led to significant neural plasticity - subjects who wrote a letter expressing gratitude showed significantly greater neural modulation by gratitude in the medial prefrontal cortex three months later.

Title: Alteration of sensitivity toward the Holocaust related media content by negative Mass Media

Authors: *S. TUKAIEV[1], I. ZYMA[1], M. MAKARCHUK[1], N. PLAKHOTNYK[1], J. GRIMM[2], A. ENZMINGER[2], Y. HAVRYLETS[3], V. RIZUN[3];

Abstract: Short-term effects of Mass Media are cumulative and lead to profound psychophysiological changes. It is well known that the negatively accented Mass Media causes insusceptibility to aggression and violence. The purpose of this study, a part of the project "Broadcasting History in the Transnational Space", was to identify the impact of TV news on the perception and processing of the emotional frames of a historical documentary. 38 healthy volunteers (21 women and 17 men) aged from 17 to 20 years, divided into two groups, participated in this study. The first group (23 volunteers) was demonstrated a video set comprised of 80 negative images, selected from the Holocaust documentary "Night and Fog" (1955, France), and 80 neutral images. The second group (15 volunteers) was presented emotional frames taken from TV news plots (150 images) in order to investigate the pre-stimulus modulations of perception and processing of the emotional frames of historical documentaries. During the exposure, event-related potentials (ERPs) were recorded. We analysed average signal amplitude of ERPs in the time intervals 40-80, 80-120, 120-220, 220-300, 300-400 and 400-700 ms after the onset of the exposure. At the end of the experiment the participants assessed each set of images on the scales of "relaxing - activating" and "unpleasant - pleasant". We noted that the emotional frames taken from TV news plots are relatively weak emotional stimuli compared to the emotional frames of historical documentary. The subjects exposed to the pre-stimulus evaluated the Holocaust pictures as more unpleasant and more activating than those without it. We demonstrated that the ERPs recorded during the presentation of the negative (historical) images had various amplitudes of oscillations due to the preliminary affective impact of TV news frames. The ERP amplitude of P300 in frontal zones was bigger for the group without the preliminary exposure to the emotional TV news frames due to the reduced sensitivity to the content of images. In this case, the historical images demand less attention and less emotional efforts for emotional evaluation of visual information, analysis, retrieval of information from memory and semantic processes, namely search for the meaning of the pictures (occipital P300 and LPP). Thus, short-term media effects include alterations of sensitivity toward the emotional content of visual information.

Title: An investigation of shared population coding for olfaction and social processing

Authors: *T. R. KOSCIK[1], W. A. CUNNINGHAM[2], A. K. ANDERSON[3];
[1]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [3]Human Ecology, Cornell Univ., Ithaca, NY

Abstract: Many key components of the human brain networks critical for social cognition are homologous to regions critical for social chemosensory evaluation of conspecifics in most mammals. Moreover, humans rely proportionally little on olfaction for acquiring social information compared to other sensory modalities, particularly vision. We propose that the neural circuitry in human olfactory brain regions have been assimilated by other sensory modalities and processes. We predict that chemosensory processes have been repurposed and extended to process multimodal social information (Koscik & Tranel, 2012). To address this prediction, we have conducted a Representational Similarity Analysis (RSA) of BOLD-fMRI data (Kriegeskorte, et al., 2008). Using RSA is particularly beneficial for our analysis as it allows us to compare across stimulus modalities (olfactory and visual) and to quantify the similarity of neural representations between stimulus types. While in the scanner, participants viewed a series of images of faces, foods (non-social, odor-related), and objects (non-social, non-odor-related) and smelled a set of different odors. We predicted that neural representations of social stimuli (e.g., face image pleasantness) would be more similar to representations of olfactory stimuli (e.g., odor pleasantness) than they would be to representations of non-social/odor-related stimuli (e.g., food image pleasantness) and non-social/non-odor-related stimuli (e.g., object image pleasantness). In addition, we predicted that the informational content of representations and their relationships across modalities would vary between neural regions. For example, the amygdala may be associated with the intensity or arousal of face and odor stimuli (consistent with Anderson, et al. 2003), but not food or object stimuli or other information about faces and foods such as valence. Preliminary results indicate several brain regions where facial and odor attributes share representations but food and object representations are dissimilar, including ACC, lateral OFC, and vmPFC. These results are consistent with notion that the neural algorithms originally evolved for social chemosensory perception have been repurposed to extract socially-meaningful information from non-olfactory, visual stimuli.

Title: Social pain changes pain sensitivity in people with anxiety state

Authors: *R. AKAGUCHI, M. OSUMI, S. MORIOKA;
Grad. Sch. of Hlth. Sci., KIO UNIVERSITY, Kitakatsuragi-Gun, Japan

Abstract: [Purpose]Pain is deep-related to emotion. The more people feel the anxiety and fear, the more they feel the pain. In recent years, the research of "social pain" has attracted attention. It had been defined that the social pain increased physical pain sensitivity, and the brain activity underlying physical pain was similar to that one underlying the social pain. In present study, we aimed to make clear that be change more pain sensitivity by feeling social pain in people of anxiety state. [Methods]29 healthy people participated in this study. Only 15 people in all were recorded electroencephalography (EEG) in addition to behavioral data. 64-channel EEG System (ActiveTwo; BioSemi B.V.,) was used for the data acquisition (Sampling rate, 512Hz). Electrodes was placed according to the 10/20 system Participant was assessed psychological state by State-Trait Anxiety Inventory 2 (STAI-2). Thermal prove (UDH-105, UNIQUE MEDICAL) was attached to the center of the left inner forearm. Participant underwent 2 blocks pain stimulus baseline pain (before social pain) and final pain (after social pain) to investigate whether the changes of physical pain due to social pain. One block was carried out 30 times. Assessment of pain intensity (stimulation of constant temperature 48℃) was using Visual Analog Scale (VAS). In order to cause participants social pain, participants read the uniquely scenario. The scenario which superior humans than hero appeared caused participants emotion feeling such as envy, elation, longing, inferiority, hostility in the present study. The degree of social pain by the uniquely scenario was assessed score by VAS. [Results & Discussion] In behavior data, in participants with anxiety state (participants with high score of STAI-2 were 16 in all), the pain intensity had negative correlation with elation score, and elation score had negative correlation with the score of STAI-2. And Pain intensity increased significantly in final pain in participants with low elation score (participants with low score of VAS were 14 in all). In EEG data, increase of the amount of pain had negative correlation with the power spectral density of prefrontal cortex (alpha band 8-13Hz). These results suggest that participants with

anxiety state have no thought process, such as the solution to social stress factors. If there is no such thought process, activation of the prefrontal cortex increases by social stress, it led to an increase in pain. In other word, it considered that it is important for the control of pain to change thought that stress factor is one that grow their.

Title: Social anxiety tendency affects event-related potential (ERP) during gaze perception

Authors: ***Y. TSUJI**[1], S. SHIMADA[2];
[1]Meiji Univ., Kawasaki Kanagawa, Japan; [2]Meiji Univ., Kawasaki, Kanagawa, Japan

Abstract: Information which we obtain from person's eye gaze is important in human social interaction and communication. We used event-related potential (ERP) to examine the effects of social anxiety tendencies on eye gaze perception. Avoidance or excessive fear is a defining feature of social anxiety disorder (SAD) or social phobia (SP) in a situation associated with being evaluated or embarrassed by others. Especially, gaze of others is known to frequently induce social anxiety. Sixteen healthy adult subjects (8 females, aged 21 ± 1.3, mean ± SD) participated in this study. Participant's level of social anxiety was examined by means of the Japanese version of the Liebowitz Social Anxiety Scale (LSAS-J). Subjects were divided into two groups, high social anxiety (HSA, n=9) and low social anxiety (LSA, n=7), on the basis of cut-off point which is at 60/144 in which SAD is probable. The experimental stimulus was either gray scale images of direct or averted eye gaze (leftward-gaze or rightward gaze), or closed eyes. In each trial, the experimental stimulus was displayed for 500ms, and then fixation cross appeared for 1500-2000ms (jittered). An experimental session consisted of 120 trials, and the subject underwent two experimental sessions. Electroencephalogram (EEG) signals were

recorded from 30 scalp sites, located according to the extended international 10/20 reference system. The amplitude and latency of P200 component of ERP at Fz were entered into two-way ANOVAs with conditions (direct, averted or closed) and groups (LSA or HSA). For amplitudes, there was a significant main effect of groups ($F(1, 14) = 9.3$, $p < .01$), which shows that amplitude of P200 was higher in HAS than in LSA. For latency, a main effect of conditions ($F(2,28) = 25$, $p < .05$) and an interaction between conditions and groups ($F(2,28) = 4.6$, $p < .05$) were significant. *Post hoc* analysis (Tukey's honestly significant difference; HSD) revealed that the latency was shorter for direct gaze and averted gaze than for closed eyes in LSA group ($p < .01$), while HSA group showed the shortest latency in the direct condition, followed in order by the averted and the closed conditions ($p < .05$). These results suggests that other's direct gaze is prominently processed in the subject who has higher tendency towards social anxiety.

Title: Mu rhythm desynchronization during the observation of emotional and non-emotional facial expressions in 30-month-old infants

Authors: *H. RAYSON[1], J. BONAIUTO[3], P. F. FERRARI[4], L. MURRAY[2];
[2]Sch. of Psychology and Clin. Language Sci., [1]Univ. of Reading, Reading, United Kingdom; [3]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom; [4]Dept. of Neurosci., Univ. of Parma, Parma, Italy

Abstract: Previous research has demonstrated overlapping neural activations for both observation and execution of facial expressions in adults. These shared activations have been assumed to provide indirect evidence for a human mirror neuron system (hMNS), which has been suggested to contribute to action recognition. The hMNS has been hypothesized to play an important role the development of infants' understanding of facial expressions; however, so far, no research has provided neural data to support this claim. The purpose of this study was to explore whether there is evidence of a functioning MNS in 30-month-old infants during observation of both emotional and non-emotional facial expressions. High-density EEG was used

to assess infant mu rhythm desynchronization, an index of MNS activity, while infants observed video clips of actors performing a number of facial expressions. The dynamic facial stimuli comprised four experimental conditions; a positive-emotion condition (joy), a negative-emotion condition (sadness), a non-emotional condition (mouth opening), and a control condition (scrambled facial movements). Any instances where infants imitated the facial expressions observed were also coded offline from video recordings made during stimulus presentation, in order to relate hMNS activity with imitative responses. Results revealed mu rhythm desynchronization in central motor areas for all experimental conditions compared to scrambled facial movements, which suggests that the facial hMNS is functional in 30-month-old infants. Additionally, we found hemispheric differences between emotional and non-emotional facial expressions, suggesting that the facial hMNS interacts with lateralized circuits for emotion processing. These results are consistent with adult facial MNS studies, and support a simulation account of facial expression processing.

Title: Do different brain systems support the ability to recognize negative and non-negative emotions following traumatic brain injury?

Authors: *A. RIGON[1], M. W. VOSS[1], L. TURKSTRA[2], B. MUTLU[2], M. C. DUFF[1]; [1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Wisconsin, Madison, WI

Abstract: Many adult individuals with traumatic brain injury (TBI) have been found to be impaired in facial affect recognition. In particular, TBI patients tend to mislabel negative emotions (e.g., anger, sadness), but perform similarly to normal healthy controls (NC) when asked to recognize non-negatively valenced expressions (e.g., happiness, surprise). Although recent studies have proposed that this finding is an artifact due to intrinsic features of non-negative emotions or task related factors, another account suggests that a separate neural system, more likely to be affected by TBI, supports the ability to recognize negative emotions. In order to examine the latter possibility, we administered a dynamic facial emotion recognition task to individuals with TBI (N=26) and NCs (N=15). Participants with TBI performed significantly worse than NCs when labeling negative emotions ($p<.001$), but there was no significant

between-groups difference for non-negative emotions ($p>.1$) and no significant within-group or across-groups correlation between scores for positive and negative emotions ($ps>.05$). Inspection of scores for participants with TBI revealed high within-group variability. As TBI is characterized by diffuse traumatic axonal injury, we used DTI (fractional anisotropy) to examine the existence of different brain systems supporting recognition of negative or non-negative emotions in the TBI sample. We examined whether specific patterns of axonal injury correlated with impairment with negative or non-negative facial affect recognition. In particular, given previous reports of the amygdala's role in recognizing negative emotions, we hypothesized that TBI group performance on negative emotion items would selectively correlate with integrity of the uncinate fasciculus, the white matter tract connecting the amygdala with the prefrontal cortex, which is important for overall emotion recognition. Indeed, we found a significant positive correlation between right uncinate fasciculus integrity and negative emotion recognition ($r=.63$, $p<.001$), but not non-negative emotion recognition ($r=-.45$, $p>.05$,). Our results support a role of specific white matter tracts damage to impairment of negative emotion recognition reported in TBI patients. This knowledge has the potential to serve a tool to predict (and target with ad hoc rehabilitation) TBI patients who will show emotion recognition deficits in the chronic phase. Future directions include enlarging the current sample and examining how functional connectivity at rest in different brain network supports negative and non-negative facial affects recognition.

Title: Transcranial direct current stimulation to dorsolateral prefrontal cortex enhances the drop of activity in the ventral prefrontal social brain network during economic game

Authors: T. NIHONSUGI[1], *M. HARUNO[2];
[1]Gifu Shotoku Univ., Gifu, Japan; [2]Natl. Inst. of Information and Communication Technol., Osaka, Japan

Abstract: Recent studies have shown that transcranial direct current stimulation (tDCS) to dorsolateral prefrontal cortex changes human economic behavior. However, little is known about how the tDCS stimulation acts on the whole network of the brain. To address this issue, we conducted functional magnetic resonance imaging (fMRI) experiment of a modified trust game (Nihonsugi, Ihara and Haruno), simultaneously using tDCS. This task was designed to dissociate the neural substrates for guilt aversion and inequity aversion, where player A chooses either 'in' or 'out' option. When player A chooses 'in', he also reveals an expectation probability of how likely player B will choose 'cooperate'. With the knowledge of the probability, player B then decides whether to 'cooperate' or 'defect'. We set inequity and guilt orthogonalized in the task. We asked subjects (n=22) to play a role of B twice in an MRI scanner (i.e., decide whether to cooperate or defect. One session was with tDCS and the other was the sham session, and their order was randomized across subjects. Behaviorally, tDCS stimulation to the right DLPFC increased guilt aversion ($p<0.05$), without affecting inequity aversion. This observation is highly consistent with our previous study (Nihonsugi, Ihara and Haruno). We next contrasted brain activity at the timing of game presentation (duration=reaction time) between tDCS and sham conditions, and then averaged across subjects (one-sample t-test, SPM12). We found a significant activity in the lateral (MNI: (-38 34 -10)) and medial (MNI: (-12 30 -8)) orbitofrontal cortices, and ACC (-10 46 34) by the sham - tDCS contrast ($p<0.001$; uncorrected). We also found larger drop of activity in these areas in the tDCS session. These results demonstrate that tDCS stimulation to DLPFC enhances the drop of activity in the ventral prefrontal social brain network, highlighting the importance of the interaction between DLPFC and the ventral social brain network in the realization of guilt aversion.

Title: Neural specializations for interpersonal interaction in a competitive gambling task

Authors: *M. R. PIVA[1], X. ZHANG[2], A. NOAH[2], S. CHANG[3], J. HIRSCH[4];
[1]Interdepartmental Neurosci. Program, [2]Psychiatry, [3]Psychology, Neurobio., [4]Psychiatry, Neurobiology, Comparative Med., Yale Univ., New Haven, CT

Abstract: Dynamic interpersonal interaction is integral to typical human social behavior. Although recent dyadic studies have investigated the paired neural correlates of communicative and cooperative tasks, little is known about the paired neural correlates that underlie competitive tasks requiring social interaction. Conventional neuroimaging techniques such as fMRI have identified key social regions in single brains specifically activated by competing with a human rather than a computer opponent, particularly the temporal-parietal junction (TPJ) [1]. A goal of our study is to extend these findings to interpersonal neural correlates between two brains in an ecologically valid context. We utilized near-infrared spectroscopy (NIRS) to directly measure BOLD signals simultaneously in pairs of subjects playing a simplified poker game. In this game, one player was first randomly dealt either a low or high card. This player was asked to bet or fold. The opposing player was then required to bet or fold in response to the action of the first player. The next trial then began with the opposite player receiving either a low or high card. This simplified poker game was played in two different conditions. In condition one, two subjects played the poker game against each other. In condition two, the same subjects simultaneously played against matched computer opponents. We hypothesized that neural areas potentially involved in social interaction, such as the TPJ, would be differentially sensitive to measures of interbrain coherence during the human vs human and human vs computer conditions. Wavelet analysis [2] was used to quantify coherence between the players for all regions sampled, including the TPJ. Behavioral results suggest that subjects play similarly, roughly obeying Nash equilibrium for a given set of contingencies regardless of the opponent. However, preliminary coherence findings indicate higher synchrony between cross-brain signals originating in the TPJ for the human vs human condition than for the human vs computer condition. These findings extend single brain studies of interpersonal competition to a dual brain paradigm and provide new evidence for a role of TPJ cross-brain coherence in social cognition.

Title: Task-related activation and de-activation predict individual differences in both empathy and analytic reasoning

Authors: S. F. DORAN, R. FERNANDEZ GALAN, H. J. CHIEL, *A. JACK;
Cognitive Sci., Case Western Reserve, Cleveland, OH

Abstract: A large body of work has established that numerous attention-demanding tasks not only tend to activate a core set of brain regions (known as the task-positive network; TPN), but also tend to drive activity below resting baseline levels in a second large-scale brain network (known as the default-mode network; DMN). Some recent work also indicates that certain social tasks activate the default-mode network while de-activating the task-positive network. How does the balance of activity in these two networks reflect individual differences in performance and behavior? In this study, we examined the degree to which core regions of these two networks were activated and deactivated during social and mechanical tasks. We relate these patterns of neural activity to previously-established psychological measures of social and intellectual function. Following theoretical predictions from opposing domains theory (Jack et al. Neuroimage 2013), we predicted that high performance on measures of analytic reasoning would be associated with greater activation of the TPN and greater deactivation of the DMN during mechanical in comparison to social tasks. In contrast, we predicted that higher levels of empathetic concern would be associated with greater activation of the DMN and greater deactivation of the TPN during social in comparison to mechanical tasks. Finally, in line with the theoretical claim that activity of the DMN is more closely associated with empathetic concern than social skill, we predicted that performance on tasks measuring theory of mind would show neither pattern. Whole brain fMRI data was collected from college-aged participants who were presented with social and mechanical tasks. Following standard pre-processing, and selection of regions of interest from a statistically independently-determined mask, data were analyzed using a variety of statistical techniques including correlation, principal component analysis, and receiver operating characteristic (ROC) curves. The data strongly supported the first two hypotheses. Surprisingly, it was also found that theory of mind performance demonstrated a relationship with network activity that was more closely aligned to individual differences in analytic performance than in empathetic concern. These results suggest that examining the balance of activity in different networks can shed light on individual differences.

Title: Estimation of inter-personal relationship in synchronous rhythmic communication by EEG and behavioral synchronizations

Authors: *M. KAWASAKI[1,2], E. MIYAUCHI[1];
[1]Univ. of Tsukuba, Ibaraki, Japan; [2]RIKEN, Brain science institute, Saitama, Japan

Abstract: In our human communication, behavioral rhythms of different individuals is spontaneously synchronized through social interactions. Recent studies using electroencephalogram (EEG) have demonstrated the brain activities along with the behavioral performance in communication, that is to say, the subjects who are good at coordinating their behaviors with the other's behaviors showed low cognitive loads. However, it is not clear about the invisible inter-personal relationship between the subjects (e.g. leader or follower). In this study, we attempted to evaluate it with the causal analyses for the behavioral rhythms and EEG rhythms. We measured the behavioral rhythms and EEG from two subjects during an alternate tapping task where 2 subjects tapped a key alternately with their right finger. Subjects were required to tap the key with an equal time interval of previous tapping of the other subject, whereas the tapping rhythms were not instructed. We evaluated the ability of each subject by the possibilities of the presentation of synchronization with other tapping rhythms, that is, a difference between time intervals of previous other's tapping (from self to other) and current self tapping (from other to self). The behavioral results divided the subjects into good and bad pairs. Moreover, the causal analysis for the behavioral data showed the division of roles between subjects in pairs. Interestingly, in both good and bad pairs there are almost two types; either a static or a variable division of roles between subjects (static pair and variable pair). The static pairs clearly dissociated between the leader and followers, whereas the variable pairs alternately switched the roles. Furthermore, the time-frequency analyses for the EEG data showed the different frontal activities in the low frequency bands among the leader the follower in the static pairs and the variable pairs. These results suggested the possibility that the behavioral and EEG synchronization could estimate the inter-personal roles in human communication.

Title: Neural substrates of motor coordination in joint action

Authors: *M. O. ABE[1], T. KOIKE[2], S. OKAZAKI[2], S. K. SUGAWARA[2], K. TAKAHASHI[3], K. WATANABE[4], N. SADATO[2];

Abstract: In daily life, we have several kinds of interactions with others for performing joint action in which two or more persons integrate their actions for a common goal. Recent psychological and social studies have demonstrated that motor coordination in joint action could be affected by motor optimization and/or social interactions among the partners, although the underlying neural substrates are still unclear. Here, we report brain activities associated with a joint motor task. Nineteen dyads (38 participants) performed single and joint force production tasks in which the goals were to match their individual and averaged grip forces, respectively, to target forces (20% of their maximum grip forces) with minimum variability for 30 seconds. The dyads performed these tasks in a dual fMRI scanner system that allowed simultaneous recording of their brain activities during the tasks. Grip forces were recorded at 200 Hz using a non-magnetic grip force measurement system and were presented online along with the target force on a screen placed in the scanner room. The joint task required almost the same motor effort and had the same visual stimuli as the single task, but the force had to be controlled jointly by the dyads. Comparison of brain activities during single and joint tasks demonstrated that the joint task significantly enhanced activities around the medial prefrontal cortex, temporoparietal junction, and inferior frontal gyrus. This result suggests that brain activities for distinction and estimation of the self-other state play a crucial role in joint action.

Title: Social cognition in amyotrophic lateral sclerosis

Authors: *E. AMBRON[1], L. PIRETTI[1], L. VERRIELLO[2], L. SEGNAN[1], R. ELEOPRA[2], R. RUMIATI[1];
[1]SISSA, Trieste, Italy; [2]Santa Maria della Misericordia Hosp., Udine, Italy

Abstract: Amyotropic Lateral Sclerosis (ALS) is a neurodegenerative disorder of upper and lower motor neurons. However, a high percentage of ALS patients show additional cognitive deficits involving executive functions. Recent evidence suggests that these deficits may extend to social cognition, impairing in particular the ability to correctly perceive and process the cognitive state of other people within a social contest. However, to date these observations have not been confirmed and tasks not specifically designed for adults have been used. The present study explored this issue in ten patients with ALS and mild cognitive deficits involving executive functions, using different experimental tasks. Thus patients were presented with a modified version of the Weapon task - a priming task used to test for race stereotype biases - and the Judgement Preference task - a task measuring Theory of Mind - in which the level of similarity with the actor was manipulated (in-group and out-group membership). Patients' performance differed from controls in both tasks. Specifically, while controls showed more classical speed advantage reflecting stereotype biases, this advantage was not present in controls. Furthermore, ALS patients were more impaired than controls in understanding the preferences of out-group than in-group members. These results suggest that subtle deficits in social cognition can be observed in ALS and might affect the ability of these patients to perceive and interact with conspecifics.

Title: Resting state functional connectivity of the anterior insula and inferior frontal gyrus predicts in-group bias

Authors: *Z. MORADI, D. MANTINI, A. YANKOUSKAYA, G. HUMPHREYS;
Exptl. Psychology, Univ. of Oxford, OX1 3UD, Dept. of Exptl. Psychology, Oxford, United Kingdom

Abstract: We examined whether biases in perception favoring in-group stimuli reflect learned changes in neural resting state activity (RSA). We examined differences in pre- and post-task RSA after football fans performed perceptual matching with in- or out-group associated stimuli. Functional connectivity was assessed from resting state fMRI scans based on three major networks in frontal cortex, the insula and parieto-occipital areas. Compared to pre-task activity,, post-task functional connectivity increased between the left AIC and the inferior frontal gyrus (IFG) and post-task connectivity was positively correlated with in-group bias in behavior. Post-task functional connectivity was significantly weaker between left anterior insula cortex (AIC) and dorsolateral prefrontal cortex (DLPFC), but this was unrelated to behavioral biases. These results suggest that functional connectivity between the AIC and IFG facilitates processing of the motivationally salient stimuli and this might explain the underlying mechanisms of enhanced performance in in-group perception.

Title: Modeling the neurodynamic interactions and organizations of teams

Authors: *R. STEVENS;
IMMEX/UCLA, Culver City, CA

Abstract: Across-brain neurodynamic synchronizations / organizations arise when teams perform coordinated tasks. Little is known about the frequency, magnitude, and duration of these organizations and their relationships with other performance variables. We present a symbolic electroencephalographic (EEG) approach that fills this gap by identifying when the neurodynamic organizations of teams occur and demonstrate its utility with three natural tasks, high school problem solving, submarine navigation, and perioperative teams. Each second, neurodynamic symbols (NS) were created showing the EEG power spectral densities (PSD) at the 1-40 Hz frequency bins for each team member. These data streams contained a history of the team's across-brain neurodynamic organizations, and the degree of organization was calculated from a moving average window of the Shannon entropy of task segments. Decreased NS entropy (i.e. greater neurodynamic organization) was prominent in the ~16 Hz EEG bins during problem solving, while during submarine navigation, the maximum NS entropy decreases were ~10 Hz and were associated with establishing the ship's location. In perioperative teams decreases in NS entropy were uniformly observed in both the 10 Hz and 16 Hz EEG bins. Neurodynamic synchronizations also occurred in the 20 - 40 Hz frequency PSD bins and were associated with other teamwork activities involving uncertainty or stress. The highest mutual information levels, calculated from the EEG values of team dyads, were associated with periods of decreased NS entropy, suggesting a link between these two measures. These studies show entropy and mutual information mapping of symbolic EEG data streams from teams can be useful for identifying organized across-brain team activation patterns associated with changing task activities and events.

Therapy, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [7]Dept. of Psychiatry, Natl. Taiwan Univ. Hosp. & Col. of Med., Taipei, Taiwan

Abstract: Trust is a key component that shapes inter-personal relationship and is known to vary with social contexts. Previous evidence has shown the power of ascribed identity (e.g., ethnicity, gender) upon trust behaviors of human beings. However, few studies have investigated the neural mechanisms underlying how acquired identity (e.g., political party) may influence one's trust-related decision making. To address this issue, we enrolled 58 healthy adults who share different political identities, defined by their presidential choices in 2012 Taiwan presidential election (i.e., KMT vs. DPP supporters), to participate in a repeated binary trust game experiment while undergoing fMRI scan. For each trial of the game, participants (investor) could choose to invest ("trust") their partner or not ("keep") in the first round and their partner would reply with either a "reciprocate" or "defect" feedback decision. Participants were informed that they would play the game with partners with the same, a different or no political identity. At the behavioral level, participants showed significantly higher probability of trust decisions when a partner shared the same political identity, suggesting that political identities indeed modulate their cooperative decisions. At the neural level, we found that identities defined by political preferences have different neurophysiological effects on decision outcomes. When playing with partners with the same political identity, functional contrasts between trials in which a partner defected participants' trust and trials in which a partner reciprocated participants' trust showed significant hemodynamic signal changes in brain regions including anterior insula (emotional processing), the temporoparietal junction (mentalizing), and the dorsolateral prefrontal cortex (self-regulatory control and/or working memory). In contrast, when playing with partners with a different political identity, participants exhibited greater activation in the striatum (reward learning) in response to trials in which a partner reciprocated as compared with trials in which a partner defected. More interestingly, increased activation in the anterior insula significantly correlated to closer perceived social distances between participants and their partners. In summary, these findings provide the first evidence on the neural foundations for the modulation effects of political identities upon trust behaviors, and indicate that studies of decision making should account for the role of social identity in altering behavior and brain response.

(CELAM), Univ. of Gothenburg, Gothenburg, Sweden; [3]3Department of Behavioral Sci. and Philosophy, Univ. of Turku, Turku, Finland; [4]Dept. of Med. Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden

Abstract: Antisocial behavior is a major problem in all societies, and incurs significant public expenditures. The etiology of antisocial behavior is unclear, but it is well-established that genetic variation is a contributing factor. In light of indications that oxytocin may amplify prosocial behavior, dysregulation of oxytocin may consequently play a part in antisocial behavior. The aim of the current study was to investigate whether single nucleotide polymorphisms (SNPs) in the oxytocin receptor gene (OXTR) are associated with antisocial behavior. A discovery sample was drawn from the Child and Adolescent Twin Study of Sweden (CATSS; n=2372), and the Twin Study of Child and Adolescent Development (TCHAD; n=1232) was used for replication. The participants were assessed for aggressive and non-aggressive antisocial behavior, measured as continuous traits. Eight SNPs in OXTR were genotyped. Mixed model statistics were used for all statistical analyses. In the discovery sample, the rs7632287 AA genotype was strongly associated with higher frequency of overt aggression (directly targeting another individual) in boys, and this

was then replicated in the second sample. The C allele of rs4564970 was also associated with antisocial behavior in the discovery sample, but we were not able to replicate this in the second sample. We conclude that the rs7632287 SNP in OXTR may influence antisocial behavior in adolescent boys. Further replication of our results, as well as investigations into the underlying mechanisms, could be crucial to understanding how aberrant social behavior arises.

Title: The effects of prefrontal lesions and oxytocin receptor gene (OXTR) polymorphism on religious fundamentalism in traumatic brain injury (TBI) patients

Authors: *W. ZHONG[1,2], I. CRISTOFORI[1,2], J. BULBULIA[4], F. KRUEGER[5,6], J. GRAFMAN[1,2,3];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Dept. of Physical Med. and Rehabilitation, Feinberg Sch. of Med., [3]Dept. of Neurology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [4]Sch. of Art History, Classics and Religious Studies, Victoria Univ. of New Zealand, Wellington, New Zealand; [5]Dept. of Mol. Neurosci., [6]Dept. of Psychology, George Mason Univ., Fairfax, VA

Abstract: The prefrontal cortex plays a critical role in regulating social beliefs, including religious beliefs. One important facet of religious beliefs is fundamentalism, which refers to the degree of belief adherence, and is related to intergroup bias. Given the important role of oxytocin in modulating social cognition including group processes, and past research identifying associations between polymorphisms of the oxytocin receptor gene (OXTR) with socio-emotional processes such as empathy and attachment style, it is likely that religious beliefs are similarly influenced by variations in OXTR. Genetic predispositions are critically involved in recovery and outcomes after brain injury, yet the impact of genetic factors and brain injury on religious beliefs has not been examined previously. In the current study, we investigated the effect of the OXTR genotype and brain lesions on religious fundamentalism in a large sample of patients with penetrating traumatic brain injury (pTBI). We genotyped the pTBI patients and

matched healthy controls for the OXTR rs53576 single nucleotide polymorphism (SNP), and measured their level of fundamentalism by administering the Religious Fundamentalism Scale. We found that lesion location and OXTR genotype interact to regulate degree of fundamentalism in patients with pTBI. In patients with lesions to the prefrontal cortex (PFC), the OXTR polymorphism did not affect level of fundamentalism; however, in patients with intact PFC, results revealed an effect of the OXTR polymorphism, with GG-allele carriers reporting higher fundamentalism than carriers of the AA or AG alleles. These findings show not only that lesion location and genetics interact to produce an effect on fundamentalism, but also that the integrity of PFC is necessary for the OXTR polymorphism to exert its influence. This result sheds light on the important role of OXTR genetic variation in mediating group affiliation processes and religious beliefs, which is also dependent on representations of social knowledge in the PFC.

Title: Aberrant paralimbic network activity during the processing of moral violations in criminal psychopathy

Authors: *M. SIMMONITE[1], D. S. KOSSON[1], C. L. HARENSKI[2], V. D. CALHOUN[2], K. A. KIEHL[2];
[1]Dept. of Psychology, Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]The Mind Res. Network, Albuquerque, NM

Abstract: A core feature of psychopathy is the commission of immoral acts against others. Prior imaging studies of the processing of moral stimuli have revealed psychopathy is associated with reduced limbic and paralimbic activity. However, no studies have investigated functional connectivity during the processing of immoral stimuli, and how activity within these networks relates to psychopathy. Incarcerated male inmates (n = 94) were rated for psychopathy using the Hare Psychopathy Checklist-Revised (PCL-R). Functional MRI data were collected across four sessions whilst participants were shown statements describing immoral, negative and neutral

acts. During the first two sessions participants were asked to indicate whether the statement describing a living thing (i.e., implicit condition). During the third and fourth sessions, participants were asked to judge whether or not the statement described an act that was 'wrong' or not (explicit condition). Group Independent Component Analysis (ICA) was used to decompose the data into 25 components. Component time courses were then regressed on to time courses describing the immoral, negative and neutral stimuli presented, with beta weights indicating the degree to which the component was modulated by the task. Consistent with hypotheses, components demonstrating significant correlations with psychopathy included a paralimbic network, for which beta weights for all three trial types correlated negatively with PCL-R scores during the implicit condition, but not the explicit condition. This suggests psychopathic traits are associated with abnormalities specific to certain aspects of moral processing. These results provide evidence for an association between aberrant functional connectivity and psychopathy, and potentially elucidate the neural underpinnings of subtle abnormalities of moral insensitivity in psychopathy.

Title: Electrophysiological markers of distinct facets of empathy and their relation to trait empathy and psychopathy

Authors: *K. L. LEWIS, J. M. COWELL, J. DECETY;
Psychology, Univ. of Chicago, Chicago, IL

Abstract: Empathy can promote a variety of positive social behaviors, motivate us to help others, and lead to greater competency in social interactions. This construct can be divided into distinct components, and the present study sought to dissociate two of these components,

affective sharing and empathic concern, using high-density electroencephalography (EEG). A second aim was to relate the neural dynamic markers of affective sharing and empathic concern to individual differences in trait empathy and psychopathy. The experiment used a novel paradigm wherein participants viewed a validated set of painful and neutral stimuli, and had to focus on and rate either their feelings of concern for the individual or how much physical distress the individual was in (affective sharing). Both the early ERP component (175-275 ms) and the late positive potential (LPP; 400-1000 ms) showed differentiations of painful versus neutral stimuli, with painful stimuli eliciting larger ERP responses, and an effect of condition, with amplitudes greater for affective sharing than for empathic concern. Differences in painful versus neutral stimuli in the LPP, a more controlled response indexing elaborative processing of valenced stimuli, were related to individual differences in empathy and psychopathy, but no such differences were found in the early window. Interestingly, while there were no significant relations between the LPP to painful over neutral stimuli during affective sharing, the LPP during empathic concern was positively predicted by trait empathy and inversely associated with dispositional psychopathy. Additionally, gamma coherence, an index of multisensory integration that has been associated with understanding the subjective states of others, did not show task-based differences, but was related to dispositional empathic concern and negatively associated with trait psychopathy. As a whole, these results suggest that affective sharing and empathic concern can be distinguished at the neural level with high-density EEG/ERP, and that their electrophysiological signatures are differentially modulated by individual dispositional measures, lending support to the notion that they are separable constructs.

Title: How do narcissistic people view others' minds?: FMRI studies on empathy and perspective-taking

Authors: *N. KIM[1], M. KIM[2], H. JUNG[1], S. KANG[2], J. KWAN[3], M. CHUNG[2], H. KIM[1]; [1]Psychology, Korea Univ., Seoul, Korea, Republic of; [2]Gachon Univ., Sungnam, Korea, Republic of; [3]Sung Shin Women's Univ., Seoul, Korea, Republic of

Abstract: Narcissism, defined as an unusually high affection towards oneself, can be primarily characterized by two key features: a lack of empathy for other people and self-centered perspective. Although these features are the signifiers in the diagnosis of narcissistic personality disorder for clinicians and are highlighted in lay public's impression of narcissistic people, few studies empirically investigated biological evidence supporting these core features of narcissism. As a result, the present understanding of its neural correlates remains poorly understood. In this study, we aimed to discover the neural processes of empathy and perspective-taking differentially modulated by the degree of narcissism. We hypothesized that high narcissistic individuals would show reduced empathic responses and/or perspective-taking, accompanied by neural processes distinguished from those of low narcissistic individuals. 38 non-clinical female participants with different degrees of narcissism score (Narcissism Personality Inventory-40) participated in these fMRI experiments. Subjects performed context-dependent facial emotion reading task (i.e., empathy task) and preference estimation task (i.e., perspective-taking task) while being scanned in MRI. In the empathy task, high narcissistic participants showed reduced emotional interpretations on contextually modulated ambiguous facial expressions. In addition, high narcissistic individuals also showed reduced bilateral insula activities, a brain region known to be involved in empathy processing, in response to negatively-cued facial expressions during empathy task. In the perspective-taking task, high narcissistic individuals had less correct guesses on estimating others' preferences with decreased activity in the dorsomedial prefrontal cortex (dmPFC), which had a positive relationship with accuracy during the estimation of others' preferences (Kang, Lee, et al., 2013). Furthermore, they also showed increased activity in the ventromedial prefrontal cortex (vmPFC), implicating an intuitive self-oriented valuation, while estimating the preferences of others vs. self. In sum, the present findings provide neural markers indicating impaired empathy and perspective-taking prevalently associated with narcissism.

Abstract: Suicide represents 1.8% of deaths in young people worldwide. Although many of them occur in people suffering from mood disorder, only a small number of these patients attempt suicide and even fewer commit suicide, suggesting that other factors, such as the neurobiological ones, play an important role in the suicide. Postmortem Neurobiological techniques of high-resolution images have shown brain morphological changes, especially in areas of the limbic system that are closely interconnected such as the medial prefrontal cortex (CMP). Changes regarding social behavior, decision-making and the emotional process are presented in patients with lesions in this region. When damage is produced to the central nervous system (CNS), the innate immune response activates glial cells (astrocytes and microglia) by synthesizing cytokines, prostaglandins and reactive oxygen species, this is a regulated process, nevertheless, if an excessive inflammatory response occurs it can damage cellular integrity, because CNS is vulnerable to uncontrolled immune and inflammatory processes. Currently there are no studies which reveal the density of neurons in prefrontal cortex of the brain in people who committed suicide; this paper shows the result of the analysis of CMP of several 14 to 24 years old suicide victims from Mexico City. They were evaluated using astrocitosis immunohistochemical markers such as GFAP and protein nitration as well as stereology to measure neuronal density. The results show that cell density is reduced and there is an increased in GFAP immunoreactivity as well as protein nitration in Orbito Frontal, Dorso Lateral and Ventro Medial Cortex . This implies that oxidative processes presented in the brains of suicide victims contributes to neurodegeneration, which consequently causes a reduction in the PFC cell number and also causes a reactive astrogliosis, which has been linked to the development of a chronic inflammatory response that contributes to neuronal death. On the other hand, it has been reported that the inflammatory process induces the expression of inducible nitric oxide synthase,

an isoform responsible for promoting the synthesis of nitric oxide, which in high concentrations promotes radical peroxynitrite formation. It is a highly oxidizing agent, capable of causing the nitration of amino acid residues of proteins. Consequently it generates a change in the structure and function of these proteins, which triggers the neuronal death mechanism.

Title: Over-arousal as a mechanism between alcohol use and intimate partner violence

Authors: *B. C. FINK[1], E. CLAUS[3], J. F. CAVANAGH[2], D. A. HAMILTON[2], D. BARTO[2]; [1]Dept. of Psychiatry and Behavioral Sci., [2]Psychology, Univ. of New Mexico, Albuquerque, NM; [3]Mind Res. Network, Albuquerque, NM

Abstract: Intimate partner violence (IPV) is a significant public health problem for which there are currently no effective treatments. Alcohol use is present in most instances of IPV and is associated with an increase in the frequency and severity of IPV. We believe that alcohol may be related to the increase in frequency and severity of IPV through a process of over-arousal that results from the cortically and psychophysiological arousing effects of alcohol during the ascending limb of intoxication and at peak BAC compounded by the unique behavioral and affective patterns of violent couples. The first aim of the study is to determine if increases in arousal after alcohol exposure is potentiated by evocative partner stimuli and is greater for distressed violent (DV) partners than distressed nonviolent (DNV) partners. A second aim is to determine if alcohol induced arousal interfered with DV partners' ability to regulate emotion in response to evocative partner stimuli compared to DNV partners. The study is an experimental comparison of the effects of alcohol on arousal and emotion regulation between DV and DNV partners. To test the overall hypothesis that over-arousal is a mechanism through which alcohol

is associated with increases in the frequency and severity of IPV, the selected partners participate in a counter-balanced placebo session and an alcohol administration session during which electroencephalography (EEG), psychophysiology and pupillary response measurements of arousal are collected during an emotion regulation task. The data is analyzed using a repeated measures ANOVA with a between-subjects factor. DV partners experience significantly greater neurophysiological arousal than DNV partners during the evocative stimuli condition. DV partners also experience greater difficulty regulating emotion during evocative stimuli than DNV partners and that this effect was compounded during the alcohol administration condition. Findings from this study provide firm evidence that alcohol is associated with IPV through a mechanism of over-arousal and provide key targets for intervention to prevent future IPV.

Title: Psychophysiological correlates of impulsive aggression in real-time

Authors: *J. FANNING[1,2], R. LEE[2], M. BERMAN[3], E. COCCARO[2];
[2]Dept. of Psychiatry and Behavioral Neurosci., [1]Univ. of Chicago, Chicago, IL; [3]Dept. of Psychology, Mississippi State Univ., Starkeville, MS

Abstract: Chronic impulsive aggression has been linked to abnormal structure and function of brain regions supporting affective processing, cognitive control, and social cognition. However, very little research in humans has focused on the neural processes that underlie an aggressive interaction. Thirteen men and women completed a standard paradigm that simulates an aggressive interaction in a controlled laboratory setting. Participants interacted with a fictitious opponent with whom they exchanged shocks at varying intensity levels under the guise of competing in a reaction-time task. High-density electroencephalogram (hdEEG) was recorded during the social interaction. Event-related potentials (ERPs) and source localization were used to assess activity related to (1) the participant's evaluation of the opponent's provocative behavior, and (2) the participant's decision to retaliate against the opponent. ERPs showed that participants engaged in greater evaluation of provocative behavior by the opponent compared to less provocative behavior, based on peak P3 amplitude. However, the P3 amplitude was

unrelated to the participant's decision to escalate, de-escalate, or match in response to the opponent. Peak P3 latency was longer on trials in which participants escalated aggressively against the opponent compared to when they equaled the opponent's level of provocation or de-escalated, suggesting that the timing of stimulus evaluation may affect the expression of aggressive responding. Reaction times did not differ as a function of the participant's choice to retaliate. Source analyses (CLARA) conducted at P3 peak latencies reveal sources in the orbitofrontal cortex (OFC) and amygdala, among other regions. EEG provides a window into neural events as they occur in real-time. The current results suggest that intense provocation, a common precipitant to aggressive behavior, elicits greater recruitment of neural resources for stimulus evaluation. Extent of stimulus evaluation as indexed by P3 amplitude was unrelated to the decision to retaliate; however, the timing of stimulus evaluation was related to the participant's behavior in response to the opponent's provocation. Future work will be informative in identifying the neural processes that relate to abnormal aggressive responding to threat.

Title: Attention deficit hyperactivity disorder: increased coupling in the salience network

Authors: *E. T. ROLLS[1], X. JI[2], T. GE[2], W. CHENG[2], J. ZHANG[2], L. SUN[3], Y. WANG[3], J. FENG[4];

Abstract: Attention-deficit hyperactivity disorder (ADHD) is a common and impairing neuropsychiatric disorder with preschool onset that may continue into adulthood. We analyzed differences in the resting state functional connectivity of brain areas in 249 ADHD patients and 253 typically developing control children with the aim of advancing the understanding of the neural bases of the disorder, and using data from the ADHD-200 Consortium. A method termed a brain-wide association study (BWAS), was used which allowed an unbiased search of the functional connectivities between all pairs of 90 regions parcellated according to the automated anatomical labeling (AAL) atlas, and associated the differences in functional connectivities with the disorder. Significantly altered functional connectivity (p~10-5) found in the ADHD children was the increased coupling in the salience network, comprising the anterior cingulate cortex and the anterior insular cortex. Correlations of this altered functional connectivity were found with the ADHD score index (Conners' Parent Rating Scale-Revised, Long version), and with the inattentive and hyperimpulsive ADHD subscores. The voxel-level locations of the voxels with the most increased functional connectivity were [-12, 44, 10] (MNI X,Y,Z), which is pregenual cingulate cortex, and [-24, 28, 6] which is anterior insular cortex, though the insular voxels spanned Y=32 to Y=0). The insular part of the network is in a region involved in visceral-autonomic function (Rolls 2014), which functions differently in people with ADHD. This is the first evidence from a large and brain-wide study for the significant involvement of the salience network in ADHD. Rolls,E.T. (2014) Emotion and Decision-Making Explained. Title: Alpha power modulations predict student distractibility in a classroom setting

Authors: *L. WAN[1], S. DIKKER[2,3], I. DAVIDESCO[2], L. KAGGEN[2], J. ROWLAND[2], J. MCCLINTOCK[4], D. POEPPEL[2,5], M. DING[1];

Abstract: Alpha oscillations (8 to 12 Hz) are a prominent EEG phenomenon in humans. Goal-oriented modulation of alpha has been extensively studied. We report a case of alpha modulation by social context and show that it can be used as a biomarker to predict student distractibility in the classroom. Wireless EEG was recorded from students in a New York City high school biology class, both before and during 50-minute class periods. Before every class period, students (1) sat face-to-face and made eye contact with one another and (2) turned toward the wall and looked at a fixation point on the wall; these two resting-state conditions were used for evaluating the modulation of alpha power in each student. Pre- and post-class questionnaires were also collected to assess the physical and emotional conditions of the students and their class performance. After preprocessing, spectral analyses were applied to the EEG data, and alpha power was computed for the two resting-state conditions. We found that (1) alpha power decreased from the face-to-wall to the face-to-face condition, and this decrease was most pronounced in occipital and frontal regions, (2) there was a positive correlation between the students' distractibility and their alpha decrease, and (3) alpha decrease was negatively correlated with pre-class expectation and post-class satisfaction. There is also evidence that alpha power decrease was positively correlated with students' social group affinity. We interpret these results in the framework of distraction conflict model and in terms of the alpha's role in attention deficit disorder.

Title: Task-related functional connectivity study of attentional control in monkeys

Authors: ***P. F. BALAN**, A. GERITS, W. VANDUFFEL;
KU Leuven, Leuven, Belgium

Abstract: We aimed to determine differences in top-down and bottom-up control of attention using monkey fMRI and psychophysiological interaction (*PPI*) *analyses*. Three macaque monkeys were trained to covertly detect a random (0.6 probability) dimming occurring with equal probability at one out of four locations at 6 deg. eccentricity in each quadrant (all objects 0.5 x 0.5 deg.). The target-dimming was cued either in a bottom-up or top-down manner, using a change in color of the target itself or the fixation point (symbolic cue for each quadrant), respectively. Target but not distractor dimmings (appearing at the 3 other quadrants) had to be indicated with a manual response. The monkeys were scanned using an event-related paradigm on a 3 T Siemens Trio scanner and an 8-channel receive coil (contrast-agent-enhanced (Vanduffel et al., 2001), 1.25 mm isotropic voxels). We measured cue related fMRI activations using standard GLM and task-specific network interactions using PPI. In addition, based on the beta-strength of the PPI interactions, we assessed network metrics (node/edge betweenness centrality; node strength) (Rubinov and Sporns, 2010) to characterize the topology of functional connectivity networks. The behavioral performance of all monkeys was better for bottom-up compared to the randomly-interleaved top-down cued trials (higher percent correct; shorter reaction times). While the GLM-defined activation patterns revealed only very marginal functional differences between key nodes within the parieto-frontal attentional network, task-based functional connectivity analyses showed a stronger contribution of LIP during bottom-up and FEF during top-down trials. In conclusion, subtle functional differences across nodes participating in attentional control might be easier to detect using task-based functional connectivity analyses compared to traditional GLM analyses. Put otherwise, it is not necessarily the degree of fMRI activation in the individual nodes but rather the interaction across nodes within a functional network which determines their functionality in attentional control.

Title: Distinct neurobiological mechanisms of top-down attention

Authors: *T. Z. LUO[1], J. H. R. MAUNSELL[2];
[2]Neurobio., [1]The Univ. of Chicago, Chicago, IL

Abstract: Neuronal signals related to visual attention are found in widespread brain regions, and these signals are generally assumed to participate in a common mechanism of attention. However, the behavioral effects of attention in detection can be separated into two distinct components: spatially selective shifts in either the criterion or sensitivity of the subject. Here we show that a paradigm used by many single-neuron studies of attention conflates behavioral changes in the subject's criterion and sensitivity. Then, we designed a task to dissociate these two components and achieved consistent isolation of spatially specific behavioral changes. We then recorded from populations of single neurons in area V4 of visual cortex in monkeys performing the dissociation task. Multiple aspects of attention-related neuronal modulations in V4--increase in firing rate, reduction in noise correlation, and decrease in Fano factor--corresponded to behavioral shifts in sensitivity but not criterion. This result suggests that separate components of attention are associated with signals in different brain regions, and that attention is not a unitary process in the brain but instead consists of distinct neurobiological mechanisms.

Title: Asymmetrical light experience affects endogenously determined lateralization pattern in the pigeon

Authors: *S. LETZNER, M. MANNS, E. UNVER, O. GUNTURKUN;
Ruhr-University Bochum Inst. For Cognitive Neurosci., Bochum, Germany

Abstract: Cerebral asymmetries are a fundamental organization principle of the vertebrate brain. A model system to analyze the development and the influence of envirotypic factors onto cerebral asymmetries is the visual system of birds like pigeons and chickens. Asymmetrical light exposure of the bird embryo is responsible for the lateralization of visually guided behavior. Due

to the asymmetrical position of the embryo in the egg, the right eye/ left hemisphere is stimulated with light meanwhile the left eye/ right hemisphere is naturally light deprived. This induces functional asymmetries of the left hemisphere for discrimination processes. In contrast, the influence of light for right-hemispheric dominances like spatial attention processes is still unknown but necessary for a better understanding of the interrelations between the development of left- and right-hemispheric lateralization. In chickens, right-hemispheric lateralization for spatial attention processes vanishes after incubation of the eggs in complete darkness, indicating that the emergence of right-hemispheric specialization depends on asymmetric light stimulation as well. Since chickens and pigeons display similar light-dependent development, it is conceivable that right-hemispheric dominance for visuospatial attention also develops in response to asymmetrical visual stimulation in pigeons. Accordingly, also the critical interaction of left-and right hemispheric asymmetries can be similar to that in chicks. On the other hand, structural asymmetries differ between two different bird species, suggesting different developmental mechanisms of left- right-asymmetries and its reciprocal interactions. Therefore, we compared the lateralization pattern of pigeons with different embryonic light experiences (light and dark incubated). The birds were required to explore an area in front of them and to sample grains of food. The results showed that light incubated pigeons attended symmetrically to target stimuli located in the left and right hemispace, whereas dark incubated pigeons showed a tendency for the right hemispace. These results imply the presence of an endogenous left-hemispheric lateralization of visual attention processes that is modified by asymmetric ontogenetic light experience. Furthermore, this result hints to species-specific differences in the lateralization pattern of specific functions.

Title: Neural correlates of posterior parietal cortex in a cross-modal selective attention task

Authors: *Y. ZUO[1], Z. WANG[2];
[2]Chinese Acad. of Sci., [1]Inst. of Neurosci., Shanghai, China

Abstract: In daily life, humans have to consistently process and integrate information of stimuli in different sensory modalities simultaneously. Voluntary 'top-down' attention is a key mechanism to select relevant subsets of sensory information for detailed and effective processing, and to actively suppress distracting irrelevant sensory information. The posterior parietal cortex (PPC) has been implicated to play a role in shifting attention from one perceptual dimension of a stimulus to another. This study examined how PPC is involved in attention shifting from one modality to another. We trained rats to perform a bimodal attention shift task. In this task, subjects have to selectively attend to a stimulus in one modality and respond to it, whereas the stimulus in the other modality has to be ignored. The subjects must alternate which modality they select multiple times within each session. Neurons in PPC were recorded during this task. We found that PPC neurons showed similar response pattern to the attended stimulus either when it was presented alone or in combination with a distractor, whereas response to ignored distractor was inhibited. These results suggest that PPC plays an important role in modality gating.

Title: The activation of the lateral septum increased the release of brain histamine

Authors: *P. FARIAS[1], J. DIAZ[2], A. OCAMPO[2], J. VALDES[2], F. TORREALBA[3];
[1]Univ. Catolica De Chile, Santiago, Chile; [2]Univ. de Chile, Santiago, Chile; [3]Univ. Catolica de Chile, Santiago, Chile

Abstract: The lateral septum (LS) processes the affective significance of sensorial information from the hippocampus and directs its outputs towards hypothalamic areas important for motivated, goal-directed behavior. The LS is one of the main afferents to the tuberomammillary nucleus of the hypothalamus (TMN), the only source of brain histamine. Both structures are

known to be implicated in mood and motivation. Furthermore, brain histamine is important in arousal and alertness. Novelty has motivational effects and can direct and reinforce behavior. We propose that the LS change the activity of histaminergic neurons, thus modifying histamine release through GABAergic inputs. The reduction of GABAergic input to the TMN should therefore increase vigilance. Here, we demonstrated, using immunocytochemistry and electron microscopy that LS inputs to the TMN region are indeed GABAergic, and that these terminals make symmetric synaptic contacts with other GABAergic terminals that do not come from of LS. We measured extracellular histamine and GABA levels in the LS using microdialysis and simultaneously obtained EEG recording. Reverse microdialysis into the LS with 0.1mM picrotoxin and 10mM glutamate increased histamine and GABA release in LS as well as increased wakefulness measured with EEG and frequency theta wave.

Title: Where and how are relevant sensory signals for perceptual decisions selected in the brain and mapped onto appropriate actions?

Authors: *J. DITTERICH;
Ctr. for Neurosci. & Dept. of Neurobiology, Physiol. & Behavior, Univ. of California, Davis, CA

Abstract: In everyday life, decisions based on sensory stimuli are usually made in the presence of an abundance of irrelevant sensory information. Successful decision-making therefore requires effective selection of decision-relevant information. To address the question where and how the brain separates decision-relevant from irrelevant sensory information and then maps the relevant information onto appropriate actions, we trained monkeys to make perceptual judgments about the direction of motion in random-dot motion stimuli that contained both a decision-relevant and an irrelevant motion component. The two components were orthogonal to each other, one horizontal (left or right), one vertical (up or down). A cue at the beginning of each trial indicated the relevant axis of motion for the current decision. Two choice targets appeared

randomly along one of the two possible diagonals, and the animals were trained to make an eye movement to the target that was most closely aligned with the relevant direction of motion. While challenging, we successfully trained monkeys to perform this task. Based on behavioral data collected so far, the relevant sensory information can have up to five times more impact on the monkey's choice than the irrelevant information. We recorded spiking activity and local field potentials from cortical areas MT and LIP, when possible, simultaneously. MT has previously been shown to carry information about the sensory evidence in motion discrimination tasks, whereas LIP carries decision-related activity. Microstimulation in either area can systematically bias the animal's choices. Based on the data we have been able to collect so far, neurons in MT respond almost identically to the decision-relevant and irrelevant motion components, indicating that neural activity is not substantially modulated by decision relevance. In contrast, ramping responses in LIP during evidence accumulation clearly reflect modulation of the motion signals according to decision relevance. The major selection of decision-relevant sensory evidence therefore apparently happens after or while the motion representation in MT is read out, but before or during the evidence accumulation process that is reflected in LIP's spiking activity. I will address the question whether simultaneously recorded neural activity provides insight into the selection process, including the possibility of reflecting decision relevance-related changes in functional connectivity.

Title: Spatiotemporal characterization of perisaccadic receptive field structure and attentional modulation in area V4

Authors: *A. C. MARINO[1,2], J. A. MAZER[3,1,4];
[1]Interdepartmental Neurosci. Program, [2]Med. Scientist Training Program, [3]Dept. of Neurobio., [4]Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Every eye movement changes the subset of neurons in visual cortex representing specific features in the visual scene. Despite frequent saccades and resulting disruptions of activity patterns in retinotopically organized cortical areas, visual perception is remarkably stable. Studies have suggested that perceptual stability is facilitated by pre-saccadic remapping of receptive fields (RFs) in several (mostly parietal) visual areas. Classical remapping translates the RF parallel to the saccade vector, towards the "future field". Other studies, particularly in V4 and FEF, showed remapping can shift RFs towards the saccade endpoint, a possible substrate for perisaccadic compression and explanation for enhanced visual processing at saccade endpoints. Behavioral and fMRI experiments in humans have shown spatial attention can be sustained at both spatiotopic (i.e., specific scene features independent of gaze angle) and retinotopic locations across saccades and suggest the neural representation of attention, like visual perception, may be remapped in preparation for or response to saccades. To investigate RF and attentional remapping in single neurons we trained macaques to perform a novel behavioral task requiring them to sustain attention at a cued, spatiotopic location and respond to targets at this attended location while ignoring distractors at nearby, unattended locations and making guided saccades. Throughout each trial, low contrast, behaviorally irrelevant dynamic probe stimuli were used to construct a detailed characterization of the spatiotemporal receptive field (SRF) as a function of attentional state and time relative to saccade onset. Data were recorded from 103 sites (60 single- and 43 multi-unit) in V4 of two animals. Behavioral analysis shows that monkeys are able to reliably sustain a spatiotopic locus of attention while making saccades. During the fixation period, before animals were instructed to execute the saccade, 47% of sites exhibited significant attentional modulation of responses to probe stimuli, defined as increased (70%) or decreased (30%) evoked responses to probes when attention was directed into the RF. In the majority of sites, responses to probes appearing in the 100ms prior to saccade onset reveal little or no evidence of classical remapping. In many cells, examination of saccade-locked responses yield a diverse pattern of saccadic suppression, the extent and time course of which are dependent on the saccade vector, suggesting that activity in V4 reflects a complex interaction between oculomotor planning, execution, and bottom-up visual inputs.

Title: Is spatial attentional gain modulation in area MT of primate visual cortex mediated by the cholinergic system?

Authors: *V. K. VEITH[1], C. QUIGLEY[1], S. TREUE[1,2];
[1]German Primate Ctr., Goettingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: Attentional modulation of sensory responses in extrastriate visual cortex of primates is characterized by gain changes, which are multiplicative changes of firing rates for a given combination of stimuli in the receptive field and the attentional state of the animal. There is evidence that the cholinergic system may be responsible for such changes in local neuronal responsivity. Herrero et al. (2008) showed that acetylcholine mediates attentional modulation in striate cortex through muscarinic receptors. Here we examined whether cholinergic influences can account for attentional modulation in extrastriate visual area MT, where neurons exhibit strong tuning for the direction of motion in their receptive field and firing rates are reliably enhanced by allocation of spatial and feature-based attention. We recorded from single cells in two awake, behaving rhesus monkeys while they performed a spatial attention task. Stimuli were two random dot patterns that were presented on a computer screen, one inside the recorded cell's receptive field and the other in the opposite visual field. In each trial, the monkey was cued to attend to one of the stimuli and to report a direction change in the cued stimulus only. We compared firing rates when the moving stimulus in the receptive field was attended vs. unattended to quantify gain changes by spatial attention. During recordings, we used pressure injection to pharmacologically manipulate the direct vicinity of the recorded neuron in a block-wise fashion. We used the antagonist scopolamine to block the muscarinic or nicotinic cholinergic receptor subtype respectively, or the agonist acetylcholine to increase its extracellular concentration. The pattern of attentional modulation during injection was compared to baseline blocks recorded before injection. Control injections with saline solution did not affect firing rate, ruling out an effect of the injection process per se on firing rates. As expected, directing spatial attention into the receptive field of a recorded neuron significantly increased responses (by about 18%) in both monkeys. The muscarinic antagonist scopolamine led to an increase or decrease in firing rate and reduced this attentional modulation (to about 12%) in both monkeys. So far this trend has not reached significance. First results from injecting the direct agonist acetylcholine show increased firing rates and indicate an increase in attentional modulation (from about 18% to 21%). Therefore our data suggest but do not yet prove an involvement of muscarinic receptors in mediating response modulations in area MT by spatial attention.

Title: Modulating the noradrenergic system at rest

Authors: C. GUEDJ[1,2], E. MONFARDINI[1,3,2], A. REYNAUD[1,2], A. FARNÈ[1,2], M. MEUNIER[1,2], *F. HADJ-BOUZIANE[1,2];
[1]INSERM U1028, CNRS UMR5292, Bron, France; [2]Univ. UCBL, Lyon 1, France; [3]Inst. de Médecine Environnementale, Paris, France

Abstract: The locus cœruleus (LC) is the principal source of noradrenaline (NA) in the brain and this neuromodulator is known to influence attentional processes. Yet, to date, the exact mechanisms by which NA acts upon the neural network sub-serving attention remain poorly understood. Current models postulate that LC activity acts as an ‘‘interrupt’’ signal (Dayan and Yu, 2006) or as a ‘‘network reset’’ signal (Bouret and Sara, 2005) that allows flexible and optimal reconfiguration of brain activity. Here, we used resting-state fMRI to investigate the functional connectivity pattern of the LC following a systemic delivery of an NA-reuptake inhibitor that enhances the level of NA in the brain. We scanned three monkeys in a 1.5 T scanner using a contrast agent (MION) while they were sitting motionless in the dark (400TRs, TR=2s, voxel size=2x2x3mm). We compared the changes induced by intramuscular injections of either saline or a NA-reuptake inhibitor (atomoxetine, 0.5 mg/kg) on the LC functional connectivity using a seed-based approach. First, in the saline condition, we found that the LC activity was strongly correlated with activity in the anterior cingulate cortex, the ventral and lateral thalamic nuclei, the somatosensory cortex (areas 1-2 and 3 a/b) and the cerebellum. This connectivity pattern fits well with the known anatomical projections of the LC neurons. Second, compared to the saline injection, the injection of atomoxetine selectively increased the strength of connectivity between the LC and the intraparietal sulcus (area LIP), the amygdala and regions within the superior temporal sulcus while it decreased the strength of connectivity between the LC and somatosensory cortex (areas 1-2). Our preliminary results suggest that the injection of atomoxetine affects the strength of connectivity between the LC and a very specific network of

brain regions, including LIP and the amygdala, two brain regions important in encoding the saliency of stimuli in our environment. It is thus possible that enhancing NA availability alters LC activity (Bari and Aston-Jones, 2013) that might in turn orchestrates brain state transitions through LIP and the amygdala, to optimally adjust attentional resources to salient incoming stimuli.

Title: An open-source and low-cost operant conditioning equipment for studying auditory discrimination in common marmosets

Authors: *M. W. RIBEIRO, J. F. R. NETO, F. L. BRASIL, M. F. P. ARAÚJO;
Edmond and Lily Safra Intl. Inst. of N, Macaiba, Brazil

Abstract: Common marmosets (Callithrix jacchus) are small New World primates that share several social, cognitive and behavioral characteristics with humans, such as cooperative breeding and a rich vocal repertoire. Therefore, understanding how the marmoset brain processes sounds, particularly vocal stimulus, can shed light into the mechanisms involved in language processing and evolution. One approach for studying vocal processing in marmosets can be

operant conditioning tasks requiring the discrimination of sound stimuli. Such tasks allow the control and manipulation of experimental variables in order to relate a specific behavior to a neural activity. The aim of this study was to develop an open-source hardware and software operant conditioning box for marmosets designed to output sound stimuli, and input motor responses. The setup consists of a plexiglass box (25x25x45cm) placed inside a double wall acoustic chamber. The back side of the box has two apertures through which retractable metal bars can be presented to the animal. Each bar is connected to a linear servo (Futaba S-148 with an EMS Linear servo Conversion Kit For Futaba S-148 and S-3151 Servos). The bars were also connected to a LN555 circuit (Texas Ins) that detects a touch and sends output signal to the controller. A recipient for reward delivery was positioned between the bars. The reward system was driven by a DC motor controlled by an H bridge LN298. The box controller was an Arduino Mega (Arduino, Italy) with a sound player shield (MP3 Player Shield, Spark Fun Inc) stacked above a custom made open source shield that controls the sound stimuli and receives the response from the bars to release the reward in correct trials. The sound shield played sound stimuli (7 kHz, 5 sec, 70 dB level) through a high fidelity speaker (D220Ti, JBL) powered by an amplifier (Versátil Mono 100W, Hayonik). The open source custom operant conditioning box showed high temporal precision to control input and output for auditory discrimination tasks with marmosets.

Title: Attention-accumulation process in gaze behavior during multi-cue decision making with manual response and free eye-movement

Authors: *R. AKAISHI, E. HOSHI;
Tokyo Metropolitan Inst. of Med. Sci., Frontal Lobe Project, Tokyo, Japan

Abstract: The eye-movement is known to reflect the internal process going on in the brain. The gaze behavior has been widely used as an instrument to obtain reward in research of decision

making. However, in natural environment of primates, the manual movement is the instrument to obtain the reward and the eye is the device to gather the information to predict the rewarding event as a result of action. To re-examine the significance of eye movement in more ecologically valid situation, we created a novel decision making task with free eye-movement and manual response to indicate the choice of action target based on multiple instructing cues. Here, we show that the eyes were increasingly more likely to be fixated on the chosen action target as the timing of response made by the hand approached though hand action was an instrument for obtaining reward in the task. The frequency of the fixation on the chosen target roughly converged on the common peak value of fixation frequency. This accumulating pattern of gaze to the chosen target coexisted with the competing pattern of fixation on the unchosen target and the divergences of the two accumulating processes were dependent on the information given by the cues and correlated with the timing of target touch. Furthermore, eyes tended to be attracted to the cues that instructed the action consistent with the actually chosen target. But these fixations on the cues were usually brief and preceded or overlapped with the earlier part of the accumulating pattern of the fixation on the action targets. These results of gaze behaviors suggest that the rapid attentional process select the information relevant for action selection and the selected information is fed into the more deliberate accumulation process that chooses the action leading to a reward. The results may also have implications for the interpretations of neural signals recorded during the decision making tasks by favoring the view of accumulating saliency signal.

Title: Response properties of neurons in the pigeon NCL during a perceptual decision making task

Authors: ***R. PUSCH**[1], J. PACKHEISER[1], O. GÜNTÜRKÜN[1], M. C. STÜTTGEN[2];
[1]Dept. of Biopsychology, Ruhr-University Bochum, Bochum, Germany; [2]Univ. Med. Ctr. of the Johannes Gutenberg Univ., Johannes Gutenberg Univ. Mainz, Mainz, Germany

Abstract: Executive functions consider external as well as internal conditions to govern cognitive processes and elicit adaptive behavior. The process of decision-making requires an integration of multimodal sensory information in order to successfully evoke appropriate

choices. In mammals, the prefrontal cortex (PFC) is the key structure involved in the execution of these cognitive processes. Recent studies conducted with avian species revealed that birds are on par with mammals regarding these cognitive processes. Despite differences in its anatomical structure the Nidopallium caudolaterale (NCL) has been hypothesized as the functional analogue to the PFC enabling birds to perform tasks that require higher-level cognition as decision making, even though it has developed through a process of convergent evolution independently from mammals. To gain insights into general neuronal principles which might be comparable across different vertebrate classes, we recorded single cell activity in the NCL during perceptual decision making. Pigeons (Columba livia) performed a single interval forced-choice categorization task. We manipulated the difficulty of the task by reducing the difference in luminance for some stimuli and further introduced different reward contingencies for a stimulus subset. While performing the tasks, single unit activity was recorded. The majority of the recorded units were responsive to different phases of the experimental task: During the sample phase a fraction of neurons exhibited differential responses in regard to the stimulus shown. For some units these responses were signaling an upcoming choice of the animals in a subsequent phase of the experimental task. A subpopulation discriminated in addition between stimulus identities. Similar results were obtained for a following delay phase. In this phase of the experimental paradigm no sensory cues were available for three seconds. Neuronal responses of some units maintained a distinctive response pattern indicating a forthcoming decision in the choice phase. We further investigated our data with regard to a possible coding of reward-expectancy in the NCL. We discuss our findings in terms of the hypothesis that cognitive processes such as working memory or judgment of reward probability might be processed in a comparable way within birds and mammals supporting the assumption of functional homogeneity between the avian NCL and the mammalian PFC.

Title: Functional connectivity properties of the rat brain during conscious wakefulness and isoflourane-induced unconsciousness

Authors: *M. E. GHANTOUS, P.-C. CHANG, A. BARIA, V. APKARIAN;
Physiol., Northwestern University-Apkarian Lab., Chicago, IL

Abstract: Identifying properties of conscious brain activity constitutes an important challenge in neuroscience. Previous studies in monkeys have shown that different states of consciousness elicit distinct spatiotemporal functional connectivity patterns. Similarly, studies in humans have demonstrated that thalamo-cortical connectivity is a key mediator of conscious wakefulness. Here we investigate functional connectivity in the brains of rats during both conscious and anesthesia-induced unconscious states to determine how conscious wakefulness is reflected in synchronized activities across the whole brain. Resting state brain activity was recorded in rats (N=10) using functional magnetic resonance imaging (fMRI) for both vigilance states. Functional images were preprocessed and co-registered to a standard anatomical template of the rat brain and two connectivity analyses were performed. To examine whole-brain connectivity, rat brains were parceled into 96 regions of interest (ROI) based on a standard rat atlas. The blood-oxygen level dependent (BOLD) time series of each ROI was extracted, and a Z-Fisher transformed Pearson correlation coefficient for all pairs of ROIs was computed to generate correlation matrices for individual brains under both conditions of vigilance. Connectivity between all brain ROIs were compared across conditions using network-based statistics. Thalamic connectivity was specifically examined using a seed-based approach. Brains of awake rats showed an overall greater average connectivity across regions, with both stronger negative and positive correlations. Additionally, the awake brain exhibited more long-distance connections between anterior and posterior regions whereas sparser and more local connections were present under anesthesia. Moreover, the anesthetized brain showed reduced thalamic functional connectivity to the rest of the brain, a finding that corroborates the notion that thalamo-cortical connectivity is a mediator of consciousness. Overall, these findings suggest that different states of vigilance uniquely contribute to resting state functional connectivity. The results also emphasize the need of awake-based fMRI scanning in animals for translational research involving conscious-brain activity in humans. Funded by NIDCR DE022746

Title: Space influences motor and visual cortical excitability: Effects of hand location on motor evoked potentials and eye position on phosphene thresholds

Authors: *H. B. COSLETT[1], M. DE WIT[2], O. FASEYITAN[3];
[1]Hosp. of Univ. PA., Philadelphia, PA; [2]Moss Rehab Res. Inst., Philadelphia, PA, PA; [3]Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: We performed two experiments to test hypotheses regarding effects of gaze and hand position on motor cortex excitability measured by TMS. First, we reasoned that if the left hemisphere is dominant for motor attention, one would expect that motor evoked potentials (MEPs) would be larger when the right or left hand is placed in the right side of space. Second, although the locations of gaze and action may be dissociated, they are usually linked; on the assumption that visual attention typically follows gaze, we predicted that gazing at the hand would increase MEPs as compared to when hand location and gaze were dissociated. Experiment 1 tested these predictions by measuring MEPs for the right hand of 20 right-handers in 4 conditions, generated by crossing the variables of side of hand (R/L) and direction of gaze (R/L) relative to the body midline. There was a main effect of side of gaze with MEPs larger on the right than left (107% vs 93%, $p < .01$). There was also an effect of congruence such that MEPs were larger when subjects did NOT gaze at their hand (105% vs 95%, $p < .01$). In Experiment 2 the effect of gaze was replicated with the LEFT hand of right-handers in that MEPs were larger for the left hand when gazing to the right side of space ($p<.03$). These data support the hypothesis that the left hemisphere is dominant for motor attention and that this is independent of effector. The data are INCONSISTENT with the hypothesis that effects of gaze-hand congruence and motor attention would be additive. One interpretation of the latter finding is that increased MEPs when gaze and hand position are dissociated reflects an increased need for surveillance of the environment outside of the field of gaze. If this is true, one would expect to observe analogous effects in other domains such as vision. In Experiment 3 we tested this prediction by measuring phosphene detection as a function of TMS intensity in the left visual field in subjects with their eyes closed but gazing ahead or to the right or left. Subjects were significantly MORE likely to detect phosphenes in the left visual field when directing their eyes to the right or center as compared to the left. That is, as in Experiments 1 and 2, cortical excitability as assessed by TMS was greater in brain regions corresponding to locations to which subjects did not direct their gaze. These data support two conclusions: first, the left hemisphere is dominant for action independent of effector; second, potentially distinct attentional systems may influence processing at attended locations as compared to non-attended locations; the latter may be manifested in part as changes in sensory-motor cortical excitability.

Title: Neural correlates of subjective value in the nematode worm Caenorhabditis elegans

Authors: *A. W. KATZEN[1], W. T. HARBAUGH[2], S. R. LOCKERY[3];
[2]Econ., [3]Biol., [1]Univ. of Oregon, Eugene, OR

Abstract: The interaction of cost and perceived quality is central to value-based decision making. Such decisions are made by correctly assessing the costs and benefits of two or more courses of action and executing the one offering the highest value--meaning the greatest benefit--relative to the costs incurred. Given the constraint of a finite budget--whether that be time, effort, or money--calculating this tradeoff between cost and benefit is critical to any decision between competing options. Here, we show that the nematode worm Caenorhabditis elegans engages in such a cost-benefit analysis when choosing between food options in a decision making task. Worms shift their consumption between foods in response to changes in relative cost, and the subjective value of each food is dependent on the worm's prior experience with that food. Furthermore, we show that response properties of primary sensory neurons reflect the subjective value of available options. Future research could identify the locus of decision making and, given the experimental advantages of *C. elegans*, these studies could be among the first to move beyond observing neural correlates of decisions to the point of identifying their physiological and genetic causes.

Purpura Dept. of Neurosci. and Dept. of Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., New York, NY; [5]Dept. of Psychology, City Col. of New York, CUNY, New York, NY

Abstract: A considerable body of research indicates that the nucleus accumbens (NAc) is critically involved in the acquisition and expression of reward-oriented behavior. This evidence points at the possibility that neuronal activity in the NAc might undergo changes as these behaviors are learned. However, most studies using electrophysiological recordings of the NAc focus on firing patterns associated with the expression of an already acquired behavior. The evolution of firing patterns in the NAc associated with the emergence of new behaviors has hardly been studied. Using *in vivo* electrophysiological recordings from the first to the last day of training, this study examined changes in neuronal activity in the NAc core as rats acquired a simple instrumental behavior (i.e. nose-poking into a receptacle when a cue indicated availability of sucrose solution). Using this technique, we identified neural correlates of different task-related events that developed as the conditioned approach response was acquired. The nature of these changing patterns, their relationship with different aspects of the incipient behavior and their significance are discussed.

Title: Enhancement of operant responding for food reward by DREADD activation of pyramidal neurons projecting from the mPFC to the nucleus accumbens

Authors: *D. M. WARTHEN[1], K. L. GASSMANN[1], S. M. KHALIL[1], N. P. ROGERS[1], L. S. ZWEIFEL[2], M. M. SCOTT[1];
[1]Pharmacol., Univ. of Virginia, Charlottesville, VA; [2]Psychiatry and Pharmacol., Univ. of Washington, Seattle, WA

Abstract: The medial prefrontal cortex (mPFC) is implicated in a wide range of cognitive functions, including reward evaluation, decision making, memory extinction, mood, and task switching. The mPFC exerts its executive control function via projections composed exclusively of excitatory pyramidal neurons that innervate target areas throughout the brain. It is likely that specific projections mediate defined aspects of mPFC behavioral control. Projections from the mPFC to the nucleus accumbens (NAc), in particular, are likely important for top-down control of motivated behaviors. Thus, we sought to determine the behavioral effects of enhancing the excitatory outflow of projections exclusively from the mPFC to the NAc of mice. To accomplish this, we used a combinatorial viral approach, targeting the NAc with a canine adenovirus (CAV) expressing Cre recombinase, while simultaneously targeting the mPFC with an adeno-associated virus (AAV) encoding a Cre-dependent Gq-coupled Designer Receptor Exclusively Activated by Designer Drugs (DREADD). We found that increasing excitatory output from the mPFC to the NAc via DREADD selectively enhanced performance in a food rewarded operant assay, while having no impact on performance in non-contingent assays. Specifically, activation of NAc-projecting mPFC pyramidal neurons had no effect on binge-like consumption of a high fat diet, social interaction, social habituation and discrimination, behavior in an open field or elevated plus maze, or exploration of a novel object. Interestingly, operant performance was enhanced only when the mice were kept on food restriction and not when they were satiated. As our prior work showed that non-selective stimulation of mPFC pyramidal cells enhanced operant responding in the fed state, it is likely that PFC projections to areas other than the NAc are also necessary to enhance responding in the sated animal.

Title: Role of the Core of the Accumbens in Operant Acquisition

Authors: *S. JONKMAN, P. KENNY;
Pharmacol. & Systems Therapeut., Mount Sinai Sch. of Med., New York, NY

Abstract: The brain regions that mediate the acquisition of operant responding have not been clearly defined to date. It has been proposed that the core region of the Nucleus Accumbens plays an important role, but the available experimental evidence is unequivocal. Local post-learning infusions of anisomycin have been shown to reduce lever pressing for food. However, subsequent work showed that intra-Accumbens anisomycin after food consumption produced a conditioned taste avoidance, presumably due to aversive effects of intra-cranial anisomycin. When these aversive side-effects were controlled for, operant acquisition was not affected by anisomycin infusions. Here we revisit this question by having rats acquire a lever press response for food in one single session, and testing for operant learning two days later in extinction conditions. We ensure that anisomycin did not affect operant reinforcer valuation by interposition of a novel food reward between operant learning and anisomycin infusions, effectively overshadowing any association between the operant reward and negative effects of intra-cranial anisomycin. We confirm that anisomycin significantly reduced subsequent consumption of the novel reward, while leaving the valuation of the operant rewards unchanged. In terms of the overall number of lever presses in the test session, anisomycin infusions did not reduce lever pressing compared to either saline or 6 hrs delayed anisomycin infusions. Based on pilot experiments, we then analyzed the lever press data in terms of the clustering of responses. Control animals engaged both in isolated lever presses and in more sustained series of lever presses that we define as bouts. Anisomycin infusions in the core of the Accumbens significantly reduced both the number of lever presses in a bout, and the percentage of lever presses that turned into a bout versus a solitary press. These comparisons were significant for both the saline and delayed anisomycin control groups. Thus, these results confirm that plasticity in the core of the Nucleus Accumbens does not play an important role in operant learning per se, but rather affects the emergence of sustained operant responding. These results are broadly consistent with the finding that dopamine activity in the core of the Accumbens is necessary for sustained responding in high ratio and progressive ratio testing. We extend those results to suggest that local plasticity is important for learned motivation.

Title: Opotogenetic activation of adenosine A2A receptor signaling in the dorsomedial striatopallidal neurons suppress goal-directed behavior

Authors: *J.-F. CHEN[1,2], Y. LI[2], Y. HE[2], M. CHEN[2], L. CHEN[3], P. LI[4], B. LI[2], H. LI[2], Z. HUANG[3], Z. LI[2];

Abstract: Striatum plays an essential role in neural control of goal-directed and habitual behavior to achieve optimal performance of task. Adenosine A2A receptors (A2ARs) with enriched expression in the striatum modulate instrumental learning, but the contributions of the striatopallidal A2ARs in dorsolateral (DLS) and dorsomedial striatum (DMS) to the control of instrumental learning are not defined. To address whether the transient activation of the striatopallidal A2AR in DMS and DLS precisely at the time of reward was sufficient to modulate instrumental learning, we have developed the rhodopsin-A2AR chimeras (opto-A2AR) and demonstrated that transient light activation of A2AR signaling in the striatopallidal neurons in a "time-locked" manner precisely at the time of reward did not affect instrumental learning at the acquisition or extinction phases, but was sufficient to change animal's sensitivity to outcome devaluation. Specifically, optogenetic activation of striatoapllidal A2AR signaling in DMS suppressed goal-directed behaviors while focally genetic knockdown of striatopallidal A2ARs in DMS enhanced goal-directed behavior by the devaluation test. By contrast, optogenetic activation or focal AAV-Cre-mediated knockdown of striatopallidal A2AR in DLS had little effect on instrumental learning. Thus, the striatopallidal A2AR signaling in DMS exerts inhibitory control of goal-directed behavior by acting precisely at the time of reward, and may represent a therapeutic target to reverse abnormal habit formation that is associated with compulsive obsessive disorder and drug addiction.

Title: The goal-directed pathway: A bilateral corticostriatal pathway mediates the acquisition of goal-directed actions

Authors: ***G. HART**, L. A. BRADFIELD, S. Y. FOK, B. W. BALLEINE;
Univ. of Sydney, Camperdown, Australia

Abstract: In the rat, the prelimbic (PL) region of the medial prefrontal cortex and the posterior dorsomedial striatum (pDMS) are critical for the acquisition of goal-directed actions. The PL has dense glutamatergic projections to the DMS arising from two subpopulations of pyramidal projection neurons; intratelencephalic (IT) neurons, that project ipsilaterally, contralaterally and bilaterally to the striatum, and pyramidal tract (PT) neurons that project to the brainstem via the pyramidal tract, with ipsilateral collaterals in the striatum. Our aim was to investigate the role of ipsilateral and bilateral PL to pDMS projections in the acquisition of goal-directed behavior. We used a recently published tissue clearing procedure (CLARITY; Chung et al., 2013) to map the bilateral projection pathway of PL neurons to the DMS in an intact rat brain (Figure 1, scale bar 2mm, ventral aspect). We then used instrumental training and outcome devaluation tests to assess the functional role of ipsilateral and contralateral PL to pDMS projections in goal-directed behavior. We infused a trans cellular tracer protein; wheat germ agglutinin (WGA) fused to a virus expressing the Cre recombinase (Gradinaru et al., 2010) into the pDMS unilaterally, and performed a cell-body lesion of the PL in the ipsilateral hemisphere. Retrogradely infected IT neurons in the contralateral PL were then selectively infected with a Cre-dependent Gi-coupled M4 DREADD virus (Armbruster et al., 2007). We used Clozapine-N-Oxide to temporarily silence contralateral and bilateral projecting IT neurons during instrumental training. We found

that goal-directed instrumental actions are acquired in a bilateral (IT) PL to pDMS pathway; rats lacking bilateral IT neurons during instrumental training failed to show goal-directed performance on test. Results are discussed in terms of the role of this pathway in top-down modulation of lateralized habit circuits to control striatal output in each hemisphere and produce cohesive action.

Title: The effect of appetitive context pre-exposure on inhibitory avoidance learning

Authors: *M. J. OLVERA-CALTZONTZIN, M. MIRANDA;
Inst. De Neurobiología Univ. Nacional Au, Queretaro, Mexico

Abstract: Memory consolidation has been studied by different learning models, particularly using aversive tasks as inhibitory avoidance (IA), where context is associated with an electric shock, and conditioned taste aversion (CTA), where taste is associated with gastric malaise. Context and flavor are directly interacting during learning, thus the aim of this research was to study how these two types of stimuli are learning together, and if they potentiated or inhibited IA learning. Accordingly, we evaluated if the consumption of appetitive stimulus during IA training has an effect on the aversive learning; we also assessed the effect of context pre-exposure with this hedonically reinforcer (i.e. sugar) on IA latent inhibition. For this purpose, some rats were pre-exposed to a new context (IA chamber), and allowed to drink a sugar solution (10% in water) inside the dark compartment of the chamber. Next day, IA training was conducted with or without sugar presentation and 24 h later IA memory was evaluated. The results demonstrated that IA chamber pre-exposure, whether reinforced or not, produced a significant reduction in the entrance latency to the dark compartment the next day. During IA memory retrieval session, animals trained in a reinforced context showed a significant decrement in the latency to enter the dark compartment of the chamber during IA test retrieval, however, animals pre-exposed or directly trained in IA, without the hedonic reinforcer, had higher latencies during memory retrieval, indicating a stronger IA. These results give evidence about the interactions between flavor and context, and indicate that context learning is modulated by the hedonic value of the experience.

Title: Symmetrical transfer effects between instrumental and consummatory tasks in rats selected for Low Avoidance/High Anxiety

Authors: *C. TORRES[1], L. CUENYA[2], M. SABARIEGO[3], R. DONAIRE[1], A. FERNÁNDEZ-TERUEL[4], M. R. PAPINI[5];
[1]Univ. of Jaen, Jaen, Spain; [2]Lab. de Psicología Exptl. y Aplicada, Inst. de Investigaciones Médicas Alfredo Lanari, CONICET, Buenos Aires, Argentina; [3]Neurobio. Section and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., Univ. of California San Diego, San Diego, CA; [4]Autonomous Univ. of Barcelona, Bellaterra, Barcelona, Spain; [5]Texas Christian Univ., Fort Worth, TX

Abstract: Transfer effects refer to the influence of training in one situation on performance in a subsequent situation. Transfer effects have been described in a variety of situations, including tasks involving reward loss. In this experiment, inbred Roman strains extensively selected for high vs. low avoidance learning were exposed to two tasks in a counterbalanced order. Extensive research on these strains demonstrates that low-avoidance rats exhibit higher levels of anxiety in a wide range of situation than high-avoidance rats. Moreover, previous research showed that repeated reward loss increases resilience in low-avoidance/high-anxiety rats, but not in high-avoidance/low-anxiety rats. Therefore, we predicted that only low-avoidance/high-anxiety rats exposed to reward devaluation in one situation would show transfer of resilience to a different reward devaluation task. One task was instrumental successive negative contrast (iSNC) and the other consummatory successive negative contrast (cSNC). In the iSNC task, rats were reinforced with either 12 or 2 pellets in the goal box of a runway for five 6-trial sessions and then all animals received 2 pellets for an additional six 6-trial sessions (a 12-to-2 pellet downshift). Response latency (in seconds) was the dependent measure. In the cSNC task, rats received access to either 22% or 4% sucrose for sixteen 5-min sessions and then all animals received access to 4% sucrose for an additional four sessions (a 22-to-4% sucrose downshift). Sucrose intake (in milliliters) was the dependent variable. Unshifted control groups were included in both tasks. These tasks differ in the involvement of the hippocampus, which plays a critical role in iSNC, but apparently not in cSNC. As predicted, low-avoidance/high-anxiety rats showed both iSNC and cSNC effects when first exposed to these task (i.e., without previous reward-loss experience), whereas both phenomena were absent in transfer animals previously exposed to the alternative task. Control groups were not affected by previous experience. By contrast, high-avoidance/low-anxiety rats did not exhibit the iSNC effect either when first exposed or after exposure to the cSNC task. This prevented the study of transfer effects in this strain. Despite extensive psychogenetic selection for low-avoidance/high-anxiety behavior (since the 1960s), experience with reward devaluation in one situation immunizes these animals against the frustration induced by reward devaluation in a different situation. These results open an opportunity to study the neurobiology of resilience in animals prone to emotional vulnerability.

Title: Binge eating rats exhibit compulsive and perseverative behaviour in a novel food reward/punished responding model

Authors: ***D. J. HEAL**[1,2], P. HUTSON[2], S. GODDARD[1], R. BRAMMER[1], S. VICKERS[1]; [1]RenaSci Ltd, Nottingham, United Kingdom; [2]Shire Develop. Inc, Wayne, PA

Abstract: Binge-eating disorder (BED) is a psychiatric condition characterised by repeated episodes of compulsive, excessive consumption of palatable foods. A rat model of binge-eating (BE) has been validated in which rats are given irregular, limited access to chocolate (Vickers et al, 2013, SfN abst 236.03). We have now developed a novel food reward/punished responding model to determine whether BE rats show compulsive and perseverative behaviours when given access to chocolate. Adult, female, Wistar rats (n=34) with continuous access to normal chow and water were given intermittent, 2 hr access to chocolate over 28 days. Non-binge (NB) controls were given an empty pot on the binge days. BE and NB rats were trained in the conditioned avoidance response (CAR) test in a 2-chamber shuttle box, ie a tone/light stimulus warned of a mild foot shock 10s later if the rats did not move to the adjacent compartment. After rats were proficient in the CAR test, the model was altered to a food reward/punishment conflict test. A jar was placed in 1 compartment of the shuttle-box (chocolate for BE rats; empty for NB rats). If the rat entered the chamber with the pot, the conditioning stimulus was presented after a variable interval and if the rat did not leave it received a foot shock10s later. Occupancy of the "safe" chamber with no pot in it did not initiate a trial or administration of foot shocks. BE rats developed robust chocolate bingeing with concomitant reductions in chow intake and maintained normal body weight. BE rats consumed ~45% of their daily food intake in the 2 hr binges. There was no difference between the BE rats and NB controls for the rate of acquisition or proficiency in performing the CAR test. In the reward/punishment conflict test, BE rats consumed 35.2 ± 5.2 kJ of chocolate. BE rats spent 309 ± 14 sec in the chocolate paired compartment (~74% of the session) compared with 237 ± 10 sec (~20%) for NB controls ($p<0.05$). BE rats responded to the

conditioned stimulus and left before receiving a foot shock (avoidance) in 78% of the trials compared with 98% for NBs ($p<0.01$). The percentage of trials when BE rats received foot-shocks before leaving the compartment (escape) was 10 fold higher than NBs ($p<0.01$). The mean total escape time when BE rats tolerated foot shocks and remained in the chocolate compartment was ~60 fold greater than the NB controls ($p<0.01$). BE rats showed compulsive and perseverative behaviours in the food reward/punishment conflict test. BE rats were unable to resist entering the chocolate-paired compartment even though the consequence of initiating a trial was potentially to receive a foot-shock. BE rats were also prepared to receive more foot-shocks than NB controls.

Title: Binge-eating rats show marked impulsivity in a delay discounting test

Authors: *S. P. VICKERS[1,2], P. HUTSON[2], S. GODDARD[1], M. HALLAM[1], R. BRAMMER[1], D. HEAL[1];
[1]Renasci Ltd, Nottingham, United Kingdom; [2]Shire Develop. Inc, Wayne, PA

Abstract: Binge-eating disorder (BED) is a psychiatric condition characterised by repeated, excessive consumption of palatable food. Impulsivity and a loss of inhibitory control are important factors in BED (Schag et al, 2013, PLoS One 8: e765421). A rat model of binge-eating (BE) has been validated in which rats are given irregular, limited access to chocolate (Vickers et al, 2013, SfN abst 236.03). We have tested BE rats in a variant of the delay discounting task to determine whether they exhibit impulsive behaviour when given access to chocolate. Adult, female, Wistar rats (n=42) with continuous access to chow and water were trained to lever press for chocolate pellets in a delay discounting task. One lever delivered a single chocolate pellet

immediately while the other delivered a 3 pellet reward with increasing delay after every 5th trial, ie 0, 4, 8, 16, 32 sec. Rats were divided in 2 groups, ie BE rats given intermittent 2 hr access to chocolate over 28 days and non-binge (NB) controls given an empty pot on binge days. Both groups were tested in delay discounting on Days 17-18 and Days 30-31. BE and NB rats gained weight at the same rate. BE rats developed robust chocolate bingeing after ~2 weeks with concomitant reductions in chow intake. BE rats consumed ~50% of their daily food intake in the 2 hr binges. The NB controls showed a decreasing preference for the larger 3 pellet reward as the delay was increased on Days 17-18 [% responses on 3 pellet lever: 0 sec = 70.1±8.3; 4 sec = 57.6±5.4; 8 sec = 51.3±8.2; 16 sec = 38.9±6.7; 32 sec = 17.8±4.9; overall = 46.1±3.4] and Days 30-31 [0 sec = 71.8±11.0; 4 sec = 48.8±5.1; 8 sec = 33.0±6.9; 16 sec = 42.3±9.2; 32 sec = 19.9±5.8; overall = 42.4±5.6]. The responses of the NB rats did not vary over the course of the study. In contrast, BE rats showed significantly lower preference for the delayed larger reward as binge-eating became more established and their level of impulsivity increased. Compared with NBs, BE rats showed enhanced delay discounting on Days 17-18 [% responses on 3 pellet lever: 16 sec = 23.5±5.7, $p<0.05$; overall = 37.3±4.1, $p<0.05$] and at several delay intervals on Days 30-31 [% responses on 3 pellet lever: 8 sec = 17.1±4.5, $p<0.05$; 16 sec = 16.7±4.1, $p<0.01$; overall = 23.3±3.9, $p<0.001$]. BE rats consumed the same number of pellets as NB rats in the tests on Days 17-18, but 10% fewer ($p<0.05$) on Days 30-31. BE rats showed an unequivocal lack of tolerance to delay for larger chocolate rewards in the delay-discounting task when compared against NB controls. This intolerance of delayed reward, characteristic of impulsive behaviour, resulted in BE rats preferring to press for the smaller immediate reward even if it resulted in them consuming less chocolate.

Title: Individual differences in voluntary alcohol consumption predict operant extinction, but not devaluation, in rats

Authors: *H. FISHER, A. PAJSER, C. L. PICKENS;
Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Alcohol use is associated with impaired decision-making. However, it is unclear whether alcohol use can lead to neurological changes that impair decision-making, or whether impaired decision-making might lead to the decision to consume alcohol. To investigate this question, we gave male Long-Evans rats chronic intermittent access (CIA) to alcohol (24-h access to 20% alcohol 3X per week) or water alone for 6 weeks during adolescence and early adulthood (PND 26-66) to examine the effects of alcohol consumption. Ten days after the final alcohol access day, rats were trained and tested in an operant devaluation task. We gave operant training using two levers, available during 40-second trials, with lever presses on the two levers earning different food reinforcers on an intermittent reinforcement schedule. After the rats received four days of training, two days for each lever, one of the reinforcers was devalued through selective satiety and devaluation was assessed through a choice test in extinction. The rats exhibited a large devaluation effect during the first five trials, with an abrupt extinction-induced reduction in responding on the nondevalued lever on the sixth trial. There were no differences in devaluation performance between the alcohol and water rats, and no correlation between devaluation performance and average alcohol intake during the last 2 weeks of alcohol access. However, alcohol intake was correlated with extinction responding, such that higher average alcohol intake was associated with a larger extinction-related decrease in responding on the nondevalued lever. These results suggest that individual differences in response inhibition, as seen in extinction, co-occur with different levels of motivation to consume alcohol. Additionally, our results provided no evidence that alcohol access altered devaluation or extinction. Our future studies will examine possible brain substrates related to this correlation between motivation to consume alcohol and operant extinction learning.

Title: Cholinergic interneurons bidirectionally control extinction learning for a cocaine associated context

Authors: *J. C. FINKELSTEIN[1], J. LEE[2], I. WITTEN[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ

Abstract: Context learning is an integral, but poorly understood, component of addiction. We have previously demonstrated a role for cholinergic interneurons in the nucleus accumbens in the acquisition of cocaine context associations. Here, we show that modulation of the firing activity of these neurons drives bidirectional control of extinction of a drug associated context. Using a cocaine conditioned place preference task, we found that optogenetically inhibiting cholinergic interneurons with eNpHR3.0-YFP during the first extinction test after conditioning increased the preference for the drug associated chamber relative to the YFP-only control group (repeated measures ANOVA, main effect opsin, $F(1,18)=6.372$, $p<.05$, n=10 NpHR3.0-YFP, n=9 YFP-only). In contrast, exciting these neurons with ChR2 diminished preference for the drug associated chamber (repeated measures ANOVA, main effect opsin, $F(1,17)=5.141$, $*p<.05$ n=10 ChR2-YFP, n=8 YFP). These changes in preference persisted throughout subsequent extinction trials without further manipulation of the cholinergic interneurons, suggesting that these neurons are both necessary and sufficient for extinction learning of a cocaine associated context.

Title: Comparing dopamine signaling in dorsal and ventral striatum during a reinforcement learning task

Authors: *N. F. PARKER[1], T. J. DAVIDSON[2], C. M. CAMERON[1], J. P. TALIAFERRO[1], N. D. DAW[3], I. B. WITTEN[1];
[1]Neurosci., Princeton Univ., Princeton, NJ; [2]Dept. of Bioenginerring, Stanford Univ., Stanford, CA; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Previous research has shown dopamine (DA) neurons that project to the striatum play an important role in reinforcement learning by encoding the difference between the expected and actual reward (i.e. prediction error). However, different sub-populations of dopamine neurons project to different striatal subregions. If, and how, the function of these sub-populations differs remains an open question. To investigate this question, we sought to measure neural activity in DA terminals in the dorsal and ventral striatum during a probabilistic reward learning task. We first validated that the task required DA activity by transiently inhibiting activity in DA cell bodies on a randomly selected subset of trials and observing disruptions in trial-by-trial learning. We then measured DA activity in terminal regions in the striatum using gCaMP6f, and developed a statistical model to dissociate the contribution of each task event to the DA signal in each striatal region. We found that DA terminals in these two regions show markedly different responses. For example, dopamine neurons projecting to ventral, but not dorsal, striatum respond to rewards even when they are predicted. These results further illuminate our understanding of the function of DA, a molecule involved in a range of disorders, as well as our general understanding of how the dynamics in neuromodulatory neurons can contribute to learning.

Mexico; [6]BIOLOGY, UNAM, MEXICO CITY, Mexico; [7]BIOLOGÍA DE LA REPRODUCCIÓN, INSITUTUTO NACIONAL DE CIENCIAS MEDICAS Y NUTRICIÓN, MEXICO CITY, Mexico

Abstract: Food is vital to human existence, and requires special care like suitable storage temperatures to increase shelf life, which leads to maintaining their nutritional qualities. However when storage conditions are not adequate, as in the case of an excessive temperature rise, this can affect its nutritional content and when the food is ingested may not provide recommended amounts of daily consumption nutrient or nutrients such as: carbohydrates, proteins, minerals, vitamins, fat and water; causing malnutrition that can lead not only physiological but also behavioral disorders, such as anxiety, depression, obsessive compulsive disorders or impaired memory. The aim for this study was to evaluate different diets and how can alter anxiety behavior. For this purpose Wistar rats (45 ± 5 g) were used; animals were divided into 4 groups (n=6 per group), and were placed in a rack individually, with the following diets: A = Reference diet, B = Control restricted diet, the following groups were given a hypocaloric diet with low vitamin C and protein exposed to different temperatures; C= 40°C, and D = 50°C, daily feed intake per rat and body weight were weighted for 30 days with free access to water and maintained under conditions indicated in the NOM 062 -ZOO-1999 and with international specifications for the production, care and use of laboratory animals standards. After 45 days with the diets, rats were evaluated with the anxiety test using the marble burying model for 10 min, and black and white model for 10 minutes, likewise the locomotors activity assessment was performed for 5 min. Data were collected and analyzed using one-way ANOVA, post-hoc test: Duncan's for significant differences with $p < 0.05$ (sigma stat program version 3.2). Anxiogenic effect and modification of biochemical parameters (Glucose, total cholesterol and triglycerides) and insulin secretion of insulin were decreased in groups C and D compared to controls. Our data suggest that and hypocaloric diet and an augment of temperature can increase the anxiety and alter the biochemical parameters involved in the control of metabolism.

Title: Systemic dopamine D1 and D2 receptor agonism differentially reverses environmental enrichment attenuated sucrose cue-reactivity after 1 or 30 days of forced abstinence

Authors: E. GLUECK, D. GINDER, J. HYDE, F. GRIFFIN, N. INGERMANN, K. NORTH, H. REISTERER, M. KROLL, *J. W. GRIMM;
Dept of Psych and Beh Neurosci, Western Washington Univ., Bellingham, WA

Abstract: Exposure to either acute or chronic environmental enrichment (EE) profoundly reduces sucrose cue-reactivity by rats. The present experiment was conducted to examine whether dopamine D1 or D2 receptor agonism could reverse these effects. The experiment also included rats tested for cue-reactivity after either 1 or 30 days of forced abstinence to examine whether drug effects would vary with the incubation of sucrose craving. METHODS: Effects of systemic dopamine D1 (SKF-81297) or D2 (quinpirole) agonism were examined following 10 d (2h/d) of sucrose self-administration and a 2h cue-reactivity test on a subsequent day (n=10-11 per group). Prior to this test, rats experienced either 1 or 30 d of forced abstinence and either overnight (acute) or 29 d (chronic) EE. Following each housing manipulation, and immediately prior to cue-reactivity testing, rats received a systemic injection of either D1 agonist (0, 0.3, or 1 mg/kg) or D2 agonist (0, 0.1, or 0.3 mg/kg). EE consisted of 3 rats housed in a large, multi-level cage with novel toys exchanged 3 times a week. Controls were returned to single housing. RESULTS: High doses of D1 or D2 agonist increased day 1 acute EE cue-reactivity compared to low dose and vehicle injected animals. This level of responding was comparable to control animals. Neither agonist affected responding of control rats. On the day 30 test, both doses of D1 agonist increased cue-reactivity in acute EE, chronic EE, and control rats. Further analysis revealed that both doses significantly increased responding of chronic EE rats above vehicle treated controls. In contrast, both doses of D2 agonist decreased lever responding of control housed rats while the high dose slightly, but not significantly, increased responding of Day 30 acute EE rats ($p=0.05$). CONCLUSION: Both D1 and D2 receptors are involved in the acute EE mediated decrease in sucrose cue-reactivity observed following one day of forced abstinence from sucrose self-administration. In contrast, following 30 days of forced abstinence D1 receptors may be especially critical in cue-reactivity as D1 agonist was effective at both restoring responding of enriched animals and potentiating responding of controls. This may indicate an

interaction between EE and incubation of craving effects specific to the D1 receptor. Furthermore, the diminished responding of controls following D2 agonist after 30 days of forced abstinence may indicate a change in D2 sensitivity (either a leftward or rightward shift) specific to the incubation of craving.

Title: Environmental enrichment attenuates incubation of cue-induced reinstatement of sucrose seeking but not sucrose consumption in rats

Authors: *K. AOYAMA;
Doshisha Univ., Kyotabnabe, Japan

Abstract: Environmental enrichment (EE) reduces drug and sucrose cue-reactivity in rats. In addition, a previous study (Grimm, Weber, Barnes, Koerber, Dorsey, & Glueck, 2013) reported that EE attenuated sucrose consumption. In the previous study, the sucrose consumption test was conducted on the day after the cue-reactivity test in which lever-press responses were not followed by sucrose presentation. Therefore, interpretation of the consumption test was difficult because the lever-press response may be extinguished during the cue-reactivity test. The present study reversed the order of the two tests. Twenty-eight rats were trained to press a lever for sucrose pellets in 10 daily sessions (self-administration training). Sucrose delivery was accompanied by a tone+light cue. Rats were then divided into three groups. In the Day 1 group, the consumption test was conducted on the day after the last day of the self-administration training (Day 1). The cue-reactivity test was conducted on the next day (Day 2). In the Day 30 and EE groups, the consumption test was conducted after 30 days of forced abstinence of sucrose (Day 30) and the cue-reactivity test was conducted on the next day (Day 31). The procedure of the consumption test was identical to the self-administration training. In the cue-reactivity test, each lever-press was followed by the tone+light cue but not by a sucrose pellet. After the self-administration training, sucrose was not provided until the consumption test. During the forced

abstinence phase, rats in the EE group were placed in larger cages with novel objects and were housed in pairs. In both tests, rats in the Day 30 group responded more than rats in the Day 1 group, indicating the incubation of sucrose craving. Rats in the EE group responded as much as rats in the Day 30 group in the consumption test, but they responded less than rats in the Day 30 group in the cue-reactivity test. The results suggest that EE attenuates incubation of sucrose seeking regardless of the order of the two tests, but the effect of EE on incubation of sucrose consumption depends on the order of the two tests. These results may be useful in the development of anti-relapse strategies for drug and food addictions.

Title: Chronic restraint stress causes a delayed increase in craving for palatable food via a dopamine D_1-like receptor-mediated mechanism

Authors: *K. T. BALL, O. BEST, J. LUO, L. MILLER;
Dept Psychol, Bloomsburg Univ, Pennsylvania, Bloomsburg, PA

Abstract: Evidence from the clinical literature suggests that relapse to unhealthy eating habits in dieters is often triggered by acute exposure to stress, palatable food, or food-associated cues. Using an animal model of relapse, we reported recently that chronic exposure to the pharmacological stressor yohimbine following extinction of food seeking potentiated later reinstatement of food seeking induced by acute yohimbine. Furthermore, SCH-23390, a dopamine D_1-like receptor antagonist, combined with repeated yohimbine injections reversed the effect of yohimbine on later reinstatement. To extend these findings, we tested the effect of chronic restraint stress on responding for food-associated cues during abstinence. Thus, male, Sprague-Dawley rats were trained to press a lever for highly palatable food reinforcers (12.7% fat, 66.7% carbohydrate, and 20.6% protein) in daily 3-hr sessions. Subsequently, rats were tested for food seeking both before and after a chronic restraint stress procedure (3 h/day x 10 days) or control procedure (unstressed). To assess dopaminergic involvement, each group received daily injections of either SCH-23390 (10.0 μg/kg; i.p.) or vehicle prior to treatment. To

examine time-dependent effects of stress, the second food seeking test was conducted either 1 day or 7 days after the last restraint. Results showed that vehicle-injected stressed rats displayed increased responding 7 days, but not 1 day, after the last restraint. Moreover, SCH-23390 combined with stress reversed this effect. These data suggest that chronic stress induces neural changes via a dopamine D_1-like receptor mediated mechanism that are expressed behaviorally as increased food seeking after a stress-free period. From a clinical perspective, our findings suggest that individuals on a dietary treatment plan who also are exposed to chronic stress may be most vulnerable to cue-induced craving and relapse at some point *after* the chronic stress has subsided. In addition, treatment with drugs targeting D_1-like receptors during chronic stress may help to prevent future cue-induced relapse.

Title: Changes on prefrontal dopaminergic receptors, appetitive taste memory retrieval and appetitive re-learning, induced by prolonged sugar consumption

Authors: *S. CAYNAS[1], G. RODRÍGUEZ-GARCÍA[1], I. DELINT-RAMÍREZ[2], M. I. MIRANDA[1];
[1]Univ. Nacional Autonoma de Mexico - Inst. de Neurobiologia, Querétaro, México, Mexico;
[2]Univ. Autonoma De Nuevo Leon, Monterrey, Mexico

Abstract: The medial prefrontal cortex (mPFC) is implicated in a variety of cognitive functions that are important for a maladaptive appetitive behavior, such as habit formation and appetitive learning. Within mPFC, the dopamine neurotransmitter system plays a key role in appetitive learning; nevertheless, it is not known if overtraining appetitive learning compromises the dopamine system in the mPFC and how these changes promote compulsive consumption despite the negative consequences. In the present work we evaluated the effect of apomorphine, a dopaminergic agonist and haloperidol an antagonist of dopamine receptors in the mPFC on the

acquisition and extinction of a new aversive association with a taste that was previously exposure either in an acute (sugared water at 10% for 20 min daily on 3 days; familiar group; F-group) or prolonged fashion (sugared water at 10% for 21 days ad libitum; high familiar group (HF-group). The result showed that HF-group had weaker memory trace of the new aversive association compared to the F-group. Also, we found that prefrontal dopamine receptors blockade in the HF-group prevents high familiar appetitive taste memory retrieval and appetitive re-learning (i.e., extinction of aversion), whereas both activation and blockade of dopamine receptors in the mPFC disrupt the new aversive association in the F-group. Furthermore, using Western Blot, we found a greater amount of prefrontal extrasynaptic receptors in the HF-group. Altogether these results suggest an increase of prefrontal dopaminergic transmission which underlies high familiar appetitive taste memory recognition and could mediate the shifting from taste preference to taste aversion.

Title: Escalation of palatable food consumption by rats with increased reward availability

Authors: *S. T. WHITE[1], I. KRASNOVA[2], J. L. CADET[2];
[1]Pharmacol., [2]Neuropsychiatry research Br., Natl. Inst. on drug abuse, Baltimore, MD

Abstract: Chronic compulsive overeating or food addiction can lead to loss of control over food consumption despite negative medical consequences. In this study, we used a rat model of palatable food self-administration in order to investigate if rats will escalate their palatable food intake and gain excessive weight. Male rats were trained to self-administer palatable food rewards for 3 separate sessions of 3-hour each separated by a 30 min break (total of 9 hours per day) for 20 days. Reward delivery was paired with a tone-light cue. After one week of palatable food reward administration, animals were divided into two subgroups that consisted of (1) stable reward (SR) and (2) reward escalation (RE) groups. The SR group received a maximum of 35 rewards throughout the entire study whereas the RE group was allowed weekly increases in the number of rewards. Subsequently, we assessed cue-induced reward seeking in 1-h extinction sessions on withdrawal days 2 and 21. We found that the RE group pressed the lever

significantly more and received greater number of rewards than the SR group. Both groups consumed most of the rewards within the first hour of each 3-hour session. The RE but not the SR group showed greater weight gains than control animals. Interestingly, both the SR and the RE group showed comparable cue-induced lever presses at day-2 and day-21 of extinction testing, with the RE group showing higher number of lever presses than the SR group. These results suggest a higher level of craving in the RE group. Further research is necessary to identify potential molecular differences that may account for the behavioral differences between the two groups.

Title: Incentive salience attributed to a reward-associated stimulus promotes suboptimal choice in pigeons and rats

Authors: *A. P. SMITH, J. J. CHOW, A. BAILEY, T. R. ZENTALL, J. S. BECKMANN; Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Previous research has shown pigeons reliably choose a suboptimal alternative associated with less food. In these instances, pigeons choose between two initial link stimuli where choice on the suboptimal alternative had a 20 percent probability of producing a stimulus that guarantees food or an 80 percent probability of receiving a stimulus that signals reward omission; the optimal alternative produced one of two stimuli (with 20 and 80 percent frequencies) that each predicted food 50 percent of the time. This effect appears driven by pigeons' overweighting of the more predictive conditioned reinforcer (stimulus that guarantees food) and not taking into account its frequency (20 percent) or the more frequent (80 percent) outcome of omission. The present experiments focused on examining how different conditioned reinforcers in an analogous task can influence choice across species. Pigeons and rats were given a choice between two initial links for a predictive and non-predictive alternative. A predictive choice had equal probability of producing a stimulus predicting food or a blackout period (non-reinforcement). Alternatively, a non-predictive choice was always followed by a stimulus that predicted food 50 percent of the time. In this phase, where food opportunities were equal between the two alternatives, choices in both species showed strong preference for the predictive

stimulus. Subsequent phases reduced the frequency of the predictive stimulus and food exponentially (from 50 percent to 25, 12.5, and 0) resulting in maintained preferences despite less food yield until close to extinction. Thus, maladaptive choice in both pigeons and rats appears to be driven by the value attributed to stimuli that predict reinforcement even if they result in fewer reinforcers. Additionally, this decision making process in gambling-like risky choice behavior shares parallels in how reward-associated stimuli are linked to substance abuse.

Title: The paraventricular nucleus of the thalamus regulates cued food-seeking during reward omission

Authors: *F. H. DO MONTE, A. M. MINIER-TORIBIO, G. J. QUIRK;
Psychiatry and Anat. & Neurobio., Univ. of Puerto Rico, San Juan, PR

Abstract: Recent studies have shown that the paraventricular nucleus of the thalamus (PVT) is a key region for retrieval of well-consolidated fear memories. Particularly, silencing of PVT projections to the central nucleus of the amygdala (CeA) impairs both retrieval and maintenance of cue-associated fear memories (Do Monte et al, 2015; Penzo et al 2015). Studies have also implicated PVT in cue-associated reward memories (Haight and Flagel, 2014; Matzeu et al., 2014). Here, we sought to understand the role of PVT and its projections in cued food-seeking. We used a reward conditioning task in which rats learned that each bar press in the presence of a light cue delivered a sugar pellet into a nearby dish. We therefore manipulated PVT activity under two conditions: 1) when food was available during the cue (positive outcome), or 2) when food was omitted during the cue (negative outcome). Inactivation of the anterior PVT, but not the posterior PVT, with fluorescently labeled muscimol increased pressing when food was omitted (aPVT Sal: 26.6 presses/min, n= 9, aPVT Mus: 40.8 presses/min, n= 5; p= 0.015). To assess the role of PVT projections to CeA during positive vs. negative outcomes, we used an optogenetic approach (halorhodopsin, AAV5:CaMKIIa::eNpHR3.0-eYFP) to specifically silence PVT terminals in CeA during the cue presentation. Silencing of PVT-CeA projections reduced pressing during the cue when the food was omitted (eYFP-Control: 21 presses/min, n= 8, NpHR-eYFP: 13.1 presses/min, n= 8; p< 0.001), but not when the food was available (p= 0.88). Our findings suggest that distinct antero-posterior subregions of PVT regulate food-seeking during negative states induced by food omission. We are currently examining PVT projections to nucleus accumbens, a region involved in reward.

Title: Approach-avoidance processing: the role of nucleus accumbens shell D1 and D2 receptors in conflict resolution

Authors: *D. NGUYEN, V. FUGARIU, R. ITO;
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The nucleus accumbens (NAc) is importantly implicated in the processing of approach and avoidance signals evoked by emotionally valenced environmental stimuli. Currently, there is evidence to suggest that such opposing motivational processes are differentially mediated by subpopulations of NAc neurons expressing either dopaminergic D1- or D2-receptors (D1R, D2R). Further, it has been suggested that dysregulation of this system is implicated in disorders such as drug addiction, where the individual elicits aberrant processing of competing motivational signals. It is therefore important to further elucidate the mechanisms that mediate approach-avoidance processing in states of motivational conflict. The present study utilized a mix-valenced conditioning paradigm to examine the effects of NAc shell D1R or D2R antagonism on approach-avoidance behavior. Male Long Evans rats were trained in a three-arm radial maze to associate visuo-tactile cues with sucrose, shock, or neutral outcomes delivered within the arms in which the cues were presented. Following conditioning, rats were intracerebrally infused with D1R antagonist SCH23390 or D2R antagonist Sulpiride in the NAc shell. Exploration time was then assessed in a conflict test where rats freely explored two maze arms containing either a neutral cue or a superimposition of the appetitive and aversive cues under extinction conditions. Our results revealed that D2R antagonism enhanced preference for the mix-valenced arm, while D1R antagonism appears to decrease preference for the mix-valenced arm, albeit our D1R data is currently preliminary. We conclude that NAc shell D2R is important for suppressing approach behaviors, and NAc shell D1R may be importantly implicated in eliciting approach behaviors, when the valence of the outcome is uncertain.

Title: Investigations of the human cortical networks involved in task-irrelevant spatial change detection

Authors: *M. F. HAUSER[1,2], V. WIESCHOLLECK[2], C. BELLEBAUM[3], D. MANAHAN-VAUGHAN[1,2];
[1]Ruhr Univ. Bochum, Bochum, Germany; [2]Intl. Grad. Sch. of Neurosci., Bochum, Germany; [3]Inst. of Exptl. Psychology, Heinrich Heine Univ., Düsseldorf, Germany

Abstract: The hippocampus, as a key structure for the formation of spatial memory, responds to, and integrates, novel information into existing frameworks. However, studies as to whether it is sensitive to novelty on an environmental level, or whether it responds primarily to content-novelty have produced conflicting results. Electrophysiological experiments in rodents suggest that the hippocampus supports both, integration of novel context as well as content, by means of synaptic plasticity (Manahan-Vaughan & Braunewell PNAS 1999, 96:8739; Kemp & Manahan-Vaughan, Trends Neurosci. 2007, 30:111). Furthermore, hippocampal long-term depression (LTD) plays a role in the processing of object novelty, as well as spatial content, even when passively viewed (Kemp & Manahan-Vaughan, PNAS, 2004,101:8192; Cereb Cortex, 2012, 22:1614). As a corollary to the abovementioned rodent studies, we conducted a human event-related potential (ERP)-study that explored passive viewing of reconfigurations of familiar abstract objects. Participants implemented a distracter-task while background images were presented akin to an oddball paradigm. The deviant condition depicted a spatially reconfigured version of the standard image. This spatial change exclusively elicited positivities in parieto-occipital electrodes at around 400ms, which after analysis using sLORETA, were traced to left inferior occipital areas. Furthermore, at around 500ms, a temporal negativity similar to that observed for novel stimuli was found. Interestingly, when images were viewed for a 2nd time in direct succession, this temporal effect was no longer evident, speaking for an immediate integration and storing of novel or changed information. Taken together, our data support that perception of task-irrelevant spatial information leads to temporal processing, in a way suggestive of memory-updating.

Title: The metabotropic glutamate receptor mGlu5 regulates the direction of opposing forms of synaptic plasticity at mossy fiber - CA3 and commissural/associational - CA3 synapses

Authors: *D. MANAHAN-VAUGHAN, H. HAGENA;
Ruhr Univ. Bochum,, Bochum, Germany

Abstract: The direction of synaptic plasticity, expressed as long-term potentiation (LTP) and long-term depression (LTD) within the hippocampus is affected by spatial experience. The CA3 region plays a pivotal role in the processing of spatial information and hence spatial experience. CA3 receives two inputs formed by mossy fibers (MF) and associational/commissural fibers (AC) that are believed to help in engaging working memory, pattern separation and pattern completion. MF-CA3 and AC-CA3 synapses both express LTP and LTD, but it is unclear how information processing is regulated at these two synapses. We speculated that the metabotropic glutamate receptor, mGlu5, could be a key player, given its contribution in enabling synaptic plasticity in other hippocampal subfields. LTD and LTP were examined at MF-CA3 and AC-CA3 synapses of freely behaving adult rats. The mGlu5 receptor antagonist 2-methyl-6-(phenylethynyl) pyridine (MPEP) inhibited LTP at MF-CA3 synapses, but not at AC-CA3 synapses. By contrast, mGlu5 antagonism prevented LTD at AC-CA3 synapses but not at MF-CA3 synapses. This suggests that activation of mGlu5 preferentially leads to LTP at MF-synapses, whereas LTD is promoted at AC-synapses. We verified this possibility by means of synaptic stimulation at 50 Hz. This frequency corresponds to Theta-m (Bienenstock et al., J Neurosci 1982, 2:32) that corresponds to the crossover-point for mechanisms that enable LTD and LTP at CA3 synapses. 50 Hz stimulation in the presence of the mGlu5 receptor agonist (R,S)-2- chloro-5-hydroxyphenylglycine (CHPG) resulted in a synaptic potentiation of MF-CA3, but not of AC-CA3 responses. These findings indicate that the mGlu5 receptor may act as a switch that alters signal-to-noise ratios during information encoding and thereby supports highly specific storage of information in CA3 by means of LTP and LTD.

Title: Engagement of the descending and ascending pathways to the piriform cortex in synaptic plasticity in behaving rodents

Authors: *C. STRAUCH[1,2], D. MANAHAN-VAUGHAN[1,2];
[1]Dept. of Neurophysiol., Ruhr-University Bochum, Med. Fac., Bochum, Germany; [2]Intl. Grad. Sch. of Neurosci., Ruhr-University Bochum, Germany

Abstract: It is known that all regions of the cortex can undergo experience-dependent modifications. The primary visual cortex for example engages in pre-processing of visual information in the form of persistent synaptic plasticity (Tsanov and Manahan-Vaughan 2007, J. Neurosci). But so far, it is not clear if this property is shared or emulated by other sensory cortices. The olfactory system contrasts strongly with all other sensory systems, because primary and higher cortical regions are involved in information processing before the thalamus is engaged. Early *in vivo* studies reported that repetitive afferent high-frequency stimulation of the olfactory bulb cannot induce synaptic plasticity in the olfactory (piriform) cortex (Racine et al. 1983, Brain Res; Stripling et al. 1988, Brain Res). Even so *in vitro* studies revealed that afferent stimulation can evoke potentiation (Kanter and Haberly 1990, Brain Res), but very rarely (Jung et al. 1990, Synapse). We explored whether synaptic plasticity can be induced in the piriform cortex by patterned afferent stimulation. Animals were chronically implanted with a recording electrode in the anterior piriform cortex, and a bipolar stimulation electrode was implanted into the olfactory bulb or the orbitofrontal cortex. Patterned afferent stimulation protocols at various frequencies (0.5-400 Hz) were applied to the olfactory bulb or the orbitofrontal cortex and evoked responses were examined in the anterior piriform cortex in behaving animals. In the ascending pathway from the olfactory bulb, no synaptic plasticity in the piriform cortex was elicited regardless of the afferent stimulation protocol used. In contrast, after high-frequency stimulation of the orbitofrontal cortex (descending pathway) long-term potentiation in the piriform cortex was evoked. These data suggest that in the ascending pathway to the piriform cortex no synaptic plasticity can be induced in behaving animals. Furthermore, top-down control, for example from the orbitofrontal cortex, might control synaptic plasticity in the piriform cortex. Title: Hippocampal synaptic information encoding in the form of LTD is enable by olfactospatial and audiospatial learning

Authors: *B. E. DIETZ[1,2], M. A. E. ANDRÉ[1,2], D. MANAHAN-VAUGHAN[1,2];
[1]Dept. of Neurophysiol., Ruhr Univ. Bochum, Med. Fac., Bochum, Germany; [2]Intl. Grad. Sch. of Neurosci., Ruhr-University Bochum, Germany

Abstract: Hippocampal long-term depression (LTD) is intrinsically involved in the encoding of novel spatial experience (Manahan-Vaughan & Braunewell, PNAS, 1999, 96:8739; Kemp & Manahan-Vaughan, Trends Neurosci., 2007, 30:111). Hippocampal LTD is especially associated with the acquisition of information about spatial content (Kemp & Manahan-Vaughan, PNAS, 2004,101:8192; Cereb Cortex, 2012, 22:1614). It is unclear to what extent spatial information derived from other sensory modalities can enable information encoding by means of LTD. Here, we explored whether novel olfactospatial, or audiospatial learning facilitates hippocampal LTD. We observed that novel spatial configurations of discretely arranged olfactory, or auditory, stimuli facilitated the expression of hippocampal LTD in freely behaving adult rats. In both cases, LTD was enable by novel spatial learning. Strikingly, audiospatial effects were more potent, and could be better differentiated by the animals when behaviorally relevant tones were used. The resultant LTD endured for at least 4h for both olfactospatial and audiospatial cues, and was tightly coupled to the learning event. Taken together with previous observations with regard to visuospatial information processing, these data suggest that for the hippocampus the sensory modality is not crucial for the enablement of synaptic information encoding. Rather it is the saliency and behavioral relevance of the modality that is decisive in triggering synaptic storage of the spatial experience. Abstract: Aβ-oligomers play a crucial role in the pathophysiology of Alzheimer´s disease. Acute treatment with human or synthetic Aβ(1-42) impairs hippocampal long-term potentiation (LTP), a cellular mechanism that is believed to contribute to hippocampus-dependent learning. Along with changes in somatic and dendritic field potentials, theta-gamma oscillations that occur during high-frequency stimulation (HFS) to induce LTP predict whether successful LTP will occur (Bikbaev et al, 2008, Front Neurosci. 2:56-63). In this study, we explored to what extent changes in neuronal oscillations accompany deficits in LTP that occur as a result of acute Aβ(1-42) treatment. Stable LTP that lasted for over 24h was expressed in 6-month-old rats. Acute treatment with Aβ prevented LTP in these animals. During HFS of control animals relative theta power was reduced in control animals, whereas in Aβ-treated animals this suppression of theta power was absent. Aβ-treated animals also exhibited a lower amount of envelope-to-signal (ESC) correlations between hippocampal theta amplitudes and fast gamma envelopes. Furthermore, during HFS of healthy animals, a significant correlation between ESC-scores, relative theta and gamma power was apparent, that was not evident Aβ-treated animals. These data indicate that Aβ(1-42) causes deficits in information processing at the level of neuronal oscillations, that occur in conjunction with impaired synaptic plasticity. These impairments are likely to contribute to the loss of hippocampus-dependent memory storage ability that occurs in Alzheimer's disease.

Title: Influence of directional information in place field representations of space

Authors: *M. LORKOWSKI[1,2], S. ZHANG[1,2], F. DRAHT[1,2], F. SCHÖNFELD[3,2], L. WISKOTT[3,2], D. MANAHAN-VAUGHAN[1,2];

Abstract: The ability of the hippocampus to reliably encode and navigate space critically relies on the integration of a variety of different input sources. Spatial representation is heavily dependent on sensory information that generates a spatial context for navigation. This predominantly derives from visual information. However, spatial navigation is also supported by internal information from e.g. the vestibular or proprioceptive systems that enable path integration (Zhang & Manahan-Vaughan, 2013). To what extent path integration, and more particularly directional information, can serve as a contextual cue for place cell activity is unclear. To elucidate this we recorded place cells in the CA1 area of the hippocampus using a behavioral paradigm that was specifically designed to create a conflict between sensory and directional information (derived from idiothetic cues). Animals (male Long-Evans rats) navigated different L-shaped routes towards two identical chambers in white noise and darkness (context A). Subsequently, the L-shaped routes were merged so that the animal could turn left or right from the access corridor, to access either chamber (context B). In context A, we observed that place fields emerged in identical locations in the 2 chambers. In context B, place fields initially did not remap, and were thus controlled by proximal visual cues that override directional information, when both are in conflict. However, upon repeated exposure to context B, remapping occurred, suggesting that information provided by directional cues became the primary determinant in driving place cell activity.

Title: Role of BDNF in context-dependent and independent extinction of an appetitive spatial learning task

Authors: *A. B. LEHR[1,2], M. A. E. ANDRÉ[1,2], D. MANAHAN-VAUGHAN[1,2];
[1]Med. Faculty, Dept of Neurophysiol., [2]Intl. Grad. Sch. of Neurosci., Ruhr Univ. Bochum, Bochum, Germany

Abstract: The process of suppressing a previously acquired behavior when it is no longer useful is referred to as extinction learning. Brain-derived neurotrophic factor (BDNF) is required for mechanisms that underlie learning and memory and supports hippocampal synaptic plasticity (Novkovic and Manahan-Vaughan, 2015, Hippocampus 25:1). Recently, it has emerged that the hippocampus is also likely to contribute to context-dependent extinction learning, whereby to-date much attention has been paid to extinction of aversive learning forms. Here, we explored the role of BDNF in context-dependent and context-independent appetitive extinction learning in rodents. Animals were trained to learn that food could be found (with low probability) at the end of one arm of a T-maze (context A). Following successful learning, the floor, distal cues and odor-context of the maze were changed and extinction learning under unrewarded conditions was examined (context B) (ABA paradigm). Reactivation/renewal of the original learned behavior was tested one day later in the unrewarded A context. In a second group, the context remained constant throughout all trials (AAA paradigm). In BDNF+/- mice tested in the ABA paradigm, extinction learning in the B context was impaired, and renewal behavior in the A context was stronger than in wildtype littermates. In BDNF+/- mice tested in the AAA paradigm, extinction in the A context was unaffected. These data suggest that BDNF contributes to context-dependent extinction. This may relate to hippocampal processes supported by BDNF, and the particular role played by the hippocampus in context-dependent learning.

Title: BDNF knock-down lead to impairments of hippocampal synaptic plasticity *in vivo* and contributes to the facilitation of synaptic plasticity through environmental enrichment

Authors: *J. AARSE[1,2], T. NOVKOVIC[1,2], D. MANAHAN-VAUGHAN[1,2];
[1]Dept. Neurophysiol., Ruhr Univ. Bochum, Med. Fac., Bochum, Germany; [2]Intl. Grad. Sch. of Neurosci., Bochum, Germany

Abstract: Brain-derived neurotrophic factor (BDNF) supports a multitude of brain processes that are required for effective cognition, such as synaptogenesis, neurogenesis, and mechanisms that underlie learning and memory. Persistent synaptic plasticity is believed to underlie long-term information storage, but to what extent BDNF is required for forms of plasticity that last for hours or days is unclear. Environment enrichment (EE) enhances hippocampal synaptic plasticity, and alters BDNF expression. Here, we explored the role of BDNF in persistent forms of hippocampal plasticity under naïve and enriched environmental conditions in transgenic mice that underwent a partial knockout of BDNF. In hippocampal slices *in vitro*, wildtype mice (WT) expressed long-term potentiation (LTP) in the CA1 region that lasted for at least 60 min. LTP was impaired in BDNF+/- mice. In freely behaving mice, LTP elicited by high-frequency stimulation (100Hz) was equivalent in WT and heterozygous BDNF+/- siblings, and lasted for over 24h. Afferent stimulation using a theta-burst protocol (TBS) elicited LTP in WT and revealed impaired LTP in transgenics. Short-term and long-term depression (LTD) was impaired both *in vitro* and *in vivo* in BDNF+/--mice. BDNF+/--mice exhibited deficits in spatial memory. EE improved LTP and object recognition memory in WT and BDNF+/--mice, whereby LTP in transgenics achieving levels seen in wildtypes in the absence of EE. EE resulted in increased levels of BDNF, but not proBDNF. These findings indicate that BDNF plays an intrinsic role in persistent forms of hippocampal synaptic plasticity, and that it is an important component in the cellular mechanisms that underlie optimal cognition.

Title: Impaired hippocampal function as a consequence of psychosis

Authors: *V. DUBOVYK, T. GRÜTER, V. WIESCHOLLECK, V. ALIANE, D. MANAHAN-VAUGHAN;
Neurophysiol., Ruhr-University Bochum, Bochum, Germany

Abstract: Changes in neurotransmission, mediated by the glutamatergic, GABAergic, and dopaminergic systems may underlie pathophysiological changes that lead to psychosis. The hippocampus is severely affected, and alterations in its neurochemistry, structure and function occur. Little is known about the underlying mechanisms. Disruptions of glutamatergic signalling may underlie the pathophysiology of psychosis. We implemented an animal model of psychosis that comprises an acute and single administration of the irreversible N-methyl-D-aspartate receptor (NMDAR) antagonist, MK801 to adult rats, to emulate the onset of first-episode psychosis (Wieschollеck and Manahan-Vaughan, Neuropharmacol, 2013, 74:48). We explored possible changes in glutamate receptor expression, as well as in hippocampal neuronal excitability and synaptic plasticity. Four weeks after MK801-treatment, receptor protein levels were examined using immunohistochemical methods. Cellular compartment analysis by fluorescence *in situ* hybridization was used to measure neuronal activation in learning-naïve animals, or following spatial learning. LTP was assessed in freely behaving rats. In MK801-treated rats, a downregulation of the NMDAR GluN1 subunit occured in the dentate gyrus (DG), whereas an upregulation of mGlu5 receptor in the hilar region, and of mGlu1 receptors in the CA1 cell layer, was evident. These changes were accompanied by a decrease in mGlu2/3 receptors in the Stratum lacunosum moleculare of the CA1 region. No changes were evident for the NMDAR GluN2A and GluN2B subunits. Concurrently, hippocampal LTP was profoundly impaired and animals exhibited significantly higher basal Arc expression in the DG, CA3 and CA1 regions compared to vehicle-injected controls. Interestingly, although spatial learning in controls triggered specific neuronal elevations of Arc, this effect was absent in MK801-treated rats. These findings indicate that in psychosis, deficits in hippocampus-dependent memory may arise through enhanced hippocampal neuronal excitability that are associated with LTP-deficits and altered glutamate receptor expression. These alterations can be expected to result in the disruption of normal information processing that contribute to the cognitive deficits associated with psychosis.

Title: The 5-Hydroxytryptamine4 (5-HT4) receptor supports differentiated encoding of informational content in the hippocampus

Authors: *H. TWARKOWSKI[1,2], H. HAGENA[1], D. MANAHAN-VAUGHAN[1,2];
[1]Ruhr Univ. Bochum, Med. Fac., Bochum, Germany; [2]Intl. Grad. Sch. of Neurosci., Bochum, Germany

Abstract: Serotonin (5-hydroxytryptamine, 5-HT) contributes to a multitude of physiological processes. At the level of cognition, the 5-HT_4-receptor is particularly relevant: it supports learning and modulates hippocampal synaptic plasticity, in the form of long-term potentiation (LTP) and long-term depression (LTD) at least at the level of the CA1 region (Kemp and Manahan-Vaughan, PNAS, 2014, 101:8192; 2005, Cereb Cortex. 15:1037-43). Interestingly, afferent frequencies that corresponds to $theta_m$ (Bienenstock et al, J Neurosci 1982, 2:32) result in CA1-LTP in the presence of a 5-HT_4-receptor agonist and CA1-LTD in the presence of a 5-HT_4-receptor antagonist (Kemp and Manahan-Vaughan, Cereb Cortex 2005, 15:1037-43). The 5-HT_4-receptor is widely expressed throughout the hippocampus. Here, we explored its contribution to synaptic plasticity at the perforant path-dentate gyrus (PP-DG) and the mossy fiber-CA3 (MF-CA3) synapse. In contrast to the CA1 region, we observed that the $5HT_4$-receptor does not regulate the direction of change in synaptic weights at PP-DG or MF-CA3 synapses, when receptor modulation occurs during stimulation at θm frequencies. However, $5HT_4$-receptor activation *prevents* LTD in both synapses. By contrast, early and late are impaired by $5HT_4$-receptor activation, whereas PP-DG synapses only late LTP is affected We propose that the $5HT_4$ receptor may serve to fine-tune information encoding within the hippocampal circuitry. Thus, information that is encoded by LTP in the DG and particularly in the CA1 region seems to be prioritised. By this means 5-HT_4-receptors may support the differentiation of experience-dependent encoding. This work was supported by a German Research Foundation (DFG) grant to DMV (SFB874, B1)

Title: Exploration of positional or directional spatial cues results in functionally distinct immediate early gene activation in different hippocampal subregions

Authors: *T. HOANG[1,2], V. ALIANE[1], D. MANAHAN-VAUGHAN[1,2];
[1]Dept. of Neurophysiol., Ruhr Univ. Bochum, Med. Fac., Bochum, Germany; [2]Intl. Grad. Sch. of Neuroscience, Ruhr-University Bochum, Bochum, Germany

Abstract: The hippocampus is a key processing and encoding structure for declarative or explicit forms of learning and memory. Hippocampal synaptic plasticity is tightly associated with the encoding and consolidation of spatial and context-dependent memories. Whereas long-term potentiation (LTP) is associated with the acquisition of knowledge about changes in space or global aspects of space in rodents, long-term depression (LTD) is tightly associated with learning about spatial content (Manahan-Vaughan & Braunewell PNAS 1999, 96:8739; Kemp & Manahan-Vaughan, PNAS, 2004, 101:8192; Kemp & Manahan-Vaughan,Trends Neurosci. 2007, 30:111). A functional segregation as to the involvement of sufield-specific LTD in content encoding is also evident: LTD in the dentate gyrus (DG) is enable by landmark content encoding, whereas LTD in the CA1 region is enabled by the encoding of discrete ,or localized aspects of spatial content (Kemp & Manahan-Vaughan, Cereb Cortex, 2008, 18:968). A differentiation with regard to LTD in the CA3 subfield is also evident (Hagena and Manahan-Vaughan, Cereb Cortex, 2011, Cereb Cortex, 21:2442). We postulated that this kind of information encoding by LTD and LTP relates to the 'what' and 'where' streams, and aligns with the parallel map theory of spatial representations (Jacobs & Schenk, 2003, Psychol Rev. 110:285-315). We conducted cellular compartment analysis of immediate early gene activity by means of fluorescence *in situ* hybridization, to assess neuronal activation after novel learning in rats. We detected increases in Arc (or Homer1a) mRNA in the CA1 region after exploration of discrete spatial features and in the dentate gyrus after exploration of large spatially-distinct landmarks. Subfield analysis of the dentate gyrus revealed distinctions in information processing in the upper and lower blades relative to the informational content. These observations are in line with the parallel map theory of spatial representations and indicate that the hippocampal subfields may contribute to functionally distinct components of a spatial representation.

Title: The locus coeruleus controls the direction of change and persistency of hippocampal synaptic plasticity through the activation of both ß-adrenergic receptors and dopamine D1/5 receptors

Authors: ***N. HANSEN**[1,2], N. LEMON[2], D. MANAHAN-VAUGHAN[3];
[1]Univ. of Bonn, Bonn, Germany; [2]Neurophysiol., [3]Ruhr-University Bochum, Bochum, Germany

Abstract: Hippocampal long-term depression (LTD) and long-term potentiation (LTP) are cellular mechanism that supports memory formation. Neuromodulation related to arousal is a key factor that determines the effectivity and persistency of hippocampus-dependent memory storage. One important structure in this regards is the locus coeruleus (LC), the activity of which increases in response to novel experience. LC activation facilitates hippocampal LTD at the level of the CA1 region. This is not mediated by noradrenaline release alone: LC stimulation leads to elevations of both dopamine and noradrenaline levels in the CA1 region of behaving rats. Effects are accompanied by LTD and improved spatial learning, and are prevented by both beta-adrenergic receptor antagonists and dopamine D1 receptor antagonists. LC projections to the hippocampus are most dense at the level of the dentate gyrus (DG). Here, we explored LC effects on DG synaptic plasticity. LC stimulation resulted in robust and persistent LTD at perforant-path DG synapses in adult behaving rats. Effects were impaired by an antagonism of ß-adrenoreceptors and dopamine D1/5 receptors. DG long-term potentiation (LTP) was impaired by LC stimulation. Our findings indicate that hippocampal LTD is tightly regulated by noradrenaline and dopamine release from the LC. LTD is promoted, whereas LTP is suppressed by LC activity. We propose that this relates to the role of LTD in content-specific aspects of spatial encoding. Title: Prefrontal connections of the perirhinal and postrhinal cortices in the rat

Authors: *E. HWANG[1], B. S. WILLIS[2], R. D. BURWELL[3];
[1]CLPS, [2]Biotech., [3]CLPS, Neurosci., Brown Univ., Providence, RI

Abstract: Recent work has addressed the role of hippocampal-prefrontal interactions in episodic memory, but other medial temporal lobe structures are also connected with prefrontal regions. Here we report the results of a detailed analysis of the prefrontal connections with the perirhinal (PER) and postrhinal (POR) cortices in the rat. The retrograde tracers were Fast Blue, Diamidino Yellow, and Fluoro-Gold. The anterograde tracers were biotinylated dextrane amine and the plant lectin, Phaseolus vulgaris leucoagglutinin. Injections were located in all parts of PER areas 35 and 36 and the POR. We assessed connections of the secondary motor cortex (MOs), dorsal and ventral anterior cingulate cortices (ACAd and ACAv), prelimbic cortex (PL), infralimbic cortex (IL), and orbital prefrontal cortex (ORB). For each retrograde case we counted labeled cell bodies in each layer of each prefrontal region in a series of coronal sections that were 300 µm apart. For anterograde cases, each layer of each prefrontal region was scored for density of labeled fibers in a series of coronal sections that were 300 µm apart. Preliminary analysis of retrograde tracers shows that PER area 36 receives moderately strong inputs from MOs, and prelimbic cortices, arising in all layers. The density of labeled cells was slightly higher in the MOs than in PL. ACAd provide moderate input to area 36. Superficial layers of MOs, ACAd, PL, and IL provide moderate inputs to PER area 35. Labeling was slightly heavier in the MOs and slightly weaker in the IL. The POR receives a very strong input from all layers of MOs, arising preferentially from caudal MOs. Strong inputs to the POR arise in all layers of ACAd and the deep layers of PL. Prefrontal projections to the PER and POR showed a rostrocaudal topography such that rostral prefrontal areas tended to project to rostral PER and POR, and caudal prefrontal areas tended to project to caudal PER and POR. For the return projections, we found that area 36 provided the strongest projections to prefrontal regions. Fibers were observed in deep and superficial layers of all prefrontal regions examined, but the heaviest labeling was

observed in IL and PL. Area 35 also provided input to prefrontal regions, preferentially to IL. Like the PER, the POR targeted all prefrontal areas. Labeling was weak in all regions except MOs, in which fiber labeling was heavy.

Title: Neuronal correlates in rat posterior parietal cortex and the lateral posterior thalamic nucleus during performance on a visuospatial attention task

Authors: *F.-C. YANG[1], R. D. BURWELL[1,2];
[1]Cog., Lin. & Psychological Sci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The posterior parietal cortex (PPC) has been identified as important for visuospatial attention. In rats, this region receives input from visual cortex and from the lateral posterior nucleus of thalamus (LPO), the functional homolog of the primate pulvinar. The LPO and pulvinar are also implicated in attention. In primates, the pulvinar differentially projects to two subdivisions of the PPC. Recent studies showed functional differentiation of these PPC subdivisions, with one region supporting top-down attention and the other supporting bottom-up attention (Cabeza, 2008). The rodent PPC can also be subdivided into dorsal and caudal subdivisions. Whether these subdivisions exhibit a similar functional differentiation, however, remains unknown. Our previous work showed that neuronal activity in dorsal PPC correlated with multiple phases of a visuospatial attention (VSA) task, including onset of the visual stimuli, decision-making, task-relevant location, and behavioral outcome (Yang, Jacobson, and Burwell, under revision). To further understand the roles of the PPC subdivisions and the LPO in visuospatial attention, we simultaneously recorded neuronal activity in all three structures in male Long-Evans rats during performance on the VSA task. This VSA task was adapted from the five-choice serial reaction time task for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze (Jacobson, et al. 2014). Trials alternated from side to side. For each trial, rats

were required to attend to three locations. In one of these locations, a target stimulus was randomly and briefly illuminated. An approach to the correct target location was followed by a liquid reward. For analysis, a trial was divided into behavioral epochs including stimulus onset, selection behavior, and reward. The task was designed to involve both goal-directed, top-down attention and stimulus-driven bottom-up attention. Using wireless recording methods (32-channel TBSI headstage in combination with a Plexon MAP system), we recorded neuronal activity of five rats during performance on the VSA task. We isolated 78 cells in the dorsal PPC, 119 cells in the caudal PPC, and 94 cells in the LPO. Our results show that the LPO and PPC units signal stimulus onset and selection behavior consistent with the interpretation that the LPO and PPC subdivisions are engaged in both top-down and bottom-up visuospatial attention. We also observed LPO and PPC units responded to allocentric and egocentric task-relevant locations. Preliminary analyses showed coherency in the theta frequency band between LPO and PPC subdivisions. Further analyses and detailed results will be presented.

Title: Disconnection of the perirhinal and postrhinal cortices impairs recognition of objects-in-context

Authors: *V. R. HEIMER-MCGINN[1], D. L. POETA[1], R. D. BURWELL[1,2];
[1]Dept. of Cognitive, Linguistics and Psychological Sci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The ability to interpret and use environmental context to inform cognitive processes and guide behavior is an essential function of the human brain. In this study we address the neural basis underlying the formation of object-context associations in the rodent medial temporal lobe. The perirhinal cortex (PER) is known to process object information from the

visual cortex, whereas the rodent postrhinal cortex (POR), homolog to the parahippocampal cortex (PHC) in primates, is thought to process spatial information received from the retrosplenial and posterior parietal cortices. Recent studies provide evidence that representations of context may be formed in the PHC/POR, upstream of the hippocampus. Anatomical data also reveals that the POR and PER are strongly and reciprocally interconnected. Our hypothesis is that the rat POR combines spatial information with object information received from the PER and forms complex representations of context that include the spatial layout of objects and features in the local environment. In this study we employ a crossed lesion approach to test the hypothesis that the POR relies on direct input from the PER in order to provide information about the current context. Rats were tested on two versions of the spontaneous object recognition (SOR) task that measure recognition of objects-in-context (cxtSOR); one is 2-dimensional (2D) and relies exclusively on visual cues, and the other uses 3D objects and relies on multimodal cues. Using the cxtSOR tasks, we examined the effect of crossed excitotoxic lesions to the POR and the contralateral PER. Performance of rats with crossed lesions was compared to that of sham-operated rats and rats with ipsilateral POR plus PER lesions. Our data (n=8 rats/group) show that rats with contralateral POR/PER lesions are impaired in their ability to recognize novel object-context combinations. This is evidenced by a decreased tendency to preferentially explore objects when they are presented in a new context. Discrimination ratios show that rats with contralateral lesions are significantly impaired compared to sham-operated rats in both the 2D and 3D versions of the task. Interestingly, when objects are geometrically simpler in the 2D version of the task, normal rats are less likely to show robust exploration of novelty. These results suggest that interaction between the POR and PER is necessary for the formation of object-context associations, especially when object information is more complex. In further studies, we will use a combination of electrophysiology and optogenetics to specifically inhibit PER input to the POR while studying behavior and neuronal correlates in a cxtSOR task.

Title: Contextual dependency of conditioning and extinction in approach and avoidance behaviors

Authors: *T. K. JACOBSON[1], J. R. PHILLIPS[1], R. D. BURWELL[1,2];
[1]CLPS, [2]Neurosci., Brown Univ., Providence, RI

Abstract: Context serves as an important framework for memory, shaping future expectations of experiences in familiar settings, therefore disruptions in the ability to appropriately use contextual information to guide behavior can cause misconstrued meaning of stimuli, inaccurate perceptions, and/or inappropriate behaviors. The context or environment in which learning takes place and the associations formed during learning are fundamentally linked, and yet how and where contextual information processing takes place in the brain is still poorly understood. Several lines of research indicate contextual information processing is deficient in several psychiatric disorders, and many treatments are context dependent. While the traditional fear conditioning paradigms have provided valuable information about the neural bases of both conditioning and extinction of fearful stimuli, they do not address appetitive (reward-seeking) behaviors, behaviors that are repeated for reinforcement (ritualistic behaviors), nor do they address behaviors aimed to avoid anxiety (active avoidance). We have developed a new task that is better suited to investigate the circuits involved in context representations during ritualistic behaviors and also directly compare and contrast the circuitry of context in behaviors that are repeated for reward versus avoidance. The proposed task utilizes the same fundamental principles of conditioning, but rats are trained to associate an approach to a specific visual cue with either reward or to avoid anxiety. We show, as with traditional conditioning paradigms, renewal, reinstatement, and spontaneous recovery of approach behavior, and that it is context dependent. With this new task, we now have a more translatable, clinically relevant model is needed to investigate the underlying circuitry of context.

Title: Impact of cues versus reward location on CA1 place cells

Authors: *F. SHARIF, S. ROYER;
KIST, Seoul, Korea, Republic of

Abstract: Place cells in CA1 are affected by both environmental cues and distance from/to reward locations. How these information reach CA1 cells and integrate is still unclear. We performed silicon probe recording of CA1 cells, in head-fixed mice running on a treadmill belt enriched with visual-tactile cues. Distinct types of cues were used, and each type of cue was repeated in two locations on the belt. A sweet-water reward was delivered on each trial (complete belt cycle) at a given position of the belt, via a lick port. The position of the reward was maintained for 50 consecutive trials, and then changed to a new position, randomly chosen, for the next 50 trials. Mice ran between 150 to 250 trials within a session, hence experienced at least 3 relocations of the reward. We showed previously that, a population of CA1 place cells is tightly controlled by specific cues (cue-cells), as they repeat identical place fields at the duplicated positions of a particular cue (Geiller et al. 2014). We also showed that a population of CA1 place cells 'follow' the reward location, with their firing field maintaining the same distance relation to the reward, while other cells maintain stable firing fields relative to the cues (Koenig et al. 2013). However, in these previous experiments, cue repetition and reward relocation were not tested together, leaving unclear if cells with single fields in the first experiment are the reward-following cells of the second experiment. As expected, a number of cells encoded the duplicated positions of the cues, while other cells followed the location of the reward. Following reward relocation, cue-cells were never converted into reward-following cells or cue-following single place cells. Interestingly, some cells with single place fields were not affected by the reward relocation. Hence, reward distance is not involved in the mechanism generating the unique place field of these cells, which instead, might result from a particular combination of cue-anchored grid cells inputs, or interference between consecutive cues through local interneurons.

Title: The default mode network in rhesus monkeys with selective bilateral lesions of the hippocampus

Authors: *A. M. SPIEGEL[1], H. GU[3], Y. YANG[3], H. LU[3], J. YOUNG[1], C. HEROLD[1], D. CHARLES[2], S. EDMONDS[2], J. LIVERMORE[2], E. A. MURRAY[4], E. A. STEIN[3], P. R. RAPP[1]; [1]Lab. of Behavioral Neurosci., [2]Comparative Med. Section, Natl. Inst. on Aging, Baltimore, MD; [3]Neuroimaging Res. Br., Natl. Inst. on Drug Abuse, Baltimore, MD; [4]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Human functional imaging studies have identified a distributed network of cortical brain regions that display temporally coordinated activity during wakeful rest, commonly termed the default mode network (DMN). The DMN is largely conserved across rats and nonhuman primates and includes a number of subsystems that converge onto primary DMN core hubs in medial prefrontal and posterior cingulate cortices. The interactions between these hubs and subsystems, and their contribution to the overall integrity and functions of the DMN, remain relatively unexplored. The default mode network and the hippocampus are vulnerable to aging and a variety of age-related neurodegenerative conditions, and here we aimed to directly test the effects of experimental damage to the hippocampus on DMN dynamics. Healthy adult male rhesus monkeys received stereotaxic MRI-guided, bilateral injections of the excitotoxin N-methyl-D-aspartic acid into the hippocampus at 5-6 years of age, approximately 10 years before fMRI. Post-operative structural imaging confirmed the extent and selectivity of the lesions. Sex and age-matched intact adults served as controls. For DMN imaging, monkeys were sedated initially with a single simultaneous cocktail injection of ketamine (3 mg/kg) and dexmedetomidine (0.025mg/kg, IM) and were maintained on a low level of isoflurane (0.5 to 1.0%) during scanning on a Siemens Tim Trio 3T scanner using an EPI sequence (scan parameters: TR =1700ms, TE = 27ms, FOV = 112×112mm, matrix = 64×64, slice thickness = 1.8mm). Initial results confirmed that intact normal monkeys display a temporally coordinated pattern of activity distributed across a number of cortical areas, including the medial prefrontal and posterior cingulate cortex, similar to the human DMN. Ongoing analysis will directly test, for the first time in a primate model, whether the integrity of the hippocampus is necessary for normal resting state cortical network connectivity.

Title: Bio-physical model of perirhinal cortex reveals memory storage mechanisms

Authors: *A. ALTURKI[1], P. SAMARTH[1], F. FENG[1], D. B. HEADLEY[2], D. PARÉ[2], S. S. NAIR[1];
[1]Electrical and Computer Engin., Univ. of Missouri, Columbia, MO; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: The perirhinal cortex supports recognition and associative memory. Prior unit recording studies revealed that recognition memory involves a reduced responsiveness of perirhinal cells to familiar stimuli whereas associative memory formation is linked to increasing perirhinal responses to paired stimuli. Both effects are thought to depend on perirhinal plasticity but it is unclear how the same network could support these two opposite forms of plasticity. However, a recent *in vitro* whole brain study (Unal et al., 2012) showed that when neocortical inputs are repeatedly activated, depression or potentiation could develop, depending on the extent to which the stimulated neocortical activity pattern recruited intrinsic longitudinal perirhinal connections. We recently developed a biophysically realistic model of perirhinal area 36 that could reproduce these phenomena. We used the model to shed light on the mechanisms that support associative memory in the perirhinal network. These analyses revealed that perirhinal associative plasticity is critically dependent on a specific subset of neurons, termed conjunctive cells. When the model network was trained with spatially distributed but coincident neocortical inputs, these conjunctive cells acquired excitatory responses to the paired neocortical inputs and conveyed them to widely distributed perirhinal sites via longitudinal projections. Ablation of conjunctive cells during recall abolished expression of the associative memory. However, ablation of conjunctive cells during training did not prevent associative memory formation because a new set of conjunctive cells emerged, revealing that competitive synaptic interactions within the perirhinal network governs the formation of conjunctive cell assemblies. We are presently extending the model to simulate *in vivo* conditions while in parallel incorporating oscillatory potentials into single cell models. Results from these extensions and from model parametric studies will also be presented.

Title: Automatic expression of recognition memory signals in the perirhinal cortex of rhesus monkeys

Authors: *S. GUDERIAN, M. ROSSA, R. SAUNDERS, M. MISHKIN;
Lab. of Neuropsychology, NIH/NIMH, Bethesda, MD

Abstract: The perirhinal (PRh) cortex is considered to be a critical structure for normal recognition memory function, and neural signals in PRh cortex have been shown to discriminate between new and familiar stimuli in a number of recognition memory tasks. However, the extent to which those signals depend on mnemonic task demands is not well understood. In the present experiment, we asked whether recognition memory signals in the PRh cortex of rhesus monkeys are expressed regardless of whether the old/new status of an image is task relevant, or, alternatively, whether being engaged in a memory task modulates how old and new stimuli are represented in PRh cortex. We trained two adult rhesus monkeys on two tasks each: a recognition memory task and a categorization task. In both tasks, monkeys were presented with a list of dogs and cats, some of which were repeated exactly once. During the recognition memory task, monkeys had to pull a right lever when an image was new, and a left lever when an image was old, regardless of whether an image was of a dog or a cat. During the categorization task, monkeys had to pull a right lever if the image was of a dog, and a left lever if the image was of a cat, regardless of whether it was new or old. This design thus allowed us to assess whether old/new signals are differentially expressed as a function of mnemonic task demand. While monkeys performed both tasks in each daily session, we recorded neural activity in PRh cortex, as well as, simultaneously, in cortical area anteroventral TE. Chronically implanted recording probes consisted of 24 linearly spaced electrodes to span the cortical depth. Spectral analysis of the single-trial current source densities (CSD) revealed that the amplitude of both low (30-60 Hz) and high (60-200 Hz) gamma oscillations discriminated between new and old stimuli in both monkeys, regardless of whether the monkeys were engaged in the recognition memory task or in the categorization task. Specifically, gamma amplitude was higher for new than for old stimuli primarily in the middle layers of PRh cortex, starting approximately 200 ms after stimulus onset. Notably, a similar difference was not observed in area TE. Thus, the present data suggest that the

PRh cortex discriminates between old and new stimuli, regardless of whether the old/new status is task relevant or not. The results will be discussed in light of their implications for our understanding of memory failure, the interaction between memory and attention, and the distinction between episodic and semantic memory.

Title: Impact of Kv7 KCNQ channel blockade in perirhinal cortex on visual recognition memory formation in macaques

Authors: B. CORGIAT[1], D. K. YU[2], A.-J. PISCOPELLO[1], M. MISHKIN[1], *J. N. TURCHI[1]; [1]LN, [2]NIF, NIMH, NIH, Bethesda, MD

Abstract: Direct administration of the muscarinic m1 selective antagonist pirenzepine into perirhinal cortex (PRh) has been shown to produce significant deficits in visual recognition memory in both rats and monkeys. To examine further the muscarinic modulation of visual mnemonic function in PRh, we manipulated an m1-associated K+ channel whose actions could potentially enhance local network connections to support visual memory formation. We conducted local microinfusions of the selective Kv7 KCNQ channel blocker XE 991 in monkeys performing a one-trial visual recognition task and compared these scores to ones following local microinfusions of equivalent volumes of saline or pirenzepine. In sound attenuating operant chambers equipped with touch screen monitors, the animals (n = 3) were first trained to criterion on the delayed nonmatching-to-sample (DNMS) rule using trial-unique clipart stimuli using a 10sec delay between sample and choice test. Next, animals were introduced to varying ratios of clipart to superimposed ascii character stimuli, and both the interstimulus intervals (ISIs) and the stimulus list-lengths were gradually increased. The final task consisted of a list of 16 trial-unique stimuli (clipart:superimposed ascii character stimuli ratio at 25:75) presented at a 15sec ISI, followed by choice tests presented at the same intervals. Thus the final task length required memory of stimuli in the list for a period of 4 - 6 minutes, and each testing session comprised five such lists presented consecutively. On attaining the performance criterion (75-80%

accuracy, no omissions), the animals received a series of bilateral microinfusions into PRh (3.5 µl/site). Relative to saline control infusions, injections of pirenzepine in this region induced visual mnemonic deficits. In contrast, preliminary data from local PRh infusions of XE 991 indicate a dose-dependent positive modulation of recognition accuracy. Our findings provide support for the crucial role of muscarinic m1 receptor-associated pathways in perirhinal cortex for the successful formation of new visual object memories.

Title: Cortical and subcortical projections of the entorhinal layer III neurons of the rat

Authors: ***S. OHARA**[1], K. ITO[1], Y. SOTA[1], K.-I. TSUTSUI[1], M. P. WITTER[2], T. IIJIMA[1]; [1]Tohoku Univ. Grad Sch. Life Sci., Sendai, Japan; [2]Kavli Inst. for Sys Neurosci and Cen for Neural Comp, NTNU, Trondheim, Norway

Abstract: The entorhinal cortex is a major input and output structure of the hippocampal formation, and plays an important role in memory and spatial navigation. Various inputs converge in the superficial layers of the entorhinal cortex, and are likely relayed to the hippocampus. Previous anatomical studies reported that the projection to the dentate gyrus and CA3 arises largely from neurons in layer II, while the projection to the CA1 and subiculum originates from neurons in layer III. We have previously examined the multisynaptic inputs to the dorsal and ventral hippocampus of the rat by using rabies virus vector. In line with previous studies, layer II and deep layer III neurons were retrogradely labeled throughout the lateral and medial entorhinal cortex after the viral injection into the dentate gyrus and CA1. However, labeled neurons were hardly observed in the superficial layer III of the entorhinal cortex. In this study, we re-examined the laminar organization of the entorhinal projection neurons in order to identify the efferent projections of the entorhinal neurons located in the superficial layer III. We

injected a retrograde tracer, either a chemical tracer (FluoroGold) or a viral tracer (rabies virus vector), into cortical (medial prefrontal cortex, insular cortex, orbitofrontal cortex, contralateral entorhinal cortex) or subcortical regions (amygdala, nucleus accumbens), and examined the distribution of retrogradely labeled neurons throughout the lateral and medal entorhinal cortex. In line with previous reports, entorhinal-cortical and subcortical projections mainly arose from the deep part of layer III, as well as from layer V. We also confirmed previously published data that superficial layer III neurons project to the contralateral entorhinal cortex. In addition, we found that a small number of superficial layer III neurons projected to the amygdala and the orbitofrontal cortex. These anatomical data indicate that neurons in the superficial half of layer III are connectionally different from those in the deep half.

Title: Characteristic neocortical ensembles encode essential information for different visual shape discriminations

Authors: *A. I. GELLER[1], G. ZHANG[1], H. ZHAO[1], N. COOK[1], M. JAN[1], E. CHOI[1], M. SVESTKA[1], 1. G. COOK[2];
[1]LSUHSC, New Orleans, LA; [2]Dept. Psychol., Tufts Univ., Medford, MA

Abstract: Neural network and synaptic plasticity theories hypothesize that essential information for specific cognitive discriminations is encoded in different neuronal ensembles, in distributed

neocortical networks. However, the critical ensembles are uncharacterized: The size, neuronal composition, and spatial distribution of these ensembles is unknown. Further, we do not know if a specific discrimination is encoded in a characteristic, or different, ensembles across multiple individuals. Here, we used a genetically-modified circuit that encodes essential information for a cognitive task to show that characteristic ensembles encode specific visual shape discriminations. For the model system, protein kinase C (PKC) pathways were activated in several hundred glutamatergic or GABAergic neurons in a critical multimodal associative area, postrhinal (POR) cortex; a constitutively active PKC was delivered using a HSV-1 vector (J Neurosci 2005 25 8468-81). This intervention activated specific PKC substrates with central roles in synaptic plasticity, including glutamatergic neurotransmission or neurotransmitter release, and increased activation-dependent neurotransmitter release. Importantly, this intervention supported enhanced accuracy for specific visual shape discriminations that were learned after gene transfer. Some of the essential information for performance is encoded in the genetically-modified circuit (PNAS 2010 107 14478-83). Following both the gene transfer and learning new image sets, neurochemical lesions that ablated ~21 % of POR cortex, centered on the gene transfer site, selectively reduced performance for only discriminations learned after gene transfer. During learning, there was increased activity for neurons in the genetically-modified circuit, as shown using activity-dependent gene imaging (c-fos and arc). Quantifying the active neurons established that the essential circuit was relatively small, ~500 neurons, and was sparse coded; the coding density of ~3 %, consistent with neural network theories. Analysis of the locations of the active neurons established that different image sets are encoded in characteristic and different ensembles of neurons. Specifically, there was a bilaminar pattern of active neurons: For one image set ([] vs. +) the superficial layer contained more active neurons than the deeper layer; and, in contrast, for a second image set (/ vs. \), the two layers contained similar numbers of active neurons. In conclusion, within a circuit that contains essential information for performance, different discriminations are encoded in characteristic and different ensembles of neurons.

Title: Long-term representation of complex stimuli in the mouse parietal cortex: *in vivo* two-photon c-fos imaging

Authors: *M. ROSHCHINA[1], O. IVASHKINA[1], K. TOROPOVA[1], A. DRONOVA[1], K. ANOKHIN[1,2];
[1]NRC Kurchatov Institute, Nbics-Center, Moscow, Russian Federation; [2]Anokhin Inst. of Normal Physiol. RAMS, Moscow, Russian Federation

Abstract: A common way to study memory of neuronal representations in the rodent neocortex is Pavlovian conditioning to a discrete sensory stimulus. However, in natural environment associative memories are complex and involve integrated conditioned stimuli (CS) consisting of different sensory modalities. Very little is known about how neuronal populations in neocortex code complex stimuli during long-term memory formation and retrieval. Previously we have developed a behavioral paradigm for multisensory compound CS fear conditioning in mice that mimics complexity of natural learning. In the present study, we examined encoding of different components of the compound CS by neurons of the mouse parietal cortex. To map neuronal responses we used transgenic mice with the expression of the EGFP controlled by the c-fos promoter. We trained mice in a fear-conditioning task to a compound cue that consisted of auditory (tone) and visual (blinking light) components. Control mice were presented with the compound CS, without the footshock. A week later, we performed three sequential retrieval sessions during which mice received separate auditory and visual components of the compound CS and the compound CS itself. To monitor retrieval-induced neuronal activation we performed two-photon *in vivo* imaging of fos-EGFP expression in the parietal associative cortex 90 minutes after each test. Based on the intensity of EGFP fluorescence, all registered neurons were divided into the two groups - high- and low-expressing. The number of high-expressing neurons increased in the trained mice compared to the control mice in all retrieval sessions, while the number of low-expressing neurons decreased in all the sessions. Next, we analyzed neurons that showed high fos-EGFP expression only in one of the retrieval session. We found three activation specificities of such neurons: light-related, sound-related and compound CS-related neurons. The number of light-dependent high-expressing neurons increased in the trained mice compared to the control mice. The number of sound-dependent and compound CS-dependent neurons was equal in the trained and control mice. Taken together our data suggests that coding of complex associative memory in the parietal cortex involves at least three neuronal assemblies with different response specificity to the components of the compound CS. This work was supported by RFBR Grant 130440334H.

Title: Sequential processing of paired stimuli in medial temporal lobe subregions perirhinal cortex, lateral entorhinal cortex, dentate gyrus and CA1 supports formation of a time-bridging associative response

Authors: *E. E. SUTER, C. WEISS, J. F. DISTERHOFT;
Northwestern Univ., Chicago, IL

Abstract: Acquisition of trace eyeblink conditioning (EBC) engages the hippocampus, however the single-neuron responses of perirhinal cortex (PR), lateral entorhinal cortex (latEC) and dentate gyrus (DG) have not previously been described during this task. Rabbits were trained on trace EBC (or given unpaired stimuli; Pseudo) and single-neuron activity was recorded in PR, latEC, DG and CA1 during learning and following a one-month consolidation period. A total of 2891 well-isolated neurons were recorded in PR (N=433), latEC (N=431), dorsal DG (N=1309) and dorsal CA1 (N=718). PR neurons responded to both CS (whisker vibration) and US (corneal airpuff), but showed little conditioning-specific activity. There was however an increase in significantly modulated PR neurons in conditioned animals, consistent with PR as a multimodal coincidence detector that may increase local LTP and transmission to latEC. LatEC and DG showed conditioning-specific trace-period responses starting before behavioral criterion. The magnitude of the stimulus response was reversed between EC responding maximally to CS, and DG firing maximally to US. LatEC showed trace conditioning-induced firing in high-firing rate cells that have not been described during spatial tasks, possibly reflecting local mGluR activation and learning-induced AHP decrease. Thus pre-criterion trace-bridging activity develops in latEC and DG with distinct stimulus-response profiles during temporal learning. PR, latEC and DG neurons showed similar response profiles on CR and no-CR trials, indicating that they are involved in learning associations but not in controlling the behavioral responses--as opposed to

regions such as medial prefrontal cortex, whose neuronal activity differs between CR and no-CR trials. However, the trace-period response in rate-decreasing cells of CA1 is stronger on CR- than no-CR trials. While DG maintained an elevated number of responsive neurons post-consolidation, the characteristic firing rate profiles of EC and DG were diminished post-consolidation, consistent with an acquisition-specific role for these regions. The present study found that within medial temporal lobe, neuronal signals representing paired stimuli are transformed in a step-wise process from individual stimuli in PR, to stimuli plus trace-bridging activity in EC and DG, to a behavior-linked response in CA1.

Title: CA1 rate and temporal coding in the absence of CA3 input

Authors: S. J. MIDDLETON[1], *T. J. MCHUGH[2,3];
[1]Riken Brain Sci. Inst., Wako-Shi, Saitama, Japan; [2]RIKEN Brain Sci. Inst. - Wako, Wako-Shi, Saitama, Japan; [3]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: Area CA1 of the hippocampus is known to receive temporally patterned inputs from area CA3 (via the Schaffer collaterals) and layer 3 of the entorhinal cortex (via the temporoammonic pathway). These inputs give rise to spatial coding in CA1 which manifests as both rate: a spatially selective increase in firing rate as the animal enters and traverses the cells receptive field and temporal coding: precise timing of spike discharge relative to hippocampal local field potential theta oscillations. Whilst the anatomical inputs to CA1 are well characterized, their respective contributions to rate and temporal coding are less clear. Using the CA3-TeTX transgenic mouse, in which CA3 output can be specifically and inducibly silenced we dissected to what degree the two types of coding are utilized by CA1 devoid of CA3 input.

Our results show that phase precession, the discharge of spikes at progressively earlier theta phases with place field distance, remains intact despite loss of CA3 input.

Title: An examination of the local circuitry and impact on network activity by supramammillary nucleus inputs to area CA2 of the hippocampus

Authors: *R. A. PISKOROWSKI, V. ROBERT, V. CHEVALEYRE, L. THERREAU; CNRS UMR8118, Paris, France

Abstract: Area CA2 of the hippocampus differs from areas CA1 and CA3 in many aspects. Recent findings indicate that this region is unlikely to code spatial information, but is critical for social memory. Neurons in area CA2 form a reciprocal connection with the supramammillary nucleus (SuM), a hypothalamic structure activated by stress and reward. We are using targeted viral vectors in combination with transgenic mouse lines in order to selectively express channelrhodopsin in SuM neurons and selectively excite projections from these neurons in transverse hippocampal slices. We have found that SuM fibers form excitatory synapses onto both pyramidal cells and interneurons in the deep portion of the somatic layer in area CA2. An inhibitory post-synaptic potential is evoked in CA2 pyramidal cells following SuM stimulation, which is entirely abolished after blocking excitatory transmission. These results reveal that SuM fiber stimulation effectively evokes action potentials in interneurons that feed-forward onto CA2 pyramidal cells. In contrast, the direct glutamatergic transmission between SuM and CA2 pyramidal cells is quite weak and unable to evoke firing. Furthermore, SuM activity results in the release of neuropeptide, allowing for an indirect modulation of inhibitory transmission in this area. We are examining the properties and axonal projections of the interneurons that receive inputs from SuM fibers in order to better understand how SuM activity alters the local circuitry

in the hippocampus. We postulate that strong recruitment and modulation of perisomatic inhibition in this area may influence network oscillatory activity.

Abstract: Understanding the flow and processing of spatial and contextual information across the subregions (CA1/CA2/CA3/DG) of the hippocampus has been a long standing goal of neuroscience and has provided key insights to the formation, consolidation and expression of declarative memory. Key to this understanding has been the combination of *in vivo* recording of the spatially selective place cells and local field potential oscillations across the structure with modern genetic tools that allow interventions in neuronal function at specific nodes of the circuit. While this approach has yielded insights into the contributions of CA1, CA3 and the DG, the role of the small, yet highly connected CA2 region to spatial processing and circuit function remain largely unexplored. CA2 is unique in its pattern of synaptic plasticity and its anatomy, possessing multiple bidirectional connections with areas both within and outside the hippocampus, including layer II of the entorhinal cortex, CA3, the supramammillary nucleus of the hypothalamus, and the medial septum. Using *in vivo* recordings in awake behaving mice we have found that while many aspects of CA2 physiology are similar to the neighboring CA3 region, the consequences of CA2 silencing are quite unique. Using multiple genetically encoded systems we have investigated the consequences of both transient and chronic silencing of CA2 synaptic

transmission on hippocampal physiology. Surprisingly, our data suggests that CA2 may serve a crucial role as a regulator of interhippocampal information flow.

Title: Supramammillary input to hippocampal CA2 modulates social memory

Authors: *M. WINTZER[1], A. J. Y. HUANG[1], R. BOEHRINGER[1], D. POLYGALOV[1], A. Z. WEITEMIER[1], S. CHEN[1], L. M. Y. YU[1], R. A. PISKOROWSKI[2], V. ROBERT[2], T. J. MCHUGH[1,3];

Abstract: The individual pyramidal cell subfields of the hippocampus (CA1/CA2/CA3) can be differentiated by their anatomy, physiology and contributions to specific types of memory processing. Recent work has demonstrated that chronic genetic silencing of synaptic transmission specifically in CA2 pyramidal cells resulted in a loss of social memory. The CA2 region is unique in that it is the only of the CA regions to receive direct projections from the hypothalamus; both the supramammillary (SuM) nucleus and the paraventricular nucleus send axons that synapse specifically in CA2. As a large body of previous work has highlighted the importance of the hypothalamus in social and affective behaviors we have begun to address the role of the hypothalamic-hippocampal circuit in modulating CA2-mediated social memory. We have generated a new Cre recombinase expressing transgenic mouse line that permits specific genetic access to projection neurons of the SuM. Stereotaxic injection of a cre-dependent AAV virus expressing optogenetic channels into the SuM of this cre line, combined with laser stimulation of terminals in CA2, provides us with a novel tool to address the role of these inputs

in CA2 physiology and memory, both *in vivo* and *in vitro*. Physiological data indicate that SuM inputs generate a complex circuit response, with both rapid and slow components. Moreover, terminal stimulation of the SuM projections in CA2 during behavior inhibits the expression of social memory, suggesting that the SuM may serve as a signal of social novelty. These experiments shed light on a novel hypothalamic-hippocampal circuit that regulates the memory of social interaction and have begun to uncover why CA2 may be a key player in this network.

Title: Hippocampal CA3 plasticity and transmission are required for social memory

Authors: *M.-C. CHIANG[1,2], A. HUANG[1], T. J. MCHUGH[1,3];
[1]RIKEN BSI, Wako City, Japan; [2]Dept. of Life Sci. and Biomed. Science, Grad. Sch. of Advanced Sci. and Engineering, Waseda Univ., Tokyo, Japan; [3]3Department of Life Sciences, Grad. Sch. of Arts and Sciences, Univ. of Tokyo, Tokyo, Japan

Abstract: Social recognition and memory are crucial for normal behavior in many animals, including rodents and primates, however, the neural circuits underlying these processes are not fully understood. Recent results have suggested an important role of the hippocampus in social memory, with a particular focus on the CA2 subregion. Here we addressed the potential contribution of the hippocampal regions upstream of CA2, CA3 and the dentate gyrus (DG). We found the deletion of the NMDA receptor subunit 1 gene (NR1), which abolishes NMDA receptor synaptic plasticity, specifically in CA3 pyramidal cells led to deficits in social memory, however, mice lacking the same gene in DG granule cells performed indistinguishably from controls. In addition, we have used transgenic and viral techniques to demonstrate CA3 synaptic

output is required for normal social memory. Together, our results provide new evidence that disruption of hippocampal CA3 function contributes to deficit in social memory in mice, and suggests an interaction between the CA3 and CA2 circuits may be required for the acquisition and expression of social memory.

Title: CA2 place cells maintain a coherent population representation of a dynamically changing environment

Authors: *H. LEE, C. WANG, S. DESHMUKH, J. J. KNIERIM;
Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: The hippocampal CA2 area was historically considered a transition zone between CA3 and CA1. However, growing evidence suggests that CA2 has unique connectivity and physiology that may contribute important roles in hippocampal processing and computation. To examine the neural representations of a dynamically changing environment within the CA2 area, we recorded CA2 neurons during a cue-shift rotation experiment. Rats were trained to run around a circular track containing salient local cues on the track in a room containing salient global cues on the walls. Three standard sessions were interleaved with two mismatch sessions, in which the local cues on the circular track were rotated counterclockwise (CCW) and the global cues in the room were rotated clockwise (CW) to result in total mismatch angles of 45°, 90°, 135°, or 180°. The individual cellular response to the double rotation manipulation showed that the majority (67%) of CA2 place fields rotated on the track (CCW, n = 80/173; CW, n = 26/173; ambiguous rotation, n = 10/173). The remaining place cells remapped their place fields, having a robust place field in only one of the two sessions (appear and disappear, n = 57/173). A population correlation analysis showed that the CA2 representations of the standard and the

mismatch environments were strongly correlated and that the representations were controlled by the local cues. The coherence in CA2 was similar to prior findings in intermediate and distal CA3 populations recorded in the same double rotation experiment, but different from the adjacent, proximal CA1 representation. Thus, under these conditions, the neural processing in CA2 resembles CA3 more than CA1.

Title: Functional dissociation along the proximodistal axis of CA1

Authors: ***S. S. DESHMUKH**[1,2], J. L. JOHNSON[2], J. J. KNIERIM[2];
[1]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India; [2]KriegerMind/Brain Inst., The Johns Hopkins Univ., Baltimore, MD

Abstract: Lateral and medial entorhinal cortex (LEC and MEC) projections are segregated along the proximodistal axis of area CA1 of the hippocampus. LEC preferentially projects to distal CA1, while MEC preferentially projects to proximal CA1. Previous experiments in our lab have shown that in response to a conflict between local (on a circular track) and global (along the circular curtain) cues, the response of the CA1 place-cell population is incoherent: some neurons rotate their place fields with the local cues, others with the global cues, and the majority remap (Lee et al., 2004). We asked if this apparent lack of coherence can be explained by a functional dissociation along the proximodistal axis of CA1 due to functionally different inputs received from LEC and MEC (Deshmukh and Knierim, 2011). We recorded from 11 rats with 16-18 tetrodes spanning the entire transverse axis of dorsal CA1 while the rats were subjected to the double cue-rotation paradigm. In addition, we included data from CA1 neurons from 9 rats reported from in previous studies. The electrodes in each of these rats targeted only a part of the transverse axis of dorsal CA1. The data from these two sets of rats were qualitatively similar and hence pooled. Analysis at the single neuron level as well as at the population correlation level

revealed a difference in cue preference along the proximodistal axis of CA1. The distal CA1 representation was coherently controlled by the global cues. In contrast, the proximal CA1 representation showed a less coherent response, with a stronger influence of local cues. Intermediate CA1 showed varying preference for local and distal cues depending on the mismatch angle. These data demonstrate functional heterogeneity along the transverse axis of CA1 in the responses of place cells to spatial reference frame conflicts.

Title: Multiscale simultaneous response of grid cells to conflicting reference frames

Authors: *F. SAVELLI, J. D. LUCK, J. J. KNIERIM;
Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Grid cells represent space over multiple, discrete spatial scales. Grids of the same scale share common geometrical features (e.g., orientation and elliptical distortion), which can differ across grids of distinct scale. While grid cells of the same scale are also known to maintain rigid geometric coupling across remapping-inducing experimental manipulations, coupling (or lack thereof) across distinct grid scales remains experimentally under-characterized despite its theoretical importance. We previously described experiments in which a proximal reference frame (foraging platform) and a distal frame (experimental room) were dissociated by translation or rotation in separate foraging sessions. These manipulations elicited diverse geometric adaptations by grid cells, ranging from locking to either frame to the disruption of grid structure. Pairs of co-recorded grid cells of both same and different scale from two rats (208+35 pairs) were analyzed here. For each pair-session, we measured (1) the difference in grid rotation (**A)** and (2) a joint correlation of the pairs (stacks) of grids across the standard and manipulated condition, under a single, rigid affine transformation (cosine of the angle between linearized

stacks, after rate maps are individually mean-centered and normalized). Pairs were divided into 2-3 discrete spacing-ratio clusters (SR1-3; n=126, 109, 8; **B**). 77% (80%) of SR1 (SR2) grid pairs displayed <5° rotation difference and 80% (83%) had joint correlation >0.7 (**B**). Neither rotation difference nor joint correlation was found to be significantly different in SR1 vs. SR2 (Rotation Difference: p>0.5, 2-sided Mann-Whitney test, both medians= 2.8°; Joint Correlation: p>0.24, medians=.78, .76). We did not find unambiguous examples of grid dissociation by visual inspection of rate maps. In these animals and experimental protocols, the responses of co-recorded grids to conflicting reference frames appeared to be generally well coordinated and independent of their scale ratio.

Title: Landmark vector coding in complete darkness in area CA1 of the hippocampus

Authors: *V. PULIYADI, S. S. DESHMUKH, J. L. JOHNSON, J. J. KNIERIM;
The Johns Hopkins Univ., Baltimore, MD

Abstract: Animals have been shown to utilize the distance and direction from landmarks to find hidden food rewards. After gerbils are trained to use two landmarks to locate buried food rewards equidistant from each landmark, moving the landmarks causes the gerbil to search in spots with the same distance and direction from each landmark (Collett et al. 1986). McNaughton et al. (1995) proposed a vector encoding model to explain this behavior, suggesting that individual place fields can generate a vector with orientation and distance from a specific landmark. Instances of such landmark-vector encoding were identified in previous recordings from our lab in the CA1 hippocampal subregion (Deshmukh and Knierim, 2013). Units with this property are defined as having place fields that maintain a specific and consistent vector relationship to specific landmarks in the environment. Since these fields are object-related but located away from the objects, visual cues would be expected to perform an important role in the generation and maintenance of these landmark vectors. To investigate the necessity of visual information, the neural activity of CA1 place cells was recorded while rats foraged on a circular platform (48" dia.) in darkness, with three novel objects set in an equilateral triangle centered on the platform. The rats had never experienced the platform in the presence of light. This paradigm was repeated for three days without any manipulation of the objects. On the fourth day, a session in which the cues were rotated by 60° was interleaved with the standard object configuration sessions. Of 458 units from seven rats, 7.5% were identified as encoding vector relationships between the rat and a subset of the landmarks, a proportion similar to the prior report in the light (Deshmukh and Knierim, 2013). These results suggest that the hippocampus can encode space relative to objects without the necessity of visual information even when the rat is not in contact with the objects.

Title: Place cells in virtual reality dome reveal interaction between conflicting self-motion and landmark cues

Authors: *M. S. MADHAV[1], R. P. JAYAKUMAR[2], F. SAVELLI[1], H. T. BLAIR[3], N. J. COWAN[2], J. J. KNIERIM[1];
[1]Mind / Brain Inst., [2]Mechanical Engin., Johns Hopkins Univ., Baltimore, MD; [3]Psychology, UCLA, Los Angeles, CA

Abstract: The generation of allocentric 'cognitive maps' in the hippocampal formation requires that positional information derived from external landmarks be reconciled with self-motion information derived from vestibular, proprioceptive, and other cues. Using a custom, hemispherical, planetarium-style virtual reality (VR) dome, we are investigating the interactions between landmarks and self-motion cues on place cells and other neural correlates believed to underpin the cognitive map. Inside the VR dome, a rat can traverse a circular path (4.5 ft. dia.) and unlike most existing rodent VR systems, the rat experiences naturalistic inertial and proprioceptive feedback, while only the visual feedback is artificially controlled. The surrounding visual scene consists of salient virtual landmarks, which are rotated coherently as a function of the rat's angular position, creating the visual illusion that the rat is walking slower or faster, depending on the sign of the landmark angular velocity. The ratio of applied landmark angular velocity to measured rat angular velocity is termed the "gain" (g) of visual feedback; in particular, g=0 corresponds to stationary landmarks and g=1 corresponds to landmarks moving along with the animal. Preliminary data demonstrated the formation of stable CA1 place fields in the presence of three stationary virtual landmarks. These place fields drifted coherently when the landmarks were turned off, mitigating concerns of interference from uncontrolled, non-VR directional cues in our apparatus and indicating that, as expected, the animal's internal representation of position accumulates error when relying solely on self-motion inputs. Continuous manipulation of visual landmarks ($0<|g|<0.9$) reliably controlled the firing location of place cells, even though the landmarks were radically displaced from their initial locations by the end of the experiment. However, at the higher gains ($g>0.5$), initial observations indicated that firing fields progressively increased in size. In addition, the fields shifted backwards relative to the location of the landmarks by up to 100 degrees, possibly due to competition between conflicting place estimates from landmark and self-motion cues. Our ongoing efforts aim at elucidating the mechanistic significance of these preliminary findings as well as further pursuing the unique experimental opportunities afforded by our apparatus to understand the computational and sensory interplay of allothetic vs. idiothetic spatial cues in a highly controlled and real-time fashion.

Title: Neurons in the hilus of the dentate gyrus have multiple place fields in multiple environments

Authors: D. GOODSMITH[1], *K. M. CHRISTIAN[2,3], S. KIM[2,3], H. SONG[2,3,4], J. J. KNIERIM[1,4];
[1]Krieger Mind/Brain Inst., [2]Dept. of Neurol., [3]Inst. for Cell Engin., [4]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Early computational models suggested that the dentate gyrus (DG) orthogonalizes overlapping input patterns from entorhinal cortex by recruiting independent ensembles of sparsely firing granule cells (GCs). This notion of "expansion recoding" has been challenged by evidence that many putative GCs have multiple firing fields and fire promiscuously in multiple environments (Leutgeb et al, 2007; Jung & McNaughton 1993). This result suggested that an active population discriminates environments (or input patterns) based on changes in the spatial or temporal coincidence of firing, rather than the sparse activation of discrete subsets of cells. In a more recent study, Neunuebel & Knierim (2012) found that tetrodes in the DG can record at least two cell types with distinct firing properties. One group of cells was rarely active in behavior and had single fields when active, consistent with the formation of a representation of the environment based on different populations of sparsely firing cells. The other group of cells was more likely to fire during behavior, had multiple fields, and was recorded on tetrodes with fewer cells active during sleep. These cells resembled the putative multi-field GCs in previous studies and were often recorded on tetrodes in the hilus; however, it was unclear if these hilar cells would also fire in multiple environments. We recorded from the DG while rats foraged for food in four distinct environments. Four unique platforms (different textures, colors, and/or shapes) were placed in four different rooms with distinct external cues. During long periods of sleep or quiet inactivity (30-120 min) in 3 rats, 13 cells were recorded on 5 tetrodes histologically identified to be located in the hilus on the day of recording. During subsequent foraging behavior, 11 of these cells (85%) had ≥ 1 place fields in all environments, and only one cell was silent in all environments. These cells had an average of 2.55 place fields per active room (range 1-5). The spatial firing of these cells in the hilus resembles the firing of cells

attributed to the granule cell layer in previous studies. Along with Neunuebel & Knierim (2012), the present results show that cells in the dentate gyrus with multiple place fields in multiple environments may be mossy cells or other hilar cell types.

Title: Deep-layer LEC neurons convey slightly more spatial information than superficial-layer neurons in open-field foraging tasks

Authors: *C. WANG[1,2], G. RAO[1,2], H. LEE[1,2], J. J. KNIERIM[1,2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Mind/Brain Inst., Baltimore, MD

Abstract: The hippocampus, which plays an essential role in episodic and spatial memory, receives its major cortical input via the superficial layers of the entorhinal cortex. The superficial layers of the medial entorhinal cortex (MEC) contain many spatially selective neurons (e.g., grid cells and boundary cells), whereas the superficial layers of the lateral entorhinal cortex (LEC) do not appear to contain many cells with robust spatial selectivity. The LEC superficial layers receive projections from other high-order sensory and association cortices, whereas the deep layers are targeted by feedback projections from the hippocampus proper, including CA1 place cells. We tested whether deep-layer LEC neurons contain more spatial information than superficial-layer LEC neurons. We trained 7 rats to forage freely in open fields in rooms with rich visual cues and measured the spatial information content of recorded neurons. There were small but significant differences in spatial information score between the firing rate maps of superficial- and deep-layer cells (Superficial: n = 114, median = 0.13, interquartile range = 0.08-0.21; Deep: n = 42, median = 0.20, interquartile range = 0.11-0.28; Wilcoxon rank-sum test, $z = 2.42$, $p < 0.02$). Thus, deep-layer LEC cells, which receive spatially selective input from CA1 backprojections and from subiculum, show slightly more spatially selective firing than

superficial-layer cells. Nonetheless, the spatial selectivity of the deep-layer cells is much lower than prior reports of hippocampal place cells and MEC grid and boundary cells, thus reinforcing the distinct functional differences among these 3 components of the hippocampal memory system. The results suggest that deep-layer LEC recodes the space-based representation it receives from the hippocampus, which may facilitate communication between neocortical regions and the hippocampus proper.

Title: Optogenetic manipulation of memory encoding in primate hippocampus

Authors: ***I. OPRIS**, L. SANTOS, D. KLORIG, D. FETTERHOFF, D. W. GODWIN, R. E. HAMPSON, S. A. DEADWYLER;
Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Prior findings from this lab have demonstrated facilitation of cognitive performance in nonhuman primates trained to perform in a delayed match to sample (DMS) task (Hampson et al., 2013). Our objective is to develop a memory prosthesis controlled by light. Therefore, we hypothesized that optogenetic stimulation (OS) in primate hippocampus is capable of modifying (enhancing or decreasing) memory encoding. To test the role of hippocampal microcircuits in memory encoding we combined OS with simultaneous recording of hippocampal subfields CA3 & CA1. OS experiments were carried out in four rhesus macaques, previously injected in CA1 with adeno-associated viral vector AAV5 (Diester et al. 2011), carrying an excitatory opsin, channelrhodopsin-2 (ChR2, blue light) and an inhibitory halorhodopsin (HR, yellow light). OS of hippocampal neurons is performed by applying laser stimuli during the Sample phase of the DMS task when the memory was encoded. Simultaneous neural recording and OS were performed using a custom coaxial tetrode developed in our lab (Santos et al., 2012). We found that neural activation patterns revealed by OS alone were determined in part by the functional connections of this region expressing ChR2 or HR. Thus, stimulation of the CA1 subfield containing ChR2 led to the activation of neighboring hippocampal cells, while stimulation of the

CA1 subfield containing HR led to the inhibition of these cells. When optogenetic stimulation was combined with visual stimulation in the task, the observed neural activation patterns revealed a complex interaction between the two stimuli (laser and task image), inducing facilitation or inhibition that depended on the stimulus type of visual stimulus presented and the timing of visual and optogenetic stimulus presentation. Our results demonstrate (1) the use of optogenetics to stimulate specific functional microcircuits in hippocampal CA1 of a non-human primate; (2) changes in neural activation and/or microcircuit state following optogenetic stimulation that facilitate or inhibit neural cell firing; and (3) differential modulation of firing in hippocampal cells encoding spatial or object features of visual stimuli. These investigations have relevance for understanding the behavioral, neurophysiological, neuropathological and neurochemical abnormalities that occur in patients with dementia, epilepsy or schizophrenia. The outcome of these results has groundbreaking implications for the design of cognitive prostheses controlled by light for patients exhibiting a broad spectrum of cognitive dysfunctions.

Title: Inactivation of the C57BL/6J mouse hippocampus disrupts discrimination and avoidance of objects that are either stationary or moving around the environment

Authors: *H. N. ASGEIRSDOTTIR[1], R. W. STACKMAN, Jr.[2];
[1]Psychology, [2]Florida Atlantic Univ., Jupiter, FL

Abstract: The cognitive map theory states that the hippocampus creates representations of locations where relevant non-spatial items or objects are encountered and where specific events occur within a contextual or spatial reference frame. The rodent hippocampus is an essential neural substrate for spatial memory and the CA1 region has been shown to play a vital role in object memory dependent and independent of context; findings consistent with the cognitive map view. Ongoing identification of an object and continuous updating of its location within the environment combines these hippocampal dependent functions. How the hippocampus integrates

these two types of information in real life situations has not been well studied. In particular, it is of interest to determine how the rodent hippocampus processes information about 3D objects-in-motion. Here, we trained mice to avoid an object under both stationary and moving conditions by delivering a mild foot shock when in proximity to the object. Intrahippocampal infusion of muscimol impaired avoidance of the object during both testing conditions; results which support the view that an intact hippocampus is required for both object memory retrieval and continuous updating of the objects' location in space. Next, we developed a novel behavioral paradigm to further test the influence of motion on hippocampal-dependent object discrimination. Here, we trained mice to avoid one object while not avoiding another one, and then tested whether the mice can discriminate between moving the objects during hippocampal inactivation. The "Knowing your enemy" task requires the mice to discriminate between two moving objects and successfully evade proximity to only one of them to avoid receiving a foot shock. This task requires mice distinguish between the objects and continuously update their location in space, both of which are believed to be hippocampal dependent. Temporary inactivation of the hippocampus in mice after training of the "knowing your enemy" task resulted in impaired avoidance and increased exploration of both objects while stationary. These results support involvement of the rodent hippocampus in non-spatial object memory.

Title: Hippocampal NMDA receptors are involved in rats' spontaneous object recognition only under high memory load condition

Authors: *K. YAMADA, M. SUGITA, Y. ICHITANI;
Univ. Tsukuba, Tsukuba, Japan

Abstract: Involvement of the hippocampus in non-spatial memory, such as recognition memory for items or objects, is still controversial. It has been reported that the hippocampus could be

involved in spontaneous object recognition under a specific condition such as a longer delay length, although some previous studies have argued that the hippocampal lesions had no effect on performance in the spontaneous object recognition test. Thus, the hippocampus seems to be involved in item or object recognition memory only under a higher memory load condition. In this study, the possible involvement of hippocampal N-methyl-D-aspartate (NMDA) receptors in spontaneous object recognition was investigated in rats under different memory load conditions. We firstly estimated rats' object memory span using 3 to 5 objects in "Different Objects Task (DOT)" in order to confirm the highest memory load condition in the objet recognition memory. Long-Evans male rats were allowed to explore a field in which 3 (3-DOT), 4 (4-DOT) or 5 (5-DOT) different objects were presented. After a delay period, they were placed again in the same field in which one of the sample objects was replaced by another object, and their exploration behavior to these objects was analyzed. Rats could discriminate the novel object from the familiar ones in 3-DOT and 4-DOT but not in 5-DOT, suggesting that rats' object memory span was about 4. Then we examined the effects of hippocampal AP5 infusion on performance in both 2-DOT (2 different objects were used) and 4-DOT. The drug treatment before the sample phase impaired performance only in 4-DOT. These results suggest that hippocampal NMDA receptors play a critical role in spontaneous object recognition only when the memory load is higher enough.

Title: Bidirectional modulation of context fear in the dentate gyrus

Authors: ***B. E. BERNIER**, H.-J. KIM, A. AYOUB, B. V. ZEMELMAN, M. R. DREW; Ctr. for Learning and Memory, Univ. Texas At Austin, Austin, TX

Abstract: Recent studies have demonstrated the importance of the hippocampal dentate gyrus (DG) in the acquisition of contextual fear memories. However, the neural substrates underlying

extinction of context fear have not been clearly defined. Here, we use optogenetic and pharmacogenetic methods to assess the role of DG in context fear extinction in mice. To rapidly and reversibly manipulate neural activity during behavior, an adeno-associated viral (AAV) vector was used to express the light-activated chloride pump halorhodopsin (eNpHR3.0) specifically within the DG. Optogenetic inhibition of the dorsal DG during the context-shock pairing impaired context fear acquisition. Silencing the DG during context re-exposure did not alter fear expression but attenuated fear extinction across 5 days of context re-exposure. Silencing the DG only during a context re-exposure after extinction failed to increase freezing, suggesting that DG is not required for expression of extinction learning. The data suggest that DG is required for acquisition of new context learning (both acquisition and extinction) but is not required for expression of context learning. To further examine the role of the DG in context learning, we used an AAV vector to express the engineered G protein-coupled receptor rM3Ds in excitatory neurons of the dorsal DG. Activation of rM3Ds via injection of clozapine-N-oxide (CNO) stimulates the cAMP pathway, leading to increased activation of dentate granule cells (DGCs) during behavior. Increasing activity of DGCs during context-shock pairing impaired acquisition of context fear, similarly to DG inhibition. Increasing excitability of DGCs during context re-exposure after acquisition had no effect on expression of the fear memory but led to a significant reduction in freezing during a subsequent drug-free context test. This reduction in freezing does not reflect an enhancement of extinction learning, as stimulating DGC activity with CNO during exploration of a novel context 24 hours after conditioning produced a similar decrement in freezing during subsequent re-exposure to the conditioning context. This finding suggests that stimulating DGCs after conditioning reduces fear by interfering with mechanisms related to consolidation. Together these data identify the dorsal DG as a critical component in the neural circuitry of context extinction and a potential therapeutic target for the treatment of emotional disorders related to aberrant fear learning.

Title: Dentate Gyrus is required for the acquisition, but not the expression, of trace eyelid conditioning in mice

Authors: *Y. KIM, B. BERNIER, M. DREW, M. MAUK;
The Univ. of Texas At Austin, Austin, TX

Abstract: Decades of studies supported a contribution of the hippocampus for various types of learning and memory. The tri-synaptic circuit, which is thought to be the heart of hippocampal information processing within hippocampus, conveys information from dentate gyrus (DG) to CA3 to CA1. The three subregions are distinct in terms of the composition of cell types, the basal activity of principal neurons, input sources and output targets, suggesting that their contribution to the hippocampal functions may not be the same. In this study, we tested the contribution of DG using trace eyelid conditioning in head-restrained mice. Previous studies using permanent lesion of the whole hippocampus have shown that the hippocampus is necessary for acquisition of trace eyelid conditioning and for the expression of the recently acquired conditioned responses (CRs). To inhibit DG selectively, we expressed halorhodopsin in DG either by injecting AAV containing eNpHR3.0-YFP in naïve C57BL/6J mice or by crossing POMC-Cre mice with floxed- eNpHR3.0-YFP mice. Trace conditioning involved a 300 ms tone CS and periorbital stimulation as the US. The US was presented 500 ms after the offset of the tone CS (i.e. 500 ms trace interval). With this training the animals acquire reliable CRs (>85% of total trials) within seven days. Muscimol infusion in the pons and deep cerebellar nuclei abolished CRs, suggesting that this is cerebellum-dependent eyelid conditioning as reported with rabbits, rats, and mice. Halorhodopsin-expressing mice did not show CRs when DG was inactivated during each trial in the acquisition sessions, indicating that DG activity is necessary for the acquisition of trace eyelid responses. In contrast, these mice can learn comparable to control (GFP-expressing mice or littermates) when laser light is blocked, suggesting that the DG is not simply blocking the expression of CRs. Once animals were conditioned, the inhibition of DG did not affect the expression of CRs. These results suggest that DG is necessary for the acquisition, but not the expression, of trace eyelid responses.

Title: Spatial memory functions for adult neurogenesis are modulated by stress in male and female rats

Authors: T. P. O'LEARY, *J. S. SNYDER;
Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The discovery that new neurons are born in the adult brain has opened the door to exciting possibilities by which experience can sculpt circuits and modify behavior. Thousands of new neurons are added to the adult human hippocampus each day even in old age. Rodent studies have shown that immature neurons are more plastic than pre-existing neurons and while there is evidence that they make functional contributions to memory their exact role remains unclear. We are interested in the possibility that new neurons are important for learning under stress. It is well known that acute stress promotes hippocampal synaptic plasticity and learning, enabling us to remember our experiences and adapt our future behaviors accordingly. Furthermore, there is a growing body of work indicating that newborn neurons regulate emotional behaviors in response to stress. To test a stress-dependent function for new neurons in memory we trained neurogenesis-deficient GFAP-TK rats in the spatial water maze under high (16°C) or low (25°C) stress conditions. We find that, in male rats, blocking adult neurogenesis indeed impairs spatial learning and memory primarily at cold, stressful temperatures. Since males and females differ in stress reactivity, and little is known about functions for new neurons in males vs. females, we then examined how stress modulates learning and memory in female rats that lack neurogenesis. In contrast to males, neurogenesis-deficient female rats were not impaired when trained at 16°C, and even showed a trend for enhanced performance relative to their wild-type littermates. Furthermore, whereas temperature did not affect wild-type female rats, neurogenesis-deficient female rats performed significantly better and had greater corticosterone levels at 16°C than at 25°C. Collectively, our data indicate that adult neurogenesis regulates learning under stress and additionally suggests that new neurons perform distinct functions in the male vs. female brain.

Title: A shared neural ensemble links distinct contextual memories encoded close in time

Authors: *D. J. CAI[1], D. AHARONI[2], T. SHUMAN[3], J. SHOBE[1], J. BIANE[5], J. LOU[3], I. KIM[1], K. BAUMGAERTEL[6], A. LEVENSTAIN[1], M. TUSZYNSKI[5], M. MAYFORD[6], P. GOLSHANI[3], A. J. SILVA[4];

Abstract: Recent studies suggest the hypothesis that a shared neural ensemble could link distinct memories encoded close in time. According to this hypothesis, one memory triggers a temporary increase in neuronal excitability that biases the representation of a subsequent memory to the same neuronal ensemble encoding the first memory, such that recall of one memory increases the likelihood of the recall of the second memory. Accordingly, using *in vivo* calcium imaging with a miniature fluorescent microscope and immediate early gene expression with TetTag transgenic mice, we found that the overlap between the hippocampal CA1 ensembles activated by two distinct contexts acquired within a day is higher than when the two contexts are separated by a week. Multiple convergent findings indicate that this overlap of neuronal ensembles links two contextual memories. First, fear paired with one context is transferred to a neutral context when the two are acquired within a day but not across a week. Second, the first memory strengthens the second memory within a day but not across a week. Older mice, known to have lower CA1 excitability, do not show the overlap between ensembles, the transfer of fear between contexts, or the strengthening of the second memory. Taken together, these findings demonstrate that contextual memories encoded close in time are linked by directing storage into overlapping ensembles. Alteration of these processes by aging could affect the temporal structure of memories, thus impairing efficient recall of related information.

Title: Functional organization of hippocampal microcircuits regarding the embryonic birthdate of neurons *in vivo*

Authors: *S. REICHINNEK[1], A. MALVACHE[2], V. VILLETTE[2], R. COSSART[2];
[1]Susanne Reichinnek, Marseille, France; [2]INMED, Marseille, France

Abstract: Cell type diversity classically reflects the available repertoire of neuronal functions in different brain regions. So far, cell diversity in the hippocampus was mainly addressed in GABAergic cells. In contrast, only few studies address the possibility that glutamatergic CA1 pyramidal cells may comprise several subtypes with different functional and morphological features (Thome 2014, Mizuseki 2011). We aim at understanding the relationship between the developmental temporal origin of glutamatergic neurons and their recruitment into behaviorally-relevant network dynamics. Using an inducible genetic fate mapping approach, we are able to label neurons depending on their embryonic birth date. Further on, we use calcium imaging (GCaMP6-M) to monitor their neuronal activity in head-fixed mouse voluntarily running on a treadmill using a 2-photon microscope. Monitoring hundreds of neurons in the dorsal hippocampus, we analyze their firing pattern during typical behaviorally relevant network oscillations e.g. theta-nested gamma and sharp wave ripples. We have probed the co-occurrence of calcium-related neuronal activity and the electrophysiological signature of the network oscillations using a contra-laterally implanted field electrode. We analyze the recruitment, the spatial organization and the inhibitory impact of neurons from different developmental ages. In this way, we investigate the functional organization of neurons born at different embryonic time-points during physiological network oscillations and provide insights into how developmental origin shapes the functional organization of hippocampal microcircuits.

Title: Hippocampal replay correlates retrieval of fear memory in inhibitory avoidance task

Authors: *C.-T. WU[1], C. KEMERE[3], D. JI[2];
[1]Neurosci., [2]Baylor Col. of Med., Houston, TX; [3]Rice Univ., Houston, TX

Abstract: The hippocampus is critical for retrieval of contextual fear memory, but the patterns of neural activity that underlie this retrieval are largely unknown.We created a novel linear avoidance task to study the hippocampal activity underlying retrieval of fear memory. The 225-cm track comprises two distinct light and dark segments of equal length. Rats initially tend to remain in the dark segment. Following an initial exploration period, we shock the rats in the final 28-cm portion of the dark segment (shock zone). After being shocked, they completely avoid the shock zone and tend to remain in the light segment. We find that reactivation of place cells associated with shock zone precedes and is strongly correlated with avoidance behavior. This reactivation occurs during the replay of place cell sequences leading to or originating from the shock-zone and is associated with the high-frequency ripple oscillations. Hippocampal replay has been previously shown to predict future trajectories in goal-directed behavior. In contrast, the hippocampal replay we observe reflects a potential path that the animal strictly avoids presumably reflecting the negative affect of the shock experience. Our results suggest that hippocampal reactivation of place cell sequences provides salient spatial information associated with past memories for general decision making, but does not necessarily predict future actions. We also find that there is rate remapping with only small proportion of cells change their firing locations following an aversive experience.

Title: Anatomical localisation of episodic-like memory in the mouse

Authors: O. MONTEIRO, A. GUTOREVA, L. M. KAFER, R. C. KING, J. J. LAMBERT, *R. F. LANGSTON;
Div. of Neuroscience, Med. Res. Inst., Dundee, United Kingdom

Abstract: Distinct areas of the cortex and the hippocampus have been found to be important for associative recognition memory in the rat, depending on the level of processing of spatial and contextual information. Lesion studies found that the hippocampus is crucial for episodic-like memory in rats. Associative recognition memory tasks that incorporate novel object (what is new), location (where is this novelty) and context (which context has this novelty been encountered) is said to resemble human episodic memory. This episodic-like memory has not been characterised in mice. We have carried out spontaneous recognition memory tasks in mice that involve: object recognition (what), object-place recognition (where), object-context recognition (which) and object-place-context recognition (episodic-like memory). We examined activity-dependent immediate early gene expression (Fos) after mice had performed each of these behavioural tasks, in order to investigate differential activation of neurons in different hippocampal and cortical regions. The Fos gene is critical for learning and memory, and its region specific activation correlates with performance in a context discrimination task. Thus, Fos protein expression can be used as an indicator of neuronal activation in relation to specific behavioural paradigms. We will compare neural networks activated during each component of episodic memory to those found to be crucial in rats. This study will shed light on the neural circuitry involved in each component of episodic memory. In addition, most available disease models for neurodegenerative diseases and dementia are in mice. Hence, this study will identify crucial brain regions involved in the processing of episodic memory in a species more relevant for studying models of memory impairments.

Title: Motivational state influences the content of hippocampal sequences

Authors: A. CAREY, *M. A. VAN DER MEER;
Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Internally generated sequences of hippocampal place cell activity, generated during sharp wave-ripple complexes (SWR), are thought to play a role in the consolidation and expression of hippocampus-dependent knowledge. The content of SWR-associated sequences emitted in awake states is not limited to literal "replay" of past experience: instead, they include biases towards goal locations (Pfeiffer & Foster, 2013), trajectories not recently experienced (Gupta et al. 2010), and even not-yet experienced sequences (Dragoi & Tonegawa, 2010). If the content of hippocampal sequences can be freed from literal experience, what factors determine their content? We hypothesized that shifts in preferred outcome influence the content of hippocampal sequences. To test this, rats (n = 4) performed a simple T-maze choice task, with one arm resulting in a 6% sucrose outcome, and the other in food pellet outcome. Animals were water-restricted or food-restricted on alternate days, such that they preferentially chose the water reward following water restriction and food reward following food restriction. We recorded ensembles of hippocampal place cells as animals performed the task, as well as during rest periods before and after the task. Overall, individual place cells were slightly more likely to participate in SWR events if they had a field on the sucrose arm compared to the food arm; importantly, however, there was no interaction with motivational state. Interestingly, a pairwise analysis revealed an interaction of activation probability with motivational state, such that pairs of cells with fields on the "water" arm were more likely to occur when water was preferred, and pairs of cells with fields on the "food" arm were more likely to occur when food was preferred. This interaction was significant even when only SWRs during the pre-task rest phase were included, and after the number of trials on either arm of the maze was matched to prevent biases in the estimation of place field locations. Next, we applied sequence detection methods to detect and classify multi-cell sequences as "water" or "food" depending on which arm of the maze they mapped onto. Individual animals tended to have idiosyncratic biases, but in animals where sequences could be reliably detected, motivational state shifted sequence content towards the preferred reinforcer. These results demonstrate that the content of hippocampal sequences is influenced by motivational state, and elucidate the complex relationship between experience and the content of memory.

Title: Neural plasticity in episodic memory: Functional and structural connectivity changes associated with learning and after fornix transection in macaques

Authors: *A. S. MITCHELL[1], D. J. MITCHELL[2], S. CHAKRABORTY[3], A. H. BELL[1,2], A. C. H. LEE[4,5];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom; [3]Bioengineering, Imperial Col., London, United Kingdom; [4]Psychology (Scarborough), Univ. of Toronto, Toronto, ON, Canada; [5]Rotman Res. Inst., Toronto, ON, Canada

Abstract: Neuroimaging studies have documented changes in connectivity strength in the motor cortex during learning new motor skills. However, it is unknown how connectivity changes during learning episodic-like memories, and the impact on relearning after damage to structures implicated in episodic memory processing. We measured functional and structural changes using MR imaging in four macaques at multiple time points, initially during learning a visual cognitive task, and then during relearning after bilateral fornix lesions. We also collected neuroimaging in a matched control group that were not exposed to any form of learning. Naïve monkeys learnt an episodic-like memory task presented on a touchscreen monitor, which emphasized rapid within session learning of context specific object-in-place information for food rewards. Two identical 'bulls-eyes' (white background black centre) were used as the objects for all the discrimination problems. In each session, a monkey learnt by trial and error, which bulls-eye was the correct target by touching it. For each discrimination problem, the bulls-eyes were randomly located within a novel colourful visual background that filled the touchscreen. There were 10 novel discrimination problems, presented concurrently and repeated 8 times (i.e. 80 problems) per session. We collected whole brain functional (blood oxygenation level-dependent imaging) and structural (diffusion weighted imaging and structural T1-weighted imaging) data under general anaesthesia, prior to the start of learning and then after the monkeys had attained specific milestones in their learning. Following a pre-operative performance test and a final preoperative

scan, the monkeys received a fornix transection (there were 4 scans in total prior to surgery). An identical postoperative performance test was administered after 2 weeks of postoperative recovery and we collected a further four MR imaging datasets at regular intervals during post-surgery relearning. Behaviourally, as expected, monkeys learnt the task and, after fornix transection, their performance was markedly impaired. For the imaging data, we observed changes in functional connections (as measured by resting state correlations) and structural connections in extended hippocampal (medial temporal lobes and cingulate cortex) and prefrontal cortex regions associated with rapid within session learning of visual object-in-place information. These data suggest that cortical neural networks can reorganise at functional and structural levels during learning of an episodic-like memory task and after brain injury to a specific subcortical white matter structure.

Abstract: Stress is considered a potent environmental risk factor for many behavioral abnormalities, including anxiety and mood disorders. Animal models can exhibit limited but quantifiable behavioral impairments resulting from chronic stress, including deficits in motivation, abnormal responses to behavioral challenges, and anhedonia. The hippocampus is thought to negatively regulate the stress response and to mediate various cognitive and mnemonic aspects of stress-induced impairments though the neuronal underpinnings sufficient to

support behavioral improvements are largely unknown. Here, we acutely rescue stress-induced, depression-related behaviors by optogenetically reactivating DG cells that were previously active during a positive experience. A brain-wide histological investigation, coupled with pharmacological and projection-specific optogenetic blockade experiments, identified glutamatergic activity in the hippocampus-amygdala-nucleus accumbens pathway as a candidate circuit supporting the acute rescue. Finally, chronically reactivating hippocampal cells associated with a positive memory resulted in a rescue of stress-induced behavioral impairments and neurogenesis at time points beyond the light stimulation. Together, our data suggest that activating positive memories artificially is sufficient to suppress depression-like behaviors and point to DG engram cells as potential therapeutic nodes for intervening with maladaptive behavioral states.

Title: Specific contribution of CA1 to the reconsolidation of contextual fear memory: an optogenetic/Arc molecular imaging study

Authors: ***V. LUX**[1], O. MASSECK[1], S. HERLITZE[2], M. M. SAUVAGE[2];
[1]Ruhr-Universitaet Bochum, Bochum, Germany; [2]Ruhr-Universität, Bochum, Germany

Abstract: Reactivation of a stored memory can lead to instability, necessitating the restabilization of the trace. This so-called reconsolidation process can be blocked using amnestic treatments following the reactivation of the memory. Thereby, the restabilization of the trace is thought to be affected, resulting in impaired memory performance when tested several hours later. While the basolateral amygdala (BLA) is known to play a crucial role in the reconsolidation process, less is known about the specific contribution of the hippocampus, especially that of the CA1 subfield, which has been reported to be critically involved in the consolidation and retrieval of fear memory and thus might also play a major role in the reconsolidation process. To investigate the role of CA1 in the reconsolidation of fear memory and evaluate the long lasting effects of a perturbation of this process on the activity of the 'consolidation network', we blocked the restabilization of memory by inhibiting cell firing in

CA1 using optogenetics and measured the effect of this manipulation on memory performance and the activity of CA1, CA3 and the BLA upon reexposure to the conditioning context the following day. Inhibiting cell firing of CA1 following reactivation of the fear memory trace led to a significant decrease in freezing behavior when mice were exposed to the conditioning box the following day. Moreover, using a high resolution molecular imaging technique based on the detection of the immediate-early gene Arc, we could show for the first time that this memory impairment was paralleled by a reduction in cellular activity in CA1, CA3 and the BLA. Thus, our results suggest that CA1 might play an important role in the reconsolidation of contextual fear memory since blockade of cell firing in CA1 upon reactivation of the memory trace results in both behavioral and cellular effects at a network level.

Title: Imaging the spatio-temporal organization of "replay" in the CA1 region of awake mice

Authors: ***A. MALVACHE**, V. VILLETTE, S. REICHINNEK, R. COSSART;
INMED, INSERM U901, Marseille, France

Abstract: Sequential activation of hippocampal neurons has been shown to carry information about current, past or future locations. These sequences can be generated by external cues, as reported for the sequential exploration of place fields, as well as internally, for example during the delay period of a memory task. Sequences formed during spatial exploration have been shown to be re-activated at a shorter timescale during voluntary rest and sleep. This "replay" occurs during ripple events in the hippocampus. Here, we have studied awake replay using two-photon calcium imaging of neuronal activation in the CA1 region of the dorsal mouse hippocampus. Mice are head fixed but allowed to travel on a self-paced treadmill. We have previously shown that during run epochs, in the absence of external cues, CA1 neurons in the pyramidal layer are sequentially activated and that these sequences integrate the distance travelled by the mouse. During rest epochs, we have imaged the partial replay of these sequences that clustered into well-defined groups. A large fraction of such events occurred together with

ripple events recorded electro-physiologically from the contralateral CA1 hippocampus. We took advantage of chronic imaging to study the spatial patterning and evolution of replay events across days.

Title: Systematic data mining of hippocampal synaptic properties

Authors: *K. MORADI, C. L. REES, D. W. WHEELER, A. O. KOMENDANTOV, C. M. WHITE, D. J. HAMILTON, S. VENKADESH, M. SULIMAN, G. A. ASCOLI;
Krasnow Inst. For Advanced Studies, George Mason Univ., Fairfax, VA

Abstract: The synaptic properties of the rodent hippocampal formation have been extensively investigated for several decades. The amplitude, kinetics, and (short- and long-term) plasticity of excitatory and inhibitory potentials depend both on the type of pre- and post-synaptic neurons, and vary substantially among regions (e.g. dentate gyrus, CA3, CA1, and entorhinal cortex). While certain connections are better characterized (e.g. the Schaffer collateral from CA3 pyramidal to CA1 pyramidal cells), the lack of a systematic accounting of published synaptic data prevents a comprehensive comparison across pairs of neuron types. Hippocampome.org, a knowledge base that identified 122 neuron types based on morphological, electrophysiological, and molecular evidence, enables integration and dense coverage of the available synaptic data. The anatomical distribution of axons and dendrites exposes more than 3200 “potential connection” among neuron types (“Peters’ Rule”). Extensive literature mining indicates that fewer than 10% of these potential connections have been tested experimentally to date. Among those, synapses have been confirmed in approximately five-out-of-six neuron type pairs.

However, less than 50% of these known connections have been characterized electrophysiologically in peer-reviewed publications. In these cases, we are extracting information about synaptic amplitude, kinetics, and, when available, short-term and long-term plasticity. Due to widely non-uniform experimental methods and conditions, these data must be normalized to enable meaningful quantification. **Keywords**: microcircuits, neural networks, connectivity, neuroinformatics, physiology, neuron types

Title: The firing of medial septal PV+ interneurons reduces the population activity of CA1 pyramidal neurons - potential microcircuit mechanisms

Authors: ***D. JUSTUS**[1], F. FUHRMANN[1], L. SOSULINA[1], H. KANEKO[1], C. HANNES[1], T. BEUTEL[1], D. FRIEDRICHS[1], S. SCHOCH[2], M. FUHRMANN[1], S. REMY[1,3];
[1]German Ctr. for Neurodegenerative Dis. (DZNE), Bonn, Germany; [2]Dept. of Neuropathology, [3]Dept. of Epileptology, Univ. of Bonn Med. Ctr., Bonn, Germany

Abstract: During locomotion the hippocampal formation undergoes a transition to a state specialized for the processing of spatial information. This brain state is associated with strong field potential oscillations in the theta band (5-12 Hz). The medial septal nucleus and the diagonal band of Broca (MSDB) are known to be major pacemakers of hippocampal theta oscillations. Using fluorometric monitoring of GCaMP6 expressed exclusively in MSDB parvalbumin positive (PV+) interneurons, we showed that this cell-type increases its activity during locomotion. Expressing ChR2-EYFP (H134R) MSDB PV+ interneurons allowed optogenetic activation of these neurons at theta band frequencies. We observed that hippocampal LFP oscillations can be reliably driven by the firing of PV+ interneurons in the medial septum. Interestingly, using whole-cell patch-clamp recordings in awake mice, an increased synchrony of both subthreshold oscillations and action potential output could also be found on the level of

single CA1 pyramidal neurons. Rhythmic stimulation of glutamatergic VGluT2+ neurons in the MSDB had similar effects on LFP oscillations and synchrony of action potential output, consistent with a strong intraseptal interconnectivity of these neurons. However, following blockade of glutamatergic transmission locally in the MSBD with NBQX and D-AP5, the correlation of hippocampal theta frequency and locomotion velocity was strongly impaired and the amplitude of LFP oscillations induced by VGluT2 stimulation was strongly reduced. This finding confirmed a crucial role of PV+ interneurons and PV+ septo-hippocampal projections for the hippocampal theta rhythm. Two-photon imaging of GCAMP6 expressing CA1 pyramidal neurons through a cranial window in awake, head-fixed mice on a treadmill revealed a second interesting function of MSDB PV+ interneurons: Their firing reduced the activity of hippocampal principal cell population by about 25 %. This finding could be confirmed on the single cell level using in-vivo whole-cell patch-clamp recordings. Thus MSDB PV+ interneurons might be important regulators of CA1 population activity during locomotion. This effect could be mediated via an intraseptal inhibition of VGluT2+ neurons or a PV+ mediated regulation of CA1 microcircuits via septo-hippocampal projections.

Title: Postnatal choline supplementation ameliorates long-term disruptions in behavior and hippocampal gene expression resulting from fetal iron deficiency

Authors: B. C. KENNEDY[1], M. KOHLI[2], J. MAERTENS[2], M. T. PISANSKY[1], P. V. TRAN[3], *J. C. GEWIRTZ[2], M. K. GEORGIEFF[3];

Abstract: Iron deficiency during late fetal and early postnatal life can lead to persistent deficits in cognitive function. In rodent models these changes are accompanied by long-term disruptions in expression of hippocampal synaptic plasticity genes, which likely contribute to the poor

spatial and recognition memory observed in formerly iron deficient (FID) rats and mice. When given prenatally from embryonic day (E) 11-18, choline supplementation improves memory and normalizes hippocampal gene expression in adult FID rats. However, this treatment is translationally limited by the difficulty of assessing fetal iron status during prenatal development. Although choline supplementation given postnatally has also been shown to improve cognitive performance in rodents, this approach has not been assessed in iron deficiency. Iron-deficient (6ppm) or iron-sufficient (200 ppm) diet was provided to rats from E3 to postnatal day (P) 7. Half of the resulting offspring in each group were given choline supplementation from P11-30, for a total of four treatment groups: formerly iron deficient (FID), formerly iron deficient with choline supplementation (FID-C), iron sufficient (IS), and iron sufficient with choline supplementation (IS-C). The effects of gestational and postnatal diet on adult behaviors were assessed using novel object recognition (NOR), Barnes maze, and pre-pulse inhibition (PPI) tasks. In separate groups of adult animals, hippocampi were extracted and processed for analysis of gene expression using qRT-PCR. FID rats exhibited poor working memory in the Barnes maze and trended toward impaired recognition memory and PPI relative to IS controls. Postnatal choline supplementation of the FID-C group improved performance in working memory, NOR and PPI. However, choline supplementation of the IS-C group resulted in impaired reversal learning and working memory in the Barnes maze. Early life iron deficiency also disrupted expression of hippocampal synaptic plasticity genes relative to IS controls. Expression of many of the affected genes was normalized by postnatal choline supplementation. Consistent with the behavioral findings, choline supplementation itself dysregulated some genes in the IS-C hippocampus, suggesting an iron status-dependent effect of postnatal choline supplementation on hippocampal function and memory. Overall, postnatal choline supplementation could hold promise for mitigating the long-term effects of early life iron deficiency but may be detrimental when given to IS individuals.

Title: SCOP mediated circadian regulation of recognition memory

Authors: *K. SHIMIZU, Y. FUKADA;
Dept. Biol. Sciences, The Univ. of Tokyo, Tokyo, Japan

Abstract: Previous studies demonstrate that diurnal rhythm affects memory formation. However it is not yet clear if the internal clock regulates the efficiency of the memory formation, and there is no molecular-based evidence that connects the memory formation and circadian rhythms. Novel object recognition tests were performed with adult male mice over the circadian time. Long-term memory efficiency varied in a circadian manner and hence it seems to be controlled by the endogenous circadian clock. In fact, electrolytic lesion of the suprachiasmatic nucleus (SCN), the master circadian clock, disrupted the circadian rhythm of long-term memory formation. We are focusing on SCOP and related molecules to find molecular processes that connect the circadian clock with memory formation. SCOP is expressed in a circadian manner in the mouse SCN, and SCOP negatively regulates K-Ras function and its downstream ERK/MAPK pathway. In the hippocampus, SCOP is indispensable for long-term memory formation for novel objects. These data together suggest that SCOP-ERK pathway plays a key role for the circadian control of long-term memory formation in the hippocampus. SCOP knockdown by shRNA expression lentivirus or SCOP knockout in the hippocampus attenuated circadian oscillation of the long-term memory for novel objects. These data suggest that circadian regulation of long-term memory formation for novel objects is dependent on SCOP protein in the hippocampal neurons.

Title: Diabetes affects adversely and differentially the hippocampal neurogenesis during pregnancy and non-pregnancy period in young rats

Authors: *M. S. RAO, S. SHIVANANDAN, A. M. SONY;
Kuwait Univ., Jabriya, Kuwait

Abstract: The pregnancy period is one of the most plastic periods in a female's life. During this period many physiological, hormonal, cellular and molecular changes happen in the female body systems and nervous system which prepare the female for the challenges of motherhood. Certain neural mechanisms, neuronal plasticity, neurogenesis are affected differently during pregnancy and non-pregnancy physiological conditions. Hippocampal adult neurogenesis has been shown to increase during later part of pregnancy and decrease after delivery through lactation period in rats. Diabetes mellitus, a disease characterized by increased level of glucose in the blood, known to affect the hippocampal neurogenesis. Although literature indicated the deleterious effects of diabetes on developing fetus, there are only a few reports on its effects on the hippocampal dentate gyrus(DG) neurogenesis in pregnant women and experimental animals. The objective of the present experiment was to study the effects of diabetes during pregnancy and non-pregnancy period on hippocampal dentate gyrus (DG) neurogenesis. Adult pregnant female Wistar rats (4 months old) were divided into two groups(n=6 rats in each group). i). Normal pregnant rats(NP) - remained without any treatment till delivery, ii) Diabetic pregnant rats(DP)- Diabetes was induced in these pregnant rats by injecting streptozotocin (50mg/kg)intravenously through dorsal tail vein on 10^{th} day of gestation. Blood glucose level was measured to confirm the diabetic condition 48 hrs after STZ injection. They were maintained in sterile cages till delivery. After delivery rat pups were discarded and dams in both groups and age matched normal control (NC) and Diabetic Control (DC) rats were anesthetized with halothane, perfused transcardially with saline followed by 4% paraformaldehyde, brain was dissected and processed for frozen sections. Sections(30µm) were immunostained with doublecortin (DCX) to analyze the neurogenesis. Data were analyzed with one way ANOVA followed by Bonferroni's test. Results showed significantly decreased DG neurogenesis in DC group compared to NC($P<0.001$). Number of DCX positive neurons in NP rat was significantly more compared to DP group ($P<0.001$), however it was significantly increased compared to NC ($P<0.001$). Comparison of neurogenesis between DC and DP, DP showed significantly less new neurons ($P<0.01$). Results of our experiment suggests that, diabetes affects neurogenesis differentially during pregnancy and non-pregnancy period. We conclude that diabetes affects the neurogenesis adversely in the pregnant female rats, which may affect the their maternal behavior

Title: What happens to mouse hippocampal-dependent behavior and neurogenesis on the way to Mars? One small step for mousekind..

Authors: *A. J. EISCH[1], M. J. LUCERO[1], R. L. REDFIELD[1], N. ITO[1], D. R. RICHARDSON[1], R. P. REYNOLDS[1], G. PALCHIK[2], S. MUKHERJEE[1], A. K. WALKER[1], C. W. WHOOLERY[1], H.-Y. SHIH[2], P. D. RIVERA[1], S. G. BIRNBAUM[1], B. P. C. CHEN[2]; [1]Dept Psychiatry, [2]Dept Rad Oncology, UT Southwestern Med. Ctr., Dallas, TX

Abstract: Space radiation consists of high atomic weight and energy (HZE) particles. Chronic low doses of HZE particles - as will be encountered on deep space missions, such as to Mars - may be detrimental to astronauts by diminishing hippocampal function and thus may compromise mission success. Studies using ground-based space radiation and relatively young adult mice (2 months of age) show that HZE particles decrease hippocampal neurogenesis and performance on hippocampal-dependent tasks. However, it is unknown how HZE radiation influences the brain and behavior of “astronaut age” equivalent mice (6 months of age), or how it alters important hippocampal functions such as contextual discrimination. To fill these knowledge gaps, C57BL/6J mice (9-week old [Young Adult] or ~6-month-old [Mature] mice) were exposed to HZE particles (28Si, 275 MeV/n, 72.1 KeV/μm LET of a single exposure of 20 cGy, 100 cGy, or 0 cGy [Sham] or 56Fe, 600 MeV/n, 174.1 KeV/μm LET of a single exposure of 20 cGy [Non-fractionated], protracted dose of 20 cGy [Fractionated, 6.7 cGy x 3 days, 48h intervals], or 0 cGy [Sham]). General behavior (e.g. locomotion) and 2 hippocampal-dependent functions, contextual fear conditioning (CFC) and contextual discrimination fear conditioning (CDFC) were studied 2 to 6 months post-irradiation (IRR). After 28Si or 56Fe IRR, Young

Adult mice showed normal general behavior, but dose-dependent changes in CFC and CDFC performance. In contrast, while Mature mice displayed normal locomotor activity and normal CFC, they also showed a dose-dependent increase in contextual discrimination ability (CDFC) compared to Sham. The improvement in CDFC in Mature mice was unexpectedly not correlated with the number of new dentate gyrus neurons. Thus, HZE particle radiation unexpectedly enhances contextual discrimination in astronaut-age equivalent mice. We are currently investigating regulatory mechanisms underlying the age-related improvement in contextual discrimination after HZE radiation exposure, including the potential role of altered dentate gyrus neural circuitry and inhibitory tone, and the relationship between improvement in contextual discrimination and performance on other mission-relevant behavioral tasks.

Title: Image-guided cranial irradiation-induced ablation of dentate gyrus neurogenesis diminishes extinction of young - but not old - morphine reward memories

Authors: *M. L. MENDOZA, P. D. RIVERA, R. P. REYNOLDS, A. L. JUST, S. G. BIRNBAUM, A. J. EISCH;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Dentate gyrus adult neurogenesis is implicated in many hippocampal-dependent functions. However, the role of adult neurogenesis in context-dependent memory is unclear, as conflicting data exist on the role for them in retrieval and extinction of fear-associated memories. In addition, the role of adult neurogenesis in performance on reward-based context-dependent paradigms, like conditioned place preference (CPP), is particularly understudied. Here we used image-guided, hippocampal-targeted X-ray irradiation (IG-IR, 15 Gy) and morphine CPP to explore whether the dentate gyrus and in particular adult neurogenesis play a role in the retrieval or extinction of young and older reward memories in adult C57BL/6J male mice. Six weeks post-irradiation or Sham treatment, mice underwent morphine CPP (Pretest, Day 1; Pairing, Days 2-4 [saline AM, morphine PM, 7 or 15 mg/kg s.c.]). In keeping with prior work in cocaine CPP in rat, retrieval of a young memory of the morphine-paired chamber (Test, Day 5, 24h post-CPP) was similar in IG-IR and Sham mice. In addition, retrieval of an older memory (Test, Day 21, 3 weeks post-CPP) was also similar in IG-IR and Sham mice. However, extinction of a young memory of the morphine-paired chamber (Test, Days 5-24) was significantly and strikingly diminished in IG-IR mice compared to Sham mice. For example, while Sham mice extinguished a young drug-associated context reward memory in 6 days, IG-IR mice took more than twice as long (14 days). In contrast, extinction of an older memory (Test, Days 25-44) was roughly similar in IG-IR and Sham mice. Taken together, these data show that hippocampal-directed irradiation and the associated decrease in dentate gyrus adult neurogenesis interfere with extinction of young context-dependent reward memories. This work suggests that a reduction or loss of adult DG neurogenesis in humans may trigger or perpetuate the cycle of addiction.

Title: Opposite effects of behavioral experience on zif268 expression in mature and immature adult-born hippocampal neurons

Authors: *K. A. HUCKLEBERRY, G. KANE, R. MATHIS, S. COOK, M. R. DREW;
Ctr. for Learning and Memory, The Univ. of Texas At Austin, Austin, TX

Abstract: The dentate gyrus is one of the few brain regions that generates new neurons throughout adulthood. To investigate the contribution of adult-born neurons to hippocampal function, numerous studies have characterized the effects of behavioral manipulations on immediate early gene (IEG) expression in adult-born neurons. These studies suggest that adult-born neurons integrate into hippocampal circuits and are recruited into networks supporting hippocampus-dependent memory. However, studies of IEG expression in adult-born neurons have typically used c-Fos or Arc, which are expressed at very low levels in neurons less than about 4 weeks of age. Here we characterize behavior-evoked IEG expression using zif268, which is expressed robustly in immature neurons (Snyder et al., 2008). We first quantified zif268 expression in doublecortin-positive (DCX+) immature neurons and in the general granule cell population after brief exposure to a novel environment. In the general granule cell population, zif268 expression peaked 1 hour after novel environment exposure and returned to baseline by 8 hours post-exposure. However, in the DCX+ cells, zif268 expression was suppressed relative to home cage for at least 8 hours post-exposure. We next asked whether suppression of zif268 in DCX+ immature cells occurs in other behavioral paradigms that recruit the hippocampus. Exposure to Morris water maze training, an enriched environment, or a novel environment caused approximately equal suppression of zif268 expression in DCX+ cells and approximately equal activation of zif268 expression among the general granule cell population. The same behavioral procedures activated zif268 expression in 6-week-old BrdU-labeled adult-born neurons, indicating that zif268 suppression is specific to immature neurons. Finally, we asked whether zif268 suppression varied as a function of age within the DCX+ population, which ranges in age from 0 to approximately 4 weeks. Novel environment exposure had no significant effect on zif268 expression in 2- or 4-week-old BrdU-labeled neurons, but it significantly suppressed zif268 expression in 3-week-old neurons. In summary, behavioral experience transiently activated expression of zif268 in mature granule cells but caused a lasting suppression of zif268 expression in immature, adult-born granule cells. We hypothesize that zif268 suppression could function to prevent neurons from undergoing learning-related synaptic plasticity while they are immature or to support learning-induced apoptosis.

Title: Behavioral alterations following combined binge alcohol and nicotine exposure in adult rats: An analysis of spatial learning and memory

Authors: R. T. LINGG, A. M. FORMICA, A. C. ROCCAFORTE, *D. M. HAYES; Radford Univ., Radford, VA

Abstract: Excessive alcohol consumption has consistently been associated with drastic impairments in neurological functioning ranging from structural to complex behavioral abnormalities, but the long term cognitive effects of nicotine use are less clearly established. Within the adult brain, researchers have shown impairments from alcohol and nicotine abuse to specific components of adult neurogenesis. Specifically, research has shown that both binge alcohol consumption and chronic nicotine abuse result in a substantial depression of cell proliferation within the subgranular zone (SGZ) of the dentate gyrus of the hippocampus; an area associated with ongoing plastic developments involved in spatial learning and memory. Importantly, reduced neurogenic activity has been hypothesized to be a potential mechanism underlying alterations in spatial learning and memory performance, in addition to a modulation of affective states. As alcohol and nicotine are the most commonly co-abused substances, further elaboration regarding the behavioral correlates of their combined use is critical. To that end, adult male Sprague-Dawley rats were injected with nicotine (0.3 mg/kg in 0.9% saline) or vehicle every 8 hours for 10 days. For the final four days of exposure, rats also received intragastric intubations of an ethanol-containing diet (25% w/v in Vanilla Ensure Plus®) or control diet thrice daily (mean dose: 6.35 ± 0.31 g/kg/day). Following extinction of acute withdrawal behaviors (~18hrs) spatial learning and memory, in addition to thigmotaxis, were assessed using a Morris Water Maze task (Days 5 - 30 post-administration). A significant impairment, attributable to nicotine exposure, was observed in latency and swim distance required to reach the submerged platform. Further, nicotine administration was associated with an increased prevalence of anxiety-related behaviors during the initial acquisition phase. Ethanol, however, was not found to influence learning or thigmotaxis; suggesting that as early as five days post exposure, the effects of ethanol on behavioral functioning are negligible. Interestingly, dual ethanol and nicotine treatment attenuated the nicotine-induced learning impairment during an analysis of cognitive flexibility, potentially a result of the anxiolytic effects of ethanol. Thus, the pattern of inhibited neurogenic action produced by chronic exposure to nicotine may be

implicated in adverse behavioral outcomes, as evidenced by impaired spatial learning and memory performance.

Title: Effects of extremely low-frequency electromagnetic fields on olfactory memory in mice: role of increased neurogenesis and characterization of underlying molecular mechanisms

Authors: *A. MASTRODONATO[1], S. A. BARBATI[1], L. LEONE[1], C. COLUSSI[2], M. V. PODDA[1], C. GRASSI[1];
[1]Inst. of Human Physiol., Univ. Cattolica Med. Sch., Rome, Italy; [2]Inst. of Cell Biol. and Neurobio., Rome, Italy

Abstract: We recently demonstrated that exposure to extremely low-frequency electromagnetic fields (ELFEF) enhances hippocampal-dependent spatial learning and memory by increasing hippocampal neurogenesis (Leone at al., 2014). Aim of the present study was to investigate whether ELFEF stimulation also affects olfactory memory by modulating neurogenesis in the subventricular zone (SVZ) of the lateral ventricle. To address this issue we first performed behavioral tests on control (sham-) and ELFEF-exposed mice. We found that 30 days after the completion of ELFEF stimulation protocol (1 mT; 50 Hz; 3.5 h/day for 12 days) ELFEF-exposed mice showed a higher discrimination index between a familiar and a novel odor than controls (82.8 % and 61.3 %, respectively; $n = 8$; $p<0.05$). Sixty minutes after the first trial, animals were exposed again to the same odor for 5 minutes: ELFEF-exposed mice showed a significant decrease in the time of exploration on the second presentation than controls (4.3 ± 0.3 vs 8.1 ± 1.3 s, respectively; $p<0.05$) and an increased digging time near the odor previously rewarded (21.3 ± 0.4 vs 16.8 ± 3.9 s; $p<0.05$). Interestingly, immunohistochemical analyses performed in ELFEF-exposed mice revealed an increase in neural stem cell (NSC) proliferation, as assessed by the number of BrdU+ incorporating cells ($3,735 \pm 25$ vs $2,010 \pm 68$ in controls; $n = 3$ mice; $p<0.05$). The number of newborn NSCs differentiating towards the neuronal phenotype (i.e.,

BrdU+/DCX+ double-labeled cells) were similarly increased in the SVZ of ELFEF-exposed mice (3,303 ± 153 vs 1,746 ± 100 cells in controls; n = 3; $p<0.05$). These effects were associated with upregulated expression of mRNA encoding for the proliferation and pro-neuronal transcription factors Hes1, Mash1 and Wnt3, assessed by real-time PCR. To identify the molecular mechanisms underlying ELFEFs' effects, we extended our studies to an *in vitro* model of NSCs isolated from the SVZ of newborn mice. We focused our molecular analyses on Wnt/β-catenin signaling as critical regulators of adult SVZ neurogenesis. Real-time PCR showed a significant increase of Wnt3 mRNA in ELFEF-exposed NSCs. More importantly, upregulation of Wnt3 expression was associated with longer lasting expression of the transcription factor β-catenin in the nucleus of ELFEF-exposed NSCs. Accordingly, both Western blotting and immunofluorescence confocal microscopy revealed increased levels of β-catenin expression in the nuclei of ELFEF-exposed NSCs. Collectively, our findings suggest that ELFEF stimulation increases olfactory memory probably via enhanced Wnt/β-catenin signaling in the SVZ.

Title: Chemotherapy impairs cognitive performance and reduces neurogenesis in mice, independent of nutritional intervention

Authors: ***A. SHERIFF**[1], T. K. BHATHACHARYA[2], A. COBERT[3], C. RENDEIRO[2], H. CHEN[4], E. J. ROY[5], W. G. HELFERICH[4], J. S. RHODES[6];

Abstract: "Chemobrain" refers to long-lasting deficits in cognitive performance resulting from chemotherapy. Nonetheless, objective evidence for the existence of chemobrain is still lacking and the underlying mechanisms are debatable. One leading hypothesis is that the chemotherapeutic agents cross the blood-brain barrier and reduce the progenitor cell population in the hippocampus, a critical region for learning and memory that continues to generate new

neurons throughout life. The purpose of this study was to first determine whether a reliable behavioral deficit can be found in mice in response to administration of the chemotherapeutic agents standardly used to treat breast cancer in humans. Secondly, we aimed to address whether a nutritional intervention containing fish oil rich in omega-3 & 6 fatty acids could ameliorate those deficits in association with increased adult hippocampal neurogenesis. Mice received two doses of the chemotherapy treatment, specifically doxorubicin (IV, 4mg/kg), cyclophosphamide (IP, 80mg/kg) and 5-fluorauracil (IP, 40mg/kg) and were also injected with bromodeoxyuridine (BrdU, 50mg/kg) to label dividing cells. Following recovery from the chemotherapy, mice received intervention diets containing fish oil rich in omega-3 & 6 fatty acids or a standard control diet. Locomotor activity in the home cage and rotarod performance were assessed as well as learning and memory performance, as measured by Morris water maze (MWM), Y-maze and novel odor recognition. Our results show a significant spatial learning impairment in the MWM as a result of chemotherapy, specifically 2.5 months after treatment. This was also accompanied by a significant reduction in hippocampal neurogenesis in the chemotherapy animals. No changes in motor performance or locomotion were detected. On the other hand, supplementation with omega 3 and 6 enriched fish oil did not rescue the chemotherapy-induced deficits in learning or neurogenesis. Overall, our results strongly suggest a long-term effect of chemotherapy on both behavioral and neurological measures. As such, the present chemotherapy model might be useful in future studies to investigate dietary strategies or other types of interventions aimed at ameliorating chemotherapy cognitive impairments.

Title: Thalamic stimulation in awake rats induces neurogenesis in the hippocampal formation

Authors: F. CHAMAA, W. SWEIDAN, Z. NAHAS, N. SAADE, *W. ABOU-KHEIR; American Univ. of Beirut, Beirut, Lebanon

Abstract: Background: Deep brain stimulation (DBS) provides substantial clinical benefits for a variety of movement disorders and lately emerged as a potential treatment for cognitive and mood disorders. Regulation of adult hippocampal neurogenesis may play a chief role in mediating DBS effects. Objective: To investigate the effects of unilateral anteromedial thalamic nucleus (AMN) stimulation on adult hippocampal neurogenesis in awake and unrestrained rats. Methods: Four groups of adult Sprague-Dawley male and female rats received unilateral stimulation (n=6 each) or sham surgery of electrode implantation with no current delivery (n=4 each) in the right AMN; another group of males (n=4) was stimulated in the right ventral posterolateral thalamic nucleus (VPL). A naïve group of males and females (n=4 each) was also included. Rats received 4 injections (50mg/Kg/injection) of 5'-bromo-2'-deoxyuridine (BrdU) 3 days post-surgery and were euthanized 24h later. The fractionator method was used together with confocal immunofluorescent analysis to probe for BrdU-, GFAP- and NeuN-positive cells in the dentate gyrus (DG) and hilar zone of the hippocampus. Results: Focal neurogenesis was induced in the ipsilateral DG after AMN and not VPL stimulation. Stimulation-induced effects were gender-independent and translated into a 76% increase in proliferation of neural stem/progenitor cells. Increased neurogenesis was most prominent at the caudal region of the DG, while no effect was detected in the hilar and the subventricular zones. Conclusions: The current study presents an exclusive hippocampal neurogenic response to AMN and not VPL stimulation; thereby suggesting the possible involvement of the components of Papez circuitry in mediating DBS effects and in the treatment of cognitive and behavioral disorders.

Med. Sci., Stem Cell Lab. for CNS disease Modeling,, Lund University, Sweden

Abstract: In mouse models of Alzheimer's disease, neurogenesis is impaired and the granule neurons that are generated fail to integrate existing networks. As new granule neurons participate to memory capacities, we hypothesized that enhancing neurogenesis should improve functional plasticity in the hippocampus and restore cognitive deficits in these mice. Thus, we performed a screen of transcription factors that could potentially enhance adult hippocampal neurogenesis. We identified Neurod1 as a robust neuronal determinant with the capability to direct hippocampal progenitors towards an exclusive granule neuron fate. Importantly, Neurod1 also accelerated neuronal maturation and functional integration of new neurons. When tested in an APPxPS1 mouse model of Alzheimer's disease, directed expression of Neurod1 in cycling hippocampal progenitors conspicuously reduced dendritic spine density deficits on new hippocampal neurons, to the same level as that observed in healthy age-matched control animals. Remarkably, this population of highly connected new neurons was sufficient to restore spatial memory in these diseased mice. In order to get insights into the mechanisms triggered by Neurod1, we focused on mitochondria, which functions are deeply impaired in neurodegenerative diseases such as Alzheimer's disease. We examined the contribution of mitochondria to neuritic maturation and spinogenesis in primary neurons and determined the impact of targeted expression of Neurod1 on the mitochondrial content of hippocampal adult-born neurons in our mouse model of AD.

Title: GSK3β isoform-selective regulation of depression-like behavior, novel object recognition and hippocampal neural precursor cell proliferation

Authors: *M. PARDO, E. ABRIAL, R. JOPE, E. BEUREL;
Departments of Psychiatry and Biochem., Univ. of Miami, Miami, FL

Abstract: Abnormally active glycogen synthase kinase-3 (GSK3) has been demonstrated to contribute to multiple pathological processes in mice, such as increasing susceptibility to dysregulation of mood-relevant behaviors, impairing performance in several cognitive tasks, and impairing adult hippocampal neural precursor cell proliferation. These deficits are all evident in GSK3α/β knockin mice, in which serine-to-alanine mutations block the inhibitory serine phosphorylation regulation of both GSK3 isoforms, leaving GSK3 hyperactive. In order to test if either GSK3 isoform has a predominant effect in each of these pathologies, here we examined these characteristics in GSK3α knockin mice and GSK3β knockin mice in which only one isoform was mutated. Only GSK3β, not GSK3α, knockin mice displayed heightened vulnerability to the learned helplessness model of depression-like behavior. Three cognitive measures that are impaired in GSK3α/β knockin mice demonstrated differential regulation by GSK3 isoforms. Novel object recognition was impaired in GSK3β, not GSK3α, knockin mice, but temporal order memory was not impaired in GSK3α or GSK3β knockin mice and coordinate spatial processing was impaired in both GSK3α and GSK3β knockin mice. Adult hippocampal neural precursor cell proliferation is impaired in GSK3α/β knockin mice and there was a severe impairment in GSK3β knockin mice, but no impairment in GSK3α knockin mice. These results demonstrate that hyperactivity of the two GSK3 isoforms display very different effects in the regulation of these processes. Specifically, increased activity of GSK3β, in the absence of additional disease pathology, is sufficient to impede mood regulation, novel object recognition, and hippocampal neural precursor cell proliferation, whereas hyperactive GSK3α does not impair these processes.

Title: Synaptic plasticity with dendritic computing achieves the association of preplay patterns and place fields in hippocampus

Authors: *T. HAGA, T. FUKAI;
RIKEN Brain Sci. Inst., Wako-Shi, Saitama, Japan

Abstract: The firing sequence of hippocampal place cells experienced in exploration is repeatedly replayed in spontaneous activity. It is often bidirectionally replayed (forward replay and backward replay) and thought to be related to path integration and memory consolidation. However, it was recently found that the same sequence is observed before the experience, which is called preplay. This cannot be realized without the association of predefined firing sequences in the hippocampal recurrent circuit and novel sensory input patterns in the path that have never been experienced and it have not been realized in previous hippocampal models. In this presentation, we propose that such learning can be achieved by synaptic plasticity caused by dendritic calcium spikes of hippocampal pyramidal neurons. Calcium spikes in the apical dendritic shaft detect the coincident inputs between apical and basal dendrites (Shai et al., PLOS Computational Biology, 2015) and cause long-term potentiation of synaptic conductance (Gambino et al., Nature, 2014; Cichon et al., Nature, 2015). We assumed two-compartmental neuron model, and synapses in each compartment were modified by single-compartmental Bienenstock-Cooper-Munro (BCM) theory and a positive cross term that corresponds to the effect of calcium spikes. Using this model, we simulated CA3 network which has afferent inputs with random initial weights in apical dendrites and recurrent connections that spontaneously generate replays and theta sequences (Romani et al., Hippocampus, 2014) in basal dendrites. It could be mathematically proven that this learning rule maximizes the correlation of activations of two compartments. Furthermore, simulation results showed that, after learning, weight distribution of afferent synapses became spatially localized and neurons which were connected with strong recurrent connection acquired the similar receptive fields for adjacent positions. It means that place fields were created in association with preplay patterns. From these results, we concluded that synaptic plasticity caused by dendritic calcium spikes is one of considerable elements to model preplay.

Title: An efficient coding theory for a dynamic trajectory predicts non-uniform allocation of grid cells to modules in the entorhinal cortex

Authors: ***N. WEISS**[1], A. MORIEL[1], H. AGMON[2], Y. BURAK[2,1];
[1]Racah Inst. of Physics, [2]Edmond and Lily Safra Ctr. for Brain Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Recent experiments established that grid cells in the entorhinal cortex are functionally organized in discrete modules with uniform grid spacing. The ratios of grid spacing approximately form a geometric series. This result is in agreement with recent theories, which postulate that grid cells implement an efficient code for the animal's position. However, the experimental data suggests also that the number of cells decreases sharply with grid spacing, in marked disagreement with existing theories. Here, we postulate that the entorhinal cortex is adapted to represent a dynamic quantity (the trajectory of the animal in space), while taking into account the temporal statistics of this variable. We first develop a theory for efficient coding of a variable that dynamically follows the statistics of a simple random walk. A central prediction of the theory is that module neuron population sizes should sharply decrease with the increase of grid spacing, in agreement with the trends seen in the experimental data. Another prediction is that the ratio between grid spacings should approach a constant value in the modules with the smallest spacing. The predicted ratio is , which is consistent with experimental data and with previously proposed models. Next, we identify a remarkably simple, near optimal scheme for readout of the grid cell code by neural circuitry, in which model place cells linearly sum inputs from grid cells, using an exponential temporal kernel, whose decay time depends on the spacing of the presynaptic grid cell. Using estimates for the total number of grid cells in the entorhinal cortex, and the statistics of rodent motion, the time scales should range from ~1ms to ~1s, depending on the grid cell module. Thus, the simple readout requires mechanisms for persistence over this range of time scales. The simple readout scheme can be optimized for trajectories that deviate in their temporal statistics from a simple random walk. As an extreme case we consider motion at constant velocity in an unknown direction. Even for such motion, we obtain from the optimization qualitatively similar results as for random walk statistics. Thus, we propose that the

sharp decrease in module population sizes, with increase of the grid spacing, is an outcome of the efficient coding hypothesis, if the dynamic nature of motion in space is taken into account.

Title: Prefrontal cortex reservoir network learns to reconstruct navigation sequences by concatenating place-cell snippets replayed in hippocampus

Authors: N. CAZIN[1], J.-M. FELLOUS[3], A. WEITZENFELD[4], *P. F. DOMINEY[2];
[1]Human and Robot Cognitive Systems, [2]INSERM U846, Bron, France; [3]Dept. of Psychology, Univ. of Arizona, Tucson, AZ; [4]Dept. of Computer Sci. and Engin., Univ. of South Florida, Tampa, FL

Abstract: Introduction: Spatial navigation in the rat involves the reactivation of hippocampal (HIP) place cells during quiet awake and sleep states. This generates short sequences of place cell activation in the order they are traversed that we call ‘snippets’. In a spatial learning task, the complete trajectory can be characterized by a set of overlapping snippets. We hypothesize that during active learning, the forward HIP replay of snippets contributes to the learning of the complete sequence in PFC. Methods: We model PFC as a recurrent reservoir network of 1000 leaky integrator neurons, with fixed recurrent inhibitory & excitatory connections, and modifiable readout connections. Readout neurons feed-back into the reservoir, allowing autonomous sequence reproduction and generation. We performed experiments where the model learned and generated the learned sequences autonomously, varying sequence length, complexity, reservoir size and noise. We then performed snippet experiments: complete sequences were split into partially overlapping subsequences of place cell activation. During training, snippets were presented in a random order. The system was then tested on its ability to generate the complete sequence after priming on the first 3 elements. Sequence length varied from 9 to 18, snippet length varied from 5 to 10, overlap varied from 2 to 8. We also tested a sparse snippet condition where elements were systematically eliminated from the snippets, so that no complete snippet was presented. Results: The reservoir displayed robust learning of

sequences of different length (10-20 elements) and complexity (1st and 2nd order). The reservoir displayed robust snippet learning, including reproducing a sequence of 18 elements, made from 3 snippets of length 10 and overlap 6. The sparse condition required 2000 neurons. Analysis of reservoir state trajectories by PCA demonstrates that the system exploits snippet overlap to learn the transitions between snippets and reconstruct the entire sequence. Discussion: These results are consistent with the hypothesis that snippet replay in HIP contribute to sequence learning in PFC. Snippets do not have to be contiguous, but they should maintain the correct order of place cell firing. This ability to align snippets depends on the fading memory property of the reservoir. This research demonstrates that the reservoir computing framework can provide novel insights into distributed coding in PFC.

Title: Retrosplenial cortical neural populations simulate future trajectories

Authors: ***A. M. MILLER**[1], W. MAU[2], H. LI[1], K. YU[1], S. PARAUDA[3], D. M. SMITH[1]; [1]Cornell Univ., Ithaca, NY; [2]Boston Univ., Boston, MA; [3]Weill Cornell Med. Col., New York, NY

Abstract: The retrosplenial cortex (RSC) plays a prominent role in learning and memory. The RSC is a major component of the default network, a group of cortical memory structures involved in generative memory processes including autobiographical memory, constructive memory, and self-projection. Many of the structures that make up the default network have been implicated in the representation of future goals, outcomes, or behaviors. For example, in rats, the hippocampus has been shown to uniquely encode trial types associated with distinct trajectories (Wood et al., Neuron, 2000) and to represent spatial locations ahead of the rat during periods of vicarious trial-and-error (Johnson & Redish, J Neurosci, 2007). Similarly, we have found that many RSC neurons fire differently on the stem of a t-maze when during left and right turn trials in an alternation task (Miller et al, 2014, SFN Abs, 465.11). Given that fMRI findings suggest a role for the RSC in self-projection and generative memory processes, we hypothesized that

neural activity related to future goals and trajectories would be observable in rodents. Specifically, we test the hypothesis that the RSC encodes future spatial and reward locations by recording neural ensembles in the RSC of rats while they performed a continuous spatial alternation task that we have shown to require the RSC (Miller & Smith, 2012, SFN Abs, 706.06). Prior to training, a microdrive with 16 independently movable tetrodes was implanted bilaterally over the granular b region of the RSC. Recording began on the first day of training and continued through asymptotic performance. Consistent with previous results, we found that 46% of RSC neurons encoded spatial locations on the maze (i.e., place cells) and 58% encoded reward-location conjunctions. Additionally, we used Bayesian decoding to compute the rat's instantaneous location given ensemble spiking and compared the probability that the rat was located along its future trajectory, p(future), to the probability that the rat was located along the trajectory that it would not visit on that trial, p(non-visited). This analysis revealed that RSC neuronal populations more strongly represented future trajectories (p(future) - p(non-visited) was greater than 99.9% of shuffled outcomes). These findings provide a link between human literature on self-projection within the default network and neuronal recordings in rats during spatial navigation tasks, and are consistent with a role for the RSC in the use of memory representations to support the simulation of future behavior.

Title: An attractor model of probabilistic localization

Authors: ***I. KANITSCHEIDER**[1], A. POUGET[2,3,4], I. FIETE[5];
[1]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Dept. of Basic Neurosci., Univ. of Geneva, Geneva, Switzerland; [3]Dept. of Brain and Cognitive Sci., Univ. of Rochester,

Rochester, NY; [4]Gatsby Computat. Neurosci. Unit, London, United Kingdom; [5]Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: To self-localize during navigation, animals integrate a wide range of spatial and movement cues of varying reliability. The optimal strategy would exploit all these cues, but with appropriate weighting. Reliability-unaware strategies are typically inaccurate and error-prone. How the brain computes and represents reliability, and how it uses this information in its position estimates is still largely unknown. In our model, an animal runs through a familiar one-dimensional track with a few landmarks. It has access to a noisy velocity signal (the noise is Gaussian) and when it encounters a particular landmark, it knows where it is up to some uncertainty described by a Gaussian of a known width for that landmark. In this scenario, a Kalman filter is the optimal location estimator. We search for a neural implementation of the Kalman filter with localized location tuning and coding of reliability. The first possibility is to encode location with a bump attractor, with bump height encoding the reliability of the estimate. For Gaussian tuning curves, the stable manifold of such an attractor is nonlinear, and we require a proper nonlinearity to project out deviations from the stable manifold. We show that an attractor with a divisive normalization-type nonlinearity can support Gaussian tuning curves of variable height. We then generalize the model so that it can perform location updates in response to a velocity signal, correctly decrement reliability in the absence of landmarks, and integrate landmark information when they are present. The experimental signature of such a model would be to find place or grid cells with lower firing rates when the reliability of location cues is reduced. The second possibility is to encode location with a one-dimensional attractor with fixed bump height and compute reliability in a separate population. The velocity signal updates the line attractor in a conventional manner, while the reliability information is used to calibrate the relative gain of the landmark input before it is used to update the bump position. Experimentally, this model predicts neurons purely tuned to reliability, but not to location. We comment on the advantages and disadvantages of each model and show that both perform very closely to the optimal Kalman filter. We also consider extensions of the model to the multidimensional case.

Title: A model of cognitive navigation inspired by the hippocampus

Authors: *A. V. SAMSONOVICH, G. A. ASCOLI;
Krasnow Inst. Adv Study, George Mason Univ., Fairfax, VA

Abstract: I am lost in a large, empty office building after business hours, and am looking for a restroom. As I enter a corridor from the staircase, I see an exit from the building on my right and an elevator on my left. I am intuitively confident I should turn left. As I pass the elevator, I spot a drinking water fountain on the right and a meeting room on the left. I head for the fountain and immediately see a restroom next to it. In contrast, the choices would be non-trivial for a state-of-the-art artificial intelligence (AI) system placed in the same situation. Indeed, efficient search strategies require either some prior knowledge of the environment (which is not assumed) or some human-level general world knowledge; otherwise uninformed search would be deemed the best strategy. Most spatial learning and navigation problems today are not considered AI-hard. Yet, there is a certain class of seemingly simple problems that still resist mainstream approaches. We call them cognitive navigation problems, referring to navigation of unknown or unpredictable environments that may require analogical reasoning, generalization, common sense, intuition, creativity, insight, theory of mind, and other forms of imprecise inductive reasoning. AI typically attempts to implement these functions using top-down approaches. Yet, we usually solve such problems in real life without logical reasoning. This work explores a plausible account of this process based on statistical learning of remotely similar environments in a model inspired by our previous studies of the rodent hippocampus (Samsonovich and Ascoli, Learning & Memory 2005; BICA 2013). A test paradigm to compare model and human performance involves exploration and then navigation of previously unseen, randomly generated labeled graphs. Features that are close to each other in one graph are typically found close to each other (if present) in other graphs as well; otherwise the graphs are dissimilar. The model network includes three layers: place cells, feature cells, and goal cells. Neuronal activity represents the current location of the actor. Exploration of available moves reveals nearby features that serve as cues in pathfinding. Preliminary simulations using graphs of 100 nodes with 30 kinds of features show that the network reaches the goal in an unseen graph after 15.1 steps on average, using less than 100 steps in 96% of all sessions. The resultant solution outperforms traditional methods, including Q-learning and Canadian Traveller Problem solvers. Expected outcomes include big data search tools, personal assistants, and a new insight into the hippocampal function. We are grateful to Prof. Theodore C. Dumas for valuable discussions.

Title: A neural computation model of the goal direction based on the reactivation of place cells, grid cells and stripe cells

Authors: *J. K.-S. LAI[1], M. S. MITSUZAWA[2], Y. YAMAGUCHI[2];
[1]Kyushu Inst. of Technol., Kitakyushu, Fukuoka, Japan; [2]NIJC, RIKEN BSI, Wakoshi, Saitama, Japan

Abstract: Place cells in the hippocampus and grid cells in the entorhinal cortex are known to be key components of the navigation system in rodents and primates. In addition, grid cells are known to show band-like firing properties. These cells may reflect neurons with a spatially periodic firing pattern with a conjunctive head direction preference as a subclass of grid cells, what we call stripe cells below. Although various types of neural firing have been experimentally demonstrated, the neural network mechanism for spatial navigation is still an open question. In this paper, we propose a model of neural computation of goal direction from a given position. The model consists of a stripe cell layer, a grid cell layer, a place cell layer and the reactivation monitoring system. The stripe cells have the ability of displacement integration with head direction preference, a group of which can generate the firing of grid cells. Each place cell has an association with a population of grid cells. We assume that the reactivation of place cells in a random manner is associated with stripe cells and grid cells. The reactivation monitoring system is composed of circular neural network attractors with input from stripe cells. The random displacement in arbitrary reactivation can be integrated to give a population vector representing the shortcut pathway to the goal. Our computer simulation successfully demonstrated the computation of a goal direction population vector in the reactivation monitoring system using continuous attractors. Thus, our model suggests the importance of concurrent reactivations of place cells and grid/stripe cells in navigation.

Title: Distal cue configuration-dependent rate remapping in the hippocampal place cells in an allocentric memory task

Authors: *S.-B. PARK, I. LEE;
Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Rats use distal cues for allocentric spatial navigation and the firing patterns of hippocampal place cells are influenced by distal cues. However, distal cue manipulations were made irrespective of task demand in most studies, or no memory demand was present between particular distal cue configuration and behavior. We investigated whether place cells fired in association with specific distal cue configurations in a task-dependent manner if a behavioral task required so. Rats (n=4) ran along a linear track at the end of which a choice should be made between two food wells. A correct response was associated with a particular distal cue configuration. A distal cue configuration was defined by the angular distance between two curtains (cue curtains) each of which contained a set of visual cues. The cue curtains were movable along the ceiling curtain track to make the following angular distances between the curtains: 0°, 14°, 66°, and 80°. The rat was initially trained to choose the left food well when the cue curtains were separated by 0°, but the right food well for 80°. After the rat learned the task to criterion, a hyperdrive was implanted and the rat was overtrained with the same paradigm. Once the recording began, the new cue configurations (14° and 66°) were intermixed with the original configurations. When facing the new configuration, the rat was required to choose the left or right food well according to its angular proximity to the original cue configurations. Rats were able to make correct choices significantly at above chance for all cue configurations. Our previous study demonstrated that inactivating the dorsal hippocampus impaired normal performance in this task. We recorded putative complex spiking units (n=114) simultaneously in CA1 of the dorsal hippocampus as the rat performed the task. There was minimal spatial remapping in place fields across different cue configurations within a session, but diverse patterns of in-field rate modulation (rate remapping) were observed in place cells across cue configurations as follows: (i) upcoming response-related firing (elevated firing for a particular food-well choice), (ii) cue novelty-related firing (elevated firing for either original or newly

introduced cue configurations), and (iii) mixed firing (rate modulation patterns not belonging to either (i) or (ii)). The three types of cells seem to exist at equal proportions in the hippocampus (approximately 33% for each). We will further investigate this neural phenomenon to find whether these neuronal firing patterns can predict the rat's behavior in the task.

Title: Computational investigation of the direct transformation of grid cell spike activities into hippocampal ramp-like input and spike phase precession of place cell

Authors: *S. PARK, J. KWAG;
Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

Abstract: Hippocampal place cell is a spatial information processing neuron where individual spike of place cell within the place field shows spike phase precession; spike phases advance 360° relative to the hippocampal theta oscillation, coding for the specific location within the place field. However, the exact mechanism underlying the spike phase precession is still unclear. Whole-cell patch-clamp recording of place cells in the hippocampal CA1 *in vivo* revealed that place cells receive asymmetric excitatory ramp-like input (ERI) in the place field. Therefore, investigating the source of hippocampal ERI could shed light on the cellular and network mechanism underlying spike phase precession. Since neurons in hippocampal CA1 receive excitatory afferent directly from layer III of medial entorhinal cortex (MEC), it is possible that the grid cells in MEC, another spatial information processing cells that spike in grid-pattern, could contribute to the ERIs observed in place cells and consequently to phase precession. Therefore, we used the oscillatory interference (OI) grid cell model and Hodgkin-Huxley (HH) place cell model to investigate the above hypothesis. Simulated grid cell spikes were modeled to give excitatory synaptic input to a distal dendrite of the HH place cell model using the single exponential function to mimic MEC-CA1 connection. Simulations and analysis were done using the NEURON and MATLAB. Each simulated grid cell spike was transformed into excitatory postsynaptic potentials (EPSPs) in the hippocampal place cell HH model, and grid-patterned

spikes resulted in summated EPSPs, giving rise to ERIs. 45% of transformed ERI were right-skewed (R-ERI), 22% were symmetric ERI (S-ERI), and 33% were left-skewed ERI (L-ERI). When R-ERI was superimposed with theta oscillation in the place cell HH model, spike phase precession occurred over distance with strong negative correlation ($\rho = -0.58$). In contrast, L-ERI showed spike phase recession with positive correlation ($\rho = 0.68$), and S-ERI had nearly no correlation ($\rho = 0.09$). Our simulation results show for the first time that grid cell spikes providing excitatory input to the place cell can be directly transformed into different shapes of hippocampal ERIs. Moreover, R-ERI with theta oscillation could give rise to spike phase precession while L-ERI could give rise to spike phase recession. Direct transformation of grid cell spikes into hippocampal phase precession suggests that grid cell activity could serve as one mechanism underlying place cell spike phase precession. Future *in vivo* testing of our results will lead us to better understand spatial information processing in the entorhino-hippocampal circuitry.

Title: Why the entorhinal grid map is discretized: how a geometric progression of grid scales enables goal-directed navigation, error correction and modular arithmetic

Authors: *M. B. STEMMLER[1], A. MATHIS[2], A. V. M. HERZ[1];
[1]Ludwig-Maximilians-Universität Munich, Planegg, Germany; [2]Dept. of Mol. and Cell. Biol. and Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Grid cells in medial entorhinal cortex exhibit a discrete set of length scales, such that the representation of space ranges from coarse to a fine (Stensola et al. 2012). Discrete modules permit a biologically plausible population vector read-out of the distance and direction towards goal locations (Stemmler et al. 2014). We show that such a read-out can be made robust to distortions in the regular grid pattern near the boundaries of the environment (Stensola et al.

2015) to permit a global grid-cell metric. While a continuum of grid scales would also permit a population-vector read-out, we prove that significant precision is lost in a continuum, even though an ideal observer receives the same amount of spatial information from the population of grid cells. The maximal spatial range represented in the grid code is the product of all scales, provided that no two scales can be evenly divided by the same (non-trivial) integer factor (Fiete et al, 2008). Such an arrangement would permit the grid code to function as a *residue number system.* We quantify the likelihood of making catastrophic mistakes in a probabilistic model of grid cell firing. In the limit of high noise and low firing rates, we show that the grid code should not use a classical residue number system. Instead, the optimal grid code relies on a geometric progression of scales so that the ratio from one scale to the next is fixed to 3:2. This strategy reduces the spatial range encoded in the population to 2^{L-1} times the longest length scale, where L is the number of discrete modules, but minimizes mistakes.

Title: From grid cells to place cells with realistic field sizes

Authors: *T. NEHER[1,2,3], A. AZIZI[4], S. CHENG[4,3];
[1]Ruhr-university-Bochum, Bochum, Germany; [2]Dept. of Psychology, Mercator Res. Group "Structure of Memory", Ruhr-University Bochum, Germany; [3]Internation Grad. Sch. for Neurosci., Ruhr-University Bochum, Germany; [4]Dept. of Psychology, Mercator Res. Group, Ruhr-University Bochum, Germany

Abstract: Grid cells in the medial entorhinal cortex (EC) have spatial receptive firing fields (place fields) highly ordered on a hexagonal grid. However, just one synapse downstream, hippocampal place cells mostly express one large place field. An ongoing debate in the field is about whether the place cells are created by the input from grid cells in a simple feedforward network. Initially, after the discovery of grid cells, it was widely believed that the simple

transformation form grid to place cells was plausible. However, recent experiments have called this hypothesis into question, when they found that grid cells were highly degraded in certain conditions, while, at the same time, place cells appeared normal. Then again, subsequent modeling studies have found evidence that these experimental results are consistent with a transformation form grid to place cells in a feed forward network since the transformation is robust to noise in the grid cell inputs. However, all the extant models that produce place cells with robust place fields suffer from an issue that has received little attention so far. The place fields are rather small, not comparable to the place fields found in the CA regions. Here, we first study the computational issues for the creation of large single fields solely out of grid input in such a network. We then propose a model that generates place cell firing based on inputs from grid cells and nonspatial cells, that are only weakly spatially modulated and abundant throughout the EC. This simple model reproduces many place cell characteristics as well as results from studies in lesioned animals and make some clear predictions. This work strongly suggests that place cells are not the result of feedforward drive from grid cells alone.

Title: A computational model of information-flow in the hippocampal formation of the rat

Authors: ***M. PYKA**[1], S. CHENG[2];
[2]Mercator Res. Group "Structure of Memory", [1]Univ. of Bochum, Bochum, Germany

Abstract: The hippocampus is a subcortical structure that is not only known for its important role in episodic memory and navigation but also for its complex 3-dimensional shape. Within and across species, there are differences in its absolute size, its exact shape and its embedding in the rest of the brain (Manns & Eichenbaum, 2006)□. Its internal structure and function are, however, assumed to be conserved across mammals (Allen & Fortin, 2013; Manns & Eichenbaum, 2006)□. Since changes of the form, size and connectivity of network structures are very prominent traits of evolutionary variations, one interesting question is: Does the morphology of the network have an affect on its functioning? To investigate this question, we

created a 3d-anatomical model of the rat hippocampus using Parametric Anatomical Modeling (PAM). PAM facilitates the translation of large-scale anatomical data into a formal description of neural networks with connection patterns and connection lengths derived from anatomical features of the biological network (Pyka and Cheng 2014). Based on this model, we computed connection lengths between entorhinal cortex and various areas within the hippocampal loop. In combination with axon caliber distributions reported by experimental studies transmission delays between the subregions in the hippocampal formation were calculated. With these data, we reconstructed the information flow within the hippocampal loop, that is the timing and temporal order, in which spiking activity propagates through the network. Our simulation results are consistent with reports from experimental studies (Mizuseki et al. 2009, Montomgery et al. 2009) and predict delay-distributions that can be experimentally tested in future studies. Moreover, we found in some areas (e.g. entorhinal cortex, CA3 and CA1) significant dependencies between transmission time and position of the neuron along anatomical axes. Thereby, the data provide estimates of how spatial relations between different brain areas affect functional and other structural properties of the network. Additionally, our simulations of information flow constrain the space of computational models of hippocampal functions.

Title: A parametric anatomic model of the pigeon hippocampal formation

Authors: *R. GÖRLER[1], O. GÜNTÜRKÜN[2], M. PYKA[3];
[1]Mercator Res. Group Structure of Memory, [2]Dept. of Biopsychology, Fac. of Psychology, [3]Mercator Res. Group "Structure of Memory", Ruhr-Universität Bochum, Bochum, Germany

Abstract: Comparative analyses of brains of different species are indispensable in order to understand how function emerges from structure. One key idea is that fundamental properties of neural circuits and information flows are broadly conserved across species despite tremendous species-specific differences in size, shape and connection scheme of the network. The hippocampus is a prime example suitable for studying general principles of nervous system organization as it seems to be structured differently in mammals and birds but is known to play an important role in memory consolidation and spatial navigation in both taxa. The pigeon

(Columba Livia) with its extraordinary navigational abilities is, therefore, a promising candidate for comparative studies of the hippocampal formation. In this study, we present a three-dimensional model of the pigeon hippocampal formation that was constructed using Parametric Anatomical Modeling. This modeling technique facilitates the translation of large-scale anatomical data into a formal description of neural networks with connection patterns and connection lengths derived from anatomical features of the real network. The pigeon hippocampus model comprises the state of research regarding subdivisions and interconnections while allowing for the connection properties to be further parametrized. We demonstrate how the model can be used to reveal temporal patterns of network activity based on connection lengths computed from the 3d model and axon diameter distributions. We further provide several estimates about the information flow in the pigeon hippocampus which can experimentally be tested in future studies. In combination with a previously presented 3d hippocampus model of the rat, we show how 3d computational models can be exploited to help comparative neuroscience to identify common and species-specific features of the hippocampal formation.

Title: The role of semantic representation in episodic memory

Authors: ***J. FANG**, S. CHENG;
Ruhr-University Bochum, Bochum, Germany

Abstract: It is widely, albeit not universally, believed that episodic and semantic memory are distinct forms of memory. Mounting experimental evidence suggests that the hippocampus is required for episodic memory, but not for semantic memory. The latter appears to be stored solely in the neocortex. This dissociation does not, however, imply that episodic and semantic memory operate independently or recruit non-overlapping brain resources. Over the years, many authors have suggested various theories about the interdependence of episodic and semantic

memory. Tulving's SPI model (1995) specifies different kinds of interdependence: serial encoding, parallel storage and independent retrieval. While Baddeley (1988) viewed semantic memory as the "accumulated residue" of multiple learned episodes. Recently, Greenberg and Verfaellie (2010) suggested that semantic knowledge provides a framework or scaffolding which facilitates the acquisition of new episodic memory. Here we propose a computational model of the interrelation between episodic and semantic memory. We hypothesize that episodic memories are represented as sequences of activation patterns that are stored in the hippocampus. These patterns are the output of a semantic representational network, in the neocortex, that compresses the high-dimensional sensory input to a lower dimensionality both in space and time. That is the semantic representation can be represented by fewer neurons and varies at a lower rate than the sensory input stream. Since the hippocampal patterns are highly compressed inputs, our model accounts for findings that episodic memory is unreliable in humans, often preserving little more than the gist of the episode, but none of the details. Using this computational model, we show that the accuracy of episodic memory critically depends on the semantic representations by comparing retrieval accuracy in two conditions. In one case, episodic memories are stored using a semantic representation that was trained on the same input statistics (appropriate representation). In the other case, the semantic representation was trained on a different kind of input statistics (inappropriate representation). Retrieval using the appropriate representation was superior to that based on the inappropriate representation. We confirm this modeling result in a behavioural experiment. We thus conclude that semantic representation plays an important role in episodic memory.

Title: A hippocampal network for spatial coding during immobility

Authors: *K. KAY[1], M. SOSA[1], J. CHUNG[1], M. P. KARLSSON[1], M. C. LARKIN[2], I. GROSSRUBATSCHER[1], L. M. FRANK[1];

Abstract: Classic hippocampal "place" cells are active in discrete locations as subjects traverse space. This place activity constitutes an explicit and precise neural code for location in the mammalian brain. Indeed the hippocampus is required for memory-guided spatial navigation, a behavior understood to be dependent on an internal representation of current position. However, studies of hippocampal place firing conventionally exclude periods of immobility. As a result, the fundamental issue of whether and how the hippocampus represents current position in the absence of movement has stood unresolved. In rats engaged in a spatial memory task, we recently found a population of neurons, located in hippocampal area CA2, that fired at specific (reward site) locations during periods of immobility. Spike-triggered analysis of LFP subsequently showed that these neurons associate with a non-canonical hippocampal network pattern (NCP): a ~200 ms, low frequency positive "wave" pattern detectable in CA3 and DG. Here we report that putative interneurons located throughout the hippocampus associate with the NCP, and further that CA1 and CA3 principal neurons associating with the NCP also show profound location specificity during immobility. These results identify a hippocampal network pattern, distinct from both hippocampal theta and sharp-wave ripples, that operates during immobility. Moreover the association of this pattern with location-specific firing indicates that the hippocampus, during immobility, is actively engaged in generating a representation of current position. Our results also demonstrate rapid switching in the hippocampal circuit between representation of current position and SWR-associated representations of past (“replay”) and potential (“preplay”) navigational experience.

Title: Self-organized formation of place cell responses in robotic simulations based on slowness principle

Authors: *S. KUMAR[1,2], F. SCHÖNFELD[2,3], L. WISKOTT[2,3], S. CHENG[1,2];
[1]Mercator Res. Group Structure of Memory, [2]Intl. Grad. Sch. of Neurosci., [3]Inst. of Neural Computation, Ruhr Univ. Bochum, Bochum, Germany

Abstract: Since the discovery of place cells four decades ago, several studies have been conducted to investigate the properties of and inputs to the place cells. However, it remains unclear what information drives place cell responses and how the brain might extract such information. Franzius et al1 previously suggested that an unsupervised learning algorithm could learn place, head direction and spatial view cell responses solely based on visual inputs. This algorithm uses a hierarchical network of slow feature analysis (SFA) nodes and exploits the fact that the pixels in the visual input vary much faster than the underlying spatial parameters that determine the visual input. However, that study simulated a virtual environment under idealized conditions with the behavior of the animal perfectly controlled. Such conditions are not representative of the real world. Here, we apply the SFA-based algorithm on data collected in robotics experiments using the small e-Puck robot and a virtual e-Puck simulated in Webots. These experiments are constrained by physical variables such as noise and distortions in the camera, lighting conditions, inertia, friction, and limits on speed and acceleration. We have used the slowness principle to explain some of the distinct properties of place cells observed in studies such as direction dependence on the linear track or direction invariance in open arena. Preliminary analysis of these responses in a linear track and an open arena suggest that spatially selective responses also arise in robotics simulations, although it remains a challenge to clearly separate responses to location, orientation and view. We tentatively suggest that the SFA-based algorithm is robust to the noise and limits imposed by physical constraints, which animals also face in the real world. Title: Apolipoprotein E4 impairs slow gamma oscillations during hippocampal sharp-wave ripples in a mouse model of Alzheimer's disease

Authors: *A. GILLESPIE[1], Y.-H. LIN[1], M. KARLSSON[2], K. KAY[2], S. YOON[1], L. FRANK[2], Y. HUANG[1];
[1]Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]UCSF, San Francisco, CA

Abstract: Apolipoprotein (apo) E4 is the major genetic risk factor for Alzheimer's disease (AD), yet we do not understand how it alters memory processes to ultimately cause cognitive decline. As the hippocampus is critical for spatial learning and memory, and is one of the brain regions first and most severely targeted by AD pathology in humans and disease models, we examined apoE4-induced changes in hippocampal network activity. In knock-in (KI) mice, human apoE4 causes age-related learning and memory impairment as well as GABAergic interneuron degeneration in the dentate gyrus (DG) of the hippocampus. *In vivo* local field potential recordings throughout the hippocampus of aged apoE4-KI mice revealed two alterations impacting sharp wave ripple (SWR) events, which are critical for memory processes. Compared to control apoE3-KI mice, apoE4-KI mice have fewer SWR events. Furthermore, we observe SWR-associated slow gamma activity in hippocampal subregions CA1, CA3, and DG, and demonstrate that this SWR-associated slow gamma power is significantly attenuated throughout the hippocampal circuit in apoE4-KI mice. Elimination of apoE4 in GABAergic interneurons, which prevents learning and memory impairment, rescued SWR-associated slow gamma activity but not SWR abundance. These results suggest that the disruption of DG-enabled slow gamma activity during SWRs is a key mechanism of apoE4-mediated learning and memory impairment.

Title: Real-time estimation of hippocampal replay content

Authors: *X. DENG[1], D. F. LIU[2], M. KARLSSON[3], L. M. FRANK[3], U. T. EDEN[1];
[1]Mathematics and Statistics, Boston Univ., Boston, MA; [2]UC Berkeley - UCSF Grad. Program in Bioengineering, [3]Physiol., UCSF, San Francisco, CA

Abstract: Sharp-wave ripple (SWR) events in the hippocampus replay millisecond-timescale patterns of place cell activity related to the past experience of an animal. Previous work has shown that interruption of awake SWRs leads to a specific learning and performance deficit. That result established the importance of awake SWRs, but as individual SWRs can contain spiking patterns that replay different sequences, the role of specific sequences in learning and decision-making is not known. A deeper understanding of how this replayed information contributes to learning and decision-making will require the ability to manipulate SWR events based on their content. Here our goal is to develop a decoding algorithm to determine if a replay event's content represents a specific sequence, which will then make it possible to interrupt events based on the spatial trajectory they represent. Accurate real-time decoding of SWR replay content requires new algorithms that estimate trajectory and the associated uncertainty, along with software and hardware that can execute these algorithms for biological interventions on a millisecond timescale. Previously, we developed an efficient decoding algorithm that does not require multiunit spiking waveforms to be sorted into single units (Deng et al., 2015). Here we extend the state of our marked point process filter to include a dynamic binary state variable that categorizes the content of hippocampal replays in real time. This allows us to incorporate into our model three fundamental features of the information content of individual replay events: the location where the trajectory begins, whether the sequence of locations represents a trajectory proceeding toward or away from the animal's current position, and whether the spiking pattern reflects place-field structure for a specific direction of movement. Using Bayes' rule, we compute the posterior distribution of the binary state variable to determine the confidence that the replay content represented in hippocampal multiunit activity represents inbound versus outbound trajectories. We illustrate our approach by decoding experimental data recorded in the hippocampus of a rat performing a spatial memory task. This algorithm is suitable for a real-time implementation with short latencies to incorporate into content-based feedback experiments.

Abstract: Given its importance in many brain functions, and due to the richness of the data available, the hippocampus was selected as one of the first brain regions to be modeled by the Human Brain Project (HBP). The HBP approach to building computational models of brain regions offers a powerful tool to integrate the available data and predict the unknowns. The available information for a given brain region, even for the most well-studied regions such as the hippocampus, is highly sparse and incomplete, and we are far from filling all the gaps. Nevertheless, methods have been developed within the HBP that start from existing knowledge, and algorithmically predict the missing data. We present a first draft model of the hippocampus

CA1 microcircuit of an adult rat. The microcircuit is a compound of a series of component models for ion channels, neuron anatomy and physiology, synapse anatomy and physiology, as well as circuit anatomy and physiology. Once a component model is constrained and validated against the available experimental data, its parameters are frozen before the model is incorporated into the next level. This forces the modelers not to change the parameters ad hoc in order to reproduce a subset of experimental data or test a particular hypothesis, but allows them instead to remain in a more general and hypothesis-free framework. For each of the most well-characterized cell types, we collected one or more Neurolucida 3d digital reconstructions. We then positioned the morphologies inside the circuit according to information on localization and composition as outlined in the literature. A connectome was predicted on the basis of vicinity - if two morphologies are located in close vicinity inside the circuit, there is a higher likelihood of connection between them - and then scaled down to reproduce biological values of bouton density and synapses per connection. A number of electrophysiological recordings and published data were used to constrain models of single cell and synapse physiology. Finally, a dataset was used to validate the full circuit. The model represents a useful platform to integrate data, to test hypotheses and support experimentations, and it can be improved periodically by refining previous assumptions and incorporating new experimental data.

Title: Differential rearing effects on NR2B subunit expression in the rat amygdala and hippocampus during acquisition of Pavlovian conditioned fear

Authors: *L. E. KOMER[1], E. K. REINHARDT[2], G. R. ERICKSON[2], M. E. CAIN[2]; [1]Psychological Sci., [2]Kansas State Univ., Manhattan, KS

Abstract: Early rearing conditions may alter the development of anxiety disorders in individuals. Not only may the rearing conditions affect the expression of such disorders, but they

also may affect the initial learning of fear. In order to understand the influence of early rearing conditions on fear learning, an animal model of differential rearing is used (Renner & Rosenzweig, 1987). Rats raised in enriched conditions (EC) have superior learning and memory compared to standard condition (SC) and isolated condition (IC) rats (Wood and Rebec, 2009). However, IC rats appear to have superior learning of aversive stimuli (Walasek et al., 2002). Differential rearing also appears to affect the NR2B subunit of the glutamatergic N-methyl-D-aspartate (NMDA) receptor, which is involved with fear learning and memory (Rodrigues et al., 2001). The present study examines if NR2B differences among rearing environments are found in the amygdala, specifically the basolateral (BLA) or the central nucleus (ACe), and in the hippocampus, specifically the CA3 region. We hypothesized that IC and SC rats would acquire fear faster than EC rats. Similarly, we predicted that IC and SC rats would show more NR2B expression in the BLA, the ACe, and the CA3. Male Sprague-Dawley rats arrived at the laboratory at 21 days of age and were randomly assigned to the EC, SC, or IC, and reared for 30 days. All rats were trained to lever press for sucrose on a VI-90 schedule of reinforcement. Rats then received one 90-min fear acquisition session. Half of the rats received four presentations of a 3000-Hz tone (CS) paired with a 0.6-mA foot shock (US) and the other half of the rats received four unpaired presentations of the tone and foot shock. Fear was measured using a suppression ratio. Immediately following the fear acquisition session, the brains were extracted and the expression of NR2B was labeled and quantified in the BLA, ACe, and CA3 using immunocytochemistry. Results revealed only the IC paired rats acquired fear. In all 3 rearing conditions, no differences in NR2B expression were observed between the paired and unpaired rats, suggesting that the acquisition of fear did not alter NR2B expression. Interestingly, in the BLA, EC rats had significantly higher levels of NR2B expression than IC rats. No significant differences in NR2B expression were found in the ACe or CA3 regions. These findings suggest that while isolation rearing enhances the early acquisition of fear, this enhancement is not due to increased expression of NR2B receptors. These findings further suggest that enrichment increases NR2B expression within the BLA and suggests that the effect of enrichment on NR2B expression is regionally specific.

Title: NMDA receptor-dependent signaling in excitatory prefrontal neurons controls fear discrimination and fear extinction

Authors: *A. CORCHES, P. VIEIRA, N. BAVADIAN, A. HIROTO, K. WESTBROOK, E. KORZUS;
Univ. of California, Riverside, Riverside, CA

Abstract: N-methyl-D-aspartate receptors (NMDARs) are implicated in synaptic plasticity and memory function including modulation of fear memory. NMDAR-dependent plasticity is widely hypothesized to be the mechanism by which memory traces are encoded and stored. Previous studies investigating fear memory focus on the amygdala and the hippocampus but the role of the medial prefrontal cortex (mPFC) in modulation of fear memory is less clear. Neurons in mPFC have been implicated in fear memory extinction. In addition, recent studies implicated prefrontal circuitry in fear memory specificity and generalization. We tested mice with locally deleted Grin1 gene (encoding the obligatory NR1 subunit of the NMDAR) from prefrontal CamKIIα positive neurons for their ability to distinguish aversive and harmless stimuli in a fear discrimination test. These mice showed impaired fear discrimination following initial generalization of conditioned fear. Mice with GRIN1 deletion in excitatory prefrontal neurons exhibit normal fear responses to aversive fear-conditioned stimuli but fail to reduce their fear response to non-aversive stimuli. These data provide evidence that NMDARs in the mPFC are part of a neural mechanism supporting discriminatory fear learning. We also found that NMDAR-dependent signaling in the mPFC is crucial for fear extinction of auditory conditioned stimuli. These studies suggest that the mPFC is required for a reduction of generalized fear to harmless stimuli that is essential for improvement of fear memory accuracy. These studies have clinical implications. Overgeneralized fear is a typical symptom of anxiety disorders including generalized anxiety disorder and posttraumatic stress disorder (PTSD), which are triggered by cues in a secure environment that resemble those of the traumatic experience.

Title: Trace-fear conditioning alters the expression of NMDA receptor related genes in relevant brain regions

Authors: *D. T. BALU, K. T. PRESTI, J. T. COYLE;
Psychiatry, McLean Hosp. / Harvard Univ., Belmont, MA

Abstract: Fear conditioning is one of the most powerful and widely used models for elucidating the neural substrates of associative learning and memory formation in the mammalian brain. In this form of Pavlovian conditioning, a neutral stimulus (conditioned stimulus; CS) acquires predictive value by pairing it with an aversive, unconditioned stimulus (US; mild foot shock) that has an intrinsic value to the subject. After training, exposure of the animal to the CS or context alone elicits conditioned fear responses. The insertion of a trace interval during CS-US presentation alters the brain circuitry that mediates conditioning. There is substantial evidence that N-methyl-D-aspartate receptors (NMDARs) in the amygdala, hippocampus, and medial prefrontal cortex (mPFC) are involved in trace-fear conditioning. We previously demonstrated that D-serine, the co-agonist at forebrain NMDARs, is required for the development of contextual fear conditioning. Accordingly, we now examine whether the expression of genes related to NMDAR activity is altered after conditioning and re-exposure to the conditioning context. We used adult, male C7BL6 mice for all experiments. Mice were either: 1) naïve, 2) trace-fear conditioned and killed 60min after training, or 3) trace-fear conditioned, re-exposed to the training context the next day (no tones), and killed 30min later. We also included additional sham control groups that went through the same conditioning procedures, but did not receive foot shocks. We found that protein levels of the immediate early gene, activity-regulated cytoskeleton-associated protein (Arc; Arg3.1), were robustly increased after training and after context re-exposure. The animals exposed to sham conditioning showed a modest Arc protein increase only in the PFC after training, but no significant increase after context re-exposure. Notably, the mRNA and protein expression of serine racemase, the enzyme that converts L-serine to D-serine, was significantly increased in the amygdala after training and after re-exposure. SR protein did not change in sham mice at either time point. Using immunofluorescence, we found that SR and Arc are localized to distinct neuronal populations in

the amygdala after fear conditioning. These findings demonstrate an activity-dependent regulation of SR in the amygdala and confirm that D-serine is important for the acquisition and expression of fear memory.

Title: Remote fear memory is regulated in the medial amygdala via tuberoinfundibular peptide of 39 residues acting through parathyroid hormone 2 receptors

Authors: *M. C. TSUDA, T. B. USDIN;
Section on Fundamental Neurosci., NIMH/NIH, Bethesda, MD

Abstract: Individuals with post-traumatic stress disorder have enhanced fear responses to trauma-associated stimuli, which is thought to result from impaired extinction of fearful memories. Our recent neuroanatomical and behavioral findings suggest that the neuropeptide tuberoinfundibular peptide of 39 residues (TIP39), via its receptor, the parathyroid hormone 2 receptor (PTH2R), modulates fear memory (Coutellier and Usdin, Behav Brain Res, 2011). We are now investigating the anatomical and cellular localization of TIP39's contribution to enhanced remote fear memory. PTH2R knockout (PTH2R-KO) and wild-type (WT) male mice were exposed to a single 2 second 1.5 mA foot shock and fear recall was assessed as conditioned freezing during re-exposure to the shock context 28 days later. Compared to WT, PTH2R-KO mice had increased freezing in the shock context, suggesting enhanced remote fear memory in mice that lack TIP39 signaling. The medial amygdala (MeA), which contains a high density of PTH2Rs and TIP39 containing terminals, projects to brain regions with well established roles in fear memory including other parts of the amygdala and the bed nucleus of the stria terminalis. We investigated the contribution of TIP39 signaling in the MeA to remote fear memory

enhancement by (1) blocking TIP39 signaling in the MeA or (2) inhibiting the activity of PTH2R expressing neurons in the MeA. TIP39 signaling in the MeA was blocked by stereotaxic injection of a virus encoding a secreted PTH2R antagonist (HYWH). Mice then received a foot shock as described above and fear recall was measured 28 days later. Similar to KO results, mice injected with HYWH had higher levels of freezing than controls. We then used the designer receptor exclusively activated by designer drug (DREADD) pharmacogenetic technique to ask whether signaling through cells that TIP39 acts on in the MeA is required during initial coding and/or recall of fear memory. A Cre-dependent Gi-coupled DREADD virus that can suppress neuronal activity was injected into the MeA of mice with PTH2R driven Cre expression. Saline or clozapine-N-oxide (CNO), a DREADD agonist that has no effect on endogenous receptors, was administered (1) 1 hour before foot shock or (2) 1 hour before fear recall testing. Fear recall was evaluated 28 days after foot shock. Inhibiting PTH2R expressing neurons with CNO at the time of foot shock increased freezing during fear recall, but inhibition at the time of recall had no effect, compared to saline treated mice. Taken together, these findings demonstrate that TIP39 signaling within the MeA at the time of an aversive event contributes to modulation of long-term fear recall of traumatic experience.

Title: Contextual fear-conditioning alters phosphodiesterase-4A intron expression in the hippocampus

Authors: *R. HANSEN, III[1], S. POPLAWSKI[2], G. PORCARI[1], R. HAVEKES[1], L. PEIXOTO[3], T. ABEL[1];
[1]Biol., Univ. of Pennsylvania, Philadelphia, PA; [2]Ibis Biosci., Carlsbad, CA; [3]Washington State Univ., Spokane, WA

Abstract: The prevalence of post-traumatic stress disorder (PTSD) is rapidly increasing due to the return of recent war veterans, but therapeutics used to treat PTSD are limited by extreme side effects or lack of efficacy. Current therapeutics act on broad targets; thus, there is a need to identify novel therapeutics that confer regional and molecular specificity to their treatment. Phosphodiesterase-4A (PDE4A) may allow for such specific regional and molecular

pharmacological targeting. PDE4A is a member of a family of enzymes that degrade cAMP, and is highly expressed in brain regions involved with anxiety, memory, and PTSD such as the hippocampus. PDE4A has six known splice variants which are created using alternative promoters and splicing, and have distinct N' termini resulting in targeted compartmentalization throughout the cell. Preliminary studies suggest knockout of PDE4A enhances fear memory; however, very little is known about how an experience such as fear-memory formation impacts PDE4A alternative splicing and subsequent splice-variant expression. The purpose of this study was to identify the effect of contextual fear conditioning (CFC) on PDE4A splice-variant expression, activity, and localization. Using RNA-Seq and exon-level analysis, we identified a specific intron in the PDE4A gene significantly elevated 30 minutes after CFC. Junction analysis reveals this intron is retained within distinct splice variants, and may be playing a regulatory role in PDE4A signaling. This is the first study to demonstrate behavioral-dependent increase of an intron, and may represent a novel mechanism for the regulation of PDE4A and fear memory.

Title: Deletion of PAC1 receptors from the medial intercalated cells of the amygdala enhances fear generalization and decreases the rate of fear extinction

Authors: *A. K. RAJBHANDARI[1], Y. HUANG[1], V. MAKHIJANI[1], J. WASCHEK[1], M. FANSELOW[2];
[1]Neurosci., [2]Psychology, Univ. of California-Los Angeles, Los Angeles, CA

Abstract: Post-traumatic stress disorder (PTSD) involves inappropriate inhibitory control over fear after exposure to life-threatening traumatic experiences. Previous studies have linked the neuropeptide pituitary adenylate cyclase activating peptide (PACAP) and its G-coupled receptor PAC1 to PTSD diagnosis and symptom severity. PACAP and PAC1 are expressed in the neural circuitry of fear and regulate conditioned fear behaviors. Using mice expressing green fluorescent protein (GFP) in PACAP containing neurons we found that PACAP-containing

neurons in the basolateral portion of the amygdala project into the medial intercalated cells (mICCs). mICCs are crucial for modulating fear extinction and express PAC1 receptors. Therefore, we investigated whether deletion of PAC1 receptors from the mICCs alters fear acquisition, generalization or extinction. In mice with floxed PAC1 gene, AAV-driven Cre-recombinase or GFP control was infused into the mICCs. After viral expression, mice went through a fear acquisition protocol (1 trial/day for 5 days) in which 4-minute after being placed into a conditioning context they were given a 0.65 mA, 1-second shock. PAC1 floxed mice that received Cre or GFP showed a similar acquisition rate and asymptote for fear learning. Mice were then placed in a different context to test fear generalization and their freezing behaviors measured for 4 minutes. PAC1 floxed mice with Cre showed enhanced freezing compared to mice with GFP. These mice also went through fear extinction in which they were placed in the acquisition context for 30 minutes every day and their fear behavior was measured from the first 4 minutes of the session. Rate of fear extinction was significantly decreased in PAC1 floxed mice with Cre compared to mice with GFP. Taken together, these results indicate that deletion of PAC1 receptors from the intercalated cells enhances fear generalization and reduces the rate of fear extinction potentially by decreasing feed-forward inhibition into the CeA. While these results are somewhat surprising given the putative role of PACAP in enhancing fear, they indicate that PACAP/PAC1 may play differential role in regulating fear depending on the site of action in the fear circuitry. The finding that the mICCs modulate fear generalization is a novel and interesting as studies have focused on the role of ICCs in fear extinction, but not generalization.

Title: BDNF val66met genotype enhances memory of fear and impairs extinction learning via glucocorticoid signaling

Authors: *M. NOTARAS[1], R. HILL[1], J. GOGOS[2], M. VAN DEN BUUSE[3];
[1]Florey Dept. of Neurosci. and Mental Hlth., Univ. of Melbourne, Melbourne, Australia;
[2]Columbia Univ., New York, NY; [3]La Trobe Univ., Melbourne, Australia

Abstract: Brain-Derived Neurotrophic Factor (BDNF) is a promoter of neuronal development and plasticity. The BDNF gene Val66Met polymorphism disrupts activity-dependent secretion of BDNF and has been associated with Post-Traumatic Stress Disorder (PTSD). However, despite being a requisite etiological factor, it has not yet been assessed whether prior stress exposure determines the expression or persistence of fear in Val66Met carriers. We therefore sought to model the long-term effects of chronic stress by using a novel Val66Met knock-in mouse that is genetically modified to express human BDNF (hBDNF) via endogenous mouse promoters. To simulate stress, corticosterone (CORT) was administered in the water of wild-type (hBDNF Val/Val) and mutant (hBDNF Met/Met) mice at a dose of 25mg/L from 6 to 9 weeks of age (adolescence). Following a two week wash-out period mice underwent behavioural testing and were screened for differences in spatial memory on the Y-Maze, memory of fear and extinction learning. At baseline, memory of contextual fear was disrupted in hBDNF Met/Met mice relative to hBDNF Val/Val controls but was rescued by a BDNF-CORT interaction which selectively enhanced the memory of hBDNF Met/Met mice. A similar phenotype was also observed on the Y-Maze, where hBDNF Met/Met mice showed a lack of preference for the novel arm over the other arms, but was reinstated to levels consistent with controls following the chronic CORT treatment. While extinction learning was unaffected in male and female hBDNF Met/Met mice at baseline, chronic CORT selectively attenuated the extinction learning of female hBDNF Met/Met mice during the late-phase of extinction trials. In summary, we report that chronic CORT exposure interacts with the BDNF Val66Met polymorphism to selectively modify the expression and extinction of fear. This novel gene-environment interaction highlights how fear is regulated by both BDNF and CORT exposure, providing mechanistic support for the treatment and prevention of stress-inducible psychiatric disorders with prominent sex-differences such as PTSD.

Title: Opioid-dependent impairment in fear learning and extinction by prefrontal cortical stimulation

Authors: A. J. KIRRY, R. C. TWINING, E. M. DONCHECK, *M. R. GILMARTIN; Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Sustained firing in the prelimbic area of the medial prefrontal cortex (PL mPFC) of rats has been suggested to bridge the gap in trace fear conditioning (Gilmartin & McEchron, 2005; Gilmartin et al., 2013) and to drive freezing behavior to previously conditioned cues (Burgos-Robles et al., 2009). These findings support a general role for PL in the acquisition and expression of conditional fear. Here we sought to determine whether sustained optical stimulation of principal cells in PL would enhance fear acquisition and expression and impair fear extinction. Male Long-Evans adult rats were injected with a viral vector containing channelrhodopsin (AAV9-CamKiia-ChR2(H134R)-eYFP) or inactive control virus (AAV9-CAG-GFP) bilaterally into PL. To test whether stimulation of PL could enhance fear acquisition, laser light (473 nm, 20-Hz 10-ms pulses) was delivered during the 20-s trace interval separating the conditional cue and shock during trace fear training. To test whether stimulation of PL would drive the expression of fear and impair extinction, we delivered light during the cue on each trial of fear extinction. We found that PL stimulation did not enhance learning, but greatly impaired the acquisition of fear, reduced cued fear expression, and impaired extinction learning. Importantly, stimulation during the 20-s trace interval disrupted both cued and contextual fear associations, suggesting that stimulation may have interfered with the ability of the shock to drive learning. Follow-up experiments supported this possibility. Pre-shock stimulation of PL during unpaired conditioning impaired contextual and non-associative fear. Post-training inflation of fear by higher-intensity shock-alone trials in a novel context was attenuated by pre-shock stimulation of PL. A recent model of predictive fear learning implicates a role for PL in modulating ascending shock signals during the acquisition of fear (McNally et al., 2011), likely through opioid signaling in the periaqueductal grey (Fanselow & Bolles, 1979, McNally & Cole, 2006). Consistent with this model, we found that pre-training systemic administration of the opioid receptor antagonist naloxone (5 mg/kg, s.c.) prevented stimulation-induced impairments in context fear and partially restored cued fear learning in trace fear conditioning. Together, these results are consistent with a role for PL in top-down modulation of ascending pain signals necessary for fear learning and provide further evidence that the integrity of prelimbic trace interval firing is crucial for associating events separated in time.

Title: Delay fear conditioning enhances the intrinsic excitability of infralimbic neurons

Authors: *C. SONG, V. L. EHLERS, J. C. AITKEN, J. R. MOYER, Jr;
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The activity of medial prefrontal cortex (mPFC) is critical for fear memory expression through its reciprocal interaction with the amygdala (AM). Our recent data suggest that trace fear conditioning (where the CS and US were separated by a stimulus-free trace interval) enhances the intrinsic excitability of regular spiking infralimbic-AM (IL-AM) projection neurons but suppresses the regular spiking prelimbic-AM (PL-AM) projection neurons. Previous data also suggest that the brain circuits involved in trace fear conditioning are different from those of delay fear conditioning (where the CS and US were co-terminated). Thus, the current study was carried out to examine how acquisition of delay fear conditioning affects the excitability of mPFC neurons. Adult rats were randomly assigned into naïve, delay fear conditioned (COND), and delay fear conditioned-extinguished (EXT). On day 1, COND and EXT rats received one 4-trial session of delay fear conditioning. On day 2, EXT rats received one extinction session consisting of 10 CS-alone trials. On Day 3, all rats (naïve, COND, and EXT) received a brief CS-alone presentation to test fear memory. Within 1-hr following testing, brain slices were prepared and whole-cell recordings were made from layer 5 pyramidal neurons in both IL and PL. Analysis of data from 125 regular spiking neurons (71 IL, 54 PL) indicated that acquisition of delay fear conditioning significantly enhanced intrinsic excitability of IL neurons ($p < 0.05$). The excitability was still high following extinction but not significantly different from Naïve. In addition, fear conditioning was associated with an enhancement of hyperpolarization-activated current (Ih; $p < 0.05$), which remained high after extinction ($p < 0.01$). The excitability of regular spiking PL neurons was not significantly changed following conditioning or extinction. Thus, delay fear conditioning enhanced the intrinsic excitability and Ih of regular spiking IL neurons, which are consistent with our observations following trace fear conditioning. Interestingly, these observations are also consistent with a recent report that local blockade of NMDARs in IL reduces the amount of conditioned fear following both delay and trace conditioning, whereas local blockade of NMDARs in PL enhances the amount of conditioned fear following trace but not delay conditioning (Kwapis et al., 2014). Taken together, our data suggest that the activity of

IL pyramidal neurons facilitates the expression of both delay and trace fear memory, whereas the activity of PL pyramidal neurons suppresses the expression of trace fear memory.

Title: Experience-dependent modulation of fear conditioning

Authors: ***S. IWASAKI**, T. SAKAGUCHI, Y. IKEGAYA;
Lab. Chem. Pharmacol., Grad. Sch. Pharmaceut. Sci., Univ. Tokyo, Tokyo, Japan

Abstract: Fear may represent a protective response against danger. It is usually suppressed under normal situations, but anxiety disorders patients cannot regulate fear responses. One of the anxiety disorders is post-traumatic stress disorder (PTSD), which occurs following an unexpected exposure to a traumatic event. When people experience a traumatic event, some develop PTSD, but others do not. Recently, it is reported that one of the risk factors is a history of a brief trauma. However, it remains unknown how a previous trauma exposure enhances the sensitivity to a late-coming trauma. In this study, we used a mouse PTSD model and found that mice that had experienced a prior foot shock showed higher freezing responses. This prior shock-induced enhancement of fear conditioning (i.e., priming effect) lasted for 21 days. The priming effect was prevented by MK801, an N-methyl-D-aspartate receptor antagonist. Thus, this effect is dependent on neuronal plasticity. Other types of aversive stressors, such as forced swimming or tail pinch, did not enhance subsequent fear conditioning. Moreover, plasma corticosterone assays, elevated plus maze, and acetic acid-induced writhing test suggest that the priming effect did not result from an increased stress level, anxiety level, or pain sensitivity. These results suggest that a trauma was not generalized to modify the sensitivity to other trauma. Our study implies that a previous trauma induces specific long-lasting plasticity in its relevant neuronal pathway and thereby specifically enhances subsequent fear conditioning. The behavioral procedure used in this study may be a platform to elucidate the etiology of PTSD.

Title: Individual differences in voluntary alcohol consumption predict fear incubation responses and fear acquisition in rats

Authors: ***A. PAJSER**, H. FISHER, M. GREER, P. KALLENBERGER, A. LIMOGES, C. LONG, C. L. PICKENS;
Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: PTSD and alcohol abuse frequently co-occur, but the cause of this co-morbidity is unclear. Alcohol exposure could alter problem drinkers' brains to promote the development of anxiety disorders, problem drinking could occur because of pre-existing anxiety (e.g.: self-medication), or a pre-existing factor could affect both anxiety and alcohol consumption. We studied the effects of chronic intermittent alcohol access (CIA) in rats from adolescence to early adulthood to determine if alcohol consumption alters or is correlated with conditioned fear responding after fear conditioning over-training, which models chronic stress. Male Long-Evans rats received CIA or water-only access for 6 weeks (PND 26-66). Rats were then food-restricted and began fear conditioning 15-16 days after the final alcohol access period. The rats were trained to lever-press and then received 10 days of fear conditioning. The rats were tested for conditioned fear (measured with conditioned suppression of lever-pressing) two days after the end of fear conditioning. Next, half of each treatment group received CIA access during a four-week fear incubation period; the other rats received only water during this time. Six days after the final day of alcohol access, the rats received a conditioned fear test. We found no effect or interaction of adolescent or adult alcohol access on conditioned fear. However, within the Adolescent Alcohol group, rats that had high levels of drinking during early adulthood exhibited lower conditioned fear both two days and one month after the end of fear conditioning. There was no correlation between alcohol consumption during the one-month incubation interval and conditioned fear in the one-month test. A follow-up experiment found that fear in a test 2 days after a single day of fear conditioning was not affected by or correlated with alcohol consumption, but high alcohol drinkers exhibited lower fear than low alcohol drinkers during the

fear conditioning session itself. Our results suggest that rats that consume higher levels of alcohol during early adulthood exhibit lower fear, which can be expressed during fear conditioning itself or during later tests. We found no evidence that alcohol consumption affected fear levels. This suggests that individual differences in the motivation to consume alcohol in early adulthood are correlated with fear acquisition or expression apart from any effects of alcohol consumption on the conditioned fear circuit. Future studies will investigate potential genetic differences or neural mechanisms in the brain that may be responsible for these differences in drinking and fear expression.

Title: Central activation of GHS-R1a in lateral amygdala blocks aversive memory formation by PLC/IP3/DAG and PI3K/Akt/mTOR pathways

Authors: M. YU, *Y. ZHOU, Q. ZHU, M. NIU, Q. KONG;
Qingdao Univ., Shandong, China

Abstract: Growth hormone secretagogue receptor-1a (GHS-R1a) is a highly conserved G-protein-coupled receptor (GPCR). Its broad distribution in the central nervous systems suggests that GHS-R1a signaling has important physiological functions beyond feeding control and energy metabolism. Our previous study showed that micro-infusion of ghrelin into the lateral amygdala (LA) activates GHS-R1a and interferes with the CTA memory acquisition in rats, however the underlying mechanisms are not known yet. In support of previous findings, we first showed here that local infusion of ghrelin into LA during CTA training inhibits Arc and zif268 mRNA expression in BLA triggered by memory retrieval. We further found that pre-infusion of either GHS-R1a antagonist YIL781, PLC inhibitor U73122 or PI3K inhibitor LY294002 into LA reverses ghrelin's blockade on CTA acquisition. YIL781, U73122 or LY294002 itself had no effect on CTA acquisition. Furthermore, IP3 receptor antagonist 2-APB, PKC inhibitor GF109203X or mTOR inhibitor rapamycin suppresses ghrelin's effect on CTA acquisition, while

MEK inhibitor, PKA inhibitor, D1 or D2 receptor antagonist does not. Those data suggests that PLC/IP3/DAG and PI3K/Akt/mTOR signaling cascades are two major downstream pathways mediating the modulatory effect of ghrelin/GHS-R1a activation on memory-related behaviors. Since both PLC and PI3K down-regulates sub-cellular concentration of PtdIns(4,5)P2 which is essential for the membrane docking and activity of inwardly rectifying potassium channes (Kir), we therefore tested the effect of Kir channel blockers ML133 hydrochloride and Tertiapin-Q on CTA acquisition. We found that both ML133 hydrochloride and Tertiapin-Q mimic ghrelin's blockade on CTA, while KCNQ channel blocker XE-991 and SK channel blocker apamin has no effect on CTA acquisition. All together, we concluded that ghrelin/GHS-R1a activation in lateral amygdala evokes PLC/IP3/DAG and PI3K/Akt/mTOR signaling and blocks aversive memory formation. PtdIns(4,5)P2 reduction caused by PLC and PI3K activation and subsequent Kir channels disfunction may also involved in this process.

Title: Exogenous BDNF into adult neocortex strengthens a taste aversion memory

Authors: ***A. MARTÍNEZ**, L. F. RODRÍGUEZ DURÁN, M. L. ESCOBAR;
Facultad de Psicología, DIstrito Federal, Mexico

Abstract: Brain-derived neurotrophic factor (BDNF) is a neurotrophin that has been considered an important plasticity-related product as well as a potent molecular mediator for long-term memory. Our previous studies in the insular cortex (IC), a region of the temporal cortex implicated in acquisition and retention of conditioned taste aversion (CTA), demonstrated that BDNF is essential for the CTA consolidation. Recent studies show that BDNF-TrkB signaling is able to mediate the enhancement of memory. However, whether exogenous BDNF infusion is able to enhance aversive memories remains unexplored. In the present work, we administrated BDNF (2µg / 2µl per side) into the IC immediately after CTA acquisition in two different conditions: a “strong CTA” induced by 0.2M lithium chloride i. p., as unconditioned stimulus, and a “weak CTA” induced by 0.1M lithium chloride i. p. Our results show that BDNF converts

a weak CTA into a strong one, in a Trk receptor-dependent manner. We show for the first time that exogenous BDNF is able to increase an aversive memory-trace in the adult neocortex, supporting the view that BDNF expression is sufficient to strengthen memory-consolidation.

Title: Long-term associative memory in Caenorhabditis elegans

Authors: S. ITO, *I. MARUYAMA;
Senior Investigator, Okinawa Inst. of Sci. & Technol. Grad. Univ., Okinawa, Japan

Abstract: Sensory neurons perceive information from the environment, which affects animal's behavior. *C. elegans* is an excellent model organism for the study of neuronal circuits that regulate the behavior, because of its relatively simple nervous system. The animal can also learn and store memory of non-associative memory like habituation and associative memory of two environmental stimuli. We are interested in molecular mechanisms and cellular networks underlying the associative memory, and have developed protocols for induction of short-term and long-term olfactory appetitive memories, STM and LTM, respectively, in *C. elegans*. We used 1-nonanol, a weak, volatile aversive chemical to *C. elegans*, as a conditioned stimulus (CS) and potassium chloride (KCl), a strong attractive substance, as an unconditioned stimulus (US). We conditioned animals with massed and spaced trainings to induce STM and LTM, respectively. Young adult animals in a small plastic tube sealed the bottom with a 30 um-nylon mesh sheet were stimulated with 1-nonanol vapor in a beaker, and then with KCl solution. For the massed training, animals were repeatedly conditioned as described above eight times without an inter-trial interval (ITI) between the conditionings. For the spaced training, on the other hand, animals were conditioned in the similar way to the massed training with ITI, during which animals were rested on an NGM plate. Immediately or hours later after the conditioning, animals were analyzed by chemotaxis assay on an agar plate spotted with 1-nonanol. As results, the trained animals successfully learned and retained the memory by the massed training and the

spaced training. We have also examined whether the training induces CS-specific memory by using 2-nonanone as a CS, instead of 1-nonanol. After training with 2-nonanone and KCl, animals formed 2-nonanone-specific, but not 1-nonanol-specific, associative memory. These results demonstrate that the protocols can successfully induce associative STM and LTM in *C. elegans*. We are currently trying to elucidate neuronal circuits responsible for the learning and memory.

Title: Dopaminergic and Serotoninergic modulation on the avoidance response

Authors: *G. F. ANTUNES[1], C. C. OLIVEIRA[2], M. C. CASTRO[2], F. V. GOUVEIA[2], M. D. J. SENO[2], L. T. SANTOS[2], M. C. CARVALHO[3], M. L. BRANDÃO[3], E. T. FONOFF[2], M. J. TEIXEIRA[4], J. P. OTOCH[4], R. C. R. MARTINEZ[2];

Sírio Libanês de Ensino e Pesquisa, São Paulo, Brazil; [3]Univ. of Sao Paulo, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Ribeirão Preto - São Paulo, Brazil; [4]Univ. of Sao Paulo, LIM 26 - HCFMUSP, São Paulo, Brazil

Abstract: Anxiety is understood as a body's response to situations in which the source of threat to the individual is not well defined. The two-way active avoidance test enables to understand the role of anxiety in the learning process. Avoidance is known to involve an instrumental response that modifies aversive, threatening emotional states and bodily responses. Two populations of animals have been distinguished in this test, the good avoiders and the poor avoiders. The poor avoiders show less than 20 avoidance responses and exhibited the freezing response. The dopamine and serotonin are important neurotransmitter activated during aversive stimulus. The aim of the work was to study the role of dopamine and serotonin as a modulator of two way

avoidance test. For that, first it was evaluated the role of dopaminergic (D1 and D2) and serotoninergic receptors (5-HT2C and 5-HT1A) on good performers in this test. Secondly, it was compared the amount of dopamine and serotonin in post-mortem amygdala comparing good and poor performers using High Performance Liquide Chromatography (HPLC) analysis. Wistar rats (n=77) have been trained in the avoidance test for 7 days. In the next day (Day 8) they received intraperitoneal injection of saline, D2 antagonist - Sulpiride (20 or 40 mg/Kg) or D1 antagonist - SCH 23390 (0.025 or 0.05 mg/Kg), or 5-HT2C antagonist - Kentaserina (1 or 2 mg/kg) or 5-HT1A antagonist - Way 100635 (1 or 2 mg/kg). On day 7, there was no difference in avoidance ($F(4,47)=0.33$ $p=0.85$. On day 8, after the administration of dopaminergic antagonist (day 8) there was a reduction in the number of avoidance response after D1 antagonist administration (SCH 0.05; 0.025mg/Kg) and D2 antagonist ($F(4,47)=15.11$, $p=0.00001$) in comparison with saline. The administration of 5-HT2C (Kentanserina 2mg/kg) and 5-HT1A(Way 1mg/kg) did not affect the number of avoidance response ($F(4,27)= 0.19$ $p= 0.99$). HPLC showed that there was no difference in dopaminergic content (Total DOPAC $F(2,53) = 1.82$ $p = 0.17$; Right amygdala DOPAC $F(2,25) = 1.50$ $p = 0.24$; Left amygdala DOPAC $F(2,25) = 1.25$ $p = 0.30$). HPLC showed an increased in serotoninergic content in the right side of amygdala in good performers in comparison with poor performers (amygdala Total HVA $F(2,53) = 0.89$ $p = 0.42$, HVA right amygdala $F(2,25) = 4.97$ $p = 0.02$; Left amygdala HVA $F(2,25) = 0.86$ $p = 0.44$). Thus, this approach suggests that dopamine and serotonin neurotransmitters may play important role in the avoidance response through D1 and D2 receptor and the amygdala is the main nucleus of serotoninergic modulation.

Title: Striatal network organization predicts initial learning of Pavlovian associations

Authors: *K. BAKHURIN[1], V. MAC[2], P. GOLSHANI[2], S. C. MASMANIDIS[2];
[1]Neurobio., [2]UCLA, Los Angeles, CA

Abstract: Animals need to rapidly learn to guide and select actions that lead to positive outcomes. The striatum, as the main input structure of the basal ganglia, is thought to play a critical role in reward-guided action learning. We used state-of-the-art silicon probes with 256 channels to perform simultaneous recording of over 100 units in the striatum of awake behaving mice. Mice performed an odor discrimination task known to recruit striatal neuron activity in a learning-dependent manner. Populations of striatal medium spiny neurons (MSNs) that encoded information about cues and rewards (discrimination of reward- vs nonreward-predicting trials) were electrophysiologically distinct from their non-cue encoding neighbors, showing higher excitability, lateralized positioning in the striatum, and an increased likelihood of synchronous spontaneous activity. The functional segregation of cue-discriminating MSNs from the non-discriminating population was negatively correlated to behavioral performance in individual animals actively learning the task. However, in well-trained animals, network organization did not predict behavioral performance. Opportunities for new learning in the well-trained group reorganized the MSN network into states that resembled early phases of learning. These findings suggest that learning to link stimuli with behavioral responses benefits from a decorrelated striatum and that striatal networks reorganize to improve performance over time.

Title: Memory forgetting: exploring the mechanisms underpinning memory decay

Authors: *L. O. ALVARES, R. SACHSER, F. SANTANA, F. DUTRA, A. CRESTANI, J. QUILLFELDT;
Federal Univ. Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Although the ability to retain and retrieve long-term memories is crucial to guide properly our behavior, most of the daily life experiences are forgotten overtime. Despite the fact that this process be the most common outcome in memory, the neural signature of forgetting remains largely unknown. In the current study we used behavioral, pharmacological and electrophysiological approaches to describe a novel mechanism that controls memory forgetting. First, using a hippocampus-dependent object location (OL) task, we determined when rats start to forget long-term memory (LTM) in a time-dependent manner. Then, we demonstrate that chronic inhibition of the (1) N-methyl-D-aspartate receptor (NMDAR), (2) L-type voltage-dependent calcium channel (LVDCC), and (3) protein phosphatase calcineurin (CaN), keep memory in a time-point in which it is ordinarily forgotten. Moreover, using a hippocampus-independent object recognition (OR) paradigm, we found that NMDAR also controls the decay of this type of information, suggesting that forgetting results from a well-regulated brain-wide active process mediated by NMDAR activation. We further demonstrate that intra-hippocampal infusion of ifenprodil after LTP induction *in vivo* prevents the depontentiation of CA1 field evoked plasticity, showing for the first time that downregulation of GluN2B-dependent signaling is critical to sustain LTP in a non-decaying state. Taken together, our findings indicate the existence of an active process that controls the synaptic plasticity responsible for LTM maintenance overtime.

Title: Separable memory formation and retrieval circuits generate aversive olfactory imprinting in *C. elegans*

Authors: *X. JIN, N. POKALA, C. BARGMANN;
The Rockefeller Univ., New York, NY

Abstract: Early life memory can be particularly stable and influential, but the sites and molecules that enable this privileged learning are not understood. Pairing olfactory stimuli with a nociceptive cue allows animals to associate aversion to the experienced odour. It has previously been reported that adult *C. elegans* can learn to avoid the pathogen Pseudomonas aeruginosa (PA14) after a 6-hour exposure, but lose the memory after 12 hours (Zhang et al Nature 2005). We have applied this aversive conditioning paradigm to newly hatched *C. elegans* larvae, and found that early pathogen experience generates long-term aversion behaviour, a process we call aversive imprinting. We found that imprinted animals specifically avoid pathogen odours for days after exposure, whereas training at any other stages cannot elicit such long-term memory. Through chemical-genetic neuron silencing, we identified two groups of neurons that act independently in memory formation and memory retrieval. The neuromodulator tyramine is required in the memory formation circuit during the learning phase. Multiple tyramine receptors are required for memory, suggesting broad circuit modulation by the learning signal. A G-protein coupled tyramine receptor is dispensable for adult aversive learning but required in one of the memory retrieving neurons for aversive imprinting, thus bridging the two subcircuits by linking tyramine production during learning to memory retrieval days later. The early imprinting experience modifies neuronal activity and output of the memory circuit, allowing animals to express their privileged memory by strategically turning away from the pathogen they experienced in the larval stage.

Title: Anesthesia-induced conditioned taste aversions

Authors: *J. ARTHURS, J.-Y. LIN, S. REILLY;
Psychology, Univ. of Illinois At Chicago, Chicago, IL

Abstract: We are interested in two types of taste learning: conditioned taste aversion (CTA) and taste avoidance learning (TAL). Each type involves a Pavlovian association between a taste (conditioned stimulus, CS) and postingestive consequences (unconditioned stimulus, US). What differentiates them is the nature of the learning. CTA involves a reduction in the hedonic value or palatability of the taste CS which determines intake whereas TAL causes a reduction of intake without a downshift in palatability (i.e., the taste CS becomes a signal for impending danger). Our laboratory has used lick pattern analysis (e.g., lick cluster size) to assess palatability and demonstrated that USs reported to cause TAL (e.g., amphetamine, gallamine, morphine) actually produce CTAs. The present experiments examined whether anesthetic drugs, thought to support TAL, may actually produce CTAs. In Experiment 1 male Sprague-Dawley rats were adapted to a water schedule allowing 15-min access in the morning (in drinking chambers) and afternoon (in home cages). Rats were assigned to three groups Group P0 (n = 10), Group P15 (n = 10), and Group P30 (n = 10), balanced for intake and lick cluster size. Conditioning trials consisted of replacing morning water with a 0.1% sodium saccharin CS followed 5-min later by an injection of the US. Group P0 was injected ip 1 ml/kg saline, Groups P15 and P30 were injected with, respectively, 15 and 30 mg/ml/kg of pentobarbital. On the following day control injections occurred 2-hrs after morning water access, Group P0 was divided into two sub-groups given either 15 or 30 mg/ml/kg of pentobarbital, while Groups P15 and P30 were injected with saline. A recovery day with regularly scheduled water access and no injections preceded the next conditioning trial. Two conditioning trials were followed by a CS-only test trial. Experiment 2 was conducted exactly like Experiment 1 except the US groups were K30 and K60 that received either 30/1.5 or 60/3.0 mg/ml/kg of ketamine/xylazine, respectively. In both experiments, each drug group showed significant decreases in both CS intake and lick cluster size (i.e., palatability), indicating the acquisition of CTAs. These findings expand the range of stimuli known to cause CTAs. Thus, our current model of CTA encompasses USs such as anesthesia, internal pain, and drugs of abuse, in addition to gastrointestinal malaise.

Title: Conditioned inhibition changes in Hermissenda type A photoreceptors

Authors: *J. FARLEY;
Indiana Univ., Bloomington, IN

Abstract: Previously, we found that conditioned inhibition (CI)/safety signal learning in *Hermissenda* (*H.c.),* established by repeated explicitly-unpaired (EU) presentations of light (CS) and rotation (US), separated by a fixed ISI > 4.0 min, resulted in increased phototactic behavior and decreased photoresponses and spike activity of ocular Type B photoreceptors (Britton & Farley, 1999, *J Neurosci*; Walker et al., 2010, *Front Behav Neurosci*). Recent studies (Farley et al., 2015) have determined the ionic conductance changes that underlie the persistent decreases in B cell light-responses and spike frequencies due to EU training: increases in two somatic K^+ currents (I_A and $I_{K\text{-}Ca}$). Because both Type B and A cells undergo long-term neurophysiological changes due to CS-US pairings, these changes qualitatively oppose one another yet are complementary in their contribution to decreased phototaxis, it seemed likely that EU-produced decreases in B cell light responses might be accompanied by parallel *increases* in the responsiveness of A cells. Here, I report on the changes observed in both synaptically-intact spiking Type A cells, as well as those of synaptically-isolated non-spiking A cells, 1-3 days following behavioral training of intact animals. Animals were randomly assigned to one of 3 treatment conditions: EU, random (RDM), or untrained home cage controls (HC). In recordings from synaptically-intact A cells, resting R_{in} values were significantly greater for EU cells (n = 8) than for CON cells (n = 16, pooled results for RDM and HC cells, which did not differ), suggesting that one or more class of ion channels open at rest were shut by CI training. During repeated 30 sec light steps, EU Type A cells showed significantly greater light-evoked steady-state generator potentials (SSGPs) than CON cells, for all light steps and at all times within the light steps. Similarly, EU A cells generally spiked more frequently than CON cells. However, the magnitude of the spike frequency difference diminished within and across light steps. Because the photoreceptors in the *H.c.* eyes reciprocally inhibit each other, and EU B cells show decreased light responses and spiking, the increased light response and spiking of synaptically-intact A cells from EU animals could be due to either disinhibition from B cells (network effects) or alterations in intrinsic ion conductance systems. In recordings from synaptically-isolated A cells, the light-responses (SSGPs) were significantly greater for EU cells (n=10) vs. controls (n=8), and were apparent throughout all light steps. Thus, these results have identified a second site of intrinsic change and memory storage in *H.c.* underlying CI learning.

Title: Aversive experiences transform amygdalar ensemble coding during fear learning

Authors: *B. F. GREWE[1], J. GRÜNDEMANN[2], J. LECOQ[1], L. KITCH[1], J. MARSHALL[1], J. PARKER[1], J. LI[1], A. LÜTHI[2], M. SCHNITZER[1];
[1]Stanford Univ., Palo Alto, CA; [2]FMI, Basel, Switzerland

Abstract: Learned emotions are fundamental aspects of human and animal behavior and are crucial for survival. The basal and the lateral amygdala (jointly abbreviated BLA) are necessary for emotional learning and link sensory-driven neural inputs to outputs controlling fearful and reward-seeking behaviors. Prior studies have uncovered molecular, synaptic and cellular substrates of fear memory in the BLA, but neural ensemble mechanisms underlying fear learning remain unknown. In our study we investigated neural population dynamics in the BLA by using a miniature (2 gram) fluorescence microscope [Ghosh et al. Nature Methods (2011) 8:871-8)] together with a chronic mouse preparation [Ziv Y et al., Nature Neuroscience (2013) 16:264-6] to track the calcium dynamics of ~150-200 individual neurons per mouse throughout a six-day fear-conditioning paradigm. This approach allowed us to follow monitor the neural ensemble representations of both neutral and aversive stimuli (tones and mild electric shocks). We found that initially neutral conditioned stimuli (CS) and unconditioned aversive stimuli (US) activated separate populations of sparse but intermingled BLA neurons. Paired presentations of a neutral CS and an aversive US initiated both down- and up-regulation of individual neurons' CS-evoked responses. Together, these bi-directional changes transformed the ensemble representation of an initially neutral CS into a response pattern more similar to that of the US. Overall, our results provide a first glimpse towards understanding associative learning at the level of large neuronal ensembles in the BLA. Further, our approach to tracking large populations of individual neurons in the amygdala opens the door to time-lapse imaging studies of neural coding in a brain structure that likely plays a central role in several psychiatric disorders.

Title: Learning to ignore: A fundamental role for the prelimbic cortex in down-regulating attention towards irrelevant cues during fear conditioning

Authors: *M. SHARPE[1], S. KILLCROSS[2];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Sch. of Psychology, UNSW, Sydney, Australia

Abstract: The prelimbic (PL) cortex is argued to promote fear expression, at odds with appetitive research implicating this region in attentional processing. This theory has prevailed despite contradictory evidence resulting from manipulation of PL function in aversive conditioning. More specifically, pre-training lesions of the PL cortex have produced enhanced conditioning to a conditioning stimulus (CS; Morgan and LeDoux 1995), enhanced conditioning to a context (Morgan and LeDoux 1995; Lacroix et al. 2000), a decrement in CS conditioning (Lacroix et al. 2000), or have no effect (Holson 1986), whereas post-training inactivation reduces fear responding (Corcoran and Quirk 2007; Sierra-Mercado et al. 2010). In contrast, there is a long history of research in the appetitive literature which implicates the PL cortex in directing attention towards predictive cues (Birrell and Brown 2000; Marquis et al. 2007; Sharpe and Killcross 2014). We investigated whether a role for the PL cortex in attentional modulation could explain the discrepant findings in aversive studies. Firstly, we found that varying the degree of competition between contextual and discrete cues produced marked differences in the ability of animals with PL lesions to express fear towards a discrete CS. Specifically, a reduction of competition between contextual and discrete cues restored CS fear responding in animals with PL lesions, consistent with an attentional account as the need for attentional modulation towards the predictive CS is reduced when competition from contextual cues is low. Secondly, we tested whether PL inactivation would impact on the ability to change the degree of attention directed towards two discrete cues in an overshadowing procedure. During conditioning, two stimuli were presented simultaneously to form an audio-visual compound and two were presented as elemental stimuli all followed by footshock. When stimuli were subsequently tested individually under extinction, saline-infused animals exhibited lower levels of responding towards the cues that comprised the compound relative to those conditioned individually, an effect attributed to the down-regulation of attention towards the less salient element of the compound during conditioning (Mackintosh 1975). PL inactivation during conditioning abolished demonstration of

the overshadowing effect at test. However, PL inactivation during the test session itself did not impact on the ability to demonstrate this effect. These data call for a refinement of the role of the PL cortex in aversive conditioning, implicating the PL cortex in directing attention towards predictive cues during fear conditioning procedures.

Title: A robotically controlled laser and real time subject tracking software for the study of approach and avoidance

Authors: *J. WILSON[1], M. KESLER[2], S.-L. PELEGRIN[2], L. KALVI[2], A. GRUBER[2], H. STEENLAND[2,1];
[1]Neurotek Innovative Technol., Toronto, ON, Canada; [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: When a predator is at a distance there is no immediate danger so we can plan an escape. As that predator comes within striking distance we behave much differently, possibly attacking the predator or simply freezing (Griebel, Physiol. Behav. 1996, McNaughton and Corr, Neurosci. Biobehav. Rev. 2004, Fanselow and Lester, Evol. and Behav. 1988). To examine these behaviors, an interactive laser beam (green color) was mounted on a 2-dimensional gimbal. Under control of the experimenter at a console, the laser could be moved around an arena to interact with a rat. Software was used to simultaneously track both the rat and the laser beam. If the laser beam came within ~90mm of the rat, the rat would either receive a reward or a subcutaneous shock (via implanted electrodes). Animals that received rewarding electrical brain stimulation could learn to chase the laser beam, while animals that received aversive subcutaneous shock learned to avoid the laser beam. Animals that acquired the aversive conditioning did not show the full spectrum of behaviors related to being an animal of prey.

Thus, the neutral stimulus (laser beam) used in this paradigm simplifies the interpretation of the interaction between distance and threat.

Title: Goal-directed visuomotor learning and long-term memory of free-swimming zebrafish larvae is unveiled via high-throughput automated detection and analyses of hunting sequences

Authors: *A. M. LAMBERT[1], M. A. MASINO[2];
[1]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [2]Neurosci., Univ. of Minnesota- Twin Cities, Minneapolis, MN

Abstract: Prey capture is a compound ethologically-relevant behavior that can be broken up into its component elements to serve as a neuroethological platform for investigating its sensory, sensorimotor, motor, neuromodulatory, engrammic, attentional, and decision-making neural components. Zebrafish larvae offer one of the best opportunities to comprehensively elucidate the many neural facets of prey capture. Zebrafish innately begin hunting at just 4 to 5 days post fertilization (dpf), but providing larvae with early hunting experience could influence later prey capture performance via either visuomotor learning and/or the obtained sustenance from prey consumption. To determine the influences of these factors, we developed high-throughput, automated detection and analyses of hunting sequences in free-swimming larvae. This unbiased approach was achieved via automated tracking of eye convergences, which is a reliable hallmark of prey detection and pursuit. Larvae provided previous experience hunting either large paramecia or small colpoda, 24 hours prior to testing, exhibited improved prey capture of paramecia at 7 dpf, compared to naïve counterparts. This experience-dependent potentiation of prey capture was not simply due to obtained sustenance from prey, because a daily regimen of colpoda from 4 dpf onward did not improve the survival rate compared to unfed counterparts, although a daily regimen of paramecia or 5% egg yolk did. Compared to naïve counterparts,

experienced larvae tested at 7 dpf exhibited: 1) a shorter latency (by ~10 min) to increases in eye convergence rate and initiation of hunting sequences following initial seeding of paramecia to the arena 2) a shorter latency (by ~150 ms) between execution of subsequent hunting maneuvers within a hunting sequence 3) a markedly better capture attempt success rate (by ~30%) 4) consumption of all prey items in half the time course of a 5 hour assay. Moreover, there was a strong negative correlation (R = -0.94) between capture attempt success rate and inter-maneuver durations, indicating that shorter latencies between hunting maneuvers is predictive of a greater precision in prey capture attempts. Many of these long-term enhancements at 7 dpf were recapitulated by providing an exclusive visuomotor training experience at 6 dpf by exposing larvae to artemia, which they actively hunted but were incapable of ingesting due to their considerably large size. Collectively, these results suggest that zebrafish larvae are capable of goal-directed visuomotor learning and long-term memory, the underlying genes of which could be isolated from high-throughput assays via our automated and unbiased hunting analyses.

Title: Neurogranin gene deletion increases stress responsivity in heterozygous mice

Authors: V. CESTARI[1,2], D. SARAULLI[2], S. FARIOLI VECCHIOLI[2], V. MASTRORILLI[2], F. D'ALESSANDRO[2,3], M. COSTANZI[2,3], S. DE MARCHIS[4], *R. VENTURA[5];

Abstract: Diathesis-stress models refer to the notion that psychological disturbances can result from the interaction between inherent vulnerability and environmental stressors. At present, genetic traits are widely considered to lie at one pole of the dyad, and specific gene variants are being continuously added to the ranks of putative predisposing factors that can determine, in conjunction with adverse life events, the onset of severe psychiatric disorders, such as

depression, anxiety and schizophrenia. Recently, evidence has been reported for genome-wide significant association between schizophrenia and a single nucleotide polymorphism (rs12807809) located upstream of the neurogranin (NRGN) gene. Based on its ability to bind calmodulin in a Ca2+-dependent manner, NRGN - a protein kinase substrate expressed in the cerebral cortex, hippocampus and amygdala - has been proposed as a major regulator of calmodulin activity in the postsynaptic compartment, likely involved in modulating synaptic strength and hippocampal learning and memory. Consistently, changes in synaptic plasticity, accompanied by significant impairments in hippocampus-dependent learning tasks, have been demonstrated to follow NRGN gene deletion in mice, along with further psychotomimetic abnormalities affecting anxiety-related and social behaviors. The present study aimed to test the hypothesis that NRGN gene deletion exacerbates mouse susceptibility to the behavioral effects of acute stress. To this aim, a fear conditioning procedure was selected, as an environmental stressor, which had proven ineffective in producing enduring behavioral alterations in wild-type mice, as assessed in the open field, dark-light emergence, forced swimming and social interaction tasks. The same procedure was subsequently adminis-tered to NRGN-knockout siblings, in both homo- and heterozygosis, which led to the following observations: (i) according to previous reports, (-/-) mice were significantly impaired in all tests, compared to wild-type mice, with constitutive behavioral abnormalities never worsened by exposure to the stressor; (ii) naive heterozygous mice performed as wild-type mice in all tests, but exposure to the stressor resulted in behavioral alterations comparable to those observed in homozygous counterparts. Thus, effects of stress exposure on heterozygous NRGN-knockout mice may constitute a model of gene × environment interaction, with useful implications for translational research on neuropsychiatric disorders. For all the experimental conditions, data on c-Fos expression in mouse hippocampus, amygdala, and prefrontal cortex are also provided.

Title: The dynamic nature of systems consolidation: stress during learning as a switch guiding the rate of the hippocampal dependency and memory quality

Authors: *L. K. PEDRAZA CORREA, R. A. SIERRA ORDOÑEZ, F. ZACOUTEGUY, J. HAUBRICH, J. QUILLFELDT, L. ALVARES;
Biophysics Dept., Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: Memories fade after a time point, becoming more schematic or abstract. The loss of contextual detail in memory may reflect a time-dependent change in the brain structures supporting memory. It is well established that contextual fear memory relies on the hippocampus for expression shortly after learning, but becomes hippocampus-independent at later time point, a process called systems consolidation. This time-dependent process correlates with the loss of memory precision. Here, we investigated whether the training intensity predicts the gradual decay of the hippocampal dependency to retrieve memory and the quality of the contextual memory representation overtime. We found that learning intensity modulates the progressive decay of the hippocampal dependency and memory precision. Strong training intensity accelerates systems consolidation and memory generalization in a remarkable timeframe match. The mechanisms underpinning such process are triggered by the glucocorticoid and noradrenaline released during training. These results suggest that the stress/arousal levels during emotional learning act as a switch, guiding the fate of memory quality. A moderate stress will create a detailed memory, whereas a highly stressful training will develop a generic gist-like memory.

Title: Temporal transcriptome and epigenome changes in the brain and blood of mouse models simulating post-traumatic stress disorder

Authors: S. MUHIE[1], A. GAUTAM[2], N. CHAKRABORTY[2], R. HAMMAMIEH[2], J. MEYERHOFF[2], *M. JETT[3];

[3]Integrative Systems Biol. Program, US Army Med. Command, CEHR, Fort Detrick, MD

Abstract: Hemi-brains were collected from mice exposed to modified social-stress (to simulate post-traumatic stress disorder) from 1 to 12 days. We carried out transcriptome profiling and genome-wide DNA methylation assays for each time point. We also did transcriptome profiling of blood, and of brain regions implicated in fear learning and fear memory consolidation (amygdala, hippocampus, medial pre-frontal cortex and ventral striatum), which were collected from mice exposed to either 5 or 10 days of social-stress. We identified greater numbers of differentially regulated genes in mice stressed for 3 or more days. Whereas, greater numbers of differentially methylated probes were observed at earlier time points (5 days and earlier) in stressed groups. The latter was not expected since DNA methylation is normally considered to be a slower process. Upon assessment of the global transcriptional binding of Creb1 using ChIP-on-chip tiling arrays, we observed reduced transcriptional activities of Creb1 in stressed groups as compared to controls. This could explain why many of its targets (nerve growth factors and transcripts implicated in fear extinction processes) were suppressed in both the hemi-brains as well as specific brain regions in the stressed mice. The time course trajectories of the correlated gene expression and DNA methylation patterns indicate that differentially changed transcripts and methylated regulatory regions at shorter stress durations (up to 7 days) were largely reported to be associated with behavioral responses (hyperactivity, fear response, circadian rhythm and cognition/learning), while longer stress durations (8 or more days) were largely reported to be associated with metabolic processes, immune response, and addiction and emotional behaviors. Our data suggest that the earlier occurrence of the epigenetic changes may be driving the ensuing changes of gene expressions, leading to responses which modulate behavioral disorders. This in turn might lead to metabolic disorders, immune dysfunction and cardiovascular problems. At the transcriptome and epigenome levels, behavioral responses seem to trigger the other comorbid conditions. A feedback loop is highly probable in these instances, as is shown in the case of inflammatory responses when comorbid conditions can aggravate anxiety disorders.

Title: Ability to discriminate between highly ambiguous contexts is dependent on the sensory modality of contextual cues

Authors: *R. J. BALOG[1], R. J. KEELEY[2], N. S. HONG[2], R. J. MCDONALD[2];
[1]Univ. of Lethbridge, Canadian Ctr. For Beha, Lethbridge, AB, Canada; [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Interpretation of contextual cues associated with different outcomes increases in difficulty when the contexts are defined with common elements or overlapping features, increasing ambiguity. We were interested in manipulating the level of cue overlap utilizing multiple sensory modalities to alter context ambiguity. Various cues were manipulated in our discriminative fear conditioning to context paradigm to investigate the influence and saliency of visual, olfactory, geometrical, and tactile sensory information in this task. For each version of the discrimination task, each context was identical except in one sensory modality. The abundance of overlapping cues defining the context chambers should represent a difficult discrimination to resolve except by the appropriate interpretation of the predictive contextual cue and proper orthogonalization of the other context details. This task was hypothesized to be dependent on hippocampal function. Results show that discriminability was affected by which sensory modality or type of information that was used for the unique feature of the context with olfactory information providing the strongest disambiguation function and geometrical information the weakest. Using this paradigm, we also observed a novel defensive behaviour that emerges in situations where the discrimination is more challenging. Essentially, when the rats are in a testing situation in which the discrimination has been difficult to resolve they remove one paw from the steel rod floors or both paws. Presumably this behaviour is elicited to avoid shock exposure. This behaviour does not appear when the context discriminations are not ambiguous and uncertainty about where the aversive outcome will occur is clear. We are also examining the impact of complete hippocampal lesions on performance in these ambiguous discriminations. This work suggests that discrimination between ambiguously defined contexts depends on the sensory modality of the unique contextual cue available during training. The results also show that when rats have difficulty discriminating between contexts they show a defensive behaviour not seen in less ambiguous context discriminations, a response elicited by the subjects likely designed to avoid the full impact of the aversive event if it occurs. It is possible that hippocampal dysfunction may impair the acquisition or encoding of the configural representation of cues needed to accurately discriminate between ambiguous contexts.

Title: Effort based decision making in people with motivational deficits

Authors: *C. LE HERON[1], S. MANOHAR[2], T. CHONG[1], A. BLAKE[2], M. JACKSON[3], M. HUSAIN[1];
[1]Nuffield Dept. of Clin. Neurosciences, [2]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Dept. of Neurol., John Radcliffe Hosp., Oxford, United Kingdom

Abstract: Apathy, a debilitating syndrome of reduced motivation, is now conceptualized as a disorder of goal-directed behavior. Effective goal-directed behavior requires an action-outcome representation, a core component of which is the effort - or cost - involved in generating an action. The integration of action effort with outcome (reward) forms the core of effort-based decision making, and has been shown in humans to involve key basal ganglia and frontal regions, particularly ventral striatum and dorsal anterior cingulate cortex. Lesions to these regions in animal models reduce effortful behavior for reward, without altering rewards' hedonic value, mimicking the apathetic phenotype. To investigate whether effort-based decision making is impaired in people with apathy, we developed a decision task probing the influence of reward and physical effort on choice, and administered it to individuals with apathy and matched controls. The task comprised six reward and six effort levels, and the 36 combinations of these were evenly sampled across 5 blocks. Reward was presented as apples on a tree (each worth a monetary value), whilst effort was expended via a handheld dynamometer, normalized for each participant. Each trial consisted of an "offer" of reward (1-15 apples) in return for effort (14-80% of maximal voluntary contraction). If the participant accepted the offer, they squeezed the dynamometer to the required force level and were rewarded, whereas if they rejected it, they waited an equivalent time before moving on to the next offer. Apathy was defined using existing scales (Lille apathy rating scale and apathy evaluation scale). Behavioral performance was analyzed by comparing effort-reward functions between groups, and a logistic regression model of choice, including reward, effort and reward/effort interaction as predictor variables. Apathetic individuals showed a baseline bias towards rejecting offers and collected significantly fewer apples across the experiment. They showed a relative insensitivity to reward, requiring a higher reward to make a given effort. Intriguingly, their decisions were relatively insensitive to the effort cost and also showed a significantly reduced interaction of effort and reward compared to

controls, consistent with disruption of effort-based decision making. These findings demonstrate dysfunction of effort-based decision making systems is associated with reduced motivation and consequent goal directed behavior. They provide evidence of a mechanism by which behavioural apathy can occur, and suggest neuropharmacological modulation of this mechanism as a potential avenue of therapy for this condition.

Title: Offline TMS-fMRI reveals integration of reward, task and response information across corticostriatal circuits

Authors: *M. VAN HOLSTEIN[1,3], M. FROBOESE[2], J. O'SHEA[4], I. TONI[2], E. AARTS[2], R. COOLS[2,5];
[2]Donders Inst. for Brain, Cognition and Behavior, [1]Radboud Univ. Nijmegen, Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands; [4]Dept. of Exptl. Psychology, Oxford Univ., Oxford, United Kingdom; [5]Dept. of Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: To respond appropriately to a constantly changing environment, cognitive processes and subsequent action selection should be informed by changes in potential gains, e.g. reward prospects. Processing of such goals from different levels occurs in anatomically and functionally segregated corticostriatal circuits. It has been previously shown that i) the ventromedial prefrontal cortex (vmPFC) and ventral striatum are involved in reward processing; ii) the dorsolateral prefrontal cortex (dlPFC), caudate nucleus and anterior putamen are involved in cognitive control (e.g. task-sets); and the premotor cortex (PMC) and posterior putamen are involved in response selection (e.g. stimulus-response mappings). However, to enable adaptive behavior, integration of these goals and their corresponding corticostriatal circuits is crucial.

Anatomical animal work has suggested that this integration between different corticostriatal circuits may occur at the level of the striatum. More specifically, integration is thought to occur in a unidirectional manner, with information being transferred from ventromedial to increasingly dorsal circuits. We aimed to assess in humans whether affecting neural excitability in reward-related cortical regions leads to a cascade of processes by which reward information influences motor responses in the motor putamen. To this end we combined offline transcranial magnetic stimulation (TMS) with functional MRI while 27 subjects performed a task-switching paradigm with a reward manipulation, which required integration of reward information with the selection of changing task-sets and adequate responses. We used a counterbalanced within-subject crossover design in which each subject received, on separate days, stimulation over each of the three task-related networks (vmPFC, dlPFC and PMC). As expected, stimulation of the vmPFC versus a no TMS baseline modulated activity in the posterior putamen in a task-related manner (i.e. as a function of reward, task, and response integration) relative to the other stimulation sites. In addition, a functional connectivity analysis confirmed a connection between the posterior putamen and regions within the reward network (e.g. anterior cingulate cortex and vmPFC) as a function of reward, task, and response integration. Congruous with anatomical evidence of integrated corticostriatal circuits in animals, we present evidence in humans showing that stimulation of the reward circuit during a task that requires integration of reward, task and response information can alter processing in a circuit further down the functional cascade, associated with response selection.

Title: Local network differences in reactive aggression measured with resting-state fMRI and graph theory

Authors: *F. D. UQUILLAS[1], G. GAN[1], A. ZILVERSTAND[1], M. A. PARVAZ[1], R. N. PRESTON-CAMPBELL[1], D. TOMASI[2], S. J. MOELLER[1], P. MALAKER[1], T. MALONEY[1], R. Z. GOLDSTEIN[1], N. ALIA-KLEIN[1];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Reactive aggression is characterized by excessive anger expression and limited anger control. Even when unchallenged by a task or provocation, individuals with trait patterns of these anger characteristics are predicted to have differences in resting-state functional connectivity as compared to non-angry controls. Here we used graph theory, a mathematical approach for studying complex network properties, in a matched clinical sample (age, education, and race) of 12 individuals with reactive aggression (RA) in comparison to 12 low aggressive controls (LA) who completed resting-state functional magnetic resonance imaging and the State/Trait-Anger Expression Inventory (STAXI-II). As expected, groups differed in the *outward expression of anger* and *anger control* ($p<0.001$) subscales. We found decreased clustering coefficient (the number of connections directly connected to a node over the number of possible connections for that node), a measure of the probability of connectedness between neighboring nodes, in the Sensorimotor Network (pre-motor cortex, mid-cingulate cortex, paracentral lobule, and dorsal precuneus), and visual superior occipital cortex in RA relative to LA ($p<0.05$, FDR-corrected). Correlations across groups between the clustering coefficient connectivity properties of the Sensorimotor Network with *outward expression of anger* and *anger control* revealed that decreased local connectedness of the mid-cingulate cortex and paracentral lobule was linked to increased outward expression of anger (p-corrected=0.001), and decreased local connectedness of the paracentral lobule and dorsal precuneus was linked to lower anger control (p-corrected<0.005), (p-threshold=0.006; 4 regions × 2 trait variables). Disrupted local connectedness of the Sensorimotor Network with neighboring regions in RA hints at deficits in monitoring, planning and control of motoric responses, and may predispose individuals prone to reactive aggression to act upon less-integrated and less-regulated reactions to salient environmental cues. This is further suggested by the relationship between decreased local connectivity in this network and increased outward expression of anger and lower anger control. We also provide a graph theoretical framework for integrating findings from previous studies showing an association between higher precuneus activity and higher negative emotionality and lower self-control in individuals with high trait aggression. Overall, lower local connectivity of sensorimotor regions may be a contributing factor for greater expression of anger and lower anger control in reactive aggression.

Title: The neural representation of optimal decision-making during human spatial forward planning

Authors: *R. KAPLAN[1,5,2], J. KING[3], R. KOSTER[1], D. BUSH[4], W. D. PENNY[2], N. BURGESS[4], K. J. FRISTON[2];
[2]Wellcome Trust Ctr. for Neuroimaging, [3]Clinical, Educational & Hlth. Psychology, [4]Inst. of Cognitive Neurosci., [1]Univ. Col. London, London, United Kingdom; [5]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: The hippocampus and medial prefrontal cortex (mPFC) are involved in planning optimal spatial trajectories, yet the computations behind this type of decision-making are unclear. We examined the neural processes that enable humans to infer the shortest path between a starting point and target location, particularly focusing on how that inference is modified by prospection. Subjects viewed mazes offering routes that varied in hierarchical depth (amount of choice points in the maze) and path length during separate fMRI and MEG experiments. We used Shannon entropy to quantify uncertainty about the shortest path length for a given maze - and the implicit computational complexity of selecting the shortest path. We constructed predictors of neuronal (fMRI/MEG) responses in terms of the entropy (uncertainty) of the choice probability in each trial. Medial prefrontal cortex (mPFC), medial temporal lobe (MTL), parietal midline, and angular gyrus BOLD responses and right MTL 3-5 Hz theta power were greater in low entropy (i.e. greater path length differences) planning trials. Conversely, responses in the dorsal anterior cingulate cortex/pre-supplementary motor area were greater in high entropy trials (i.e. smaller path length differences). Notably, 3-5 Hz right MTL theta phase coupling with mPFC and right angular gyrus correlated with planning trial entropy. We then examined whether

any brain regions selectively responded to entropy during forward planning, i.e. choosing between different paths at points further in the maze. We found that rostral dmPFC and lateral frontopolar cortex BOLD responses correlated with increasing forward entropy and that right MTL-mPFC theta phase-locking predicted forward entropy. In sum, we found BOLD responses for spatial planning that overlap with brain regions observed during value-guided choice, with spatial forward planning responses overlapping with regions observed during prospective choice. Furthermore, regions displaying BOLD responses to planning entropy also showed theta phase coupling with the MTL that predicted planning entropy. Our findings illustrate how distributed responses in the MTL and mPFC contribute to optimal decision-making during spatial forward planning.

Title: Dissociation of amygdala and dopamine contributions to exploratory decision making in rhesus monkeys

Authors: *V. D. COSTA, O. DAL MONTE, D. R. LUCAS, E. A. MURRAY, B. B. AVERBECK;
Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: The amygdala and dopamine are both known to regulate learning to enable flexible affective responses when contingencies are extinguished or reversed. By comparison less is known about the roles of the amygdala and dopamine in managing the tradeoff between exploitation and exploration that underlies decisions between multiple choice options. Novelty seeking represents a specific case of the explore/exploit dilemma as animals explore novel and unfamiliar stimuli and environments in pursuit of potential reward. From this perspective the utility of exploring novel options can be formally expressed as a combination of its immediate expected value and the future expected value of actions that could be made after choosing the novel option and receiving feedback (i.e. an exploration bonus). Using a Markov decision

process (MDP) model to explicitly compute these value estimates, we compared to a group of unoperated controls (N = 8), the relative impact of bilateral excitotoxic lesions of the amygdala (N = 4) or systemic blockade of the dopamine transporter (N = 3) on the novelty seeking behavior of rhesus monkeys. During the task, the monkeys learned to choose between three, probabilistically rewarded images. Periodically one of the three choices was replaced with a novel image the monkey had not yet associated with reward. A finite state, discrete time, discounted MDP was used to derive immediate and future value estimates for each of the monkeys' choices and then used to predict the monkey's exploration of the novel choice options. We found that both amygdala lesions and systemic increases in extracellular dopamine heightened the selection of novel choice options. However, compared to controls, increased novelty seeking in the animals with amygdala lesions was related to their overweighting of the estimated exploration bonus ($p < .001$) and reduced weighting of an option's immediate value ($p < .001$). Thus, monkeys with amygdala lesions were more exploratory but learned less efficiently from reward feedback. By comparison dopamine levels had no effect on learning and instead caused a persistent overvaluation of novel choice options in terms of their immediate expected value ($p < .001$). Together the results from these two experiments suggest the amygdala is important for learning consistent statistical relationships needed to optimize exploratory behavior, whereas dopamine more generally biases exploration.

Title: Why Adaptive Coding? Signal and noise in neural transmission and adaptive coding in economic choices

Authors: *A. RUSTICHINI[1], C. PADOA-SCHIOPPA[2], N. BRUNEL[3];
[1]Econ., Univ. of Minnesota, Minneapolis, MN; [2]Washington Univ., St. Louis, MO; [3]Univ. of Chicago, Chicago, IL

Abstract: In the context of economic decisions, adaptive coding refers to the fact that neurons encoding the subjective value of a given option adjust their firing rate to the range of values available in the environment. Adaptive coding has been found in the orbitofrontal cortex (Padoa-Schioppa, 2009, Kobayashi et al 2010), amygdala (Bermudez and Schultz, 2010), anterior cingulate cortex (Cai and Padoa-Schioppa 2012), ventromedial prefrontal cortex and ventral striatum (Cox and Kable, 2013). Adaptive coding has also been observed in dopamine cells encoding reward prediction errors (Tobler et al, 2005). All these studies found that the neuronal activity slope is larger when the range of values is smaller, while the range of firing rates remains constant across different environments. Importantly, adaptive coding can introduce biases in decision making (Padoa-Schioppa and Rustichini, 2014). Thus a fundamental question is: What (if anything) does the choice system gain from adaptive coding? Here we show that the slope adjustment induces an improvement in the speed-accuracy trade-off, and we provide a quantitative estimate of this gain. The improvement is essentially because the process governing signal transmission across neuronal layers has a drift proportional to the firing rate of pre-synaptic cells, but standard deviation proportional to the square root of that firing rate. Everything else equal, and assuming a linear encoding of values, increasing the slope affords a faster and/or more accurate decision. The speed-accuracy trade-off is regulated by the stopping policy, which may depend on the environment and the details of the rules allocating rewards. We apply this general result to the several neural models of economic decisions, including the Drift Diffusion model (Ratcliff, 1978), the Leaky Competitive Accumulation model (Usher and McClelland, 2001), and several versions of the Pooled Inhibition model (Wang 2002; Wong and Wang, 2006). The general result that adaptive coding affords a better set of speed and accuracy is robust to the specific model, and we estimate this gain. We also show that in non-linear decision models the accuracy may be a non-monotonic function of the input slope. Thus the limited activity ranges typically recorded in orbitofrontal cortex and other brain regions may be set to optimize decisions, and not be due to intrinsic physiological bounds.

Title: A neuro-computational model of economic decisions

Authors: *C. PADOA-SCHIOPPA[1], A. RUSTICHINI[2];
[1]Washington Univ. in St Louis, Saint Louis, MO; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Lesion studies and neurophysiology indicate that key aspects of economic decisions take place in the orbitofrontal cortex (OFC). Specifically, single-cell recordings in monkeys choosing between different juices identified in this area three groups of neurons: offer value cells encoding the value of individual goods, chosen juice cells encoding the binary choice outcome, and chosen value cells encoding the value of the chosen good. An important and open question is whether and how decisions could emerge from a neural circuit formed by these three populations. Here we adapted a biophysically realistic neural network previously proposed for perceptual decisions (Wang 2002; Wong and Wang 2006). The domain of economic decisions is significantly broader than that for which the model was originally designed, because offers vary independently of each other whereas coherence in the random-dot task is a 1D parameter: Yet the model performed remarkably well. The input and output nodes of the network (OV and CJ cells) were naturally mapped onto two groups of neurons in OFC (offer value and chosen juice cells, respectively). Surprisingly, the activity of interneurons in the network (CV cells) closely resembled that of the third group of neurons, namely chosen value cells. This resemblance reflect the fact that inhibitory interneurons in Wang's model receive the input from the two types of CJ cells. The model reproduced several phenomena related to the neuronal origins of choice variability including choice hysteresis, the "predictive activity" of chosen juice cells and the "overshooting" of chosen value cells (see Padoa-Schioppa, 2013). It also generated testable predictions on the excitatory/inhibitory nature of different neuronal populations and on their connectivity. Some aspects of the empirical data were not reproduced, but simple extensions of the model could overcome these limitations. These results render a biologically credible model for the neuronal mechanisms of economic decisions. They demonstrate that choices could emerge from the activity of cells previously identified in the OFC, suggesting that chosen value cells directly participate in the decision process. Importantly, Wang's model provides a platform to investigate the implications of neuroscience results for economic theory.

Title: Neural activity in basolateral amygdala encodes reward magnitude and risk of punishment in a risky decision-making task in rats

Authors: *C. A. ORSINI, M. FEBO, J. L. BIZON, B. SETLOW;
UNIVERSITY OF FLORIDA, Gainesville, FL

Abstract: Elevated levels of risk-taking behavior are characteristic of substance addiction, and have the potential to precipitate and exacerbate substance use. A potential treatment strategy for addiction could be to attenuate such maladaptive choice behavior, so as to mitigate drug-seeking and potential relapse. To realize this goal, however, a thorough understanding of the neurobiology underlying normal risk-taking behavior is required. Using a rodent model of risk-taking, in which rats choose between a small, "safe" reward and a large, "risky" reward accompanied by a variable probability of punishment, we showed previously that an intact basolateral amygdala (BLA) is critical for integration of risk- and reward-related information to guide adaptive risk-taking. In the present experiment, we evaluated how neural activity in the intact BLA encodes risk- and reward-related information during task performance. Rats were trained in a modified version of the risky decision-making task in which reward magnitude and probability of punishment (50%) were independently manipulated in separate blocks of trials. During stable performance, rats chose the large reward significantly more than the small reward and chose the reward associated with risk of punishment significantly less than the reward associated with no punishment. Two drivable microwire bundles were then implanted immediately above the BLA. Upon recovery, neural activity was recorded while rats were tested in the risky decision-making task. Initial analyses indicated that during reward magnitude trials, there was an increase in BLA activity in anticipation of the large reward and a decrease in activity in anticipation of the small reward relative to baseline. A difference was also observed during risk of punishment trials, such that BLA activity increased in anticipation of the risky reward and decreased in anticipation of the safe reward relative to baseline. Importantly, the reward magnitude associated with each choice during the risk of punishment trials was held constant, indicating that differences in firing were due to encoding of risk-related information. Together, these data suggest that BLA neurons track the most salient option during choice behavior. Future work will compare BLA neural activity in this task between drug-naïve and cocaine-exposed rats to determine whether dysfunctional BLA activity contributes to drug-induced maladaptive risk-taking behavior.

Title: A novel group of dopamine neurons encoding stable object value memories

Authors: *H. F. KIM, A. GHAZIZADEH, O. HIKOSAKA;
NIH, NEI, LSR, Bethesda, MD

Abstract: Midbrain dopamine (DA) neurons are thought to be critical for reward-value based learning by modulating synaptic transmission in the striatum. Using macaque monkeys, we recently showed that visual object-value learning occurred slowly and the value memory was retained stably in neurons in caudate tail (CDt), unlike neurons in caudate head (CDh) (Kim & Hikosaka, Neuron 2013). We then found that CDt receives DA inputs exclusively from caudal-dorsal-lateral region of substantia nigra pars compacta (cdlSNc), which is segregated from rostral-ventral-medial SNc (rvmSNc) projecting to CDh (Kim et al., Front Neuroanat 2014). These data suggest that cdlSNc-DA neurons guide learning and retaining of stable object values in CDt. To test this hypothesis, we examined DA neuronal activity in two stages: 1) object-value learning, followed by 2) passive viewing with no reward feedback. Both rvmSNc neurons and cdlSNc neurons learned to discriminate high- and low-valued objects. However, they behaved completely differently in the passive viewing task: rvmSNc neurons stopped responding to the objects, whereas cdlSNc neurons continued to respond to the objects differentially: excited by high-valued objects and inhibited by low-valued objects. rvmSNc and cdlSNc neurons showed similar spike shapes and firing patterns, which are characteristic of DA neurons. We then histologically reconstructed recording sites of cdlSNc neurons and found them within a cluster of tyrosine hydroxylase-positive neurons, suggesting that they are dopaminergic. Furthermore, these cdlSNc-DA neurons were activated antidromically by stimulation in CDt, indicating their axonal projections to CDt. Our data suggest that DA neurons localized in cdlSNc contribute to the learning and maintaining of object value memories in CDt neurons. Since CDt exerts strong disinhibitory-inhibitory effects on the superior colliculus through the substantia nigra pars reticulata (Yasuda & Hikosaka, J Neurophysiol 2015), this novel DA mechanism would enable automatic gaze orienting to high-valued objects.

Title: Temporal backpropagation of basal forebrain reward-prediction-error signals underlies associative learning

Authors: *H. MANZUR[1], K. VLASOV[2], S.-C. LIN[2];
[1]NIH, Baltimore, MD; [2]Neural Circuits and Cognition Unit, Natl. Inst. of Hlth. - Natl. Inst. on Aging, Baltimore, MD

Abstract: Reward prediction error (RPE) signals have long been proposed in reinforcement learning (RL) theories as the driving force for new learning. A key prediction of RL theories that has rarely been observed experimentally is that, during learning, RPE signals should back-propagate from the unexpected outcome to the cue predicting that outcome through gradual shifts in latency. Here we provide evidence for such a temporal backpropagation in a novel RPE signal in the basal forebrain (BF). We first established that BF neuronal activity reflected RPE by encoding the difference between predicted and received reward. In rats exposed to a new stimulus-reward association, the receipt of unexpected reward following the new stimulus triggered a cascade of continuous backpropagation of BF activity to earlier events leading up to reward, which quickly emerged within a few trials and stabilized over several sessions. Backpropagated BF activity was tightly coupled with behavioral performance in single trials throughout learning. Furthermore, BF activity at an intermediate stage of RPE backpropagation, which was activated even in the absence of the new stimulus, underlied exploratory reward-seeking behaviors during the early learning phase in both stimulus-absent trials as well as in new stimulus trials. The evolution of BF RPE signals therefore reveals the underlying temporal dynamics of new learning, and also provides a rare glimpse into the internal models animals created to predict reward and guide reward-seeking behaviors.

Title: Topographic mapping of neocortical oscillations elicited by optogenetic stimulation of basal forebrain parvalbumin neurons

Authors: *E. HWANG[1], B. KIM[1], R. E. BROWN[2], T. KIM[3], J. T. MCKENNA[2], R. W. MCCARLEY[2], J. CHOI[1];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Dept. of Psychiatry, VA BHS & Harvard Med. Sch., Brockton, MA; [3]Dept. of Psychiatry, Kyung Hee Univ. Hosp. at Gangdong, Seoul, Korea, Republic of

Abstract: Particular behaviors are associated with different spatio-temporal patterns of cortical EEG oscillations. However, little is known about how subcortical projections to the cortex control these responses. GABAergic, parvalbumin-positive (PV+) projection neurons in the basal forebrain (BF) innervate GABAergic interneurons in multiple regions of neocortex and inhibitory neurons in thalamic reticular nucleus. Recent studies from our group (Kim et al., 2015, PNAS 112(11): 3535-3540) suggest that the BF PV projection to the cortex plays an important role in the state-dependent control of cortical oscillations, especially those in the gamma band (30-80 Hz). However, the cortical topography of this response is unknown. Thus, here we combined optogenetic stimulation of BF PV+ neurons with high-density (hd) EEG recordings in mice and determined for the first time the spatio-temporal frequency responses in the cortex. PV+ neurons were selectively targeted by double-floxed adeno-associated viral vector-mediated delivery of channelrhodopsin 2 to BF of C57BL/6 mice expressing Cre recombinase in PV+ neurons. hd EEG recordings were made using custom-made 32-channel EEG films laid over the skull. Optical stimulation at 10, 20, 30, 40 and 50 Hz was delivered via a patch cable connected to a 470-nm LED light source, while the mice were allowed to move freely in an unrestrained condition. Optogenetic stimulation of BF PV+ neurons at gamma band frequencies (30 and 40 Hz) induced preferential enhancement of frontal gamma band oscillations and increased frontal-frontal connectivity (N=3). On the other hand, stimulation at 10 and 20 Hz led to dominant

responses on centro-parietal and fronto-central regions, respectively. Thus, there were distinct topographical responses with varying stimulation frequencies. Anti-phasic oscillatory responses were observed between frontal and centro-medial areas only during stimulation with frequencies higher than 30 Hz raising the possibility of non-uniform mechanisms of coordinating cortical oscillation in a spatially distinctive manner by BF PV+ neurons. Our results supports the idea that increasing the activity of BF PV+ neurons may be a potential target for restoring abnormal frontal cortical gamma oscillations associated with disorders such as schizophrenia and Alzheimer's disease.

Title: Optogenetic dissection of motivational salience neuronal circuits in the basal forebrain

Authors: *A. SCAGLIONE, R. GREENFIELD, S.-C. LIN;
NIA-NIH-IRP, Baltimore, MD

Abstract: The survival of animals depends critically on prioritizing responses to motivationally salient stimuli. Recent studies have identified a group of neurons in the basal forebrain (BF) that encodes motivational salience of attended stimuli using robust bursting responses (Lin & Nicolelis, 2008). Such salience-encoding BF responses generate an event-related potential response in the frontal cortex (Nguyen & Lin, 2014) and lead to faster decision speed (Avila & Lin, 2014). However, the neurochemical identity of salience-encoding BF neurons remains unknown. Determining their neurochemical identity is a key step toward understanding their circuit-level functions especially because BF is an anatomically complex and heterogeneous region, comprised of multiple spatially overlapping macrosystems and several distinct neuronal populations. The goal of this study is to determine the neurochemical identity of salience-encoding BF neurons by optogenetically tagging and recording the three major cortically-projecting BF neuronal populations in freely behaving mice. To achieve this goal, we first established an experimental platform in three strains of transgenic Cre mice (PV-, ChAT- and VGluT2-Cre) that combines operant behavior, electrophysiology and optogenetics. Mice were trained to maintain fixation in a nosepoke port and then respond quickly to a reward-predicting

tone to collect reward in an adjacent port. Mice were able to achieve high hit rates (>90%) and high trial numbers in a session (>150 rewarded trials) with fast reaction times (<300ms). Neuronal recording in combination with photo-stimulation of the BF show that: 1) The majority of recorded BF neurons in mice showed robust bursting responses to the motivationally salient tone similar to salience-encoding BF neurons in rats and 2) photo-stimulation of the three major cortically-projecting BF neuronal populations can directly or indirectly modulate (excite or inhibit) bursting responses to the salient tone. Taken together, these results suggest that the three main populations of neurons participate in concert, directly or indirectly, in the circuit underlying motivational salience in the BF.

Title: Neuroanatomical investigation of basal forebrain glutamatergic neurons using vGlut2-tdTomato mice

Authors: *J. T. MCKENNA[1], M. GAMBLE[2], C. YANG[1], J. M. MCNALLY[1], A. HULVERSON[2], S. WINSTON[1], S. THANKACHAN[1], R. W. MCCARLEY[1], R. E. BROWN[1]; [1]Research/Psychiatry, VA Boston Healthcare/Harvard Med. Sch., Brockton, MA; [2]Stonehill Col., Easton, MA

Abstract: Basal forebrain (BF) neurons play a crucial role in cortical activation, attention, and sleep-wake behavior. Of the three major BF neurotransmitter classes, glutamatergic neurons are the least well understood due to difficulties in identification. Thus, here, we validate a novel

transgenic mouse model that expresses a red fluorescent protein (tdTomato) in BF glutamate neurons. Vesicular glutamate transporter, subtype 2 (vGluT2)-tdTomato mice were created by crossing vGluT2-Cre Recombinase mice with a Cre-reporter strain expressing tdTomato. This mouse model allows online identification and combinatorial approaches with other transgenic mouse lines or viral vectors utilizing green/yellow fluorescent proteins. Immunohistochemical staining was performed against choline acetyltransferase (ChAT, synthetic enzyme for acetylcholine); parvalbumin (a subset of GABAergic neurons); and calbindin, to identify putative cortically-projecting neurons. The distribution of tdTomato+ neurons in the BF of vGluT2-tdTomato mice resembled that of BF vGluT2+ neurons identified previously by means of *in situ* hybridization. tdTomato was not expressed in cholinergic (N=3, 3154 vGlut2-Tom+, 1903 ChAT+ neurons analyzed) or parvalbumin (N=3, 3049 vGlut2-Tom+, 3528 PV+ neurons analyzed) neurons. 25.9±3.3% (ave±SEM) of BF vGluT2-Tomato neurons contained calbindin (N=3, 2872 vGlut2-Tom+ neurons analyzed). vGlut2-tdTomato mice were also crossed with GAD67-GFP knock-in mice to test for co-localization in GABAergic neurons. tdTomato was not expressed in GABAergic neurons (N=1, 1172 neurons analyzed). To investigate BF vGluT2 projections, floxed adeno-associated viral vectors (AAV) expressing ChR2-EYFP (Enhanced Yellow Fluorescent Protein) were unilaterally injected into BF. Efferent projections were identified in cortical regions, thalamus, and hypothalamus, as well as fibers apposed to BF cholinergic and PV neurons. BF vGluT2 neurons may modulate cortical activity through both direct cortical projections and interactions with BF cholinergic and parvalbumin neurons. Validation of this mouse model allows further study of the role of BF glutamatergic neurons in sleep-wake behavior, using *in vitro*, *in vivo* optogenetic, and pharmacogenetic approaches.

Title: Basal forebrain vGluT2-positive neurons: electrophysiological properties and cholinergic modulation

Authors: *C. YANG, J. T. MCKENNA, R. E. BROWN;
Psychiatry, VA Boston Healthcare Syst. and Harvard Med. Sch., Brockton, MA

Abstract: Basal forebrain (BF) wake-active neurons play an important role in cortical activation, attention and cortical plasticity. Among the three major types of BF cortically-projecting neurons (cholinergic, GABAergic and glutamatergic), glutamatergic neurons are the least understood, due to difficulties in identification. Here, we take the advantage of a novel transgenic mouse model [vesicular glutamate transporter 2 (vGluT2)-tdTomato mice] expressing a red fluorescent protein in the major group of BF glutamatergic neurons to characterize for the first time the intrinsic membrane properties and neurotransmitter modulation of identified BF glutamatergic neurons. Whole-cell, patch-clamp recordings were made from vGluT2-positive neurons in coronal brain slices. Most of these neurons were small/medium sized (Mean long-axis diameter: 14.6±0.8 μm, n=19). Most vGluT2 neurons were silent at rest (13/19) and had a maximal firing frequency of ~40 Hz i.e. they had a maximal firing frequency which is larger than that of BF cholinergic neurons but smaller than that of large-sized GABAergic/parvalbumin neurons. We categorized vGluT2 neurons into two groups: medium-sized (>15 μm) and small-sized (≤ 15 μm). Medium-sized vGluT2 neurons were located in HDB/SI/LPO regions of BF (5/6) and were strongly hyperpolarized (-17.5 ± 2.2 mV, n=5/5) by the cholinergic agonist, carbachol (50 μM) in the presence of 500 nM tetrodotoxin. Most small-sized vGluT2 neurons were located in the lateral MCPO or HDB/LPO (9/13) and did not show a postsynaptic response to carbachol (n=2). Our results suggest that BF glutamatergic neurons have distinct intrinsic membrane properties from BF cholinergic and GABAergic neurons. Unlike BF GABAergic neurons, glutamatergic neurons are hyperpolarized by cholinergic inputs, which may facilitate burst firing of these neurons during wakefulness and REM sleep via de-inactivation of low-threshold calcium currents.

Title: Decoding the value related signal represented in the multiple areas of the prefrontal cortex using the ECoG electrodes

Authors: *S. TANAKA[1], K. KAWASAKI[2], I. HASEGAWA[2], T. SUZUKI[3], M. SAKAGAMI[1]; [1]Tamagawa Univ. Brain Sci. Inst., Machida, Tokyo, Japan; [2]Dept. of Physiol., Niigata Univ. Sch. of Med., Niigata, Japan; [3]Natl. Inst. of Information and Communications Technol., Ctr. for Information and Neural Networks, Osaka, Japan

Abstract: Decision making is one of the important mental processes. For making a decision between multiple options, sometimes the values of the options are used. Wide-ranging areas of the brain are involved in this economic decision making process. Especially, a lot of studies show that areas in the prefrontal cortex (PFC) play important but different roles for value calculation and comparison. Because of the different rolls of the areas in the PFC, the value signal should be reciprocated within areas in the PFC. However few studies directly examined the signal transmission between multiple areas of the PFC. Here, we tried to reveal the dynamic mechanism of value signal transmission in the wide-ranging areas of the PFC. A monkey was trained to perform a free-choice task. After start cue presentation monkey pressed a button then a hold cue appeared. While the monkey kept pressing the button, two visual cues which indicated the kinds of juices were presented sequentially with a short blank. Finally, two cues were presented simultaneously and the monkey touched one of them to obtain juice reward. From the choice behavior between two alternatives, the values of the rewards could be estimated. While the monkey performed this task, the local field potentials (LFPs) were recorded from electrocorticographic (ECoG) electrodes implanted on the left lateral prefrontal cortex (LPFC), the left orbitofrontal cortex (OFC) and both side of the medial prefrontal cortex (MPFC) of a macaque monkey. To examine whether the value of the reward is represented in 3 areas of the PFC, we tried to decode the values of the juices from the signal during 1st cue presentation for each area separately. We calculated the power in six frequency domains (δ, θ, α, β, *low-*γ, *high-*γ) and extracted the value related features which showed correlation to the value of the reward estimated from the behavior. With this extracted features, we tried to decode the value of the reward with Sparse Linear Regression (SLiR) algorithm. The decoded values calculated from 3 areas were highly correlated with the estimated value. The R^2 score was biased to be larger than 0 indicating a good decoding performance. We also performed ROC analysis to examine whether the decoder could discriminate most preferred juice and least preferred juice. Area under the ROC value was significantly larger than 0.5 and close to 1 indicating nearly perfect discrimination ability. Furthermore, the time windows, from which the features used to decode the value were selected, of MPFC was earlier than that of LPFC and OFC. From these results, we suggest that the value signal exists in 3 areas of the PFC and the temporal stage for value calculation were different.

Title: The neural basis of self-initiated movements in the larval zebrafish

Authors: ***A. JOUARY**[1], S. MEHYAOUI[2], G. SUMBRE[1];
[1]Section Neurosci., [2]IBENS INSERM U1024, Paris, France

Abstract: Animal behaviors can be induced by sensory stimuli or reflect intentional self-initiated motor patterns. In the absence of salient sensory cues, the larval zebrafish spontaneously produces stereotypical tail movements similar to those produced during goal driven navigation. Our goal is to understand the mechanisms by which sequential activations of neuronal assemblies across different brain region predict the onset of a specific tail movement. In head-restrained larva, we simultaneously recorded tail movements and neuronal activity from a large portion of the brain using light- sheet microscopy (~5000 neurons at 10Hz).The tail movements were categorized according to stereotypical maneuvers using an unsupervised classifier. We identified spatio-temporal features of the neural activity predicting the onset of a specific tail movement around 1 sec before this onset. Moreover, preliminary analysis suggests that neurons whose activity predicts the occurrence of a tail movements are distinct and operate on shorter time scale than neurons predicting the categories of movements. This suggests that parallel pathways are coding the initiation and selection of the type of upcoming movement.

Abstract: Decision-making is one of the most complicated cognitive processes that require integration of neural activities across several brain regions. In the present work, we analyzed hippocampal local field potential (LFP) during a lever-pressing task, in which restrained rats pressed the right or left lever with their right or left hand, respectively, to control an e-Puck mobile robot that brought them a small amount of food. We found a predominance of theta range oscillation (4-8 Hz) in the hippocampal LFP, which began 1 s before the lever press and lasted for 2-3 s. The time course of theta convergence was similar between the right and left lever-pressings, suggesting that this convergence was not directly implicated to the motor output. Interestingly, we found stark differences in some behavioral and LFP parameters between earlier and later periods of a daily session, which were thought to correspond to hungry and satiated conditions in rats, respectively. As expected, the rats pressed the lever more frequently in the earlier period. Along with this, peak frequency of the theta oscillation significantly changed from 7.2 to 7.8 Hz, while total amount of the theta power (4-8 Hz) did not change. The peak frequency shift of hippocampal theta was also reported during decision-making epoch for the right-left selection in plus maze task and hence likely to reflect a change in behavioral state of the rat. Based on these results, we developed a method to predict the lever-pressing using the spectrum pattern of hippocampal LFP and the theta peak frequency. Using these parameters as features, we run the machine-learning algorithm and calculated cross-correlation between the template and temporal pattern of relative theta power. We found spectrum pattern was useful to predict the lever-pressing in this kind of cognitive effort-demanding task.

Title: A medial prefrontal-striosome circuit is selectively engaged by cost-benefit conflict decision-making

Authors: *L. G. GIBB, A. FRIEDMAN, D. HOMMA, K.-I. AMEMORI, S. J. RUBIN, A. S. HOOD, M. H. RIAD, A. M. GRAYBIEL;
MIBR/BCS, MIT, Cambridge, MA

Abstract: The striosomal compartment of the striatum can be distinguished from the surrounding matrix based on patterns of gene expression and connectivity, and imbalances between striosomes and matrix occur in neurological disorders. The function of striosomes is a decades-old mystery, but their connectivity suggests a function related to mood and motivation. Here, we developed a method for identifying, in tetrode recordings from the dorsomedial striatum of rats, the putative striosomal spiny projection neurons (SPNs) that preferentially receive input from a region of the rodent prefrontal cortex called the prelimbic cortex (PFC-PL). Our method is based on the response pattern of putative striosomal SPNs to electrical stimulation of the PFC-PL, which we validated in a set of rats by determining the positions of tetrode tips relative to striosomes in 3D reconstructions from immunofluorescently stained sections post-stimulation. We analyzed the activity of putative striosomal SPNs in five T-maze tasks: a cost-benefit conflict (CBC) task, in which the rat had to accept high cost in order to receive high reward; two versions of a benefit-benefit task, in which the rat chose between two rewards, either similar or dissimilar; a non-conflict cost-benefit task, in which high reward was paired with low cost; and a cost-cost task, in which the two options had equal rewards but different costs.

Strikingly, the activity of striosomal SPNs during the period between starting cue (click) and turn was low in the CBC task and high in the other four tasks. By contrast, SPNs not identified as striosomal, which based on the relative volumes of the striatal compartments should largely consist of matrix SPNs, were active in the click-to-turn period in all tasks. The behavioral results of optogenetic manipulation of the PFC-PL input to striosomes showed similar CBC selectivity. Optogenetic inhibition predominantly affecting PFC-PL input to striosomes had a large effect on decision-making only in the CBC task, increasing the animals' choices of the high-cost, high-benefit option, whereas optogenetic excitation of the same input increased the animals' choices of the low-cost, low-benefit option, again only in the CBC task. Optogenetic inhibition of the input to matrix from the anterior cingulate cortex significantly shifted the animals' choices toward the higher reward in all tasks having unequal rewards. Logistic modeling of the data suggested the possibility that optogenetic manipulation the cortico-striosomal circuit modulated sensitivity to cost selectively in the CBC task, whereas optogenetic manipulation of cortical input to matrix modulated sensitivity to benefit in all tasks.

Title: Striatal high-firing interneurons mediate inhibitory prefrontal-striosomal signaling during cost-benefit conflict decision-making

Authors: *A. FRIEDMAN, D. HOMMA, L. G. GIBB, L. G. GIBB, K.-I. AMEMORI, S. J. RUBIN, A. S. HOOD, M. H. RIAD, A. M. GRAYBIEL;

Abstract: The functions of cortical inputs to the striosomal compartment of the striatum are unknown. Here, we compared the activity patterns of striosome-projecting prefrontal cortical neurons and striosomal spiny projection neurons (SPNs) in rats across five T-maze decision-making tasks: a cost-benefit conflict (CBC) task, in which a high-reward option is paired with high cost; two benefit-benefit tasks with similar or dissimilar rewards; a non-conflict cost-benefit task, in which the high-reward option is paired with low cost; and a cost-cost task with equal rewards but different costs. We antidromically identified putative striosome-projecting neurons of rodent prefrontal cortex in the region called the prelimbic cortex (PFC-PLs neurons) and orthodromically identified putative striosomal SPNs. Strikingly, we found that the activity patterns across tasks of PFC-PLs neurons and striosomal SPNs were complementary: In the period between the start cue and the turn, PFC-PLs neurons had high activity in the CBC task but low activity in the other tasks, whereas striosomal SPNs had low activity in the CBC task and high activity in the other tasks. Since the corticostriatal projection from PFC-PLs neurons should be excitatory, we hypothesized that the complementarity of the PFC-PLs and striosomal SPN patterns could be due, at least in part, to feedforward inhibition via striatal interneurons. Thus we examined the activity of high-firing neurons (HFNs, putative inhibitory interneurons) that we identified on the basis of spike and firing characteristics. We found that HFNs had burst-like episodes and that the within-burst firing rate pattern of HFNs across tasks was remarkably similar to the pattern of PFC-PLs neurons. Moreover, the firing rates of striosomal SPNs were negatively correlated with the within-burst firing rate of HFNs. These results emerged only when we used the within-burst firing rate of HFNs, suggesting that phasic, rather than tonic, activity of HFNs may be essential for the feedforward inhibition. Also consistent with the hypothesis of feedforward inhibition, SPN spikes aligned to the time of peak firing rate of simultaneously recorded HFNs exhibited inhibition, and the response latency of HFNs to electrical stimulation of PFC-PL was ~3 ms shorter than that of striosomal SPNs. When the corticostriatal axons were optogenetically inhibited in conjunction with electrical stimulation of PFC-PL, striosomal SPN activity decreased, whereas HFN activity increased. Our results suggest that the PFC-PLs pathway to striosomes is selectively engaged in CBC decision-making and that PFC-PL activation inhibits striosomal SPNs via striatal HFNs.

Title: Compartmental selectivity of a prefronto-striosomal pathway controlling decision-making under motivational conflict

Authors: *D. HOMMA, A. FRIEDMAN, L. G. GIBB, K.-I. AMEMORI, S. J. RUBIN, A. S. HOOD, M. H. RIAD, A. M. GRAYBIEL;
MIBR, MIT, Cambridge, MA

Abstract: Striosomes form a labyrinthine striatal compartment originally distinguished from the surrounding matrix by neurochemical properties. Although parts of the striosomal compartment are anatomically connected with regions related to motivation and emotion, the functions of striosomes are virtually unknown. Here, we developed rat models for optogenetic manipulation of striosome- or matrix-selective corticostriatal inputs. We verified the selectivity of virally labeled projections to striosomes and matrix, respectively, from zones within the prefrontal regions called in rodents prelimbic cortex (PFC-PL) and anterior cingulate cortex (PFC-ACC) by using immunofluorescence histology, confocal imaging, 3D reconstruction and densitometric analysis of corticostriatal axons in the region below the optical fiber tips. In this analysis, we used three different models to estimate the effect of optogenetic manipulation of these corticostriatal pathways. We found that the density of PFC-PL input labeling was ~5.2 times greater in striosomes than in matrix and that of PFC-ACC input labeling was ~2.6 times greater in matrix than in striosomes. We optogenetically manipulated these selective inputs in rats performing five T-maze-based decision-making tasks that we developed. Our tasks allowed us to measure quantitatively the motivation to approach reward and the motivation to avoid cost under different levels of motivational conflict. The rats' sensitivity to reward was measured by a benefit-benefit task in which different levels of benefit (chocolate milk concentration) were provided at each end-arm. The sensitivity to cost was measured by a cost-cost task in which the same benefit was given on both sides but one was coupled with higher cost (brighter light). To

investigate how the rats integrate cost and benefit under different levels of motivational conflict, we introduced a cost-benefit conflict task in which higher benefit was coupled with higher cost, and a non-conflict cost-benefit task in which higher benefit was coupled with lower cost. Optogenetic inhibition of the striosome-targeting input shifted the rat's choice toward high-benefit, high-cost options in the cost-benefit conflict task but not in the other tasks. By contrast, optogenetic inhibition of the matrix-targeting axons shifted the choice toward high-benefit options except in the cost-cost task. Our results suggest that the PFC-PL corticostriatal pathway is selective for striosomes and controls the animals' choice under motivational conflict, whereas the PFC-ACC corticostriatal pathway is selective for matrix and is involved in the control of motivation toward benefit.

Title: Properties of striatal beta oscillation at sites identified by microstimulation as controlling approach-avoidance choice behavior

Authors: *K.-I. AMEMORI, S. AMEMORI, D. J. GIBSON, A. M. GRAYBIEL;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: The primate striatum is a node in circuits controlling emotion and motivational states affected in a range of anxiety and obsessive-compulsive disorders. Deep brain stimulation targeting the ventral striatum and related circuits has been applied for the treatment of these disorders, but the neural mechanisms underlying these effects are not fully identified. Here, we adopted a combined approach of focal intrastriatal microstimulation and simultaneous recording of local field potentials (LFPs) in two macaque monkeys performing an approach-avoidance (Ap-Av) decision-making task. The monkeys were required to decide whether to accept or reject

an offered outcome that included both benefit (food) and cost (air puff), whose amounts were indicated in advance by a visual cue. The neural signals in the cue period were dissociated from those related to movements, as the choice was associated with the randomly placed targets. To test for causal evidence of striatal function in such decision-making, we examined the influence of localized microstimulation of the striatum (1-sec trains, biphasic pulses, 70-100 μA at 200 Hz, during cue period) on the Ap-Av choice behavior. At 18 of the 137 sites examined, microstimulation sharply increased avoidance choices (defined as greater than 10% change in the decision boundary), suggesting that the primate striatum has local sites dedicated to modulation of pessimistic states influencing approach-avoidance decisions. We further recorded LFP oscillations from the stimulated sites, performed band-pass filtering (13-28 Hz) to extract beta-band oscillations, and calculated the mean beta-band power during the decision period for each trial. Among 220 channels recorded from the effective sites inducing increased avoidance (allowing overlap in recording from the same sites day to day), beta power during the decision period was positively correlated with the upcoming avoidance decision significantly (Pearson's correlation, $p < 0.05$) on 77 channels (35.0%). At sites at which microstimulation did not induce change in approach-avoidance decision (41 sites), beta power was correlated with the avoidance choice on 16.1% of the recording channels (43/267, including overlap). The frequency of observation of beta power predicting avoidance choice was thus significantly higher in the effective stimulation sites than that in the non-effective sites (Fisher's exact test, $p < 0.01$). These results raise the possibility that pessimistic states can be modulated by local activity in the dorsal striatum, and that striatal local circuits exhibiting beta-band oscillations can participate in such modulation.

Title: Differential effects of granular and agranular inactivations on a rodent slot machine task

Authors: *P. J. COCKER[1], M. Y. LIN[1], M. M. BARRUS[1], B. LE FOLL[2], C. A. WINSTANLEY[1];

Abstract: Gambling is a relatively ubiquitous phenomena that many people engage in without adverse effect, yet for a significant minority gambling can become a maladaptive compulsion with phenomenological similarities to substance abuse. Cognitive theories of gambling suggest that the transition from recreational to problematic engagement with gambling is due to the presence of cognitive biases or distortions. One of the most widely recognised of these biases are near-miss effects. Near-misses are unsuccessful outcomes that are structurally proximal to a win. Although subjectively aversive, near-misses have been reliably shown to generate reward expectancy and galvanize further game play. We have developed a rodent slot machine task (rSMT) wherein animals respond to a series of three flashing aperture lights, analogous to the three wheels of a slot machine, nose-poke responses in each hole cause the light to set to on or off. A win is signalled by all three lights setting to on, whereas any other light pattern indicates a loss. At the end of a trial the animal chooses between the 'collect' lever, which delivers 10 sugar pellets on winning trials, but a 10-second time-out penalty on losing trials, or the 'roll' lever which allows the animal to begin a new trial immediately. Animals are sensitive to the number of illuminated apertures presented within the array and 2 out of 3 illuminated apertures are able to generate erroneous responses on the collect lever. Indicating that rodents, like humans, are susceptible to the reinforcing effects of winning signals conveyed within non-winning trials, consistent with a near-miss-like effect. Data from human imaging and lesion studies have implicated an important role for the insula in gambling related decision making. However, imaging studies have yielded relatively inconsistent results and lesion studies lack specificity, such that the relative contributions of insula sub-regions are currently unclear. The granular and agranular insula have differential connectivity and have been ascribed different roles in mediating decision making; a demarcation of function between these two areas may meaningfully inform the neurobiology of disordered gambling. Here, we present data indicating that inactivations of the granular and agranular insula cortex differentially impact reward expectancy on the rSMT. These results have necessarily different mechanistic interpretations regarding the reinforcing effects of near-misses within gambling and consequently different implications for potential treatment options.

Title: Motivation and reward/effort tradeoff: insights from local field potentials in the ventromedial prefrontal cortex

Authors: *C. VARAZZANI[1], A. SAN-GALLI[1], F. MEYNIEL[2], T. ANDRILLON[3], S. BOURET[1];
[1]ICM - Brain & Spine Inst., Paris, France; [2]Cognitive Neuroimaging Unit, U992, INSERM, CEA, Paris, France; [3]Lab. de Sci. Cognitives et Psycholinguistique, EHESS/CNRS/ENS-DEC, Paris, France

Abstract: One key problem faced by the brain is deciding how much effort to mobilize in order to attain a specific goal. The problem is particularly difficult as it requires not only an initial discounting of potential rewards according to effort costs, but also a persistent monitoring of effort until the goal is reached. The ventromedial prefrontal cortex (vmPFC) has been strongly implicated in representing predictive rewards and choice preferences. What is less clear, however, is the extent to which the vmPFC contributes to discount effort costs from expected rewards. The current study aims at identifying the contribution of the vmPFC to the encoding of such reward/effort trade-off in monkeys. We recorded local field potentials (LFPs) in the vmPFC in two rhesus macaques performing a reward-effort task, where they must squeeze a hand grip (3 levels of effort) in order to get a reward (3 sizes of reward). In each trial, a visual cue indicated both effort level and reward size. The expected value associated to each cue was assessed by measuring the abandon rates (the decision to perform the trial, or not). Abandon rates rose as reward decreased and effort increased, indicating that the reward was discounted by the amount of physical effort required to obtain it. The pupil response, a measure of autonomic arousal, increased with the expected reward at the cue and with the amount of physical effort produced during the action. We used a time frequency decomposition to assess the influence of task parameters on specific frequencies of the LFP signal. Right after the cue onset, the expected reward positively modulated the LFP power ($p<.05$, cluster-corrected) in the 5-30 Hz range. The power in this frequency band was also negatively modulated by the anticipated effort cost ($p<.05$, cluster-corrected). During the action itself, the LFP power in the 5-30 Hz range scaled positively with the imposed effort level (p0.1, $p<.05$). These results suggest that the population activity of vmPFC neurons is affected by the expected value, which depends upon the reward/effort tradeoff. Our results also reveal a relationship between vmPFC and autonomic arousal, as reflected in the positive correlation with pupil dilation. To sum up, the activity of

VMPFC neurons reflects both the expected value prior to the effortful action and the autonomic arousal during its execution.

Title: Individual differences in reward sensitivity modulate ventrolateral prefrontal cortex responses to choice

Authors: *C. CHO, D. V. SMITH, M. R. DELGADO;
Psychology department, Rutgers Univ., Newark, NJ

Abstract: Human behavioral and neuroimaging studies suggest engaging in choice behavior is inherently rewarding (e.g., Leotti & Delgado, 2011), which leads to enhanced motivation and allocation of cognitive resources towards a particular behavior. Indeed, regions involved in cognitive control, such as the ventrolateral prefrontal cortex (VLPFC), show greater activation during reward-motivated trials (Taylor et al., 2004). One interesting question is whether the opportunity for choice enhances motivation by modulating the engagement of such regions involved in cognitive control. We hypothesized that the opportunity to exert control would engage VLPFC according to individual's sensitivity to rewards. Participants (N = 33) performed a simple decision-making task in an fMRI scanner. On each trial, participants were presented with two options that could either offer similar or dissimilar outcomes. Trials offering similar options effectively forced the participant's choice (i.e., no-choice trials); whereas trials offering dissimilar options allowed the participant to choose freely (i.e., choice trials). Reward sensitivity was measured using the Temporal Experience of Pleasure Scale (TEPS; Gard et al., 2006) and individuals' scores ranged from 26-45. During choice trials (relative to no-choice trials), we found that greater reward sensitivity recruited activity in the VLPFC. Specifically, individuals with greater self-reported reward sensitivity evoked greater VLPFC activation than individuals

with low reward sensitivity. These findings suggest that individuals who are more reward sensitive engage the VLPFC when given the opportunity to choose. These data lend support to the idea that exercising choice enhances motivation via allocating cognitive resources necessary for effective decision making.

Title: Neural evidence of good-based economic choice under varying action costs

Authors: ***X. CAI**[1,2], C. PADOA-SCHIOPPA[1];
[1]Washington Univ. Sch. of Med., St Louis, MO; [2]New York Univ. Shanghai, Shanghai, China

Abstract: Previous work showed that economic decisions can be made independently of the spatial configuration of the offers and independently of the action necessary to implement the choice (in goods space). However, goods available for choice may be associated with different action costs. In such conditions, the decision process must necessarily take into account some aspect of the action. Two schemes have been proposed to account for decisions under variable action costs. One possibility is that the brain first computes the "stimulus value" of each option and then combines the stimulus value with the corresponding action cost in an action-based representation. In this scheme, decisions are action-based and take place in premotor regions (Rangel and Hare, 2010). Alternatively, action costs could be integrated with other determinants of value (commodity, quantity, etc.) in an abstract representation. In this view, decisions under variable action costs could take place in the space of goods (Padoa-Schioppa, 2011). To shed light on this fundamental issue, we recorded from the orbitofrontal cortex while monkeys chose between different juices offered in variable amounts and with variable action costs. Specifically, we manipulated the cost associated to each offer by varying the amplitude of the saccade necessary to indicate the chosen option. At the beginning of each trial, the animal fixated the center of a computer monitor. Two offers then appeared on the two sides of the fixation point. Each offer was represented by a set of color symbols. Different colors represented different juices, the number of symbols represented the juice quantity, and the shape of the symbols

represented the saccade amplitude (short or long). Offers remained on the monitor for 1 s, followed by a 1 s delay. Two saccade targets then appeared on the monitor. The color of each saccade target was that of the corresponding juice, the radial distance from the center fixation was set accordingly to the action cost, and the angular position of the two targets was chosen randomly on each trial. After a go signal, the animal indicated its choice with a saccade. Critically, this design provided the opportunity to dissociate in time the decision from the formation of an action plan. We recorded the activity of 754 cells. Different groups of neurons encoded the offer value, the chosen value and the identity of the chosen option. Remarkably, both juice-based and cost-based neuronal representations were present at the same time. Furthermore, chosen juice and chosen cost neurons encoded the choice outcome well before the presentation of saccade targets, indicating that economic decisions were made in goods space.

Title: Dissociation of local field and action potentials in supplementary eye field during value based decision-making

Authors: X. CHEN[1,2], *V. STUPHORN[1];
[1]Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurobio., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Cooling experiments show that neural activity in the supplementary eye field (SEF) causally contributes to value-based decision making. Various decision-related signals have been found in SEF during value based decision tasks. However, SEF occupies an intermediate stage in the neural network underlying decisions. It is therefore not clear, if SEF activity mainly reflects signals reverberating in an extended network, or if any of the signals are computed locally. The cooling experiments disrupted action potentials representing the outcome of local neural computations. Synaptic potentials in dendrites represent input from other brain areas, but they are difficult to record. Local field potentials (LFPs) represent the slower frequency spectrum (below 500 Hz) of extracellularly recorded potentials. The previous literature suggests that both

synaptic inputs and action potentials contribute to LFPs. Thus, the analysis of signals carried by action potentials and LFPs provides a possible way to differentiate between computations within the local cortical network and synaptic input into the network. We therefore recorded LFPs in SEF during a value based decision task, while reversibly blocking action potentials. We had two main results. First, in the cooled cortex, LFP activity in the low-frequency band consistently increased during cooling and likely reflects largely synaptic potentials. In the non-cooled cortex, LFP activity in the high gamma/gamma frequency band was closely correlated with spiking activity. In contrast, during cooling the high gamma/gamma activity was not consistently reduced. In different task periods, activity could be both larger and smaller than in the non-cooled condition. Thus, high frequency LFP activity does not reflect mainly action potentials, but also largely synaptic currents. Second, we found that information about the chosen value, chosen action, and reward evaluation were not only represented in the action potentials, but also in the LFPs. Moreover, these different kinds of information were represented both before and after inactivation. These results suggest that SEF reciprocally receives value and action information from other cortical areas and is part of a larger network contributing collectively to the value based decision process.

Title: Free choice in a novel reward preference paradigm: Effects of striatal lesions and diverse control experiences

Authors: *J. RICKER[1], R. KOPCHOCK[2], A. SCHMIDT[2], D. DANIEL[2], A. TYSON[2], H. C. CROMWELL[2];
[1]Bowling Green State Univ., Napoleon, OH; [2]Bowling Green State Univ., Bowling Green, OH

Abstract: Making an advantageous choice between multiple rewards requires an organism to properly and efficiently assign value to each option. Factors such as magnitude of reward, time of delivery, and effort put forth must be taken into account. Reward choice and decision-making have typically been investigated under limited “free” choice. For example, animals often have a choice between one lever and another. This expression of preference is spatially constrained and limited in terms of appetitive actions. The current study employs a novel testing apparatus that

consists of a middle “decision” box, which is connected to two boxes with differing food reward magnitudes. One box is associated with a reward value (1 pellet every 5 seconds), while the other would be associated with another reward value (1.5 pellets every 7.5 seconds). The animals must choose between these two outcome values that combine parameters of magnitude and delay. The total apparatus resembles an expanded conditioned place preference paradigm consisting of 3 boxes and that totals nearly 250 centimeters in length. Our analysis compared free choice among groups: striatal lesion, sham surgery group, no surgery group, and a sucrose-exposed group. This new apparatus also allows for multiple dependent measures to be recorded. These include: food cup checks, total time in box, number of rewards obtained, and ultrasonic vocalizations. These measures allow an examination of free choice in terms of relative reward, reward discrimination, and reward preference. Preliminary data suggests that striatal lesions led to a higher preference for a box with a shorter delay of reward delivery. Our new data investigates differences that may occur between our original striatal lesion groups and groups of “control” rats that have been exposed to different experiences. One “control” group underwent a sham lesion surgery using phosphate buffered saline as opposed to quinolinic acid. A second “control” group had a history of exposure to drinking a sucrose solution. The final “control” group consisted of rats that had no exposure to any surgery or alternate food or water intake. We expect that different experiences will lead to diverse results amongst our control groups. These types of differences between our control groups could allow us to determine how the experience of a sham surgery could alter the overall results of a choice study. This novel design may allow for a fresh perspective on testing reward choice, and it may lead to a better understanding of psychiatric disorders ranging from substance abuse to anxiety disorders.

Title: Optical voltage imaging of self-evoked lever-pressing task in head-fixed animals

Authors: C. SONG, *T. KNOPFEL;
Imperial Col. London, London, United Kingdom

Abstract: Understanding the brain mechanisms underlying behaviour requires identification of neural circuitries involved in the generation of individual behavioural components. Mesoscopic optical imaging of brain activity during these behavioural components using head-fixed animal models expressing optogenetic indicators provides an unparalleled opportunity to achieve this goal. In contrast to mainstream small area two-photon imaging approaches, large area wide-field imaging can capture the integration and distribution of multi-area cortical processing that underlies cognition. Recent advances were made towards understanding the neuronal activity patterns during stimulus-response actions, yet the cortex-wide mechanisms for internally-evoked actions and their differences to stimulus-evoked activity patterns are largely unknown. With this in mind, we developed a lever-pressing task with visual stimulus-associated reward in head-fixed transgenic animals expressing the genetically encoded voltage indicator VSFP Butterfly 1.2 in layer II/III pyramidal cells. We first demonstrated the feasibility of employing a lever-pressing task under stable head-fixation, where the animal is capable of learning and skilfully executing both stimulus-evoked (visual cue) and internally-evoked (self-triggered lever-press) goal-directed reward collection (water licking). Mice were trained to execute these actions while neuronal activities were imaged across large portions of the cortex, including visual, somatosensory and motor cortices.

Abstract: While spherical treadmills are widely used in mouse models, there are not many experimental set ups that can be also employed in rats. We introduce a novel training apparatus that allows animals to perform motor responses while being head fixed and can be implemented in lager rodents. The apparatus includes a freely rotating spherical treadmill, an iron structure where animals are head fixed, a fluid delivery system, two video cameras and a software that controls training parameters and performs data storage for posterior analysis. Here we report training two Long Evans rats in an auditory discrimination task. The paradigm employed was of the Go/No-Go type, where walking/not-walking on the treadmill after presentation of an auditory stimulus was rewarded with a drop of water depending on the frequency of the stimulus. Rats showed a favorable response to the training apparatus, handling and procedures and were able to successfully discriminate between a 8KHz and a 1KHz stimulus and execute the correct response.

Title: Prelimbic α1-adrenergic receptors modulate extinction of amphetamine-induced conditioned place preference

Authors: *S. PUGLISI-ALLEGRA[1,2], P. SACCOCCIO[1], C. MILIA[1], P. CAMPUS[1], E. LATAGLIATA[2];
[1]Dept. Psychology, Sapienza Univ. of Rome, Rome, Italy; [2]Fondazione Santa Lucia, IRCCS, Rome, Italy

Abstract: Norepinephrine (NE) in medial prefrontal cortex (mpFC) is critical for the acquisition of conditioned place preference (CPP) based on different addictive drugs or natural rewards (Ventura et al., 2003 J Neurosci, 23(5): 1879-1885; Ventura et al., 2007 Proc Natl Acad Sci U S A. 104 (12):5181-5186). Moreover, it has been demonstrated the involvement of prefrontal NE also in the modulation of the extinction of conditioned response, in particular, through its action on β-adrenergic receptors (LaLumiere et al., 2010 Learn Mem 17, 168-175. ; Otis et al., 2013 J

Neurosci 33, 1271a-1281a). However, recent results have suggested a potential contribution on the extinction of appetitive conditioned response also of α1-adrenergic receptors (Bernardi and Lattal 2010 Behav Neurosci Apr;124(2):204-; Bernardi and Lattal Neuroreport. Dec 19;23(18):1048-51.; 2012), although their role in mpFC has not yet been fully clarified. Here, we assessed whether and how α1-adrenoceptors in the prelimbic (PL) portion of the mpFC are involved in modulation of the persistence of drug-associated cue memories. We investigated the effects of the α1-adrenoceptor antagonist Prazosin infusion in PL mpFC on extinction of acquired CPP to amphetamine and on expression of c-Fos levels in Nucleus Accumbens (NAc) core and shell of C57BL/6J mice in a spontaneous extinction paradigm (subsequent daily testing sessions). In Prazosin treated mice the place preference is no more evident from the first day of extinction, while in the Vehicle group the preference persists for further thirteen days. Moreover, Prazosin treated mice showed a lower c-Fos expression in both NAc core and shell region in comparison with Vehicle group. These results indicate that prefrontal cortical NE contributes to delay extinction of memories associated with drugs, modulating NAc activity, through α1-adrenergic receptors in PL cortex.

Title: Outcome monitoring and behavioral adjustment by putative pyramidal neurons and interneurons in the primate anterior cingulate cortex during a reversal learning task

Authors: *T. KAWAI[1], H. YAMADA[1], N. SATO[2], M. TAKADA[3], M. MATSUMOTO[1]; [1]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan; [2]Dept. of Psychological Sci., Kwansei Gakuin Univ., Nishinomiya, Japan; [3]Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: The anterior cingulate cortex (ACC) is known for its crucial roles in monitoring the outcome of a choice and adjusting a subsequent choice behavior. In the present study, we investigated how different types of ACC neurons, i.e., pyramidal neurons and interneurons, contribute to these two processes. We trained two monkeys to perform a reversal learning task. While the monkey was gazing a fixation point, two saccadic targets were presented on both the left and the right sides of the point. The monkey was required to choose one of the targets with a saccade. Choosing one target was followed by a liquid reward with 50% probability, whereas choosing the other was followed by no reward. The reward-position contingency was fixed within a block of 20 to 40 trials, and then reversed without any instruction. The monkey adjusted their choice behavior based on past outcome experiences. We recorded the activity of 329 ACC neurons. Depending on their spike waveforms, 227 neurons were classified as putative pyramidal neurons and 102 were classified as putative inhibitory interneurons. We found that both types of neurons transmitted signals that were associated with outcome monitoring and behavioral adjustment. Indeed, 153 of the 227 pyramidal neurons (67%) and 71 of the 102 interneurons (70%) exhibited a significant outcome-dependent modulation of their activity (i.e., a significant difference between their reward and no-reward evoked responses) ($p < 0.05$, Wilcoxon rank-sum test). On the other hand, 34 of the pyramidal neurons (15%) and 13 of the interneurons (13%) showed a significant adjustment-dependent modulation that predicted whether the monkey would shift the current choice to the alternative in the next trial ($p < 0.05$, Wilcoxon rank-sum test). There were no significant differences in the proportion between the pyramidal neurons and the interneurons ($p > 0.05$, Fisher's exact test). However, a notable difference between the neuron types was seen in the magnitude of the outcome-dependent modulation. We divided the recorded neurons into two subgroups; neurons more strongly activated by no reward than the reward were classified as "negative-outcome type" and those more strongly activated by the reward than no reward were classified as "positive-outcome type". In the negative-outcome type, interneurons exhibited a stronger outcome modulation than pyramidal neurons. In the positive-outcome type, on the other hand, pyramidal neurons showed a stronger outcome modulation than interneurons. These data suggest that pyramidal neurons and interneurons in the ACC may participate in outcome monitoring in distinct ways.

Title: Reward simulation in orbitofrontal cortex

Authors: *Z. WANG, B. Y. HAYDEN;
Univ. of Rochester, Rochester, NY

Abstract: Evaluation is critical to reward-based decisions. A key question about the evaluation process is: While evaluating each offers (reward stimulus), how does neural machinery recollect previous reward experience with the offer and encode the value associated with the experience? We hypothesized that the decision-making circuits achieve this evaluation process via reward simulation. We defined reward simulation as representing reward stimulus by reactivating neural activity patterns that are evoked by actual receipt (experience) of a reward. Previous studies have shown that orbitofrontal cortex (OFC) is involved in reward representation and value encoding through credit assignment to stimulus. Here, we used a novel task paradigm and single-unit recording in rhesus macaques to record from neurons in Area 13 of OFC. We wanted to know how neurons encoded information about reward when it was offered (and thus motivated choice) and when it was received (and thus did not motivate choice). We also wanted to know how encoding of reward changed across context when the reward was experienced vs. merely described. To answer these questions, we compared coding format of offer and reward within context and experienced vs. described offers across contexts. We defined coding format as the set of regression weights from regression of firing rates against reward magnitude. We find that offer and reward were encoded using the same format within context. And yet, across context, experienced and described offers were not coded with the same format. These results suggest a common reward simulation process in both experienced and described contexts but different coding scheme of offers across context.

Title: Formation of a pair bond occurs during the nest coo phase of the breeding cycle in ring doves, Streptopelia risoria

Authors: A. M. DIOS[1], *M.-F. CHENG[2];
[1]Psychology, [2]Rutgers Univ., Newark, NJ

Abstract: Pair bonding is typically measured by an animal maintaining a preference for its mate. In ring doves, males that have gone through a breeding cycle will seek out their mate in a large aviary and will prefer to spend time with their mate despite a seven month period of separation (Morris and Erickson 1971). Our current study sought to determine whether pair bonding occurs prior to the completion of a breeding cycle. Our laboratory has found that a neuronal marker for pair bonding, ZENK counts in the nucleus taeniae, is more accurate than preference tests at predicting whether doves have formed a pair bond (Dios et al 2013). Using this marker, we found that both male and female doves form pair bonds during the courtship (nest coo) phase of the breeding cycle. In female ring doves, the nest coo phase of the breeding cycle triggers the hypothalamic-pituitary ovarian system which culminates in ovulation (Cheng et al 1998; Cheng and Balthazart 1982). The formation of a bond at this stage of the breeding cycle, suggests that males and females may be predicting the successful completion of a breeding cycle with their mates- a concept in line with the evolutionary view that pair bonding is a reproductive strategy used to ensure survival of the individual forming the bond.

Title: The effect of estrous cycle on binge-eating behavior induced by intermittent access to sucrose in rats

Authors: *J. O. SUAREZ-ORTIZ[1], F. CORTÉS-SALAZAR[2], D. DÍAZ-URBINA[2], A. HERNANDEZ-GUTIERREZ[4], J. M. MANCILLA-DÍAZ[2], V. E. LÓPEZ-ALONSO[2], D. N. VELÁZQUEZ-MARTÍNEZ[3], R. E. ESCARTÍN-PÉREZ[2];
[2]FES Iztacala, [1]Univ. Nacional Autónoma de México, Tlalnepantla de Baz, Mexico; [3]Facultad de Psicología, Univ. Nacional Autónoma de México, México D.F., Mexico; [4]Inst. Politecnico Nacional, Mexico,D.F., Mexico

Abstract: Binge Eating Disorder (BED) is characterized by episodes of consumption of an amount of food that is significantly larger than most individuals would eat under similar circumstances in a discrete period of time. It is well known that the prevalence of BED is higher among women than among men and that high-carbohydrates foods are preferred during a binge eating episode. Since the hormone estradiol has the ability to modulate the food intake and body weigh it has been suggested that the cycling concentration of female hormones through the estrous cycle may inhibit food intake during binge eating. Accordingly, the aim of our study was to evaluate the effect of estrous cycle on binge-eating behavior of sucrose in adult rats. Independent groups of Sprague Dawley female rats (250-350 g) were individually housed and its estrous cycle phase was determined by the relative amount of cells in vaginal smears dyed with cresyl violet and examined under light microscopy. The subjects were matched by weight in three different groups and were differentially exposed to a sucrose solution (10% w/v): no access (control), intermittent access (2 h a day), and ad libitum access (24 h per day) throughout 28 days with standard chow and tap water ad libitum. All animals started the BED-inducing protocol at the beginning of diestrous phase, food and sucrose solution intake (2 and 24 h access groups) and estrous phase were measured on a daily basis. As expected, we found that the sucrose intake of intermittent access group significantly increased (compared to 24 h access group) during the final 5 days (24-28) of the protocol; however this effect was independent of the estrous phase, since the intake of chow, sucrose or total intake (sucrose+chow) was not different between groups in estrous or diestrous phase. When data were split by initial days of training and days of full established binge-eating behavior, we did not find any difference on sucrose intake between rats in estrous or diestrous phase. Our findings suggest that the inhibitory effect of estrous phase on the food intake did not affect the establishment of binge-eating induced by intermittent access to a sucrose solution.

Title: Prosexual effects of a cabergoline derivative with 5-HT 2b antagonist binding properties

Authors: *R. A. ANTONIE, J. PFAUS;
Concordia Univ., Montreal, QC, Canada

Abstract: Cabergoline is a unique ergot derivative typically prescribed off-label to treat low sexual desire and anorgasmia associated with hyperprolactinemia and similar effects of chronic SSRI medication. Compound Number 9 (CN9) is a semi-synthetic proprietary cabergoline derivative with a similar pharmacological profile, but with 5-HT2b antagonist, instead of agonist, properties. This makes CN9 a potential alternative to cabergoline as it is unlikely to induce the cardiac fibrosis that comes with high-dose systemic administration. The objective of the current study was to assess whether chronic administration of CN9 retains the prosexual effects of cabergoline. Male Long-Evans rats (N=40) were given 5 multiejaculatory sexual experiences at 4-day intervals in bilevel chambers prior to daily oral administration by gavage of one of three doses of CN9 (0.003, 0.015, or 0.03 mg/ml/kg) or the saline control for 36 days. During this period, males received an additional 9 copulation tests in bilevel chambers at 4-day intervals. Similar to cabergoline, the medium and high doses of CN9 produced a dramatic and significant increase in ejaculations and a decrease in the post-ejaculatory interval compared with the low dose and control. These effects were observed at the beginning of test number 3 and persisted throughout the treatment regimen, suggesting a lack of tolerance to CN9. These results demonstrate that CN9 has prosexual effects in sexually experienced males, suggesting that it can be a viable alternative to cabergoline. To examine the pattern of brain activation by CN9, rats were gavaged with their corresponding dose of the compound or control 4 days following the last copulatory trial and sacrificed for immunohistochemical analysis of Fos protein. The number of Fos positive cells in the nucleus accumbens, medial preoptic area, and ventromedial hypothalamus of rats given CN9 are being examined. Title: Effects of sucrose concentration on performance on a progressive schedule in rats

Authors: *F. GONZÁLEZ-NIETO[1], K. REYES-SANTIAGO[2], D. N. VELAZQUEZ-MARTINEZ[2];
[1]Univ. Nacional Autónoma De México, Distrito Federal, Mexico; [2]Psicofisiología, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Rats prefer sucrose over chow and their palatability effect produces high breakpoints (BK) in a progressive ratio schedule (PR). The progressive ratio schedule has been utilized as a procedure to estimate the reinforce value of a substance and the motivational state of an organism. While in a fixed ratio (FR) schedule the requirement for the reinforce delivery is constant throughout a session, in a PR the number of responses required for the delivery of reinforcer increases constantly. The BK has been considered as both a measure of the motivational state and of the incentive value of the reinforcer; however, in several studies has been demonstrated that the BK is sensible to non-motivational procedures. Killen and Bradshaw have made an adaptation of the Mathematical Principles of Reinforcement to apply such model to PR schedules. According to MPR, the performance on PR schedules may be determined by three parameters; one of them is a parameter of specific activation, a, that estimates the organism's motivational state sensitive to level of the food deprivation. The aim of this work was to determine the effect of the changes in motor and motivational parameters associated to the use of different sucrose concentrations. Method: Twelve Male Wistar rats were evaluated into the PR for four concentrations of sucrose (0.178, 0.31, 0.56 & 1M) daily until they got stabilization criteria (les than 10% variation in BK) in 45 sessions approximately. Higher response rate was observed with the 0.56M concentration and the lower response rate with the 0.178M; although such differences in response rate did not attain statistical significance, performance was well described by fitting the model to performance data.

Title: Nucleus accumbens shell orexin signaling promotes alcohol drinking in mice

Authors: *K. LEI, F. W. HOPF, S. A. WEGNER;
Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Multiple neural systems are involved in the regulation of alcohol consumption. Previous research has demonstrated that orexin (OX) signaling, particularly via the type-1 receptor (OX1R), promotes alcohol drinking. Here, we used C57BL/6 mice to elucidate the role of OX1R signaling in alcohol consumption in a 2 bottle choice drinking paradigm. Adult, male, mice were allowed to drink a 15% ethanol solution or water for 2-hr/day, starting 3-hr into the dark cycle. We first systemically administered various doses (0, 0.3, 1, 3, or 10-mg/kg) of SB-334867 (SB), an OX1R selective antagonist, and found that global blockade of OX1R reduced alcohol consumption in a dose-dependent manner, with alcohol consumption significantly reduced only by 10-mg/kg SB. We then microinfused SB into selected areas of the brain to determine the region(s) in which OX1R signaling acts to promote alcohol drinking. The nucleus accumbens shell (NAsh) was found to be one region where OX1R blockade reduced alcohol intake in mice. SB within the NAsh also reduced operant alcohol intake in Wistar rats. In addition, there was a positive correlation, in mice, between the effect of NAsh SB on alcohol drinking and basal alcohol intake. We also performed *in vitro* electrophysiology experiments in adult, alcohol-drinking mice, and found that orexinA (100 nM) increased action potential firing in NAsh neurons, with no effect on input resistance or evoked AMPA receptor currents. Furthermore, pretreatment with SB blocked the orexinA mediated increase in cell firing. Together, our data suggest that Ox1Rs act within the NAsh to promote alcohol drinking, with a correlation between drug efficacy and the amount of alcohol consumed. We are currently investigating other brain regions that may be involved with alcohol consumption regulation through OXR signaling. This research is supported by P50 AA017072.

Title: Compulsion-like alcohol drinking changes ampars and d-serine-inhibited nmdars in the accumbens core

Authors: T. SEIF[1], J. A. SIMMS[2], K. LEI[2], S. WEGNER[2], A. BONCI[4,5], R. O. MESSING[6], *F. W. HOPF[3,2];
[1]Gallo Ctr., Emerville, CA; [3]Dept Neurol, [2]UCSF, San Francisco, CA; [4]NIDA Intramural Res. Program, Baltimore, MD; [5]The Johns Hopkins University, Sch. of Med., Baltimore, MD; [6]The Univ. of Texas at Austin, Austin, TX

Abstract: Compulsive drinking despite adverse social, legal, and physical consequences is a central hallmark of human alcohol use disorders (AUDs) and is a pernicious impediment to treatment. The specific brain circuits that promote this compulsive behavior are poorly understood. We have shown in rats that connections from the anterior insula and medial prefrontal cortex (mPFC) to the nucleus accumbens core (NACore) are critical for driving alcohol intake in a model of compulsion-like alcohol drinking (CLAD), where rats drink alcohol despite adulteration with quinine or despite the presence of footshocks. This compulsion-like drinking also requires activation of hyperpolarization-active NMDARs (HA-NMDARs) within the NACore (Seif et al., 2013, Nat Neurosci 16:1094). We recently demonstrated that the NMDAR modulator D-serine selectively suppresses CLAD when infused within the NACore or systemically; we also found that D-serine inhibits mPFC-evoked HA-NMDAR activity in the NACore, as measured with *in vitro* electrophysiology and optogenetics (Seif et al., 2015, NPP epub). This study involved Intermittent Alcohol Access (IAA, 20% alcohol under 2-bottle choice, 3 overnights starting Mon., Wedn. and Frid. afternoons). After ~2.5 mo IAA, rats then drank alcohol 20-min/day, 5-day/wk for ~2 mo before *in vitro* analysis of HA-NMDARs. Here, we show that mPFC-evoked, D-serine-inhibited HA-NMDARs also appeared after 4-5 mo IAA, together suggesting that NACore HA-NMDARs appear after different patterns of alcohol drinking, in addition to promoting CLAD. Thus, D-serine may represent an FDA-approved, immediately accessible pharmacotherapy for treatment of compulsive aspects of human AUDs. We also combined *in vitro* electrophysiology and optogenetics to show functional adaptations in

cortically-evoked AMPARs in the NACore from alcohol-drinking rats, in addition to HA-NMDAR changes. In alcohol-naïve rats, the AMPAR-NMDAR ratio at +40 mV was lower in aINS-NACore inputs relative to mPFC-NACore inputs or electrically-evoked NACore inputs. In alcohol-drinking rats, the AMPAR-NMDAR ratio was decreased in both aINS-NACore and mPFC-NACore but not electrically-evoked inputs, relative to alcohol-naive. AMPAR EPSC kinetics were similar for all conditions (ChR2-evoked vs electrical, naïve vs alcohol drinker), except for a slowed AMPAR decay in aINS-NACore inputs in drinkers. Thus, long-term alcohol intake alters both HA-NMDARs and AMPARs under aINS and mPFC cortical inputs to the NACore. The behavioral impacts of AMPAR changes in the NACore, and possible interactions of cortically-activated HA-NMDARs and AMPARs, remain to be elucidated.

Title: Sign-tracking rats have more thalamic mast cells than goal-tracking rats

Authors: *C. J. FITZPATRICK, E. BISWAS, J. D. MORROW;
Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Mast cells contain numerous neurotransmitters within their granules (e.g., histamine, serotonin, and cytokines), and are capable of influencing neuronal activity. Degranulation of mast cells occurs in response to a variety of behavioral states and drugs of abuse, and mast cell activity influences behavior even under basal conditions. However, it is unknown whether mast cells in the brain contribute to addiction vulnerability. Attribution of incentive motivational properties to reward-related cues is believed to be a key etiologic factor underlying addictive behavior, particularly relapse. Individual differences in the attribution of incentive salience can be measured using a Pavlovian conditioned approach (PCA) procedure, wherein some rats,

termed sign-trackers (STs), attribute incentive salience to reward cues and are more vulnerable to addiction-like behaviors while other rats, termed goal-trackers (GTs) and intermediate responders (IRs), do not. STs have been shown to have higher neural activity within thalamic brain regions in response to both food- and drug-related cues, and brain mast cells are selectively concentrated in the thalamus. Using a PCA procedure, we screened rats over the course of seven daily PCA training sessions, waited a week to restore baseline activity, then quantified thalamic mast cells using a toluidine blue stain. We found that STs, compared to GTs and IRs, have higher numbers of mast cells within the thalamus. These results suggest that thalamic mast cell signaling may contribute to individual differences in the attribution of incentive salience to reward cues and, therefore, addiction vulnerability.

Title: Orbitofrontal cortex mediates inhibition within the basolateral amygdala to promote appetitive Pavlovian conditioning

Authors: *B. T. SAUNDERS[1], K. R. VITALE[2], P. H. JANAK[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Pavlovian conditioning is mediated in part by the strengthening of excitatory synapses onto basolateral amygdala (BLA) neurons that carry sensory information about the conditioned cue. Many single-unit recording studies find that a subset of BLA neurons are excited by a conditioned cue after either appetitive or aversive Pavlovian conditioning, which is thought to mediate behavioral responding. To further explore how the amygdala contributes to this process, we recorded single-unit activity in the BLA of rats as they underwent appetitive Pavlovian conditioning. Training consisted of repeated presentations of a 30-s auditory stimulus (CS+) paired with sucrose solution delivered at a variable latency. An equal number of presentations of a different sound (CS-) are paired with nothing. We found that more than half of recorded

pyramidal neurons were inhibited by the CS+, while only <10% were excited. BLA inhibition was highly correlated with behavior during acquisition, expression, and extinction task phases. We next asked whether this inhibition is required for the expression of conditioned cue responding, via bilateral optogenetic activation of ChR2-transduced BLA neurons. On a test session after training on the same task, we activated the BLA with blue laser (10s@20Hz) on 50% of CS+ trials. Rats showed reduced conditioned port entry on stimulated versus unstimulated trials. As the BLA is a complex structure that contributes to both aversive and appetitive behavior, one possible role for cue-evoked inhibition is to suppress competing behaviors and facilitate decision making during Pavlovian responding. To investigate this possibility, we examined the effect of pharmacological inactivation of the orbitofrontal cortex (OFC), an area involved in decision making. OFC inactivation reduced cue-evoked BLA inhibitions and impaired conditioned port entry behavior. We next looked at the role of OFC inputs directly on behavior by transducing OFC neurons with a viral vector containing the inhibitory opsin ArchT3.0 and targeting optic fibers to the BLA. On test day, we inhibited OFC terminals in the BLA with green laser (10s pulse) on 50% of CS+ trials. Rats spent significantly less time in the port on stimulated trials compared to unstimulated trials, indicating that direct input from the OFC to the BLA mediates conditioned responding. These data suggest a critical role for BLA inhibition and an OFC-BLA circuit in appetitive Pavlovian conditioning, and expand our understanding of how cortico-amygdalar interactions contribute to motivated behavior. We are currently exploring local circuit connectivity to understand how BLA inhibitions are generated.

Abstract: Hedonic hyperphagia - eating for pleasure independent from hunger - is a phenomenon nearly everybody knows. Snack food like potato chips are ingested without homeostatic need and may lead to non homeostatic energy intake. Our aim was to detect modulations in neural activity due to chips craving in humans. For this purpose, we used standard 3T BOLD fMRI to investigate brain activation patterns in 15 humans (8 female, 7 male, age 24-45, BMI 23,6 ± 3.1) induced by visual application of either chips or non hedonic food such as zucchini and cucumbers. Before each fMRI session the participants were informed that they were allowed to eat either chips or zucchini for 2 minutes after the fMRI session. Each participant was measured two times, eating chips after the first and zucchini after the second session. The obtained BOLD fMRI activation patterns were correlated with individual "hedonic scores" determined from a questionnaire that was designed to evaluate general food craving behavior. Additional to this general craving behavior the participants were asked for their current appetite to chips or zucchini. The questionnaire had to be answered before and after the experimental session. As expected, the usual affinity to chips was much higher than to zucchini and consequently the percentual amount of eaten chips was also higher. Interestingly, eating chips seems to enhance the craving for chips whereas the "craving" for zucchini remained unchanged after eating zucchini. The activation of basal ganglia (predominantly striatum and nucleus accumbens), insula and precuneus were strongly modulated due to visual stimulation with chips. The activated volume of the striatum was significantly enhanced; its maximum BOLD response amplitude (activation intensity) was significantly reduced in both sessions. Instead the activity of the nucleus accumbens, an important structure of the reward system, was only modulated during the first session when the participants expected to eat chips after the session. The insula also showed different activation changes depending on the provided food. Expecting chips seems to be related to an increasing activation volume due to visual stimulation with chips whereas during the zucchini-session the insula's activated volume was decreased. Additionally, BOLD activation of striatum and precuneus, activation volume as well as activation intensity, was strongly negative correlated to the individual hedonic score. In conclusion, visualizing potato chips in the context of expected food influence the activity of several brain structures responsible for reward, motor control and self-awareness.

Title: The striatum multiplexes distinct reward signals

Authors: *D. V. SMITH[1], K. S. WANG[2], M. R. DELGADO[1,2];
[1]Dept. of Psychology, [2]Behavioral and Neural Sci. Grad. Program, Rutgers Univ., Newark, NJ

Abstract: A wide range of rewards -- from monetary incentives to praise from a supervisor -- shape our behavior and contribute to the substantial variability observed across the population. To study the neural underpinnings of reward processing, researchers have employed various paradigms that isolate responses associated with the receipt of reward. In one popular paradigm, participants are presented with a card and asked to guess whether the number on the card is higher or lower than the number five (Delgado et al., 2000). When participants guess correctly, they gain money; but when participants guess incorrectly, they lose money. Comparing responses to gains relative to losses has revealed widespread activation across the striatum in multiple populations, including healthy adults (e.g., Hariri et al., 2006), adolescents (Forbes et al., 2009), and older adults (Cox et al., 2008). Yet, these canonical observations may obscure other, unidentified relationships between reward and the striatum. Indeed, the striatum is composed of multiple interacting functional subunits that are difficult to examine using standard neuroimaging resolution (e.g., 3.5 cubic mm voxels) and analytical approaches that do not take into consideration how distinct spatiotemporal responses. To investigate this issue, we measured striatal responses using high-resolution neuroimaging (1.8 cubic mm voxels) in participants (N = 22) playing the card task. We quantified the spatiotemporal responses to monetary gains and losses using tensorial independent component analyses (Beckmann & Smith, 2005) and dual-regression analysis (Smith et al., 2014). Consistent with prior work using the card task, we found one spatiotemporal component within the striatum that exhibited an increased response to gains (relative to losses). Strikingly, we also observed another spatiotemporal component within the striatum that exhibited increased responses to losses (relative to gains). Our findings demonstrate that the striatum multiplexes distinct reward signals: monetary gains and losses are simultaneously represented by distinct spatiotemporal response patterns within the striatum. These observations highlight how advanced analytical approaches in neuroimaging can enhance knowledge about the spatiotemporal contributions of regions such as the striatum to reward processing.

Title: Neural value estimations related to limited partner perspective during social exchange

Authors: *A. VALDESPINO[1,2], B. T. HILTON[2], H. SULLIVAN-TOOLE[2], B. KING-CASAS[2], J. A. RICHEY[2];
[1]Psychology, [2]Virginia Tech., Blacksburg, VA

Abstract: The current study leveraged neuroeconomic techniques during fMRI to probe whether brain regions supporting value computations assign positive value to partner uncertainty in a social exchange. SUMMARY Introduction: The vmPFC has been implicated in computing abstract social rewards such as being liked, or understood (Davey et al., 2010; Morelli, Torre & Eisenberger 2014). We leveraged a social neuroeconomic task in which it is inherently valuable, from participants' perspectives, for an interaction partner to be uncertain about participants' financial resources. Specifically participants could exploit partners' limited perspectives and keep more money for themselves. We hypothesized that regions supporting abstract reward computations (vmPFC) would positively scale with partner uncertainty. Consistent with hypotheses, reward-computing subregions of vmPFC positively scaled with partner uncertainty. Method: Students at Virginia Tech (N=20; mean age = 19.9, SD = 1.6) completed a One-Sided Uncertainty Ultimatum Game (Rapoport & Sundali, 1996). For each round, participants offered a split of a financial 'pie' between themselves and a responder. Responders did not always know the pie-size with certainty and uncertainty was systematically varied. Specifically, under conditions of certainty, responders knew the pie size; under conditions of uncertainty, responders knew the pie would be drawn from a numeric range, without knowing the exact pie. Uncertainty was manipulated by increasing the range by increments of $10 across runs. Analyses (preprocessing, first- and second-level) were conducted in FSL (Smith et al., 2004). To assess brain activity scaling with partner uncertainty, activity during the decision phase was orthogonalized with respect to trial-wise money kept, offered, and percentage money offered. We performed a linear trend analysis on the orthogonalized decision phase activity by weighting scan run [certainty, low uncertainty, medium uncertainty, high uncertainty] as [0,1,2,3], respectively. Results: Behaviorally, there was a significant main effect of certainty, indicating proposers offered participants less as uncertainty increased ($p<.001$). Neurally, orthogonalizing relevant aspects of the design including money kept and given, activity within a cluster spanning the vmPFC/mOFC scaled monotonically with increasing partner uncertainty ($p<.01$, FDR corrected). Discussion: Brain regions implicated in reward-computations scaled positively with partner uncertainty, possibly indicating these regions assign a value tracking the amount of information interaction partners reveal to each other.

Title: Roles of the medial prefrontal cortex and basolateral amygdala in punished ethanol seeking

Authors: *A. KOCHARIAN, L. R. HALLADAY, A. HOLMES;
Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: Compulsive ethanol-seeking despite aversive consequences is prevalent among those with alcohol use disorders (AUD). Evidence has shown that circuitry within the basolateral amygdala (BLA) and the medial prefrontal cortex (mPFC) modulates the persistence of drug-seeking, and may contribute to the suppression of behavior during punishment. For example, shock-induced suppression of cocaine-seeking is attenuated by lesions to the BLA (Pelloux et al., 2013). Additionally, while the prelimbic region of mPFC (PL) has been proposed to promote drug-seeking behaviors (Corbit, 2003), the infralimbic region (IL) may function to inhibit drug-seeking in a variety of behavioral settings, such as following extinction training (Peters, et al., 2008). Prefrontal cortical control over limbic-striatal systems has been thought to drive executive top-down control over drug seeking, and impairments in these circuits might underlie the persistence of drug seeking in the face of adverse outcomes. *In vivo* recording studies conducted in our lab (unpublished data) have demonstrated that neurons in BLA and IL are responsive to ethanol-seeking in a manner that not only depends upon whether animals have received punishment or not, but also upon whether individual mice are resistant or sensitive to punishment. To further examine the role of BLA and IL in punished reward seeking, we employed an operant task in which C57BL/6J mice were first trained to reliably lever-press for (10%) ethanol, and then given a punished probe test during which every other lever-press produced a footshock. Punishment consisted of a 40 minute operant session, during which 50% of lever presses were followed by a 0.75 second, 0.3 mA footshock. Retention of punished-suppression of ethanol-seeking was measured on each of the next two days, via a 40-minute unpunished, rewarded session (FR1). We used an optogenetic approach to silence (with the inhibitory opsin, archearhodopsin) neurons in either BLA or IL during the retention test,

specifically during periods when the mouse entered a designated “reward lever zone”. These findings could provide novel insight into the circuitry modulating compulsive responding for ethanol. Research funded by the NIAAA Intramural Research Program.

Title: Application of neural ensemble labeling techniques to the investigation of aversion encoding in the ventral striatum

Authors: *D. M. OPLAND, C. W. BOND, D. S. ABRAMOV, D. OTTENHEIMER, R. J. DILEONE;
Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: The ventral striatum is known to take part in responses to both primary appetitive and aversive stimuli, a component of its role in mesocorticolimbic reward processing. Previous research has elucidated the role of D1R-containing medium spiny neurons (MSNs) in encoding appetitive stimuli and potentiating behavior (“Go” neurons). Conversely, D2R-MSNs encode aversive stimuli and attenuate behavior (“No-Go” neurons). Recent evidence suggests that both D1R- and D2R-MSNs are activated by aversive stimuli. It has yet to be determined whether these subpopulations encode similar information (cooperative encoding schema) or opposing information (competitive encoding) where behavioral output is dependent on output of the dominant subpopulation. We have applied a molecular technique that allows for labeling and optogenetic manipulation of whole neural ensembles to investigate aversive stimuli encoding in the ventral striatum (nucleus accumbens medial core/shell boundary). This technique utilizes a transgenic mouse line (ArcTRAP) in which tamoxifen-inducible Cre recombinase is driven by the endogenous Arc promoter permitting labeling of neural ensembles active during an 8-hour time window. In our experiment neural ensembles activated by exposure to an aversive stimulus (5x 1s, 1mA foot shocks) are labeled following viral-mediated microinjection of Cre-inducible channelrhodopsin-eYFP to the ventral striatum. Subsequent optogenetic reactivation of these ensembles during the conditioning epochs of a conditioned place preference (CPP) paradigm was

sufficient to produce place aversion without locomotor effects suggesting aversive encoding was captured. In addition to whole ensemble labeling experiments we are developing a novel molecular tool, the 2-key FLEX switch, in which stable expression of the target gene (channelrhodopsin-eYFP) is dependent on both Cre and Flp recombinase activity. This utilizes an AAV-vector where a synthetic Arc promoter drives expression of tamoxifen-inducible Flp recombinase, yielding activity dependence and temporal constraints as in the ArcTRAP mouse. Combining the 2-key FLEX switch with the Arc-Flp virus in D1R-Cre and D2R-Cre transgenic mice allows labeling of just D1R- or D2R-MSNs activated by footshock. This system can be used to interrogate the encoding of aversion in the two major populations of ventral striatal projection neurons.

Title: Surface-based morphometry in lateral prefrontal cortex is associated with reward processing and impulse inhibition in combat deployed veterans with post-traumatic stress disorder

Authors: *N. D. FOGLEMAN, F. NAAZ, B. E. DEPUE;
Dept. of Psychological & Brain Sci., Univ. of Louisville, Louisville, KY

Abstract: A significant portion of previously deployed combat Veterans from Operation Enduring Freedom and Operation Iraqi Freedom/Operation New Dawn (OEF/OIF/OND) are affected by post-traumatic stress disorder (PTSD). Despite this fact, neuroimaging studies examining whether the neural correlates of cognitive control, outside of emotion provocation paradigms, are compromised within this population are extremely sparse. Our previous work suggests that individuals with PTSD have difficulties with inhibitory control (as assessed by a response inhibition task) and that these difficulties are associated with volumetric differences in limbic regions. The current study further examined whether disinhibited behavior was exhibited when these individuals performed a task involving reward processing. Using the modified Iowa

Gambling Task (mIGT), we investigated whether differences in surface-based morphometry (SBM), assessing cortical volume, thickness and area, were associated with behavioral measures related to reward processing and impulse inhibition. Results indicated abnormal morphometry in specific regions of the lateral prefrontal cortex (LPFC), including the orbitofrontal cortex (OFC) predicted poorer performance on the mIGT. Furthermore, morphometric results were related to an individuals' level of symptomatology. The lateral prefrontal cortex (LPFC), known for its role in cognitive control, and orbitofrontal cortex (OFC), an area involved in making stimulus-reward associations with the reinforcement of behavior appear to be compromised in this population. Furthermore, these findings suggest that morphometric changes in the OFC in OEF/OIF/OND Veterans with PTSD are associated with cognitive and cognitive-emotion integration deficits in reward processing and impulse inhibition.

Title: Effects of attentional context and stimulus valence on cortical-limbic responses in youth

Authors: *R. MANIMALETHU[1], T. BAWA[1], K. RAMASESHAN[1], M. RE[2], P. BRAMBILLA[3], V. DIWADKAR[1];
[1]Wayne State Univ., Detroit, MI; [2]Univ. of Udine, Udine, Italy; [3]Univ. of Milan, Milano, Italy

Abstract: Background: Attentional context and stimulus valence are strong modulators of cortical activity. Using a continuous performance task (Soloff et al., 2015), we manipulated congruence between context and valence and assessed its effects on fMRI-measured responses. We analyzed responses to positively or negatively valenced faces when participants were required to amplify attention to one or the other class. We investigated differential effects of congruence by comparing positive (+ Context & + Stimuli) to negative (- Context & - Stimuli) conditions. We suggest that the observed effects reflect the salience of rewarding and punitive stimuli on brain responses in adolescence, therefore focusing the study on youth (9-21 yrs). **Methods:** fMRI, using a mixed-block design, was collected (3T, TR/TE: 2000/30 ms, 30 slices, Voxel size: 3.75 x 3.75 x 3.8 mm^3, FOV 64 x 64 mm^2). 35 youth performed the task. A block of trials began with instructions indicating the affective context (positive or negative). Next, participants were shown a series of faces (1 Hz, jittered ISI) with letters ("A" or "X") imposed

on the bridge of the nose. "X" was a target only if the valence of the face was consistent with the valence of context. SPM8 was used in event related analyses to model responses to congruent events. Each participant contributed two contrast maps (positive and negative) modeled at a second level using pair-sample t-tests. **Results:** Congruence amplified cortical responses, but relative to negative, the positive condition resulted in substantively increased modulation of cortical-limbic responses ($p<.05$). Increases were observed in a network of regions including the amygdala, basal ganglia, dorsal anterior cingulate, fusiform gyrus, hippocampus, orbitofrontal cortex, ventromedial prefrontal cortex, and thalamus. **Conclusions:** Amplified modulation in context and stimulus congruence suggests that coupling of top-down (attention-driven) and bottom-up (stimulus-driven) processing is important in driving brain responses. Moreover, positive congruence was evocative, pointing to the salience of positive stimuli and contexts (Todorov et al., 2008) on reward circuits in development. The effect of positive congruence may reflect sensitivity of the cortical-limbic system for social reward.

Title: Central obesity is predicted by contrasting prefrontal and striatal BOLD responses to food words in a color-naming Stroop task

Authors: *L. K. JANSSEN[1], I. DUIF[1], I. VAN LOON[1], J. H. M. DE VRIES[2], R. COOLS[1,3], E. AARTS[1];
[1]Radboud University, Donders Inst. For Brain, C, Nijmegen, Netherlands; [2]Div. of Human Nutrition, Wageningen Univ., Wageningen, Netherlands; [3]Dept. of Psychiatry, Radboud university medical center, Nijmegen, Netherlands

Abstract: The motivating force of food can override homeostatic signals leading to loss of control and overconsumption. Elevated neural reward responses to food cues have been shown to

predict weight gain[1] and the likelihood of self-control failures in daily life, whereas prefrontal responses were found to be associated with successful resistance to temptations[2]. However, these findings were obtained using different types of tasks, probing reward and cognitive control functions respectively. In daily life, reward and cognitive control processes are likely to act simultaneously during the resistance of high caloric food. It is yet unclear whether processing of food stimuli in fronto-striatal regions within the same task can differentially predict obesity. Here, we used the food Stroop task to obtain neural measures of (overcoming) attentional bias to food stimuli. Previous studies have used the behavioral attentional bias effect, i.e. slower responding to the color of food words than to the color of matched neutral words, to predict obesity, but with mixed results[3]. Here, we tested 79 healthy participants with a wide body mass index range (BMI: 19-35 kg/m2) using fMRI. During scanning, participants performed a food Stroop task. In addition, we measured height, weight, and waist and hip circumference as measures of central obesity. Regression analyses showed that central obesity was best predicted by a combination of decreased dorsolateral prefrontal cortex and increased striatal BOLD responses to food versus neutral words during color-naming. These data suggest that attentional bias to food stimuli, perhaps leading to overconsumption and central obesity, is modulated by an interplay between striatal reward responses and top-down control from dorsolateral prefrontal cortex. Title: Neural responses to cigarette and monetary gains and losses in deprived smokers

Authors: *A. H. LEWIS, H. MANGLANI, M. R. DELGADO;
Psychology, Rutgers Univ., Newark, NJ

Abstract: Research examining addicted populations posits that these individuals exhibit decreased sensitivity to non-drug rewards (e.g. Goldstein et al., 2007; Martin-Soelch et al., 2003;

Rose et al., 2012). For instance, deprived smokers show enhanced neural responses to the anticipation of cigarette rewards compared to monetary rewards (Sweitzer et al., 2014). One interesting question is how abstinence influences reward-related neural activity during both the receipt and loss of drug (cigarette) and non-drug (monetary) reinforcers. In the current study, we examined the effects of smoking deprivation on the anticipation and processing of both smoking and monetary-related gains and losses. Participants were deprived of smoking for 12 hours and engaged in a card-guessing paradigm (Delgado et al., 2000) that afforded the opportunity to earn both money and cigarette puffs that would be delivered at the end of the experiment. Notably, a willingness to pay (WTP) measure taken prior to the task was used to equate the cigarette and monetary outcomes in terms of value. For example, a participant who indicated a WTP of $0.20 for one cigarette puff played the card-game using those specific incentive values. Participants underwent four rounds of the task, two of which dealt cigarette outcomes and two of which dealt monetary outcomes. At the start of each trial, participants guessed whether the number on the back of a card was higher or lower than 5 (anticipation phase). Correct guesses led to monetary or cigarette gains while incorrect guesses led to monetary or cigarette losses (outcome phase). Preliminary neuroimaging analyses highlight the involvement of the insula during the anticipation phase, which showed greater activation when anticipating cigarette compared to monetary reinforcers. During the outcome phase, we focused on activity in the striatum, which typically shows a greater response to gains compared to losses in this task. Interestingly, this differential response was replicated for trials involving monetary outcomes, but was diminished for trials involving cigarette outcomes. Taken together, these findings highlight differential brain responses to both appetitive and aversive drug (cigarette) and non-drug (monetary) reinforcers in a deprived smoking population.

Title: Fast, non-motorized focus and drift correction for long-term spine imaging with an Electrical Tunable Lens

Authors: ***M. S. SMIRNOV**, A. FERRARI, R. YASUDA, L. YAN;
Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: During micron-scale photostimulation and imaging of neuronal activity, the presence of focal and lateral drift can often lead to errors in measurement and loss of data. We present a low-cost method to automatically correct for X, Y, and Z drift during live, two-photon imaging without relying on a motorized stage. With the use of an electrically tunable lens in the excitation path, we are able to rapidly and precisely alter focal distance, while changes in scan angle are used to shift the field of view in the XY plane. Correction in all three axes can be as large as 1000μm using a 20x objective. Quick and seamless switching between scan fields allows users to define multiple imaging/photostimulation regions, and automatic drift and focus correction insures that imaging can proceed unattended. All hardware is controlled through a user-friendly interface and accessible MATLAB code.

Title: Design of an implantable artificial dural window for chronic two-photon optical imaging in non-human primates

Authors: ***E. TRAUTMANN**[1], D. O'SHEA[1], S. SHRESTHA[2], S. LIN[3], S. RYU[4], K. SHENOY[3,5];
[1]Stanford Neurosciences, San Francisco, CA; [2]Stanford Mechanical Engin., San Francisco, CA; [3]Stanford Electrical Engin., San Francisco, CA; [4]Dept. of Neurosurg., Stanford Univ., San Francisco, CA; [5]Neurobio., Stanford Univ., Stanford, CA

Abstract: Optical functional imaging methods such as calcium imaging have become a powerful tool for investigating neural activity in-vivo. We present an implantable titanium chamber with silicone artificial dura, which enables two-photon (2P) calcium imaging in non-human primates (NHP). This chamber accommodates imaging with large, multiphoton objective lenses, and remains sealed, protecting the brain from the environment. In addition, we describe a stabilization system to restrict tissue motion while imaging during motor behaviors. Calcium

imaging presents several advantages over more traditional multi-electrode recordings, including the ability to genetically target specific cell types and to densely sample from every neuron within a recording volume. However, translating optical imaging techniques to awake, behaving macaques presents a set of unique challenges. First, the optical window must be designed around the large, high numerical aperture objective lenses typically required for 2P imaging. We developed a novel optical imaging chamber for NHP, which is compatible these lenses. Second, the imaging chamber must be durable enough to last for several months to years to align with trained NHP experimental timescales. Our design incorporates a replaceable window, which is sealed from the external environment to minimize immunoreactivity. Third, cardiac and respiratory rhythms induce cortical pulsations, making stabilization prerequisite for 2P imaging in NHP. In our case, a motor reaching task provides another source of potential brain motion, increasing the need for stabilization. To address this, we developed a stabilization system, which uses gentle pressure on the window to restrict total XY motion to ~5-10 μm for prolonged experiments. The work here describes a system that addresses each of these three key challenges, enabling the capture of stable, cellular resolution, 2P images of superficial motor cortex, and facilitating optical interrogation of neural activity using calcium reporters in future work. The applications of this artificial dural window are not limited to 2P calcium imaging. This implant design may benefit a number of experimental modalities, including single and multiphoton imaging of voltage and calcium reporters, optogenetics, or electrophysiology experiments using fragile silicon electrodes, high-density multielectrodes, or where precise localization relative to identifiable cortical landmarks is essential. We anticipate that this design may soon facilitate a new class of circuit and systems neuroscience experiments in behaving non-human primates.

Title: Improvement in focusing properties enables *in vivo* two-photon laser ablation in deep cortical regions of living mouse brain

Authors: *K. YAMAGUCHI[1,2], R. KITAMURA[1,2], R. KAWAKAMI[1,2], T. NEMOTO[1,2]; [1]Res. Inst. of Electronic Sci., Sapporo, Japan; [2]Grad. Sch. of Information Sci. and Technol., Sapporo, Japan

Abstract: Optical dissection of nerve fibers in the living mouse brain will provide insights into the functions of neural networks. Although dendrites of pyramidal neuron and axons spread across all cortical layers, the dissection using ultrashort pulse laser has achieved in superficial cortical region. This phenomenon is a result of degradation of laser focusing, especially in deep regions, due to refractive index mismatches between tissue, immersion liquid, and glass, as well as laser light scattering in the living brain. In this study, we achieved *in vivo* two-photon laser ablation at focal regions of the living brain under an optimized laser irradiation condition. For *in vivo* fluorescence imaging and laser ablation, adult Thy1-eYFP-H transgenic mouse were used. Surgeries were performed using the "open-skull method, in which a piece of skull bone is replaced with a round cover slip (φ4.2 mm), which serves as a cranial window. Under anesthesia, mice were placed in a two-photon microscopy system with a Tsunami near-infrared laser (Spectral Physics). First, under normal conditions, we confirmed that single nerve fibers were dissected in cerebral cortex layer II/III, and also observed dendritic degeneration *in vivo*. Next, in order to visualize single nerve fibers in deeper regions, we optimized the parameters of laser irradiation in these regions. To prevent degradation of laser power and focus in deeper layers, we examined the effects of beam diameter and refractive index of the immersion liquid. Thereby we found a suitable combination of a narrower laser beam diameter and an immersion liquid, and successfully achieved laser ablation of single dendrites of neurons in cerebral cortex over 500 μm from the brain surface. We hope that this technique will be useful for severing neural connections in cortical regions, with the goal of revealing brain functions.

Abstract: Understanding the axon-glial cell interaction underlying myelination is hampered by the lack of suitable imaging techniques. Here we describe a new method, namely third harmonic generation microscopy (THGM), for label-free imaging of myelinating Schwann cells in live culture and *ex vivo* and *in vivo* tissue. Three-dimensional structure was acquired for a variety of compact and non-compact myelin domains, including juxtaparanodes, Schmidt-Lanterman incisures, and Cajal bands. Other subcellular features of Schwann cell that escape traditional optical microscopies were also visualized. We tested THGM for morphometry of compact myelin. Unlike current method based on electron microscopy, g-ratio could be determined along an extended length of myelinated fiber in the physiological condition. The precision of THGM-based g-ratio estimation was corroborated in mouse models of hypomyelination. Finally, we demonstrated the feasibility of THGM to monitor morphological changes of myelin during postnatal development and degeneration. The outstanding capabilities of THGM may be useful for elucidation of the mechanism of myelin formation and pathogenesis.

Title: *In vivo* two-photon imaging of hippocampal neurons in dentate gyrus using a newly developed a high-peak power 1064-nm light source based on a gain-switched laser diode

Authors: *K. SAWADA[1,2], R. KAWAKAMI[1,2,3], Y. KUSAMA[4], Y.-C. FANG[4], S. KANAZAWA[5], Y. KOZAWA[3,5], S. SATO[3,5], H. YOKOYAMA[3,4], T. NEMOTO[1,2,3]; [1]Grad. Abstract: Conventional *in vivo* two-photon microscopy has revealed vital information about neural activity in relation to brain function, despite its limitations in imaging events at depths greater than several hundred micrometers from the surface of the brain. In a previous study, we clearly demonstrated that the feasibility of using a near-infrared picosecond high-power pulse laser for *in vivo* two-photon microscopy (Kawakami, et al., Sci. Rep. 2013). This laser enables us to visualize cortex pyramidal neurons spreading to all cortical layers, as well as hippocampal CA1 neurons, especially in young adult mice. In this study, we developed a novel two-photon microscope consisting of a 1064-nm gain-switched laser diode-based light source with average power above 4 W, pulse width of 7.5 picoseconds, repetition rate of 10 MHz, and a high-sensitivity photomultiplier tube for efficient detection of fluorescence. By applying this newly developed two-photon microscope to *in vivo* imaging, we were able to successfully visualize hippocampal neurons in dentate gyrus and panoramic views of CA1 pyramidal neurons and cerebral cortex, in both young adult and adult mice. Fine structures of dendrites in CA1 neurons could be visualized with a high peak-signal-to background ratio that could not be achieved by

titanium sapphire laser excitation. Furthermore, our system achieved multicolor imaging with neurons and blood vessels in the hippocampal region *in vivo* . Notably, we did not observe any photobleaching or photodamage within the area through which the laser light passed, including the cortex above the hippocampal area, even though the applied laser power used for imaging hippocampal neurons was about 500 mW. We hope that our two-photon microscopy system will be applicable to investigations of various neural functions, including the morphological changes undergone by neurons during physiological phenomena.

Title: Brain temperature changes under near-IR laser illumination

Authors: ***A. SONG**, S. Y. THIBERGE, N. T. EMERSON, H. YANG, D. W. TANK; Princeton Univ., Princeton, NJ

Abstract: Two-photon microscopy and two-photon optogenetic stimulation are widely used techniques for imaging and manipulating activity of neurons *in vivo*. Recent developments in these areas include improved methods for volumetric imaging, strategies for imaging deeper brain structures, and techniques for cellular resolution photostimulation. These advances, however, generally increase the average power used for two-photon excitation to hundreds of mW, which may cause significant tissue heating. Heating can cause changes in neuronal function, and at high levels, it can cause tissue damage. For this reason, we explored the heating effects due to one-photon absorption of near-IR laser illumination used for two-photon excitation. We examined near-IR laser heating effects in the brains of awake mice using an optical cranial window with a small silicone elastomer plug, allowing access for injections and probes. A hypodermic probe thermocouple measured the amount and distribution of heating in the mouse brain at different positions and depths outside the scanned area. We explored a variety of different parameters, including wavelength (800nm-1060nm), power, two-photon excitation strength, and imaged area (200μm-2mm). We find that laser heating can be significant, causing

temperature increases of several degrees Celsius with high average power (hundreds of mW). This effect is primarily due to one-photon absorption, and spreads out from the imaged area with a 30-60s timescale. A previous study has demonstrated that cranial windows typically used for imaging experiments can decrease the brain surface temperature by up to 10°C [1]. The near-IR illumination temperature increases we measured were produced relative to this altered baseline temperature. We modeled the temperature distribution across the brain using a 3D thermal diffusion model with terms for laser heating (source), blood flow (sink), and convective cooling from the cranial window (sink). Finally, we have begun to explore the use of ratiometric temperature-sensing quantum dots to record local temperature fluctuations within the scanned region. In general, our experiments and model suggest limits on average power used during two-photon based techniques, and highlight considerations that must be taken to ensure neuronal homeostasis. Title: Brain transmission in four optical windows of near infrared spectral regions from 700 to 2500 nm for deep optical imaging

Authors: L. SHI[1], L. SORDILLO[1], *A. RODRIGUEZ-CONTRERAS[2], R. ALFANO[1]; [1]Physics, Inst. for Ultrafast Spectroscopy and Lasers, CCNY, New York, NY; [2]Biol., CCNY, CUNY, New York, NY

Abstract: Near-infrared (NIR) radiation has been used for deep imaging inside brain by 1-Photon and 2-Photon imaging at the wavelength ranging from 650 - 950 nm, which is also called the “therapeutic window”. It is well known that scattering blurs and absorption reduces the photons for imaging. Using longer wavelengths will reduce scattering. However, longer wavelengths in far NIR region have been overlooked due to a lack of suitable NIR-CMOS imaging detectors. The focus of this research is to introduce 3 new optical windows beyond the therapeutic window, and to demonstrate their potential for deep imaging. Optical attenuation measurements were obtained by using the Cary 500 scan UV/VIS/NIR spectrophotometer in the spectral range from 400 to 2,500 nm. The transmission lengths (Lt) were measured in rat brain tissues (thicknesses 50 - 200 µm) in the second (1,100 - 1,350 nm), the third (centered at 1700 nm), and the fourth (centered at 2,200 nm) optical tissue windows, respectively. The transmission vs. thickness of tissue was measured and compared theoretically (results not shown). The total attenuation length (Lt) in brain tissues is shown in Figure 1. The Lt is the longest in the third optical tissue window, indicating that the wavelength around 1700 nm potentially provides the largest penetration depth. We conclude that the third optical tissue window (centered at 1700 nm) is ideal for deep imaging with relatively less scattering or absorption for multiphoton excitation and confocal one photon imaging applications.

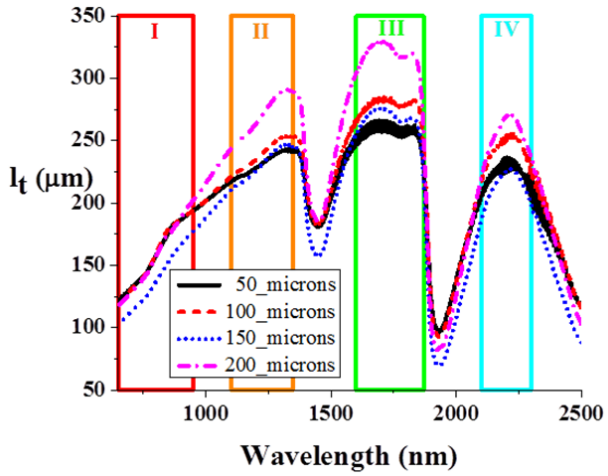

Fig. 1. Spectra of the total attenuation lengths (Lt, µm) from rat brain tissue thickness of 50 µm, 100 µm, 150 µm and 200 µm using the optical tissue window I, II, III and IV.

Title: Improvement of green fluorescence imaging system based on implantable CMOS imaging device for freely moving mice

Authors: *Y. SUNAGA[1], H. YAMAURA[2], M. HARUTA[1], T. YAMAGUCHI[1], M. MOTOYAMA[1], Y. OHTA[1], H. TAKEHARA[1], T. NODA[1], K. SASAGAWA[1], T. TOKUDA[1], Y. YOSHIMURA[2], J. OHTA[1];
[1]Nara Inst. of Sci. and Technol., Ikoma-Shi, Nara, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan

Abstract: To observe neural activities in the brain of an animal, fluorescence imaging technologees are widely used. Especially, autofluorescence of mitochondrial flavoprotein is attarctive because its intensity is changed by neural activities without dying neural cells nor introduction of genetically modification [1]. In this study, we report details of an implantable imaging device for freely moving mice, and also report experimental methods and results of *in vivo* fluorescence imaging experiments. To observe fluorescence in a mouse brain under freely moving condition, we have proposed a fluorescence imaging technique based on an implantable (CMOS) imaging device. By implanting a dedicated CMOS image sensor integrated with a fluorescence filter and LEDs as excitation light sources directly into a mouse brain, neural activity imaging based on fluorescence can be performed even under freely moving conditions. In our previous works, we have developed an implantable imaging device for green fluorescence imaging, and achieved to improve the detection sensitivity of green fluorescence [2]. Recently, we have succeeded in observing visually evoked flavoprotein fluorescence changes across 25 trials in the visual cortex of a tethered mouse using the implantable imaging device [3]. In this experiment, a full-field sinusoidal grating with vertical orientation was applied to activate visual cortex. To apply this technology to observing flavoprotein fluorescence in a freely-moving condition where noise may increase, we have developed a new implementation method to reject excitation light more efficiently. The previous implementation method has two issues. One is to reduce leakage of excitation light. The imaging area near LEDs was especially influenced by leakage of excitation light. In this work, we succeeded in reducing leakage of excitation light by filling space between LEDs and a sensor chip with the same component of a fluorescence filter.

The other is that it is difficult to fabricate a flat fluorescence filter. The fluorescence filter was directly formed on the small sensor chips by a spin-coating method, which easily produces some bumps in the corners of the filter. In this work, we succeeded in fabricating flatter filter as follows; the filter is separately made on a cover grass which has lager area than the chip, and then is cut into a chip-size with a laser. Finally, the fabricated filter is put on the sensor surface. We are now working to confirm the performance of the improved device. [1] K. Shibuki et al. J. Physiol.. 549(3), 919927, 2003. [2] Y. Abstract: *In vivo* two-photon imaging combined with targeted fluorescent indicators is nowadays extensively used for attaining critical insights into brain functionality and structural plasticity. Additional information might be gained from back-scattered photons from the NIR laser without introducing any exogenous labelling. Here, we describe a complimentary and versatile approach that, by collecting the reflected NIR light, provides structural details on the myelinated axons and blood vessels in the brain, both in fixed samples and in live animals under a cranial windows. Indeed, by combining NIR reflectance and two-photon imaging of a slice of hippocampus from a Thy1-GFPm mouse, we show the presence of randomly-oriented axons intermingled with sparsely fluorescent neuronal processes. The back-scattered photons guide the contextualization of the fluorescence structure within brain atlas thanks to the recognition of characteristic hippocampal structures. Interestingly, myelin formations allowed the label-free detection of axonal elongations over the layer 2/3 of mouse cortex under a cranial window *in vivo*. Finally, blood flow can be measured in live preparations, thus validating label free NIR reflectance as a tool for monitoring haemodynamic fluctuations. The prospective versatility of this label-free technique complimentary to two-photon fluorescence microscopy is demonstrated in a mouse model of photothrombotic stroke in which the axonal degeneration and blood flow remodelling has been investigated.

Title: Novel skull optical clearing facilitates imaging *in vivo* of Neural Circuitry in infantile mice cerebral cortex

Authors: Y. ZHAO, C. ZHANG, *T. XU, D. ZHU;
Wuhan Natl. Lab. For Optoelectronics, Hubei, China

Abstract: Two-photon microscopic *in vivo* imaging of cerebral cortex in fluorescent protein transgenic mice have shown great potential for understanding of a broad array of neurobiological phenomena, especially the dynamics of individual synapses and the functional organization of cortical maps in learning and memory and various brain diseases. Regarding the imaging performance always suffers from the turbid skull above the cortex, various cranial windows, such as remove skull, cranial window, thinned-skull cranial window, and polished and reinforced thinned skull window were developed to improve imaging. However, these models are not options available for infantile mice due to the vulnerability of young animals. Actually, the critical period for cortical development for young mice (2-6 weeks) is always a matter of concern. Specifically, the peak of anatomical and physiological plasticity of dendritic spines occurs during the third week. Up till now, the plasticity of neural infactile mice circuitry less than one month has not been studied *in vivo* very well. In this work, we developed an innovative skull optical clearing method, which can make the skull transparent by topically treatment with skull optical clearing agents instead of craniotomy. Through the clearing skull, we could image the dendritic protrusions of infactile mice *in vivo*. Our preliminary data showed the high dynamics of cortex circuitry in three-week old mice. In addition, the safety of skull optical clearing method was approved by dynamical monitoring the blood flow and observation of inflammation reaction.

Title: An implantable hemodynamic imaging device for revealing relation between a blood flow and brain activity in animal behavior

Authors: *M. HARUTA, Y. SUNAGA, T. YAMAGUCHI, H. TAKEHARA, Y. OHTA, M. MOTOYAMA, H. TAKEHARA, T. NODA, K. SASAGAWA, T. TOKUDA, J. OHTA;
Nara Inst. of Sci. and Technol., Ikoma / Nara, Japan

Abstract: We have developed an implantable hemodynamic imaging device for detecting a blood flow and brain activity in a small animal brain in a same time (Fig. (a)). The device includes a CMOS image sensor and LEDs for illuminations on a flexible substrate. A photo of the device is shown in Fig. (b). We can simultaneously measure a blood flow and brain activity by using two-color, or green and red LEDs on the device. A green LED emits at the peak wavelength of 535 nm where one of the peaks of hemoglobin absorption in the blood exist. We can measure a blood flow in a blood vessel with the LED, and observe both a blood flow velocity and a direction in a brain. A red LED emits at the peak wavelength of 605 nm where absorbance is different between oxy-hemoglobin and hemoglobin in the blood. We can measure brain activity with the red LED. Our device has advantage that it can measure hemodynamic signals under the implant state in a small animal, and such advantage provides a cerebrovascular disease study with an effective method. For measurement of the cerebrovascular disease study, magnetic resonance imaging (MRI) and computed tomography (CT) were generally used. However, these methods were not useful for a behavior study of a small animal such as a mouse. Our device can measure the blood flow and the brain activity in the behavior experiment of a small animal. This makes it possible to reveal relations between the blood flow, the brain function and the animal behavior. In this study, we successfully measured blood flow changes before and after a photothrombotic brain ischemia. Figure (c) shows images captured by the device before and after the ischemia. In the next step, we are planning to measure the blood flow and the brain activity in animal behavior to reveal relation between the cerebrovascular disease and the brain function.

Title: Quantitative evaluation of the resolution of *in vivo* two-photon microscopy by imaging of single fluorescent beads in living mouse brain

Authors: *R. KITAMURA[1,2], K. YAMAGUCHI[1,2], R. KAWAKAMI[1,2], T. NEMOTO[1,2]; [1]Res. Inst. for Electronic Sci., Sapporo / Hokkaido, Japan; [2]Grad. Sch. of Information Sci. and Technology, Hokkaido Univ., Sapporo / Hokkaido, Japan

Abstract: Synaptic plasticity induces morphological changes in post-synaptic structures, including dendritic spines, which have been implicated in information processing by neural network. Visualization of morphological changes in the living mouse brain will provide insight into brain functions such as learning or memory. Usually, observation of dendritic spines in living specimens is performed by *in vivo* two-photon microscopy, because of its high spatial resolution and deep imaging capability. In our previous studies, we found that penetration depth could be improved by changing the diameter of the irradiation excitation laser beam. However, the resolution under these conditions was not determined, because the focal spot size of the excitation light was not measured precisely. In general, the resolution of a laser scanning microscope is correlated with the focal spot size. This size is sometimes evaluated by measuring full width at half maximum (FWHM) of a structure with a known shape (e.g., a fluorescent bead) that is smaller than the diffraction limit. In this study, we injected fluorescent beads into the living mouse brain, and succeeded in *in vivo* two-photon imaging of single beads at various depths in the brain. Next, we estimated the resolutions by measuring FWHM from single-bead images, and then examined how the resolutions depended on the laser diameter and refractive

index of the immersion liquid.The results showed that FWHM on narrower laser beam diameter with higher average power was larger than that on full-filled condition. However, degradation of resolution was not remarkable for imaging of cortical neurons. Furthermore, differences between the refractive indices of the immersion liquids and the object being imaged resulted in degradation of focus. By decreasing mismatches in the refractive index , we achieved higher resolution at deeper regions of living mouse cerebral cortex. Thus, adjustment of the observation conditions to match the optical properties of the brain improves resolution at high penetration depth without requiring the use of a special device. We hope that this technique will be applicable to investigations of various neural functions, including the morphological changes undergone by neurons during physiological phenomena.

Title: High speed 3D two-photon imaging and real time movement correction *in vivo* with a second generation Acousto-Optic Lens Microscope

Authors: *V. GRIFFITHS[1], S. K. M. NADELLA[2], H. ROS[2], G. KONSTANTINOU[2], T. KOIMTZIS[2], C. BARAGLI[2], P. A. KIRKBY[2], A. R. SILVER[2];
[1]UCL, Huntingdon, United Kingdom; [2]UCL, London, United Kingdom

Abstract: Neuronal signals are brief and sparsely distributed in 3D across synapses, neurons and networks. Mechanical focussing used in conventional two-photon microscopes therefore limits functional measurements of brain activity. To overcome this limitation several groups have developed two-photon microscopes based on Acousto Optic Lens (AOL) technology, which allow high speed 3D random access point measurements. However, the performance of current AOL microscope design is not ideal for *in vivo* applications, because fast full frame raster scanning is limited to the natural focal plane and pointing to voxels sequentially is inefficient for

creating the 3D z-stacks required. Moreover, rapid 3D random access point measurements are prone to movement artefacts, which unlike raster-scan imaging, cannot be corrected post hoc. Previous studies have shown lateral movement artefacts of up to 10μm in awake, head restrained mice. This makes random access point measurements from dendrites and spines challenging in awake animals, because brain motion must be detected and the motion-corrupted recordings discarded. To address these serious limitations we have developed a second generation 3D AOL microscope with a fast Field Programmable Gate Array (FPGA) control and acquisition systems. This allows the AOL to perform raster scanning in any focal plane within the field of view (FOV) and voxel dwell times down to 50ns. Full resolution (512x512 voxel) imaging can be performed at 39Hz, while reduced resolution (128x128) can be performed at 252Hz. The ability to jump to any location in the 3D FOV within 24.5 μs enables the AOL to scan planes that are tilted in Z, allowing features such as dendrites that span several Z planes, to be monitored with a single tilted plane at full imaging speed. Alternatively, multiple planes of interest, sparse 'patches' or multiple small volumes distributed in the 3D FOV can be imaged. By linking up real time movement tracking, implemented in the acquisition system, with the control FPGA, we have implemented real time movement detection and correction. The system performance was quantified using fluorescent beads mounted on a piezoelectric stage. Continuous sinusoidal movement of +/-10μm could be compensated with an error of <1μm for frequencies up to 20Hz. For movements of up to +/-8μm and frequencies of up to 20Hz the AOL microscope could consistently monitor a 1μm beads with random access point measurements. Preliminary experiments on awake, head restrained mice, using the somata of cerebellar interneurons expressing GFP as reference objects, suggest that movement can be compensated in real time to within 0.5μm, even during periods of intense running.

Title: SCAPE microscopy of the awake, behaving mouse brain

Authors: *E. M. HILLMAN[1], V. VOLETI[1], C. O. LACEFIELD[2], M. B. BOUCHARD[1], W. LI[1], R. BRUNO[2];
[1]Biomed. Engineer, [2]Neurosci., Columbia Univ., New York, NY

Abstract: Swept, confocally-aligned planar excitation (SCAPE) microscopy is a new approach to fast 3D microscopy of the living brain which combines light-sheet optical sectioning with confocal descanning. SCAPE uses a single, stationary objective lens and can image at rates exceeding 20 volumes per second. This unique imaging geometry makes SCAPE suitable for high-speed 3D imaging of cellular function in the awake, behaving mouse brain. In recent experiments we have demonstrated that, despite its current implementation with 488 nm single-photon excitation, SCAPE can image to depths of over 250 microns in the intact, in-vivo mouse cortex at up to 40 volumes per second. Results show dynamics of both local and global dendritic spikes across identifiable apical tufts of layer 5 neurons expressing GCaMP6F. Animals are simultaneously monitored to track stimulus delivery, behavioral responses to stimulation and spontaneous behavior. SCAPE is also well suited to imaging small organisms such as *Drosophila* melanogaster and zebrafish, and can capture cellular function and structure during free movement. Improving SCAPE for in-vivo mouse brain imaging will include extending this penetration depth and resolution through the use of longer excitation wavelengths, red-shifted proteins, structured light approaches and two-photon implementations. Approaches to analysis and visualization of this high-speed 4-dimensional data are also under development. Our latest developments and results will be presented.

Title: Flexible, nimble, and quiet two-photon microscope platform for auditory functional imaging of awake marmosets

Authors: *X. SONG[1], Y. GUO[2], X. LI[2], X. WANG[2];
[1]Johns Hopkins University. Dept. of Biomed. Engin., Baltimore, MD; [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Two-photon laser scanning microscopy (TPLSM) has been widely employed to study neuronal population functions *in vivo*. The standard implementation of TPLSM utilizes a pair of galvanometer mirrors to scan the imaging beam. However, this mechanical oscillation introduces a remarkable acoustic noise bearing a distinct pitch. This unwanted noise as well as the cooling noises from a Ti:Sapphire laser system, introduces potential auditory artifacts which haven't been carefully investigated in previous studies. Alternatively, a beam scanner based on acousto-optical deflector (AOD) enables fast, silent and random-access scanning; yet a pure random-access scanning mode might be vulnerable to movement artifacts and thus limits its imaging use in awake animals. We have designed and built a system capable of flexible and nimble two-photon AOD scanning imaging in awake animals (FANTASIA). We isolated the laser cooling system outside a double-walled acoustic testing chamber. Such a system can perform (1) 2D random-access scanning at a speed of 50,000 points per second; or (2) 2D raster scanning at video rate, or (3) even 3D multi-layer scanning without moving the objective. To test the system, we injected adeno-associated virus carrying GCaMP and GFP into the cortex of a marmoset monkey (callithrix jacchus), a highly vocal non-human primate species, which was implanted with an artificial dura based optical window and imaged under awake condition. Clear cellular structures could be resolved. Both scanning flexibility and nimbleness were achieved without generating noticeable acoustic noise. This research is supported by an NIH grant (DC-03180).

Title: *In vivo* imaging of zebrafish brain structure and function with light sheet microscopy

Authors: *T. V. TRUONG[1], A. ANDREEV[1], D. B. HOLLAND[1], J. M. CHOI[1], S. MADAAN[1], W. DEMPSEY[2], G. GROSS[2], D. B. ARNOLD[2], K. CZAJKOWSKI[3], C. KESSELMAN[3], S. E. FRASER[1];

Abstract: Light sheet microscopy, also known as Selective Plane Illumination Microscopy (SPIM), has emerged in recent years as the modality of choice to deliver high, balanced performance in resolution, speed, and penetration depth, while minimizing photo-induced damages (fluorophore bleaching and cellular toxicity). We have used SPIM to image both the structure and function of live, intact, larval zebrafish brains. In one-photon (1p) excitation mode, SPIM delivers the high signal rate and signal-to-noise ratio necessary for us to visualize synapses that have been fluorescently labeled, at endogenous concentration, with recombinant probes. In two-photon (2p) excitation mode, SPIM delivers higher penetration depth than the 1p-counterpart, though with lower signal rate (due to lower 2p absorption cross section), but still is more than 10 times faster than conventional 2p point-scanning microscopy. The near-infrared light of 2p excitation, invisible to most animals' eyes, is critical to allow observation of brain activity without perturbing the animal's behavior. Furthermore, the minimal photo-induced damage allows us to continuously record for extended periods of twelve hours or more. Together, the ability to image both the structure, at synaptic resolution, and function, at whole brain coverage, lays the foundation for our ongoing studies to understand the information coding and processing involved in learning and memory.

Title: Fast three-dimensional imaging of neuronal assemblies in the mouse visual cortex using genetically-encoded neuronal indicators and two-photon microscopy

Authors: *G. SZALAY[1], J. LINDA[1], G. KATONA[1], P. MAÁK[2], M. VERESS[2], B. RÓZSA[1,3]; [1]MTA KOKI, Budapest, Hungary; [2]Dept. of Atomic Physics, Budapest Univ. of Technol. and Econ., Budapest, Hungary; [3]Pázmány Péter Catholic Univ., The Faculty of Information Technology, Hungary

Abstract: The understanding of brain computation requires novel methods that read out neural activity on different spatial and temporal scales. Two-photon calcium imaging is a powerful means for monitoring the activity of distinct neurons in brain tissue *in vivo*. Genetically-encoded fluorescent calcium sensors are widely used to image neural activity; therefore we imaged calcium indicator-expressing neurons in the mouse visual cortex (V1) through a cranial window *in vivo*. During *in vivo* imaging movement artifacts caused by heartbeat and breathing artifact poses other challenges. In this work we present multiple 3D, acousto-optical, two-photon laser-scanning technologies to monitor neuronal activity at different scales with genetically-encoded calcium indicators in a near-cubic-millimeter scan range (up to 700 × 700 × 1,400 μm^3), with a high scanning speed (up to 1 Mhz), with high (<500 nm) resolution in the center core, and less than 1.9 x 1.9 x 7.9 μm^3 resolution throughout the whole scanning volume. We used volumetric random-access calcium imaging of spontaneous and visual stimulation-evoked activity from hundreds of neurons. We applied 3D trajectory scanning technique to measure multiple dendritic segments *in vivo* with motion compensation possibility. Finally we introduced an expansion of trajectory scanning technique to monitor the activity from more than 100 cells *in vivo* while obtaining information for motion correction.

Title: Multilayer cortical imaging in freely behaving animals

Authors: S. GULATI, V. CAO, P. JOSHI, *S. L. OTTE;
Inscopix, Palo Alto, CA

Abstract: The ability to study cortical function in behaviorally-relevant contexts is essential to dissecting neural network dynamics underlying cognition, attention, and sensory-motor integration. The evolutionary recent six-layered neocortex is the seat for many of these higher-order brain functions. It is thus of paramount importance to understand how the intra and inter-laminar flow of information in this anatomically complex region of the active brain regulates these functions. This requires the technological capability to simultaneously image multiple layers of the necortex at cellular resolution (and with cell-type specificity) during active behavior. Until now, such imaging was limited to either *in vitro* cortical slices, which lack physiological connections, or to *in vivo* two-photon preparations, which requires animal immobilization, precluding analysis during active, naturalistic behavior. Here, we pair Inscopix's nVista head-mounted, miniaturized microscope with 1mm chronically implanted glass microprisms to simultaneously record the calcium activity of upto ~500 neurons across all six layers of the somatosensory cortex during naturalistic behavior. The calcium dynamics of individual cells were monitored over time and across behavioral states. This study allowed us to compare the intra and inter-layer responses of individual cell responses during a novel object recognition task. These experiments extend the reach of *in vivo* calcium imaging to chronic, simultaneous monitoring of entire cortical columns during free behavior.

Title: *In vivo* deep two-photon brain imaging with a red-shifted fluorometric Ca^{2+} indicator

Authors: *C. H. TISCHBIREK, A. BIRKNER, H. JIA, B. SAKMANN, A. KONNERTH; Inst. of Neuroscience, TU Munich, Munich, Germany

Abstract: *In vivo* Ca^{2+} imaging of neuronal populations in deep cortical layers has remained a major challenge, as the recording depth of two-photon microscopy is limited due to scattering and absorption of photons in brain tissue. A possible strategy to increase the imaging depth is the use of red-shifted fluorescent dyes, as scattering of photons is reduced at long wavelengths. Here, we tested the red-shifted fluorescent Ca^{2+} indicator Cal-590 for deep tissue and dual-color two-photon imaging experiments *in vivo*. Cal-590 has a maximum for two-photon excitation at a wavelength around 1050 nm and a maximum emission wavelength at 590 nm. To explore the potential of Cal-590 for measurements of neuronal activity in deep cortical layers of the mouse brain, we used bulk loading of the acetoxymethyl (AM) ester version of Cal-590 to label populations of neurons in layers 5 and 6, respectively. Combined two-photon imaging and cell-attached recordings revealed that, despite the relatively low affinity of Cal-590 for Ca^{2+} (Kd = 561 nM), single action potential-evoked Ca^{2+} transients were discernable with a good signal-to-noise ratio in most bulk loaded neurons. We were able to record spontaneous Ca^{2+} transients with rapid kinetics in the six layers of the cortex at depths of up to -900 μm below the pial surface. Similar results were recorded for individual neurons electroporated with Cal-590, with dendritic rise and decay times sufficient to distinguish the peaks of individual Ca^{2+} transients even for high-frequency trains (100 Hz) of action potentials. In addition to the deep imaging experiments, we used Cal-590 for multi-color functional imaging experiments in combination with other Ca^{2+} indicators. Ca^{2+} transients in the dendrites of an individual OGB-1-labeled neuron and the surrounding population of Cal-590-labeled cells were recorded simultaneously on two spectrally separated detection channels. We conclude that the red-shifted Ca^{2+} indicator Cal-590 allows acute *in vivo* two-photon Ca^{2+} imaging experiments in all layers of the mouse cortex as well as multi-color functional imaging experiments.

Title: Transmission of Laguerre Gaussian, Bessel, and Gaussian beams through rat brain with different orbital angular momentum

Authors: *L. SHI[1,2], W. WANG[2], R. GOZALI[2], M. LAVERY[3], P. MARQUES[2], A. RODRÍGUEZ-CONTRERAS[1], R. ALFANO[2];
[1]Biol., City Col. of New York, New York, NY; [2]Inst. for Ultrafast Spectroscopy and Lasers, New York, NY; [3]Sch. of Physics and Astronomy, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: One of the key problems of optical imaging in neuroscience is to image deep within the brain. In addition, imaging resolution is always blurred due to scattering, which needs to be overcome by selecting the appropriate coherent ballistic component. One solution is to choose a wavelength in one of the four optical windows within the near-infrared (NIR) region. Another method is to use the optimal types of spatial light beams. A salient property of the light is spatial wave front, which can be planar or helical. Examples of helical wave front are the Laguerre Gaussian (LG) and the Bessel vortex laser beams. These beams carry orbital angular momentum (OAM) and can be used to probe biological tissues, such as the brain, for deep imaging. Most recently, the transmission of tight focused vortex beams have been theoretically studied. Sun et al. proposed that the electric fields of vortex beams have more penetration capacity through the turbid media than that of no-vortex beams, and the larger the OAM of the vortex beams, the higher the penetration capacity. Ou's group calculated the scattering of the LG beam at different OAMs. They showed that the magnitude of the scattering intensity decreased as OAM increased, suggesting the increase of transmission intensity with OAM. Bessel beam, due to its property of self-healing, is hypothesized to be able to image deeper into the tissue than other beam types. Therefore, the objective of this study was to examine transmission effects of LG and Bessel beams with different OAMs in the brain tissue. We measured light scattering of the LG and Bessel vortex beams with different momentums in rat brain tissues *ex vivo*. These results were compared with that measured from a Gaussian (G) beam, a special case of LG beam with a planar wave front with OAM=0, which is commonly applied in brain imaging. The optical transmissions of LG, Bessel, and G beams were measured at different ratios of thickness (Z)/scattering distance (Ls), 1 to 117, where Ls was ~60 μm in rat brain. The entire transmission intensity after the beam propagating through the brain tissue was measured. Our experiments indicate that LG, Bessel, and G beams showed no significant difference of donut beams transmission in brain tissue at different OAMs in both the ballistic and diffusive regions. The transition points from the ballistic to diffusive region for different scattering media were located at Z/Ls=18 for all three beams in brain tissue. This preliminary data suggests that different types of laser beams have similar limitations for deep imaging in the brain.

Title: Optimizing all-optical interrogation for closed-loop control of neural circuits

Authors: *L. E. RUSSELL, A. M. PACKER, M. HAUSSER;
Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Manipulating activity patterns as they are occurring, moment-to-moment, in a flexible manner will permit new classes of experiment, enabling us to dissect the encoding and decoding schemes of mammalian neural circuits (Grosenick et al 2015). We have developed a novel approach for interrogation of neural circuits in which real-time analysis of population calcium imaging data is combined with near-instantaneous manipulation of the circuit via targeted two-photon optogenetic stimulation. Simultaneous calcium imaging and optogenetic manipulation is enabled through the use of a genetically encoded calcium indicator (GCaMP6s) and a red-shifted opsin (C1V1). A spatial light modulator allows multiple, defined cells to be targeted for concurrent and spatiotemporally precise photoactivation. Real-time analysis of the calcium imaging data is made possible by intercepting the raw acquisition data stream from our microscope, in combination with fast algorithms for activity detection in identified cells. In proof of principle experiments in mouse visual cortex, we demonstrate dynamic network perturbations guided by the activity patterns of multiple identified cells. We designated multiple “trigger” cells in a single field of view with corresponding sets of “targets”. When activity in any of the trigger cells exceeded threshold the corresponding targets were selectively activated. We have photostimulated up to 50 neurons simultaneously and validated the high-power handling of new SLM devices, which switch three times faster than in our previous work (Packer et al 2015).

Work is in progress to optimize beamlet delivery to wider fields of view as well as generate advanced analytical routines for dealing with the resulting datasets. This approach will enable new classes of experiment, such as: correcting erroneous network trajectories recorded from animals performing a decision-making task; inducing plasticity in neural circuits by recruiting cells into functional, existing or artificial ensembles; and processing functional connectivity maps in real time to update predictions and guide subsequent interrogation.

Title: Quantitative phase imaging (QPI) of optogenetic signals in neurons

Authors: *T. KIM[1,2], P. SENGUPTA[1,2], M. U. GILLETTE[1,2], G. POPESCU[1,2];
[1]Univ. of Illinois At Urbana-Champaign, Champaign, IL; [2]Beckman Inst. for Advanced Sci. and Technol., Urbana, IL

Abstract: Fast signals in neurons play a central role in intercellular communication. These signals are generated through the ion channels on the plasma membrane, when the membrane potential increases and surpasses the threshold. This subtle and rapid event occur in millisecond timescale, which makes it extremely difficult to detect them without an expensive electrophysiology system. These systems also require a highly precise control during its operation and are limited to single point measurements. More recently, electrophysiology systems based on MEMS devices have been developed for multipoint detection of these signals. However, it remains challenging to do a wide-field imaging of these cells in action because of the required imaging speed and sensitivity. Recent advances in quantitative phase imaging (QPI) allowed unlabeled live biological specimens to be imaged with sub-nanometer sensitivity and diffraction limited resolution. A recently developed technique called Spatial Light Interference Microscopy (SLIM) has been applied for discovering the emergent behavior in human neuronal

networks and the intercellular dynamics and has proven its potential to be used in neuroscience [Z. Wang et al., Opt. Exp., 19, 1016 (2011) & M. Mir et al., Sci. Rep., 4, 4414 (2014)]. This technique, which allows for a wide-field imaging of live neuronal activities, therefore, can be used for a measurement of rapid and subtle action potentials in optogenetically engineered cells. By implementing a projector and imaging a pattern onto the sample plane, SLIM system acquires a light stimulation system, which is capable of lighting up individual cells. The cellular signals generated as a response to the light stimulation then are measured with a sub-nanometer sensitivity as they propagate through the cells. This new method of measuring action potentials in neurons can help understanding the cellular signaling mechanism and dynamics at a higher resolution.

Title: Real-time analysis of calcium imaging data

Authors: *A. MITANI, T. KOMIYAMA;
Dept. of Neurosciences, UCSD, La Jolla, CA

Abstract: *In vivo* Ca2+ imaging has become a powerful method to record the activity of ensembles of single neurons. Compared to electrophysiological recordings, it is more reliable to

identify the same set of neurons over a long period of time. In addition, with the expanding set of genetic tools, distinct cell types can be identified relatively easily. These advantages make calcium imaging well suited for closed-loop experiments, in which behavioral feedback is given in real time based on neural activity to probe brain plasticity. However, closed-loop experiments with calcium imaging are so far limited to only a few studies (Clancy et al (2014), Hira et al (2014)), partly due to technical challenges of real time processing of high-volume imaging data. Here we discuss our effort to streamline real time processing of full-field, 30Hz two-photon calcium imaging data from mouse neocortex. We developed a fast motion correction algorithm and integrated it into ScanImage4 as a plugin function. This system processes the same images saved for post-hoc analysis, and therefore there is no loss of information. In addition to closed-loop experiments discussed above, real-time motion correction would facilitate additional applications. First, task parameters could be tuned based on the response properties of imaged neurons. This has been a widely used approach in single-unit recording studies in monkeys to enhance the responses of the recorded neurons by selecting their preferred stimuli. Second, motion corrected images can be used to estimate drift in imaging plane automatically. Imaging sessions can last for hours, and the focal plane of the microscope relative to *in vivo* samples can shift over time. In most studies this issue is ignored or manually corrected, thus the deviation has to become large enough to be visible before corrected. We will show that automatic Z correction with Piezo-controller achieves more frequent and finer Z-plane adjustment and hence increases the stability of the imaging. This study will show the enhanced performance of the online image processing system in Ca2+ imaging and its promising applications.

Title: The role of conserved polar amino acids at the transmembrane loop regons of a genetically encoded voltage sensor

Authors: M. SEPEHRI RAD[1], B. J. BAKER[1], *M. ALLAHVERDIZADEH[2], L. B. COHEN[3]; [1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Thechnonoly, Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Dept. of Mol. and Cell. Physiology, Yale Univ. Sch. of Medicine, New Haven, CT., New Haven, CT

Abstract: Designing genetically encoded voltage indicators (GEVI) to respond to specific voltage ranges will simplify the interpretation of optical recordings of neuronal activity *in vivo*. To identify potential regions of the voltage-sensing domain that could shift the voltage sensitivity, we aligned 183 voltage-gated sodium channels (Nav) from different organisms. Conserved polar residues were identified at multiple transmembrane-loop junctions in the voltage sensing domain. Similar conservation of polar amino acids were found in the voltage sensing domain of the voltage-sensing phosphatase (VSP) gene family. These conserved residues were mutated to nonpolar or oppositely charged amino acids in a GEVI that utilizes the voltage sensing domain of the VSP from *Ciona intestinalis* fused to the fluorescent protein, super ecliptic pHlorin (A227D) to determine their potential role in sensing voltage across the plasma membrane. Preliminary results show that some of the polar residues shift the optical response to more positive potentials. Interestingly, one conservative change of aspartic acid to glutamic acid abolished the membrane trafficking of the GEVI suggesting that the length of the side chain is important at the plasma membrane/extracellular interface.

Title: Imaging subcellular voltage dynamics *in vivo* with improved genetically encoded indicators

Authors: *F. ST-PIERRE, H. Y. YANG, M. PAN, X. DING, Y. YANG, T. R. CLANDININ, M. Z. LIN;
Stanford Univ., Stanford, CA

Abstract: Nervous systems encode information as spatiotemporal patterns of membrane voltage transients, so accurate measurement of electrical activity has been of long-standing interest. Recent engineering efforts have improved our ability to monitor membrane voltage dynamics using genetically encoded voltage indicators. In comparison with electrophysiological approaches, such indicators can monitor many genetically defined neurons simultaneously; they can also more easily measure voltage changes from subcellular compartments such as axons and dendrites. Compared with genetically encoded calcium indicators, voltage sensors enable a more direct, accurate, and rapid readout of membrane potential changes. However, several challenges remain for *in vivo* voltage imaging with genetically encoded indicators. In particular, current voltage sensors are characterized by insufficient sensitivity, kinetics, and/or brightness to be true optical replacements for electrodes *in vivo*. As a first step towards addressing these challenges, we developed a new voltage indicator, ASAP2, that further improves upon the sensitivity of the fast voltage sensor Accelerated Sensor of Action Potentials 1 (ASAP1). We also describe here how ASAP2 can report stimulus-evoked voltage responses in axonal termini of the fly visual interneuron L2. In this system, ASAP sensors enabled the monitoring of neural activity with greater temporal resolution than three recently reported calcium and voltage sensors. Overall, our study reports novel voltage indicators with improved performance, illustrates the importance of sensor kinetics for accurately reporting neural activity, and suggests L2 as an *in vivo* platform for benchmarking neural activity sensors. We anticipate that ASAP2 will facilitate current and future efforts to understand how neural circuits represent and transform information.

Title: Viral delivery of new biosensors for voltage and cAMP signaling

Authors: S. MARTINKA[1], *T. E. HUGHES[2], P. TEWSON[1], J. PLATISA[3], V. PIERIBONE[3]; [1]MontanaMolecular, Bozeman, MT; [2]Dept Cell Biol/Neurosci, Montana State Univ., Bozeman, MT; [3]The John B. Pierce Lab., New Haven, CT

Abstract: Action potentials are the fundamental currency of neuronal signaling, and concerted activity eventually raises intracellular calcium within the cell. Calcium signaling influences cAMP levels, which in turn cause changes in the activity of a wide variety of proteins and gene transcription. While this chain of events is now doctrine in neuroscience, imaging neural activity is largely limited to biosensors for calcium such as GCaMP6 or GECOs. Here we present fluorescent sensors for voltage and cAMP that can be simultaneously imaged with sensors for calcium in living neurons. For imaging voltage, we used ArcLight, the most robust green fluorescent voltage sensor available today. For cAMP, we created an EPAC-based sensor that is both bright and produces a large change in fluorescence in response to cAMP signaling. Both Arclight and the cAMP sensor were made under the control of the CMV or Synapsin I promoter. These sensors are built with a single green fluorescent protein, making it possible to combine them with red sensors. Both are packaged in a viral delivery system that provides high transfection efficiency, enables transfection of difficult to transfect cell types, including primary cultures, and produces homogeneous cellular expression levels. The genome of the baculovirus used in our delivery system is silent in mammalian cells and produces virus that is non-replicative, making it a biosafety level I reagent. Testing the viruses in HEK 293 cells revealed CMV driven expression of the sensors to be quite consistent from cell to cell. In the case of ArcLight, entire waves of spontaneous depolarization can be captured with remarkable fidelity, and in the case of the cAMP sensor, endogenous Î²2 adrenergic receptor activation produces changes in fluorescence intensity that can be readily detected even with low magnification, low N.A., lenses. In cultures of primary cortical neurons, the CMV version of the Arclight sensor transduced ~25% of the cells in culture (includes glia). The Synapsin I promoter produces restricted sensor expression that is limited to neurons. Pairing each of these green sensors with the red fluorescent R-GECO1.2 calcium sensor makes it possible to simultaneously measure voltage and calcium signaling or calcium and cAMP signaling.

Title: Imaging voltage in brain slices in Cre-lox targeted interneurons with a hybrid voltage sensor

Authors: *P. BAYGUINOV, Y. MA, Y. GAO, X. ZHAO, M. JACKSON;
Dept. of Neurosci., Univ. of Wisconsin, Madison, WI

Abstract: Voltage imaging offers the possibility of studying the concomitant function of large numbers of neurons, and to reveal the emergent properties of neural circuits. Synthetic dyes stain tissues indiscriminately, and in intact circuits the use of these probes is limited to the study of population responses. Recent advances in genetically-encoded voltage probes have allowed voltage imaging in brain slices with single-cell resolution. However, the diversity of neuronal cell types remains an obstacle in exploring the functionality of distinct neural circuits. The development of Cre recombinase driver mouse lines provides a general strategy for targeting probes to specific classes of neurons, allowing the examination of circuits formed by distinct neuronal populations. We have used the Ai35 vector to generate a rosa26 knock-in mouse with a hybrid voltage sensor (hVOS) probe. In the presence of dipicrylamine, this probe serves as a genetically encoded voltage sensor. Cre driver lines for Parvalbumin, glutamic acid decarboxylase 2 and calcitonin-like gene receptor (CalCrl), were crossed with the Ai35-hVOS Cre reporter line to express hVOS probes in three different genetically-defined populations of neurons. Mice from all these crosses express hVOS in sparse populations of neurons in the somatosensory cortex and hippocampus, and report voltage responses to electrical stimulation with single-cell resolution. Voltage imaging experiments revealed action potentials and subthreshold synaptic events in single trial recordings. Furthermore, the generation of this rosa26-hVOS Cre reporter line, generalizes the targeting of hVOS probe to other neuronal subpopulations, depending on the availability of Cre driver lines. This work presents a significant addition to the voltage imaging toolkit, allowing the study of electrical activity in

large groups of specific subpopulations of neurons with high spatial and temporal resolution.

Title: Semi automated screening system for testing genetically encoded voltage indicators

Authors: *G. VASAN[1,2], J. PLATISA[1,2], A. YANG[1], V. A. PIERIBONE[1,2];
[1]The John B. Pierce Lab., New Haven, CT; [2]Cell. and Mol. Physiol., Yale Univ. Sch. of Med., New Haven, CT

Abstract: In recent years, a number of novel genetically-encoded voltage indicators (GECIs) have been developed. For many of these voltage indicators, including ArcLight - there is an interest to further modify the indicator's sequence (i.e. protein evolution) in order to improve their kinetics and optical response properties. But such a development process demands large-scale mutagenesis of the original probe combined with intense testing of thousands of variants in varied cell systems. Imaging optical response of each variant individually while simultaneously recording electrical response using patch electrodes is a time consuming process. Here, we report on our custom built medium throughput screening process specifically designed to image optical response from cultured neurons in a 96-well plate. The in-house made screening platform is built around a Nikon eclipse Ti microscope equipped with a Perfect Focus system. The movement of the imaging stage, electrode actuator, light source and filter turret rotation are all controlled using custom electronics interfaced with LabView software. The software is programmed to identify the best neurons in each well, stimulate them via a field electrode and record optical response at high temporal resolution (<200 hz) using a Hamamatsu ORCA Flash4.0 camera. Once recorded, a machine vision algorithm identifies and tags neurons in a field of view, performs analysis and

stores response plots in a database to be later reviewed by the researcher. We also discuss the possibilities of using the screening platform for other cell types with varied testing requirements.

Title: Evaluation of genetically encoded voltage indicators (GEVIs) performance in *Drosophila* melanogaster

Authors: *J. PLATISA[1,2], X. JIN[2], M. KUNST[2], M. N. NITABACH[2], V. A. PIERIBONE[1,2]; [1]The John B Pierce Lab., New Haven, CT; [2]Cell. and Mol. Physiol., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Neurons exhibit a collection of different transient electrical events that vary in both spatial and temporal domains. To be able to analyze these events *in vivo* we need methods with both high temporal and spatial resolution and large signal to noise (SNR) ratio. Use of light to record brain electrical activity represents a less invasive and more scalable alternative to classical electrode-based methods and provides higher spatial resolution. Optical methods allow simultaneous recordings from different locations within a field of view, from the level of single cell and cell compartments to the level of neuronal circuits comprising of hundreds, even thousands neurons simultaneously. Development of Genetically Encoded Voltage Indicators (GEVIs) whose expression can be cell-type-specific allows for voltage imaging to be preformed in targeted cells and in the structures buried deep within the brain. In the last two decades a range of different voltage indicators have been developed but one of the major problem for their adoption by the wider community is poor and unreliable performance under real world experimental conditions. Indicators often work well in cultures of immortalized cells, less well in neurons *in vitro* and usually not at all in more intact preparations. Here we present a comparative study in which a range of most promising "new generation" GEVIs were subjected to standardized evaluation under a real world experimental paradigm. To this end, we used the

GAL4/UAS binary expression system to develop several transgenic fruit flies (*Drosophila* melanogaster) that express each of the most promising GEVIs in, lateral ventral circadian clock neurons (LNvs). Simultaneous whole-cell current-clamp recordings and high-speed (500Hz) fluorescence imaging allow for precise assessment of GEVIs performance. We compare expression levels, membrane localization, brightness, signal size and SNR of GEVIs under standardized imaging condition and using conventional imaging equipment.

Title: Automated dye microinjection to label mouse and human neurons

Authors: *B. R. LONG, E. LEIN, H. PENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Neuronal morphology is a key feature for identifying cell types in the brain. In the case of *H. sapiens*, suitable tissue samples are rare and cover a wide range of ages, genetic backgrounds and disease states. To quantitatively assess morphological cell types across such a diverse population, large numbers of digital reconstructions are needed. Although decades of Golgi studies have established morphologically -defined neuronal types across many species, the Golgi method is limited by the its inability to control the precise location of labeled cells. Furthermore, for high-throughput extraction of neuronal reconstructions, the density of labeled cells must be tightly controlled to avoid labeling closely -apposed neurites in neighboring cells. One method that allows control of both location and density of labeled cells for morphological reconstruction is microinjection of fluorescent dye, typically Lucifer Yellow (LY), into the cell body of neurons in lightly fixed samples. In addition to labeling cells in the mouse brain, LY microinjection can be used to target cells in fixed human tissue, allowing many cells to be filled in each slice. However, LY microinjection requires extensive training and an expert manual operator to obtain good quality morphology data. Here we present an automated system for LY microinjection that can be targeted to DAPI-stained neurons in fixed tissue. By reducing LY microinjection to a point-and-click process, we are able to rapidly fill neurons in user-defined regions of fixed slices. Automated cell filling can facilitate high-throughput cell filling targeted

to specific anatomical regions or in a spatially unbiased manner to survey morphologies across the sample.

Title: Transmembrane transport of proteins into neurones by cholera toxin B

Authors: *J. L. HAIGH[1], W. B. TURNBULL[2], S. DEUCHARS[1], J. DEUCHARS[1];
[1]Fac. of Biol. Sci., [2]Fac. of Mathematics and Physical Sci., Univ. of Leeds, Leeds, United Kingdom

Abstract: Cholera toxin B (CTB), the non-toxic subunit of the toxin produced by Vibrio cholerae is taken up by motor, sensory and autonomic preganglionic neurones in the CNS when administered systemically (Havton & Broman, 2005). This work aims to modify CTB as a means to deliver other proteins into these neurones to influence their function. To test this we chose parvalbumin, which is a calcium buffer protein generally not expressed in motor neurones. A C-terminal fusion protein of CTB and parvalbumin (CTBparv) was expressed via Escherichia coli. Isothermal titration calorimetry revealed that CTBparv maintained binding affinity for its receptor GM1 ganglioside with a Kd = 49 nM, similar to that of wild-type CTB (Kd = 40 nM). This suggested that the fusion protein would be endocytosed, and was confirmed by its uptake by HEK 293T cells after incubation with 5 μg of CTBparv for between 1 and 24 hours. To test if CTBparv is able to be taken up by motor neurones, C57BL6 mice were anaesthetised with isoflurane and 40 μg of CTBparv in 2 μl of 50 mM HEPES administered at multiple sites of the tongue musculature. After 1, 2, 4 or 7 days, mice were anaesthetised with 80 mg/kg pentibarbitol IP and transcardially perfused with 4% paraformaldehyde. The brainstem was sectioned at 50 μm on a vibrating microtome. CTBparv successfully labelled the hypoglossal nucleus as revealed by immunoreactivity to both CTB and parvalbumin. Control mice injected with 40 μg CTB in 2 μl of 50 mM HEPES had CTB labelled hypoglossal neurones with no parvalbumin immunoreactivity. For IP injections, unanaesthetised C57BL6 mice were injected with 2000 μg, 1000 μg, or 500 μg of CTBparv in 100 μL of 50 mM HEPES and after 4 days, tissue was prepared as before. There were CTB immunopositive cells in the dorsal vagal nucleus of the brainstem and motor neurones in the ventral horn of the spinal cord, but not all cells were

positive for parvalbumin. Further experiments will seek to determine the sub-cellular localisation and functionality of the parvalbumin within the neurones. The results highlight CTB as a useful means to deliver other proteins past the blood-brain barrier and into the CNS by entering neurones with axons in the periphery. CTB has the potential to be utilised as therapeutic tool to target specific subsets of neurones within the CNS affected by neurological diseases.

Title: Methods for assessing internalization of microparticles into neuronal cells

Authors: *V. WALLACE[1], F. RUBIO[1], R. CIMBRO[2], M. J. HENDERSON[1], L. V. FORTUNO[1], R. MADANGOPAL[1], B. HARVEY[1], B. HOPE[1];

Abstract: While it has been well-established that neurons can internalize particles on the nano scale, little has been done to assess the internalization of micron-sized particles in neuronal cells. Confirming that neurons can internalize microparticles could open the door to a host of cell-level diagnostic technology. However, few studies have established reliable and widely applicable methods that allow distinction between internalized and surface-adsorbed particles, as well as precise quantification of the internalized fractions. Combining the techniques of flow cytometry, fluorescence activated cell sorting (FACS), epifluorescent and confocal microscopy, we have developed a set of robust and reliable methods for confirming that cells *in vitro* can internalize micron-sized particles. These methods can be applied to a vast array of particle types and sizes, and can allow for further investigation into the characteristics of microparticles that affect uptake into cells. Together, the results will further the development of potential applications of intracellular micron-scale technology in neuronal cells.

Title: SHAFT: A novel method for mapping long-range projections at single neuron resolution and in high-throughput using DNA sequencing

Authors: *J. M. KEBSCHULL[1], P. GARCIA DA SILVA[2,1], I. PEIKON[1], D. F. ALBEANU[1], A. M. ZADOR[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Champalimaud Neurosci. Programme, Lisbon, Portugal

Abstract: Long-range connections provide the substrate for integrating information across brain areas. Recently, several large-scale efforts, such as the Allen Mouse Brain Connectivity Atlas, have provided a systematic survey of long-range connectivity in the mouse brain. However, although knowledge of the aggregate connectivity from one brain area to another has proven invaluable, in some cases resolution at the circuit and even single neuron level is needed. Unfortunately, established methods for determining projection patterns at higher resolution are extremely labor intensive and therefore low-throughput. Here we describe SHAFT ("Sequence-based High-throughput Analysis of Far Targets"), a relatively simple, inexpensive, and highly muti-plexed method for establishing the projection pattern of single neurons in the mouse brain. Our method transforms the problem of long-range connectivity from a problem of microscopy into a problem of DNA sequencing, thereby enabling us to exploit the tremendous recent increase in sequencing throughput. In our approach, we label a defined population of neurons using a viral tracer injection. However, instead of labeling the population with a fluorophore such as GFP, we use viruses to express short random sequences of RNA or "barcodes". A barcode of length 30 nucleotides has a theoretical diversity of 4^30=10^18, far more than the number of neurons in the mouse brain (~10^8). Random barcodes can thereby provide a unique label for all infected neurons. We engineered the RNA barcodes to bind to a modified pre-synaptic protein, so that upon co-expression, the protein drags the RNA barcode to distal axonal projections. We then use high-throughput DNA sequencing to read out projection patterns at

selected regions of interest (ROIs). By determining which barcodes are present at which ROIs, we obtain the projection patterns of single neurons. Our method scales well, and has the potential to provide a systematic survey of long-range projections in the mouse brain at single neuron resolution.

Title: Neocortical projection neurons receive class-specific patterns of long-range inputs

Authors: *K. E. BORGES[1], N. YAMAWAKI[1], I. R. WICKERSHAM[2], C. R. GERFEN[3], G. M. G. SHEPHERD[1];
[1]Physiology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [3]Lab. of Systems Neurosci., NIH, Bethesda, MD

Abstract: Excitatory cells in the cerebral cortex can be classified based on their axonal projections. Intratelencephalic (IT) neurons terminate exclusively within cortex and striatum, and are the only cortical neurons that project contralaterally. Pyramidal tract (PT) neurons send axons toward the brainstem and spinal cord and branch into ipsilateral cortex, striatum, thalamus, and midbrain. Finally, corticothalamic (CT) neurons project to the thalamus. Each cortical area contains its complement of IT, PT, and CT neurons. However it is not known, in a given brain area, whether these three projection classes receive input from the same, partially overlapping, or entirely separate areas of the brain. We pursued this question using viral methods for

monosynaptic tracing, focusing on primary motor cortex and (in separate experiments) auditory cortex of the mouse. We used mice from BAC-Cre driver lines that express Cre recombinase in IT (line Sepw1_NP39 for layer 2/3 and line Tlx3_PL56 for layer 5), PT (line Sim1_KJ18), or CT (line Ntsr1_GN220) neurons. We injected either motor or auditory cortex with adeno-associated virus (AAV) encoding cre-dependent TVA (the receptor for EnvA) and rabies virus glycoprotein. The same cortical area was later injected with glycoprotein-deleted rabies virus encoding a red fluorescent protein and coated with EnvA. Complementation of glycoprotein by AAV allowed rabies virus to retrogradely jump across one synapse, labeling the monosynaptic inputs to either PT, IT, or CT neurons. Preliminary findings indicate that IT, PT, and CT neurons receive long-range connections from distinct but partially overlapping cortical and subcortical areas. For example, in motor cortex all three classes receive input from retrosplenial cortex, but IT and CT neurons tend to receive more input from premotor and orbital areas than do PT neurons, and only PT and layer 2/3 IT neurons receive input from secondary somatosensory cortex (S2). All three classes receive input from thalamus, but from somewhat different subsets of thalamic nuclei. IT and CT neurons receive input from globus pallidus, whereas PT neurons do not. Similarly, projection classes in auditory cortex receive differential input from frontal, motor, and somatosensory cortical areas, as well as from the medial geniculate body and other subcortical areas. Our results suggest that IT, PT, and CT neurons may route information from different subsets of presynaptic sources to their respective targets throughout the brain.

Title: C.O.M.E.T: Optimized genetic tracers for viral mediated neuronal projection mapping

Authors: J. N. DULIN[1], E. VAN NIEKERK[1], T. GRIDER[1], M. H. TUSZYNSKI[1,2], *D. GIBBS[1];
[1]UCSD Sch. of Med. - Dept of Neurosciences, UCSD - Dept Of Neurosciences, La Jolla, CA;
[2]Veterans Affairs Med. Ctr., San Diego, CA

Abstract: Existing neuronal tracing techniques have greatly facilitated the detailed study of the anatomy and connectivity of neurons in the nervous system. Mapping of axonal projections using these tracing techniques has allowed investigators to study how neural circuits may change in response to the environment, during development or in disease states. Viral vectors, in particular rAAV-based vectors, provide the ideal vehicle for delivery of genetically encoded neural tracers to specific neuronal populations. Any enhancement in the resolution of existing neuronal tracers will potentially lead to new insights into neuronal anatomy and connectivity in the intact or damaged nervous system. To improve the detection sensitivity and spatial resolution of genetically encoded tracers, we have developed AAV8 vectors expressing Codon Optimized Membrane Embedded Tracers (COMET). Green fluorescent (gCOMET) and red fluorescent (rCOMET) tracers were derived from the highly fluorescent superfolderGFP and tdTomato fluorescent proteins respectively. The sensitivity and spatial resolution of axonal projections traced using AAV8-COMET was quantified in the adult rat spinal cord and optic nerve following vector delivery to either corticospinal motor neurons (CST) or retinal ganglion cells (RGC). AAV8-COMET traced axons were compared to axons traced using either titer-matched AAV8-EGFP or Biotinylated Dextran Amine (BDA). In both the spinal cord and optic nerve, a significant increase in the detection of axons was observed using AAV8-COMET when compared to AAV8-EGFP. AAV8-COMET tracing also resulted in markedly improved spatial sensitivity, with a significant increase in the number and density of labeled fine axonal processes detected. The increased sensitivity and resolution with AAV8-COMET was even more dramatic when compared to BDA tracing in the same animals, highlighting the limitations of this commonly used chemical tracing technique. AAV8-COMET tracing of the CST in rat spinal cord identified novel patterns of CST innervation. In addition, AAV8-COMET tracing of CST in a rat model of axonal regeneration following spinal cord injury (Lu et al, Cell 2012) demonstrated dramatically increased detection of regenerating axons penetrating a neural stem cell graft at the site of injury. These studies demonstrate the utility of using COMET vectors to uncover previously undetectable neuronal anatomy and connectivity patterns in the intact or diseased nervous system.

Title: Reversed topographical projection pattern from medial thalamus to anterior cingulate cortex

Authors: *H.-Y. YEH[1], I.-C. WU[1], J.-C. LEE[1], C.-T. YEN[1,2];
[1]Dept. of Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [2]Neurobio. and Cognitive Sci. Center, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Thalamocortical connections between medial thalamus and cingulate cortex are important for emotional and cognitive functions. Functional imaging studies of the anterior cingulate cortex revealed anterior-posterior subdivisions. It is, therefore, interesting to test whether there is a rostrocaudal differentiation of connection between medial thalamus and anterior cingulate cortex. We tested this hypothesis by injecting the retrograde tracer, FluoroGold (FG), into the cingulate cortex of the rat from 4 mm rostral (A4) to 1 mm caudal to the bregma and analyzed the distribution of the anti-FG immunohistochemically positive thalamic neurons quantitatively. A tendency of reversely connected pattern from medial thalamus to anterior cingulate cortex was observed. Rostral part of the anterior cingulate cortex received heavier projections from the caudal part of the medial thalamus; and conversely, the caudal part of the anterior cingulate cortex received more projections from rostral medial thalamus. These medial thalamic nuclei included mediodorsal nuclei, paraventricular thalamic nuclei, ventromedial nucleus, intralaminar nuclei and the midline nuclei. Cingulate cortex posterior to A1 had lighter projection from medial thalamus, but received most of their thalamocortical projection from the anterior thalamic nuclei. This topographically arranged connection with the medial thalamus may underlie the functional heterogeneity in the anterior cingulate cortex.

Title: 3d imaging of axons in transparent spinal cords from rodents and nonhuman primates

Authors: *D. LEE, C. SODERBLOM, A. DAWOOD, M. CARBALLOSA, A. J. SANTAMARIA, F. D. BENAVIDES, S. JERGOVA, R. M. GRUMBLES, C. K. THOMAS, K. K. PARK, J. D. GUEST, V. P. LEMMON, J. LEE, P. TSOULFAS;
Univ. of Miami Miller School/ Miami Project, Miami, FL

Abstract: The use of anterograde and retrograde dyes as well as genetic labeling techniques has advanced our understanding of the structure-function relationship of the CNS. Most of this of data is collected from two dimensional histological sections, which makes it difficult to accurately study complex anatomical and structural changes that occur during development and disease. Therefore, three dimensional visualization and quantification directly from whole CNS tissue would immensely benefit studies on CNS structure and function. The histological assessment of spinal cord tissue in three dimensions has previously been very time consuming and prone to errors of interpretation. Advances in tissue clearing have significantly improved visualization of axonal origins and targets. While these proof-of-concept studies have been performed with transgenic mice in which axons were pre-labeled with green fluorescent protein (GFP), investigating axonal paths and regeneration often requires stringent axonal tracing methods. Using mouse and rat models of spinal cord injury, we labeled different axon tracts using several types of adeno-associated viruses (AAVs) and chemical-based tracers and performed tetrahydrofuran-based tissue clearing to image multiple axon types in the spinal cord using light sheet and confocal microscopy. Using this approach, we investigated the relationships between axons and scar-forming cells at the injury site as well as connections between sensory axons and motor pools in the spinal cord. In addition, we used these methods to trace axons in nonhuman primates. This reproducible and adaptable virus-based approach can be combined with transgenic mice or with chemical-based tract-tracing methods, providing scientists with flexibility in obtaining axonal trajectory information from transparent tissue.

Title: Labeling of vagal terminals in the area postrema of Nav1.8-Cre-ChR2 mice

Authors: *L. GAUTRON;
Univ. Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Neurons located in the area postrema exclusively receive synaptic input from vagal afferents. In this study, Nav1.8-Cre-ChR2 mice with restricted expression of the Channelrhodopsin 2 (ChR2) in Nav1.8-expressing afferents were used to fluorescently label vagal terminals in the area postrema. In these mice, the membrane of nodose ganglion neurons and their axons terminating in the dorsovagal complex including the area postrema were marked with bright green fluorescence. Using confocal microscopy and immunohistochemistry, we identified ChR2-labeled specialized endings of vagal origin resembling synapse-like contacts. In summary, Nav1.8-Cre-ChR2 mice can be useful for further studies of vagal terminals in the area postrema.

Title: Development of fluorescent small molecules capable of labeling Lewy body pathology in Parkinson's disease tissue

Authors: *T. J. GRAHAM[1], M. BJERKE[2], P. T. KOTZBAUER[3], V. M. -. LEE[2], J. Q. TROJANOWSKI[2], R. H. MACH[1];
[1]Radiology, [2]Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA; [3]Neurol., Washington Univ., St. Louis, MO

Abstract: Background Dementia with Lewy bodies (DLB) and Parkinson's disease with dementia (PDD) are progressive neurodegenerative diseases characterized by intracellular neuronal accumulations in the brain, termed Lewy bodies, composed of a protein called α-synuclein. A large portion of patients afflicted with DLB or PDD also show the pathological hallmarks (Aβ plaques and tau tangles) of Alzheimer's disease (AD) at autopsy. So far, no tracer or fluid biomarker has proven to reliably detect Lewy body pathology *in vivo*. Monitoring of early regional disease progression through *in vivo* visualization of Lewy body pathology through positron emission tomography (PET) imaging would improve the understanding α-synuclein pathological mechanisms and early accurate diagnosis, which will have profound implications on early treatment. **Methods** The affinity of tg-1-25 and similar compounds for aggregated Aβ, tau, α-synuclein fibrils was determined using fluorescence based thioflavin-T displacement assay. Immunohistochemistry (IHC) was performed by incubating the autofluorescent ligand (emission λ ~540 nm) on fresh frozen human PDD and AD tissue. Double labelling (with tg-1-25 and antibodies directed to detect Lewy bodies, Aβ plaques and tangles) was performed to verify ligand binding to specific target pathology. The primary antibodies were coupled to secondary fluorescent antibodies (emission λ 618 nm) and mounting medium containing DAPI (emission λ 460 nm) in order to visualize intracellular and target co-localization of tg-1-25 by fluorescent microscopy. **Results** A high throughput screen identified alkylidene-aurones as binding agents to aggregated α-synuclein fibrils. Subsequent structure modification improved affinity for α-synuclein fibrils (<20 nM; >100 nM for Aβ fibrils) and resulted in the discovery of tg-1-25. It was observed that aurone dienes, such as tg-1-25 exhibited moderate autofluorescence, and could thus be utilized for IHC. Tg-1-25 is capable of staining Lewy body pathology in PDD human tissue, but also stains extracellular Aβ plaques and to some extent intracellular tangles in AD tissue at the concentration needed for IHC. Radiolabeling of tg-1-25 with Fluorine-18 may provide suitable agents for the detection of Lewy Body pathology. **Conclusions** Initial optimization of alkylidene-aurones through structure modification produced tg-1-25, an autofluoresent small molecule that binds α-synuclein and Lewy body pathology in PDD human

tissue. Selectivity over extracellular amyloid plaques and intracellular tangles was not observed, although this may be the result of high ligand concentration required for IHC.

Title: The use of optogenetic vector constructs as a dynamic neuronal tracer

Authors: *D. C. PETERSON, G. MLYNARCZYK;
Biomed Sci., Iowa State Univ., Ames, IA

Abstract: Optogenetic vector constructs provide a novel technique that allows reversible light activation or deactivation of individual brain circuits. Although these techniques are promising, the transport activity of the individual vector constructs has never been documented. Because the analysis of optogenetic experiments could vary dramatically based on whether the vector constructs are transported anterogradely, retrogradely, or trans-synaptically; the transport activity for each vector construct must be documented. The results describe the transport of the AAV5-CaMKIIa-eNpHR 3.0-EYFP vector construct obtained from the stock stored at UNC Vector Core at Chapel Hill, NC. Injection into the amygdala showed both terminal and neuronal labeling in areas known to project to and receive projections from the amygdala, however no trans-synaptic labeling was observed. These results indicate that the vector is transported readily in both anterograde and retrograde directions. Because the full pathway seems to be labeled, it is possible that light may activate the light-sensitive chloride channels at any portion of the pathway. Therefore care must be taken when analyzing the results of light activation so that the results reflect all pathways that could be influenced by the light.

Title: *In vivo* tracing of neurons using dye delivery electrodes

Authors: *S. L. HEIZMANN, A. KILIAS, P. RUTHER, U. EGERT, M. ASPLUND;
Dept. of Microsystems Engin., Univ. Freiburg, Freiburg, Germany

Abstract: Introduction: A stable long term monitoring of neuronal signals is essential for the investigation of disorders like epilepsy and Parkinson's disease. Penetrating microelectrode probes can be inserted in mouse hippocampus and measure local field potentials (LFPs) revealing information about neural network activities in diseased animals. Histological analysis provides additional information about the cell type and status. To correlate LFP recordings with the underlying histology, a precise labelling of neurons *in vivo* is necessary. However there is a lack of suitable techniques. Therefore a new approach was developed to pinpoint the exact electrode positions in neuronal tissue, using a combined PEDOT/dye system. A conductive PEDOT/PSS coating on top of the recording electrodes allows a controlled exchange of positively charged neurotracer dyes. Defined dye release can thus be triggered at the experimental endpoint after weeks of implantation and limited to the neurons present at the electrode site. Methods: A PEDOT/PSS coating was electrochemically grown on top of iridium oxide (IrOx) recording electrodes integrated in single shaft multielectrode probes. Positively charged dye DiI was incorporated into the PEDOT/PSS layer using an ion exchange method. The coated single shaft multielectrode probe was implanted into mouse hippocampus for LFP recordings. Two weeks after implantation the electrodes were triggered to release the dye. Probes were explanted, the tissue sectioned and the neuronal staining confirmed by fluorescence microscopy. Results: The proof of concept measurements with spectrofluorometry *in vitro* show the possibility to exchange the neurotracer dye DiI in a PEDOT/dye coating in well controllable mode. A reduced impedance and stable LFP recordings *in vivo* show the suitability of this approach for recording electrodes. The PEDOT/PSS layer was tested to act as dye reservoir for time periods of weeks. Subsequently the dye can be actively released by electroactivation of the PEDOT/dye system. The released dye locally stained the neurons and allowed a retroactive tracing of electrode positions in hippocampal tissue. Correlation of cell labelling with the probe shaft lesion site was evaluated.

Title: A digital rat brain atlas derived from ultra-high-resolution MRI images scanned in three dimensions

Authors: ***T. J. BROZOSKI**[1], B. ODINTSOV[2], D. T. BROZOSKI[1], K. W. WISNER[1]; [1]Div. Otolaryngology, SIU Sch. of Med., Springfield, IL; [2]Beckman Imaging Ctr., Univ. of Illinois, Urbana Champaign, Urbana, IL

Abstract: Objective. To derive an idiographic high resolution brain atlas from *in situ* MRI images of adult Long Evans rats. Subjects. Two young adult Long Evans (Harlan, Indianapolis, IN, USA) male rats, wt. 506 - 510 g age 135 days, were imaged under identical conditions on successive days. The experimental protocol was approved by the Laboratory Animal Care and Use Committee of Southern Illinois University School of Medicine. Imaging. Magnetic resonance images were acquired on an ultra-high resolution micro-imaging scanner (Oxford Instruments, Abington, UK) equipped with a Unity/Inova console (Varian, Palo Alto, CA), operating at 14.1 T. Image slices were 0.2 mm thick, with a planar resolution of 100 µm, and were acquired using 20 scans per slice. Images were processed using custom-written Matlab codes that reduced contrast variation between slices and improved image quality. A patented tunable transmit/receive radiofrequency (RF) coil was used for image acquisition (Odintsov, 2011). Obtained from each brain were 120 transverse (coronal), 70 saggital, and 48 horizontal slices. Subject preparation. Scans were acquired *in situ* and *ex vivo*. Immediately before imaging the rats were lethally anesthetized (Euthasol, Virbac, Ft. Worth, TX), decapitated, and their dorsal skull exposed. Holes were drilled into the skull at Bregma and Lambda (defined in Paxinos and Watson, 1998) and each was filled with gelfoam saturated with 3 mM CuSo4. These provided empirical image landmarks at Bregma and Lambda. Image reconstruction. TIFF images of each brain slice, produced by MatLab code, were imported into Adobe Photoshop (CS2 v9.0, Adobe Systems) and saved in Photoshop format at 500 pixels/inch. Photoshop was used to enhance image contrast, rotate to a normal orientation, and overlay a 1 mm grid. Image dimensions were unaltered. Descriptive labels were added to each image and surrounding tissue

was digitally removed, except where tissue landmarks were useful. Image brightness and contrast were normalized to a standard. Atlas assembly and viewing. Images, one slice per page, were assembled into a PDF book, of 3 chapters, each devoted to a different slice orientation (transverse, saggital, horizontal). The atlas can be viewed using Adobe Reader. Each image consists of 4 layers (named below) that can be independently turned on or off. “Brain” depicts the brain and its associated labels (Bregma/Lambda coordinates, etc.). “Grid” depicts color-contrasted rectilinear gridlines. “Reference Lines” indexes the dorsal surface of cortex, midline in transverse sections, and Bregma and Lambda in transverse and saggital sections. “Background” enables a black background to be turned on and off.

Title: Development of an SLM-based sheet illumination microscope for large-scale 3-D neural structure and dynamics observation in model organisms

Authors: ***B. A. MADRUGA**[1,2], L. A. BENTOLILA[3,2], K. ARISAKA[1,2];
[1]Physics, UCLA, Los Angeles, CA; [2]Advanced Light Microscopy, California Nano Systems Inst., Los Angeles, CA; [3]Chem., Univ. of California, Los Angeles, CA

Abstract: Sheet Illumination microscopy has made a large impact on the microscopy community due to its many advantages. Increased photon efficiency allows for lower power light sources, which in turn reduce phototoxic damage to the sample, while providing an increased signal to noise ratio. To take advantage of such technique, a type of phase modulator, known as a Spatial Light Modulator (SLM) is used to generate a deep-penetrating, extremely long and narrow bessel beam pattern. Through the use of an SLM, one can easily modulate characteristics of the illuminative beam in real time, to generate multiple versions and combinations of Gaussian beams, sectioned bessel beams, and lattice beams for example- enabling greater flexibility and faster readout speed, while ensuring high resolution across multiple scientific applications. The bessel beam provides a much longer region of micron-order uniformity along the illumination

axis, mapping well onto the rolling-shutter readout of the sCMOS camera, resulting in orders of magnitude improvement in data acquisition speed with line-confocal resolution. A piezoelectric objective collar is used along the detective axis, to enable rapid z-dimensional scanning in depth, thereby creating three-dimensional volumes with adequate time resolution to characterize and observe active neural dynamics in systems of several hundred neurons across multiple species, such as zebrafish and C.Elegans. Long working distance, refractively-corrected detective objectives, specifically designed for the observation of clarified tissue, such as CLARITY-treated neural tissue, along multiple wavelength channels are used for studying neurobiology on a whole mouse brain scale in multiple magnifications. Utilizing several high speed, sub-micron accuracy linear stages, it is possible to take many data sets quickly and continuously, to acquire three dimensional information on the order of 1.5 cm cubed, with sub-micron spatial resolution in a matter of hours. Tools of such flexibility will enable the study of large-scale neuronal activity and structure under controlled or experimental conditions across many model organisms.

Title: Swept confocally aligned planar excitation (scape) microscopy for large-scale brain imaging in adult *Drosophila* melanogaster

Authors: *W. LI[1], V. VOLETI[2], E. S. SCHAFFER[3], C. MENDES[4], N. MISHRA[3], R. S. MANN[4], E. M. C. HILLMAN[2];
[2]Biomed. Engin., [3]Neurosci., [1]Columbia Univ., NEW YORK, NY; [4]Biochem. and Mol. Biophysics, Columbia Univ. Med. Ctr., NEW YORK, NY

Abstract: Understanding complex, distributed neural circuits depends heavily on our ability to observe them in action. Although the size of the adult *Drosophila Melanogaster* brain makes it accessible to light microscopy, standard confocal and two-photon approaches are limited in their ability to achieve sufficiently high volumetric imaging rates over large enough fields of view to capture whole-brain activity. Here, we use Swept Confocally Aligned Planar Excitation (SCAPE) microscopy to image brain activity of adult behaving *Drosophila*. SCAPE is a translationless, single-objective light sheet imaging technology recently developed by our group, which enables single-cell resolution recording at over 10 volumes per second with large fields of view. Compared with conventional dual-objective light sheet configurations, the single objective configuration of SCAPE makes it more suitable for *in vivo* brain imaging in awake, behaving animals. In combination with diverse genetic tools, SCAPE's temporal and spatial capabilities make it an ideal match for studying the complexity of neural processing in the *Drosophila* brain. We have used SCAPE to record multi-region brain activity in response to olfactory stimuli in GCaMP6-labelled, behaving adult fruit flies. We are currently utilizing more specific labeling strategies to permit more complex analysis of olfactory circuits throughout the brain, and establishing the ability to simultaneously track and alter walking behavior. Our latest results will be presented.

Abstract: Mapping neural networks is important in studying cerebral development and disease states of the brain. Recently, the use of fluorescence in combination with various methods of tissue clearing, have revealed entire mouse brain connectivity. However, when using fluorophores, the information gathered is limited to only specific structures tagged in the brain. Here we present a holistic picture of the brain microstructure using label-free imaging. We visualized distributed neuronal circuits in mouse brain slices using Spatial Light Interference Microscopy (SLIM). SLIM is a novel microscopy technique that provides quantitative phase imaging information with nanoscale sensitivity to pathlength and high-transverse resolution. We then reconstructed the three dimensional neural circuit topology through image mosaicking. We demonstrate the successful reconstruction of a group of neuronal networks with subcellular resolution. With SLIM, we are able to image long-range and local connections, and reveal the macro architecture of neural networks as well as single cell cartography. This novel murine connectome visualization technique provides the opportunity for studying neural connections in both healthy and disease brain models.

Abstract: 3D neuron morphology reconstruction at single-neuron resolution at large scale remains a challenging task in neuroscience. Accurate neuron reconstructions are crucial for

morphology quantification and cell type classification. For the Allen Cell Types Database at the Allen Institute for Brain Science, 3D neuron morphologies are reconstructed from the biocytin labeled bright-field large-scale mouse neuron images, which present the following two challenges: 1) Unlike confocal images, bright-field images contain a substantial amount of noise and have high intensity backgrounds; and 2) The size of the image data is typically in the range of 10 to 100 GB, which is too large to process using standard PCs. We present our neuron reconstruction workflow for the Allen Cell Types Database project. First an adaptive image enhancement method was used to improve the signal-to-noise ratio of bright-field images by detecting the salient features of neuron structures with adaptive estimation of the optimal window size. We then deployed an automatic 3D neuron tracing method called NeuronCrawler to efficiently reconstruct large-scale neuron images by iterating a depth-first search strategy over a number of image tiles with continuous neuron structures. Finally, manual curations were carried out on the auto-traced results to finalize the 3D neuron morphologies by applying a family of new human-machine interaction Virtual Finger algorithms. We used the open source software Vaa3D (http://vaa3d.org) for automatic reconstructions and manual annotations, as well as visualizations (Figure 1).

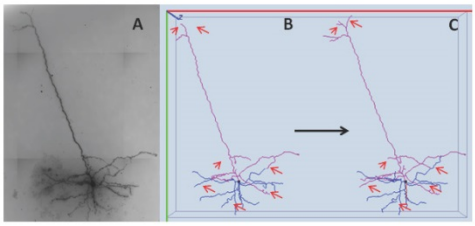

Figure 1. Example image of a single biocytin-filled neuron and its associated uncorrected and corrected autotrace. A. Minimum intensity projection image of a biocytin-filled neuron. B. 3D automated reconstruction. C. Final reconstruction following manual correction. (Dark pink = Apical dendrite, blue = dendrite) It took approximately 3.5 hours to manually correct the automated reconstruction.

Abstract: The zebrafish is a premier model in neuroscience research. As vertebrates they share significant physiological and genetic homology with humans. They possess the vertebrate brain archetype as well as all major neurotransmitters, hormones and receptors. While the larval zebrafish has been traditionally used, more recently experiments with adult zebrafish are becoming widespread due their well-developed sensory, motor, and endocrine systems, and diverse behaviour. This has been demonstrated by the use of adult zebrafish as an important model for a range of neurological diseases such as epilepsy, Parkinson's disease, autism, post-traumatic stress disorder, and addiction. Despite the increased use of the model, few detailed maps of the adult zebrafish brain exist. Therefore we have developed a detailed multi-modal atlas of the zebrafish brain. The atlas is made up of 1) a minimum deformation model generated from 23 high-resolution magnetic resonance imaging data sets (AB strain); 2) five super-resolution short-track density imaging data sets; and 3) six brains cleared and labelled for myelin, dopamine, serotonin, acetylcholine, γ-Aminobutyric acid, and parvalbumin. This data has been nonlinearly registered into a single template space and segmented into just under 150 structures. We have also created minimum deformation models for the Absolute, Tübingen and Tübingen long fin strains and performed voxel-based morphometry to compare differences in brain structure. The complete data set will be a freely available reference atlas and resource for automatic segmentation of novel zebrafish mutants.

Title: Expansion microscopy of lipids for scalable morphological analysis of neurons and neural circuits

Authors: *E. D. KARAGIANNIS, A. H. MARBLESTONE, E. S. BOYDEN;
MIT, Cambridge, MA

Abstract: Although electron microscopy provides a platform to image and reconstruct neuronal morphology with nanoscale resolution, it is slow, expensive, does not easily facilitate multicolor labeling, and is not readily accessible to most neuroscientists. Recently, our lab has introduced a new modality of imaging, which uses physical sample magnification, Expansion Microscopy (ExM; Science 347(6221):543-548), which allows imaging of large 3D specimens with nanoscale resolution because fast diffraction-limited optical microscopes can be used. The physical magnification of the sample results from synthesizing a polyelectrolyte gel network directly within the specimen, which is then physically expanded to achieve a ~50nm resolution using a common confocal microscope. Applying ExM to the imaging of neuronal membrane morphology requires the development of a lipid-binding tag which can be anchored to the ExM hydrogel. We have now designed and implemented ExM-compatible lipid-binding labels that can selectively bind the plasma membranes of neurons and other cells. These labels are water soluble, and have small molecular weights (<2kDa), which facilitates the fast 3D diffusion of the labels within tissue, and thus allowing staining of large tissue volumes. The tags contain chemical groups that facilitate the chemoselective conjugation of multiple types of fluorescent labels, important for multicolor and amplified labeling. These chemical approaches will allow ExM-based analysis of neural ultrastructure in diverse neural circuits, including that of the human brain.

Title: Sparse reconstruction light-field microscopy for high-resolution 3d-imaging of neuronal activity

Authors: *Y.-G. YOON[1], N. PAK[2], L. FREIFELD[3], M. A. HENNINGER[4], J. DEGUCHI[3], N. SAVIDIS[3], E. S. BOYDEN[5];
[1]Dept. of Electrical Engin. and Computer Sci., [2]Dept. of Mechanical Engin., [3]Media Lab., [4]Dept. of Physics, [5]Media Lab. and McGovern Institute, Departments of Biol. Engin. and Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: We recently developed an approach using light-field microscopy (LFM) to image the entire *C. elegans* nervous system and the entire zebrafish brain in 3D, at high speeds (e.g., ~20 Hz), possible since no moving parts are required for light-field microscopes to acquire 3-D images (Prevedel et al., 2014). However, the spatial resolution was limited, and the activity of only a subset of the neurons could be extracted as it relied on a computational method based on independent component analysis (ICA) to extract the activity of neurons during post-processing. For ground-truth studies of the nervous system, ideally it would be possible to pick up the activity of all neurons, even those that are quiet during the recording (whereas ICA tends to select for highly active neurons). And, ideally, it would be possible to assign neural activity to defined sites in the circuit, in order to link anatomical and dynamical descriptions of neural circuits. We have developed a novel sparse reconstruction lightfield microscopy (SRLFM) strategy that can, in simulation, accurately reconstruct neural activity throughout the entire brain of the larval zebrafish, expressing a GCaMP variant, with single cell resolution, at up to 100 Hz. No post-processing (e.g., via ICA) is needed with SRLFM, meaning that even quiet neurons can

be detected, and also neural activity can be accurately assigned to specific neurons in the neural network, important for linking neural circuit dynamics to the underlying network architecture. The effective resolution of light-field microscopy is improved by >2-fold with our new algorithm. We are currently implementing this algorithm on an optimized light-field microscope, aiming to assess the technology in the context of living brain dynamics. (Yoon, Pak and Freifeld are co-first authors.)

Title: Nanoscale resolution, multiplexed, biomolecular imaging of brain circuits via expansion microscopy

Authors: *F. CHEN, A. T. WASSIE, S. ALON, E. S. BOYDEN;
MIT, Cambridge, MA

Abstract: Nanoscale-resolution imaging of RNA transcripts and proteins throughout brain circuits in a multiplexed fashion would enable the molecular characterization of cell types, synapses, and signaling pathways, in normal as well as pathological brain states. Although many multiplexing strategies, primarily using serial application of affinity tags and/or biomolecule-

encoding nucleic acid barcodes, have been demonstrated in cell culture and in thin tissue sections, it remains difficult to use such technologies in large 3-D tissues such as brain circuits - especially if nanoscale resolution imaging is desired. Recently we developed an approach to physically magnify tissues, which we call expansion microscopy (ExM, Science 347:543-548). Expansion microscopy not only isotropically (e.g., with ~60 nm resolution) magnifies tissues, enabling super-resolution imaging on fast diffraction-limited microscopes, but also surrounds anchored biomolecules with a homogeneous aqueous environment appropriate for fast serial multiplexed tag exchanges. Here we present a suite of tools utilizing this principle, based on serial in-situ hybridization, that enable the facile, multiplexed, and super-resolved imaging of transcripts and proteins in thick (> 100 microns) brain tissue sections. We anchor both native RNA as well as antibody-targeted DNA barcodes to the ExM polymer, then perform rapid serial *in situ* hybridization using probes against these nucleic acid sequences to read out the identity and location of both native RNAs as well as DNA barcodes targeted via antibodies. Using these strategies, we demonstrate nanoscale imaging of several transcripts and proteins in brain tissue specimens. We anticipate that these methods can be used for transcriptomic and proteomic profiling of neuronal cell-types in-situ, as well as for the super-resolved characterization of neuronal connectivity and synaptic organization in intact brain circuits, key for an integrative understanding of the mechanisms underlying neural circuit function and dysfunction.

Title: Expansion microscopy in zebrafish

Authors: *L. FREIFELD[1], O. RANDLETT[2], I. ODSTRCIL[2], D. MARTIN-ALARCON[1], J. GAGNON[2], A. SCHIER[2], F. ENGERT[2], E. BOYDEN[1];
[1]Media Arts and Sci., MIT, Cambridge, MA; [2]Harvard Univ., Cambridge, MA

Abstract: We recently discovered that it was possible to physically magnify samples by embedding them in a dense swellable polymer, performing a series of chemical treatments, and then swelling the polymer (and thus the sample), a process we call expansion microscopy (ExM; Science 347(6221):543-548). Thus, one can image large 3-D samples, e.g. entire brain circuits, with nanoscale precision using ordinary diffraction-limited microscopes. Expansion microscopy enables imaging of fine details of neural projections and synaptic protein distributions, while preserving the contextual information of entire cell and circuit structures. We here report on the application of expansion microscopy to the study of the larval zebrafish, a key organism in neuroscience. The larval zebrafish is a transparent vertebrate whose brain spans only ~500μm X 500μm X 1000μm in volume. We expand entire brains of 5-7 dpf larval zebrafish and examine the detailed structure of different neural populations at multiple spatial resolutions throughout the entire brain. We follow neural projections across brain regions and describe their fine inter-region distributions and synaptic contacts at a resolution exceeding the diffraction limit, across volumes that span the entire central nervous system. As this vertebrate model lends itself to whole-brain functional imaging (Ahrens et al., 2012, Ahrens et al., 2013, Prevedel et al., 2014), applying expansion microscopy to larval zebrafish may enable rapid analysis of connectivity information. This, in the context of interpreting neural activity, may facilitate better mechanistic understanding of neural information processing in complete neural circuits. We also demonstrate expansion microscopy of zebrafish embryos, enabling high-resolution imaging of different developmental stages. (Freifeld, Randlett, Odstrcil, Martin-Alarcon and Gagnon have equally contributed to this work)

Title: Spatial multiplexing for simultaneous imaging of multiple signaling pathways in a living cell

Authors: *G. XU, K. PIATKEVICH, K. ADAMALA, E. BOYDEN;
MIT Media Lab., Cambridge, MA

Abstract: Monitoring multiple signals at once in a living cell is challenging because the emission spectra of fluorescent biological reporters are limited to a few colors, e.g. green or red. By spatially multiplexing multiple reporters, however, we could in principle scale up the number of distinct signals simultaneously being monitored in a single cell to very large numbers, because the identity of each signaling pathway being reported upon would be encoded by the spatial position of the corresponding reporter within the cell - even if the fluorescent reporters themselves emit the same color of light. Here we design such a spatial multiplexing system, which targets fluorescent reporters that optically indicate different cell signaling pathways, to different sites in the cell. This system potentially offers the capacity for 10-20 multiplexed signals to be imaged simultaneously in mammalian cells, using reporters even of a single emission color, allowing high-content live cell imaging with commonly used epi-fluorescent microscopes. We are currently exploring targeting both ionic sensors (e.g. Ca2+, Cl- sensors) as well as kinase sensors (e.g. PKA sensors) to defined sites within neurons, with the goal of opening up the ability to survey a wide variety of signaling pathways involved with neural plasticity simultaneously within a single living neuron. We are testing the method in both primary hippocampal mouse neurons as well as human HEK293 cells, with an aim towards eventual *in vivo* use. By bringing spatial multiplexing into live cell biology, we will open up the ability to image many signals at once in living cells and organisms, providing key insights into how multiple signaling cascades work together to implement living functions.

Title: Next-generation expansion microscopy: 20-nm resolution imaging via physical specimen magnification

Authors: *J.-B. CHANG[1], F. CHEN[1], E. JUNG[1], H. BABCOCK[2], X. ZHUANG[2], E. BOYDEN[1];
[1]MIT, Cambridge, MA; [2]Harvard, Cambridge, MA

Abstract: The identification and localization of proteins and other biomolecules, throughout entire brain circuits, with nanoscale precision would enable many fundamental insights into the mechanisms underlying the operation of normal and pathological neural networks. We recently discovered that we could physically magnify specimens by embedding them in a dense swellable polymer, anchoring key biomolecules to the polymer mesh, and adding water to swell the polymer, a process we call 'expansion microscopy' (ExM; Science 347(6221):543-548). Despite the high isotropy of the expansion process, the initial polymer recipe enabled just 4-4.5x expansion, or roughly 60-70 nm spatial resolution. Ideally it would be possible to improve the expansion chemistry so as to enable, ultimately, the imaging of membrane boundaries, as well as protein complexes. Here, we report on a next-generation ExM chemistry that can achieve ~15-20x physical magnification of mouse brain tissues, or 20-nm lateral resolution on conventional optical microscopes. As with the first version of ExM, next-generation ExM-processed samples are optically clear. Thus, next-generation ExM may be useful for imaging nanoscale neuronal structures such as synaptic clefts or synaptic vesicles over entire neural circuits in intact mammalian tissues. Brain circuit mapping using next-generation ExM may open up a variety of insights into the underpinnings of behavior, cognition, and disease. We continue to refine the chemistry and to explore how affinity tags can be adapted to work in this new expanded environment.

Title: Expansion Sequencing (ExSEQ): comprehensive *in situ* transcriptome characterization throughout intact brain circuits

Authors: *S. ALON[1], F. CHEN[1], E. R. DAUGHARTHY[2], P. W. TILLBERG[1], A. H. MARBLESTONE[1], A. T. WASSIE[1], G. M. CHURCH[2], E. S. BOYDEN[1];
[1]Media Lab., MIT, Cambridge, MA; [2]Wyss Inst., Harvard Med. Sch., Boston, MA

Abstract: Enabling the mapping of the cell types of the brain, as well as the systematic analysis of cell types in complex behavioral and disease states, would benefit greatly from a technology for the comprehensive analysis of gene expression patterns in neurons throughout a neural circuit. Ideally we could perform this analysis in intact brain circuits, so that these transcriptional profiles could be combined with morphological and circuit topology information, resulting in unified pictures of the cell types and cell states of the brain. Current tools do not permit this: optical methods maintain the spatial location of molecules, but the number of molecules that can be studied simultaneously is limited. On the other hand transcriptomic approaches allow the multiplexed measurement of potentially all the RNA molecules, but spatial information is lost in the process. Here we devise a new method for *in situ* sequencing of nucleic acids throughout all the neurons of an intact brain circuit, by creating new forms of expansion microscopy (ExM), a technology we previously developed that physically magnifies brain tissues while preserving nanoscale isotropy (Science 347:543-548), as well as fluorescent *in situ* sequencing (FISSEQ; Science 343:1360-1363). Using this new technology, which we call expansion sequencing (ExSEQ), users can expand brain circuits, then sequence the RNAs within the expanded tissue, resolving transcripts throughout entire neurons and neural circuits, enabling systematic cell type and cell state classification in health and disease.

Abstract: Expansion microscopy (ExM) is a recently developed technology that physically magnifies tissues isotropically by ~4-4.5x, and thus enables nanoscale super-resolution imaging of large 3-D specimens using conventional, high-speed, diffraction limited microscopes (Science 347(6221):543-548). The simple tissue preparation procedure of ExM, i.e. embedding intact tissues in networks of swellable polymers, in conjunction with conventional histological tissue handling procedures (e.g., antibody labeling) can be easily applied to various tissue types. Applied to human brain samples, ExM could potentially enable new forms of circuit-level

disease classification, diagnosis, and therapeutic target identification. Here, we use ExM to perform super-resolution imaging of non-human primate as well as human brain tissues. We demonstrate the ability to image multiple proteins in intact neural circuits from multiple brain regions, in normal and pathological brains, using conventional antibodies and fluorophores. The ability to perform super-resolution imaging of human and non-human primate brain tissues will dramatically advance our ability to understand human disease mechanisms, expand post-mortem confirmation and differential diagnosis, and enhance the identification of pathways implicated in the development of novel therapies for many brain disorders.

Title: Protein retention expansion microscopy

Authors: ***P. W. TILLBERG**[1], F. CHEN[2], J. YU[2], K. PIATKEVICH[3], E. BOYDEN[3]; [2]Bioengineering, [3]Media Lab., [1]MIT, Cambridge, MA

Abstract: Expansion microscopy (ExM) is a method we recently developed for physically magnifying biological samples, which enables 3-D super-resolution imaging of tissue specimens

over large volumes relevant to neural circuits (Science 347(6221):543-548). One limitation of our first implementation of expansion microscopy is that antibodies must be delivered pre-expansion, followed by gelation and strong proteolytic digestion; only the fluorophores, which are anchored directly to the gel, are physically moved apart. If, in contrast, native proteins could instead be directly anchored to the swellable gel, and the antibodies delivered post-expansion, this could enable more comprehensive staining, and more detailed interrogation of biological macromolecules in intact tissues. In addition, the resolution of the expansion microscopy process may be improved, since the size of the antibodies, which normally adds noise to the localization of the biomolecule being tagged, would effectively be divided by the expansion factor. We here report a variant of ExM in which we anchor native proteins to the expandable polymer, followed by a novel treatment strategy that enables uniform expansion. We find, using this protein retention ExM technique (proExM), that native proteins are retained in the expanded specimen, and can be stained with antibodies post-expansion. We demonstrate that, in accord with expectations, staining speed, depth of penetration, and brightness are enhanced relative to the original ExM protocol and standard immunofluorescence protocols.

Abstract: The ability to monitor and perturb RNA in living neurons--which would open up the investigation of many processes that contribute to development, plasticity, and disease progression--would benefit greatly from a method of systematically targeting unmodified RNA sequences for observation and control. We report that the RNA-binding protein PumHD (Pumilio homology domain), which has been widely used in native and modified form for targeting RNA, can be engineered to yield a set of four canonical protein modules, each of which binds to one RNA base with high specificity and fidelity. We call these modules Pumby (Pumilio-based assembly) modules. Pumby modules can be concatenated in chains of varying composition and length, to bind desired target RNAs with the same behavior as PumHD but capable of binding to longer targets. We demonstrate, using Pumby chains as well as PumHD variants, RNA-directed protein assembly, quantification of RNA translation in living cells, and enhancement of translation of RNAs, without the need for appending artificial sequences to the target RNAs. These modules may prove useful for many applications in the imaging, manipulation, and biotechnological utilization of endogenous RNA targets in intact neurons and neural circuits.

Abstract: The extraordinary complexity and variability of the human brain sets very high requirements for experimental methods suitable to meaningful exploration. Even when focusing on one specific neuron type within a specific brain region, variation within populations can obscure the relationship between function and underlying structure. To address such problems, we have developed a novel correlative electrophysiology-array tomography (ATomo) method to investigate the anatomical and molecular structure of individual electrophysiologically characterized neurons and their synaptic connections. Live tissue is obtained from surgical resections and prepared for patch electrophysiology. While performing whole cell intracellular recordings of individual neurons or neuronal pairs, cells are filled with Lucifer Yellow, biocytin or other fixable dyes, chemically fixed, and embedded in resin for ATomo analysis. Presence of the dye allows the subsequent localization of the physiologically characterized cells, as well as the reconstruction of their axonal and dendritic arbors. Individual input and output synapses of the filled neurons are identified and characterized by distribution, targets and molecular composition. Because ATomo enables the super-resolution imaging of dozens of different antibodies and other fluorescent markers within the same sample, filled neurons are further characterized by cytoskeletal content and presence of molecular markers such as calcium-binding proteins, while their synapses are probed for a variety of receptors and signaling molecules. Several examples will be presented, including synaptomes of inhibitory neurogliaform and chandelier cells, and excitatory pyramidal neurons. This powerful combination of electrophysiology and ATomo allows a detailed investigation of human cortical neurons by associating functional measurements with thorough descriptions of axonal and dendritic arbor morphologies and synapse distributions, sizes and molecular contents.

Title: An integrated imaging and staining platform for cubic millimeter scale array tomography

Authors: *F. C. COLLMAN, S. DAVIS, O. GLIKO, T. M. KEENAN, K. PARKER, L. E. OSTROFF, S. J. SMITH;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Array tomography (ATomo) involves reconstruction of images acquired from arrays of serial ultrathin sections, which can be imaged by fluorescence microscopy (FM-ATomo) for proteometric analysis, or by scanning electron microscopy (EM-ATomo) for higher resolution. Axial resolution is defined by the thickness of physical sections (50-200 nm); the lateral resolution of FM imaging is optimal given the direct adhesion of sections to an optical coverslip. However, the throughput of data acquisition is slowed by the image acquisition time, and the need for human intervention to stain and set up samples on the microscope. The first ATomo systems acquired data at a throughput of ~18 seconds per 4 channel image (Micheva 2007). Recent work incorporated a hardware-based autofocus technology that improved throughput to 5-12 sec per 4 channel image (Rah 2013), achieving 0.1 mm^3 in 878 imaging hours with 200 nm-thick sections. Data acquisition throughput is further impaired by the overhead involved in staining and setting the sample up for imaging. As part of the Open Synaptome Project (http://opensynapto.me) effort to improve all aspects of ATomo based synaptic analysis, we are developing a next-generation system to achieve imaging throughput on the order of 0.2 mm^3 per day per microscope. We will describe the design of the imaging system, which include hardware-based autofocus, large format sCMOS sensors, motionless high intensity wide-field laser illumination, and a custom open-source software solution. We will also describe our efforts to construct a robofluidic staining solution fully integrated with the microscope. Our goal is to enable continual staining and imaging without human intervention, thus increasing both throughput and consistency of results. Title: Scalable, automated synapse detection using the open connectome project

Authors: *W. R. GRAY RONCAL[1,4], A. K. SIMHAL[5], J. T. VOGELSTEIN[2,3], F. COLLMAN[6], M. A. CHEVILLET[4], R. BURNS[1], G. SAPIRO[5], G. D. HAGER[1]; [2]Biomed. Engin., [3]Inst. for Computat. Med., [1]Johns Hopkins Univ., Baltimore, MD; [4]JHU Applied Physics Lab., Laurel, MD; [5]Duke Univ., Durham, NC; [6]Allen Inst. for Brain Sci., Seattle, WA

Abstract: New neuroimaging datasets are large (10GB-100TB), and volumes may soon exceed a petabyte for some modalities. Object detection is a canonical problem in computer vision, so a rich library of techniques is available to aid in neuroscience inference tasks. However, Big Vision requires a paradigm shift to overcome challenges such as data storage, computation and multiscale semantic understanding. We have developed open-source tools for scalable object detection (http://w.ocp.me/tools:object_detect), leveraging the Open Connectome Project (OCP, http://openconnecto.me) infrastructure and the Laboratory of Neuroimaging Pipeline processing framework. This allows users to quickly adapt their algorithms in a flexible, reproducible environment. As a case study, we demonstrate our pipeline by generating and deploying a lightweight, scalable synapse detector to find approximately 50,000 putative synapses in 60,000 μm^3 of electron microscopy data. This framework is extensible to other challenges and modalities. For example, Immunofluorencence Array Tomography (ATomo) can provide high-dimensional proteometric characterization of large populations of synapses, supplementing the information available with EM imaging. ATomo is a high-throughput approach, requiring scalable infrastructure. To ensure maintainability, reproducibility, and comprehensive testing across datasets and techniques, we used the OCP framework to create a common infrastructure to support ATomo based synapse detection. Manual and computer detected synapses are uploaded to OCP and interactively viewable via 2D Web-services. We are scaling up the synapse detection work for IF synapses, leveraging the framework used to detect synapses in EM data as part of the Open Synaptome Project (http://opensynapto.me).

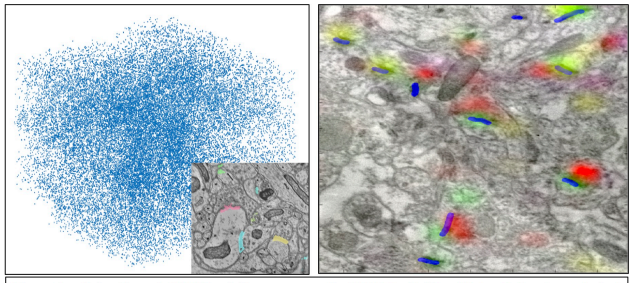

Figure 1: Detection of 50,000 putative synapses in EM Data (left), with inset showing selected individual detections. Array Tomography IF Data (right); shows an EM slice (in grayscale) with IF channels overlaid: PSD-95 (green), synapsin (red), VGluT1 (pink), NR1 (yellow). The EM identified synaptic clefts (manual ground truth) are highlighted in blue.

Title: Quantifying mesoscale neuroanatomy with X-ray microtomography

Authors: *E. L. DYER[1,2], H. L. FERNANDES[1,2], X. XIAO[3], W. GRAY RONCAL[4], J. T. VOGELSTEIN[5], C. JACOBSEN[6,3], K. P. KORDING[1,2], N. KASTHURI[7];
[1]Dept. of Physical Med. and Rehabil., Rehabil. Inst. of Chicago, Chicago, IL; [2]Northwestern Univ. Med. Sch., Chicago, IL; [3]Argonne Natl. Lab., Lemont, IL; [4]Applied Physics Lab. of Johns Hopkins Univ., Baltimore, MD; [5]Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD; [6]Physics and Astronomy, Northwestern Univ., Evanston, IL; [7]Boston Univ., Boston, MA

Abstract: The structure of the brain is constantly being modified due to experience, learning, aging, and in some cases, disease. Understanding the impact of such modifications on brain architecture, at various spatial scales, will have wide reaching impacts. Unfortunately, existing methods for quantifying the neuroanatomical structure of the brain, such as light and electron microscopy (EM), cannot be readily applied to large brain volumes. For this reason, there exists

an information gap at the mesoscale: we require new techniques to produce brain maps that characterize the cell shapes, densities, and positions and their long-range projections across large spatial extents. Synchotron-based X-ray microtomography (XRM) is uniquely poised to fill this gap. Compared to electrons or visible light photons, X-rays undergo very little multiple scattering so that thick objects can be studied at sub-micrometer resolution. Unfortunately, XRM has not been completely adapted to meet the demands of large-scale brain imaging. Here, we provide a host of new methods and an end-to-end pipeline for quantifying neuroanatomy from large brain volumes with XRM. Our pipeline consists of methods for: (i) sample preparation, (ii) image reconstruction from raw XRM measurements, and (iii) automated segmentation, cell detection, and spatial statistics. We integrated our data and analysis tools into the Open Connectome Project infrastructure (OCP, http://www.openconnecto.me), an open-access framework for large-scale analysis of neuroimaging datasets. We show that XRM of samples prepared for electron microscopy (i.e. aldehyde fixed, osmicated, and embedded in plastic) produces images stack with sufficient resolution (~1 micron isotropic) to identify all cell bodies, their sizes, locations and in some cases partial reconstructions of their dendritic processes. The trajectory of all the vasculature and many of the myelinated axons can also be reconstructed. Our results suggest that XRM promises a new avenue for neuroscientists to study the mesoscale architecture of large brain volumes.

Title: Automated GPU-accelerated segmentation of volumetric fiber networks

Authors: *P. A. GOVYADINOV, D. MAYERICH;
Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: High-throughput microscopy techniques such as Knife-Edge Scanning Microscopy, allow three-dimensional imaging of whole organ tissue samples at sub-cellular spatial resolution. Filaments are common structures in biomedical tissue samples, however they are extremely

difficult to image and reconstruct using standard techniques. With the gaining popularity of new techniques that can image entire tissue samples at cellular levels, segmentation methods focused on large data sets are becoming extremely important. The most common examples filament networks in tissue samples are neuronal networks and microvasculature. These examples are composed of cellular structures that form complex interconnected networks of thin fibers. Since these structures are often less than a few micrometers in diameter, high-resolution imaging is required, despite the fact that the networks embedded can comprise < 6% of the entire volume. However, existing segmentation algorithms are ill-equipped to deal with data sets that often exceed several terabytes. We present a fast, hardware accelerated predictor corrector algorithm for segmenting networks embedded in large volumetric datasets. Segmentation is performed with a filament tracking algorithm using a predictor-corrector approach. Beginning from an initial seed point, the current fiber trajectory is estimated using template matching. In order to provide fast segmentation, we take advantage of GPU texture memory for spatially cached sampling and limit out analysis to data close to the embedded network, representing a small fraction (2-6%) of the total data set. By using graphic acceleration hardware we eliminate the need for supercomputing, while increasing usability for biomedical professionals.

[1]Univ. of Houston, Houston, TX; [2]Texas A&M Univ., College Station, TX

Abstract: Knife-Edge Scanning Microscopy (KESM) allows researchers to quickly collect terabytes of three-dimensional tissue data. This provides the potential for extracting detailed information about cell positions and connectivity across large (cubic centimeter) volumes of tissue. However, the size and complexity of these volumetric data sets makes segmentation difficult. The size of the acquired KESM data makes any form of manual intervention in the segmentation impractical. Therefore, fully automated techniques are required in order to

realistically process these data sets. Maintaining high accuracy with minimal user input is a well understood problem in segmentation. In this presentation, we will describe a fully automated method for finding the position of cell soma in KESM images stained en bloc using thionin. An iterative voting technique is used to generate a binary segmentation of the volumetric data, which is then refined to determine the location of cell soma. This technique requires minimal user input and no user feedback, making it amenable to fully automated processing of terabyte-scale data sets. We demonstrate the effectiveness of this algorithm on volumetric images of the rat somatosensory cortex obtained using KESM by comparing to a manually segmented ground truth. In addition, the proposed algorithm can be readily parallelized in order to provide efficient evaluation using heterogeneous (GPU-based) hardware commonly available in commercial computer systems.

Title: Automatic reconstruction of neurons and vessels in CLARITY-cleared specimens

Authors: ***S. TAPPAN**[1], D. M. KROLEWSKI[2], B. MARTIN[2], M. A. A. KARIM[1], D. HOPPES[1], N. ROUSSEL[1], P. J. ANGSTMAN[1], S. J. WATSON, Jr.[2], J. R. GLASER[1]; [1]R&D, MBF Biosci. - MicroBrightField Inc., Williston, VT; [2]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: CLARITY and other related tissue clearing agents have opened the possibility for unprecedented studies of neuroanatomy and cytoarchitecture by removing the necessity of tissue sectioning. As imaging methodologies evolve for these intact specimens it is also evident that specialized quantitative tools are needed. CLARITY-cleared specimens are often multi-millimeter thick, which require sophisticated and expensive microscopy equipment (e.g., COLM microscopy and super long working distance objective lenses) and long duration acquisition

times. The resulting image data can be very large (>0.5 TB). Further, the focus resolution limitations due to the objectives generally result in voxel dimensions that are challenging for automated reconstruction. As such, quantitative software that can analyze CLARITY image data faces special challenges. To balance the exceptionally long imaging times, quantitative data extraction must be fast and robust. In the current study, we demonstrate the utility of CLARITY image data and the functionality of specialized quantitative software. Decades of research indicate a critical role of the microvasculature in the plasticity of the brain under various physiological and pathological conditions, including fundamental processes during brain development, learning, recovery from traumatic brain injury and brain inflammation, aging and neurodegeneration. Tissue cleared with CLARITY offers the opportunity to investigate these processes in detail. We used Neurolucida 360 to visualize and quantify neuronal structures in large image volumes. In addition, preliminary data from new prototype software, Vesselucida, for reconstruction of microvasculature is presented. These novel automated methods are computationally efficient and therefore greatly reduce the time needed for analysis. Image management is a central concern, because there is a simultaneous need to have the ability to interact with the entire image volume and a small subset that represents the current region of interest. Neurolucida 360 and Vesselucida address this need by using an interactive 3D visualization environment that enables multi-resolution image handling. Real-time volume rendering of large amounts of data using non-specialized computer hardware is then used to elucidate spatial orientation. Automated methods for reconstructing neuronal features across multiple fields of view further streamline the data acquisition. This new development now makes it possible to perform automated quantitative analyses at the maximal resolution of the image volume while having the morphological and organizational context of the intact tissue specimen.

Title: Automatic stereology of substantia nigra using a novel segmentation framework based on the balloon active contour model

Authors: *P. R. MOUTON[1], P. A. PHOULADY[2], L. O. HALL[2], D. GOLDGOF[2];
[1]Pathology & Cell Biol., Univ. of South Florida Col. of Med., Tampa, FL; [2]Engin. & Computer Sci., Univ. of South Florida, Tampa, FL

Abstract: The use of manual (non-automated) computer-assisted approaches to collect stereology data from stained neural structures can be tedious, time-consuming and subject to bias from user fatigue. Feature-based segmentation algorithms holds great promise for quantifying stereology parameters with higher throughput efficiency without a loss of accuracy. The present study proposes a novel segmentation framework using an Active Contour Model (balloon snakes) to automate area and volume quantification by the point-counting method. Balloon snakes are energy minimizing splines that conform to the boundaries of arbitrary shaped objects. Energy is derived from external forces driven from the image and internal forces such as elasticity and stiffness of the snake. This approach is demonstrated for three month-old Fisher 344 rats with experimental Parkinsonism (n = 2) and vehicle control (n = 4). Brains were perfused in-vivo with aldehydes and frozen sections cut at 30 um thickness. From each rat brain 12 sections were sampled in a systematic-random manner through the entire substantia nigra pars compacta (SN) and immunostained for tyrosine hydroxylase (TH)-positive neurons. Ground truth data from manual stereology was collected using a computerized stereology system (Stereologer, SRC, Tampa, FL). For the automatic framework, the system's motorized xyz stage automatically collected between 500 and 1000 images through the entire SN at high magnification (100x oil). The novel framework was applied to segment TH-positive neuronal cell bodies using a balloon active contour model with non-constant balloon force. After 200 iterations, several contours were initialized within the images and classified as TH-positive cell bodies (signal) or background. Cell contours were automatically selected based on predefined inclusion/exclusion criteria (e.g., area of contour, dispersion measures, degree of overlap) and the total area and volume of TH-positive neurons automatically calculated by the system software. There was a strong correlation (R2 >/=0.95) for total area and volume of TH-positive neurons by the automatic framework as compared with ground truth by manual stereology, with a ten-fold increase in efficiency as quantified by reduced time for the automatic framework to achieve the same level of precision as manual stereology. In light of the enhanced efficiency and

comparable accuracy with the automatic balloon active contour framework, these findings strongly support continued development of pattern recognition algorithms for automatic stereology of neural structures.

Title: nTracer: An ImageJ software package for neural circuit reconstruction and analysis from multi-spectral 3D images

Authors: *D. H. ROOSSIEN, JR[1], A. S. DIZAJI[1], R. HUTH[1], J. STECHER[1], J. WEBB[2], L. BOGART[3], T. HENSCH[3], E. D. HERZOG[2], D. CAI[1];

Abstract: The biological principle that structure determines function is perhaps most evident in the brain. As such, the ability to reconstruct neuronal networks is a central goal in modern neuroscience, be it of local circuits or an entire connectome. A notable challenge is to extract intuitive and quantifiable information from the wealth of images that record the microscopic structures of neural circuits. Several software platforms have been developed that enable the reconstruction of cell morphologies in “Cartesian” descriptions. However, these have been limited to single cells in sparsely labeled samples to avoid ambiguities between neurites in close proximity, thereby prohibiting analysis of connectivity. Recent advances in multicolor genetic labeling strategies, such as Brainbow, offer advantages over traditional single color/tracer approaches by being able to identify multiple cells in a sample based on unique colors with

limited redundancy. Hence we developed nTracer, a user-guided ImageJ plugin with the ability to trace multiple neurons in a densely labeled brain tissue based on color profile. Being able to mark synaptic locations and establishing connections between neurons, nTracer allows the user to analyze circuit connectivity. The software includes a user-friendly output interface, which can reconstruct a customizable 3D rendering of a traced circuit based on morphology, cell type, connectivity, or any other custom parameter(s) and can export tracing results of single neurons in SWC format for use with currently available morphometric tools. To demonstrate the software's versatility, we traced a variety of densely-labeled neurons throughout the brain. Specifically, we traced granule cells in the dentate gyrus and hypothalamus, vasoactive intestinal peptide (VIP)-expressing inhibitory neurons in the suprachiasmatic nucleus, basket cells and pyramidal cells in the CA1 region of the hippocampus, or cholinergic excitatory neurons in the striatum. The unambiguously traced profiles allowed us to perform morphology-based neuronal subtype classification. Furthermore, we were able to provide direct measurement for how basket cells assemble into CA1 circuits in terms of total number of cells making synaptic connections onto excitatory pyramidal cells and other basket cells. nTracer is thus the first software package with the ability to answer questions requiring reconstruction and analysis of single neurons to complex circuits. Moreover, nTracer results provide a ground truth for validating automated 3D neuronal tracing algorithms applicable to densely labeled tissue, the development of which remains a major long-term goal for the field.

Title: NeuroMorpho.Org: connecting neuronal morphology with digital neuroscience

Authors: *R. ARMANANZAS, R. PAREKH, S. POLAVARAM, S. NANDA, G. A. ASCOLI; Krasnow Inst. For Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Distributed multidisciplinary collaborations produced many success stories in 21st century science. Leveraging the Internet model of hyperlinked information, molecular biology rapidly expanded in the early 2000s from isolated wet labs to online repositories of shared digital data. Neuroscience is now similarly evolving into a networked ecosystem, integrating and augmenting individual research projects with big data initiatives. NeuroMorpho.Org is to date the largest freely accessible online repository of digital reconstructions of neuronal morphology. Version 6.1 (May 2015) included 31,983 reconstructions from 24 species and 139 brain regions contributed by 147 laboratories worldwide. Axonal and dendritic reconstructions are useful for neuronal identification, compartmental models, and circuit analysis, but accurate metadata are necessary for proper interpretation. NeuroMorpho.Org cross-links digital reconstructions with BrainInfo.org, providing valuable details about mammalian brain regions. An effective computational modeling pipeline is achieved by links to NeuroMorpho.org entries from the SenseLab repositories ModelDB and NeuronDB. Continuous collaboration with the BigNeuron initiative for automated tracing is coalescing into a virtual neuromorphological data network. Interlinking data with the relevant source original articles is also essential. NeuroMorpho.Org maintains a literature database of ~25,000 neuroscience publications identified by full-text searches, indexed by PubMed IDs, and mined for digital reconstruction content. When digital morphologies are uploaded to the repository, each PubMed entry is linked (via Neuroscience Information Framework) to its reconstructions and vice versa. Publishers can promote data sharing and facilitate access to available data. In an ongoing process, NeuroMorpho.Org and Elsevier are reciprocally cross-linking articles and corresponding reconstructions by Digital Object Identifier (DOI). Cross-integration of NeuroMorpho.Org with an increasing number of complementary resources creates a knowledge network providing not only data content, but also rich contextual information.

Title: A new block-face serial microscopy tomography for computational mapping of brain cells, and an unbiased comparative analysis

Authors: *K. SEIRIKI[1], A. KASAI[2], T. HASHIMOTO[3], W. SCHULZE[2], M. NIU[2], T. NAKAZAWA[2], H. HASHIMOTO[2];

Abstract: Identification of anatomical alterations and functional activation patterns in a systemic manner is of the greatest importance to understand brain function and dysfunction. To this end, several whole brain imaging techniques such as light-sheet fluorescent microscopy with tissue-clearing methods has emerged last few years. Despite of these great advances in microscopic techniques, it is still challenging to properly detect these alterations in even the whole brain of mouse by a quantitative comparison. Here, we developed a high-speed imaging apparatus based on automated mechanical sectioning and confocal imaging, named FAST (blockface serial microscopy tomography), and image data processing pipeline for 3D image construction without denaturing (e.g. tissue-clearing techniques). Image processing in FAST could identify individual fluorescent signals and analyze the distribution in the whole brain. We imaged whole mouse brains stained with hoechst33258 using FAST and acquired spatial information of cell distribution. To achieve detection of the structural alterations from whole brain data, we established semi-automatic registration with FAST processing system, and detected the loss of cells in a neurodegeneration model which shows particularly in injured dentate gyrus. Moreover, FAST is also applicable to conventional histological studies using stored sections after whole brain imaging, because this system does not need any denaturing of tissues for whole brain imaging. Including conventional histological methods, various subsequent applications in FAST could provide more useful information, such as cell type in the altered brain regions. Therefore, FAST could identify anatomical and functional alterations, much of which have been overlooked in conventional hypothetical studies, and unbiased comparison with FAST will contributes to further understanding of brain function and dysfunction.

Title: Methods for reconstructing 3D brain data from histological sections for making axonal projection maps in the marmoset

Authors: *H. ABE[1], T. TANI[1], H. MASHIKO[1], N. MIYAKAWA[2], K. MIMURA[2], K. SAKAI[2], W. SUZUKI[2], T. KUROTANI[1], N. ICHINOHE[2,1];
[1]RIKEN Brain Sci. Inst., Wako, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

Abstract: The common marmoset (Callithrix jacchus) is becoming a popular non-human primate model in neuroscience research due to several advantages including the well-developed prefrontal cortex and the availability of transgenic technologies. Because its brain connectivity is poorly understood, it is necessary to collect and present data in comprehensible ways as a marmoset brain connectivity atlas to further enhance neuroscience research. The previous anatomical studies using tracers often show results only from a part of the brain which may not meet readers' own interests. And a brain atlas needs a 3D coordinate, but histologically processed sections have no obvious coordinate across the sections on the glass-slides due to mounting and the tissue shrinkage. To overcome these problems, the present study is aimed to make axonal projection maps of the whole marmoset brain using a non-rigid registration method implemented in Advanced Normalization Tools. Axons were labeled by virus tracers encoding fluorescent proteins. Bain sections were examined with a fluorescent microscope for the axonal projections and with myelin and Nissl staining for brain annotations, and were integrated into a common 3D space for each animal. To achieve this, every time before a section was sliced with a sliding freezing microtome, a picture of the coronal section of the remaining brain was taken using a camera fixed above, to have a 2D coordinate held across the pictures. Additionally the slice thickness gives information about the orthogonal axis, which results in having a common 3D space. The brain images segmented from the pictures were used as reference images to register the corresponding brain sections into the 3D space using the registration method. Thus axonal projections and brain annotations based on the staining can be integrated. In addition, for easier brain segmentation, a picric acid was added to a PFA solution to make the brain yellowish since otherwise the frozen brain looks similar in the color to the surrounding dry ice. To enhance fluorescent signals, images were taken with an additional dummy channel and processed with independent component analysis. This signal processing technique effectively separated signals from the fluorescent proteins and from the background auto-fluorescence which appeared similarly across the channels. We applied these methods to marmoset brains and successfully reconstructed axonal projections from multiple areas in the frontal, temporal and occipital cortices.

Lab., The Salk Inst., La Jolla, CA; [7]Scientific Imaging and Computing Inst., The Univ. of Utah, Salt Lake City, UT

Abstract: The quantification of biologically relevant data from 3D electron microscopy (EM) datasets is a long-standing bottleneck for the study of nervous system form and function. Such analyses typically rely upon manual segmentation, a labor-intensive process that does not scale to accommodate the rapidly increasing throughputs afforded by techniques such as serial block-face scanning EM or electron tomography. Though much effort has been spent developing methods to automate segmentation processes, many solutions remain inaccessible to the research community due to steep learning curves or difficulty in gaining access to high performance computing resources (HPC). A web portal was developed that employs semi-automatic segmentation solutions into scalable Kepler workflows for HPC, addressing this issue. This approach reduces complexity for the user by wrapping complicated, multi-step computational processes into single pipelines that can be submitted by a simple mouse click. Once initiated,

segmentation jobs are processed in parallel and distributed across numerous geographically distributed HPC resources using a multi-cluster submission system. Following this processing, workflows for object filtering, contour generation, and tetrahedral mesh generation are available. Our current segmentation system utilizes the cascaded hierarchical model (CHM), a supervised machine learning algorithm, to produce voxel probability maps of input data. These probability maps are then segmented by the evolution of automatically seeded active contours, and 3D reconstructions are computed using the IMOD software package. Organelle-specific quantification routines have been developed to automatically compute numerous, advanced morphological descriptors, including mitochondrial branching and branch length and nuclear envelope curvature. Such routines will be incorporated into the web portal, providing the user with an end-to-end process beginning with raw images and ending with quantitative data and cellular models. These methods simplify and expedite the process of developing and quantifying complete microanatomical models of cells, and can be used, for example, to study the effects of neurodegenerative diseases on organelle morphology and distribution. The web portal and related services are available at https://slashsegmentation.com.

Title: Deconvolution in sem - enhancing resolution in x, y and z

Authors: ***B. H. LICH**[1], F. BOUGHORBEL[1], P. POTOCEK[1], E. KORKMAZ[1], M. LANGHORST[2];
[1]FEI Electron Optics BV, Eindhoven, Netherlands; [2]FEI Munich, Munich, Germany

Abstract: In recent years there has been a considerable advancement in SEM-based methods for 3D reconstruction of large tissue volumes. Serial Block-Face SEM (SBF-SEM) involves combination of imaging and in-situ sectioning of plastic embedded tissue blocks within the SEM vacuum chamber1, allowing for automated imaging and subsequent reconstruction of volumes of tissue. The use of low electron energies for imaging limits sample charging which can be further mitigated with imaging in low vacuum mode and by further increasing the conductivity of the

sample through sufficient amount of heavy metal staining3. Last year we introduced a novel solution for high spatial resolution and throughput SEM volume imaging overcoming the resolution limits set by mechanical slicing by combining it with virtual sectioning. Virtual slicing is realized by Multi-Energy Deconvolution SEM (MED-SEM), a non-destructive technique that allows high resolution reconstruction of the top layers of the sample.2 After cutting a thin layer of the blockface using a diamond knife, freshly exposed tissue is imaged several times using various accelerating voltages. These images are subsequently used for deconvolving the information into several virtual subsurface layers. This cycle of physical and virtual sectioning offers isotropic datasets with excellent z-resolution and are fully integrated and automated. Here we introduce novelties on how different image acquisition and processing (deconvolution) methods help to achieve goals that are also very relevant for neuroscientists. For instance achieving enhanced resolution, not only in the orthogonal plan like we have demonstrated with multi-energy deconvolution, but also in the x-y (image) plane. We can achieve this in various ways but here we demonstrate how this can conceptually be achieved by dedicated detector design and by combining different beam-tilts.

Abstract: We report a new correlative-microscopy technique that combines two highly complementary imaging techniques, synchrotron X-ray microtomography (microCT) and transmission electron microscopy (TEM), giving unprecedented access to the tridimensional reconstruction of a histological sample with details down to the microscopic level as well as to its nanometer-scale ultrastructure. To this end we identified fixative and staining procedures that rendered the sample of interest observable with both these techniques by preserving the ultrastructure for TEM analysis while yielding at the same time optimal contrast for microCT imaging. We demonstrate the potency of this technique by targeting pathological changes arising in the sciatic nerves of Twitcher mice (TWI), a murine model of globoid cell leukodistrophy (GLD), also known as Krabbe disease. GLD is a genetic disease caused by the deficiency of galactocerebroside-beta-galactosidase (GALC) activity that induces the accumulation of lipid-raft associated neurotoxin psychosine and the infiltration of multinucleate (globoid) cells. We were able to identify individual infiltrating cells, a hallmark of the pathology, in the 3D rendering of the sample determining their precise position. With this knowledge, we could section the sample only in the region of interest, avoiding the time-consuming process required by conventional serial-sectioning methods, for further observation at TEM, allowing the characterization of the ultrastructure of the chosen globoid cell. The correlation technique allows to locate, with the micrometric resolution of the microCT, in a large volume all regions interested by the pathological process, and select only these for further ultrastructural characterization. The method represents an invaluable tool for the investigation of those pathologies in which the microscopic alterations are localized in few confined regions, rather than diffuse in entire tissues, organs or systems. For that reason, we are going to show that this method is applicable to samples with a larger volume, arising from different animal models.

Title: Top-down bidirectional control of innate anxiety and learned fear

Authors: *A. ADHIKARI[1,2], T. N. LERNER[2], J. FINKELSTEIN[2], S.-Y. KIM[2], J. H. JENNINGS[2], L. YE[2], L. A. GUNAYDIN[2], J. MIRZABEKOV[2], S. PAK[2], A. LEI[2], K. DEISSEROTH[2,3,4];

Abstract: Previous studies showed electrical stimulation of the ventral medial prefrontal cortex (vmPFC) during cued fear extinction increases extinction retrieval. As fear conditioned responses are dependent on the central amygdala, it has been hypothesized that the vmPFC decreases fear by activating inhibitory intercalated cells in the amygdala, which in turn inhibit the central amygdala. However, this model has not been directly tested. Here, we tested these ideas directly by optogenetically activating vmPFC cell bodies and their projections to the amygdala during innate anxiety and cued and contextual fear extinction. Animals were injected with viral vectors encoding ChR2-EYFP, eNpHR3.0-EYFP or EYFP under the CamK2α promoter in the vmPFC and fiberoptic cannulae were implanted either in the vmPFC or above the amygdala. While activation of vmPFC cell bodies did not alter anxiety, optical activation of the vmPFC-amygdala projection decreased anxiety in the elevated plus maze and decreased respiration rate, which is a physiological marker of anxiety ($n=10$ EYFP, 11 ChR2, $p<0.05$). Conversely, inhibiting this projection in mice expressing eNpHR3.0 had the opposite effects ($n=8$ EYFP and 11 eNpHR3.0, $p<0.01$). Furthermore, optogenetic activation of vmPFC cell bodies ($n=7$ EYFP and 7 ChR2, $p<0.05$) during fear extinction decreased freezing specifically during cued fear extinction retrieval. Remarkably, activation of the vmPFC-amygdala projection only during fear extinction decreased freezing both during extinction and retrieval of extinction, for both cued and contextual conditioning ($n=7$ EYFP, 10 ChR2, $p<0.05$). Surprisingly, retrograde viral tracing, histology and *in vivo* and *in vitro* functional connectivity showed that the intercalated cells do not receive vmPFC projections. Instead, the basomedial amygdala was found to be the major post-synaptic target of the vmPFC in the amygdala. Lastly, direct optical activation of basomedial amygdala cell bodies decreased expression of both innate anxiety and learned cued fear conditioning ($n=8$ EYFP and 9 ChR2, $p<0.05$). Taken together, these data suggest the vmPFC-amygdala projection robustly inhibits learned fear and innate anxiety by activating the basomedial amygdala.

Title: Anatomical and functional characterization of the rat cholinergic pedunculopontine neurons and projections to dopaminergic cells in the ventral tegmental area

Authors: *J. CHO[1], C. XIAO[2], J. TREWEEK[2], K. CHAN[2], V. GRADINARU[2];
[1]Computation and Neural Systems, [2]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: The pedunculopontine nucleus (PPN) in the rostral brainstem is postulated as an important region mediating reward learning by sending excitatory signals to ventral midbrain dopaminergic neurons. The PPN consists of an intermingled population of cholinergic, glutamatergic, and GABAergic neurons. To investigate the causal role of specific PPN cell types in promoting reward seeking behavior, we used optogenetics in a transgenic rat line that expresses Cre-recombinase under choline acetyltransferase (ChAT) promoter. Cre-dependent viral tracing (AAV5-Ef1a-DIO-ChR2(H134R)-eYFP) demonstrated highly specific expression (~95%) in cholinergic neurons. Thick brain slice imaging with the passive CLARITY technique (PACT) showed that cholinergic PPN fibers innervate dopaminergic neurons in both of the ventral tegmental area (VTA) and substantia nigra pars compacta. Optogenetic activation and inhibition of cholinergic PPN cell bodies induced conditioned place preference and aversion, respectively. (PPN-ChR2, PPN-mCherry, PPN-Arch3, n=6 rats each). *In vivo* electrophysiological recordings during anesthesia demonstrated that cholinergic PPN neurons can be identified by optogenetics-based phototagging (2/13 neurons, n=2 rats), and activation of these fibers leads to increased firing rate of VTA neurons (~3 to 7 fold, 7/11 neurons, n=2 rats). These results can aid future studies aimed at investigating the causal role of cholinergic PPN inputs to VTA in reward seeking behavior.

Title: Optogenetic rescue of impaired social behavior phenotype in autism

Authors: ***A. SELIMBEYOGLU**[1,2], C. K. KIM[1], M. WRIGHT[3], A. S. O. HONG[4], C. RAMAKRISHNAN[4], L. E. FENNO[1], T. J. DAVIDSON[4], K. DEISSEROTH[2,3,4]; [1]Neurosciences, [2]Hhmi, [3]Psychiatry and Behavioral Sci., [4]Bioengineering, Stanford Univ., Stanford, CA

Abstract: Altered cellular excitatory/inhibitory (E/I) balance is emerging as a common pathophysiological characteristic that could link diverse autism-associated genetic variations in mouse models. To understand possible disease relevance, it may be of great interest to identify specific cells and circuits within which such E/I imbalance changes could cause autism-related phenotypes in real time. Increased excitability in medial prefrontal cortex (mPFC) pyramidal (PYR) neurons was previously found to reduce social interaction in mice, which can be partially recovered by simultaneous compensatory excitation of inhibitory parvalbumin (PV) neurons. Here, we investigate the role of real-time changes in E/I balance in a clinically-inspired CNTNAP2 KO mouse line with decreased cortical PV neurons and impaired social behavior. We crossed CNTNAP2 mice with PV::Cre mice, and expressed bistable SSFO channelrhodopsin in PV cells. Without stimulation, CNTNAP2 KO mice spent less time engaging socially than WTs ($n=7$ WT, $n=11$ KO, $p<0.05$). Increasing PV cell excitability reversed the impaired social behavior ($n=11$ KO no-stim, $n=6$ KO stim, $p<0.05$) in KOs while not affecting WT littermates

(n=9 WT no-stim, n=7 WT stim, $p>0.05$). We did not find any differences in novel object interaction between WTs and KOs, and the SSFO stimulation did not affect object interaction (n=4 WT, n=6 KO, $p>0.05$, for both stim and no-stim). The phenotype could be largely traced to decreased mean interaction time in the initial KO social bouts (n=6 KO, n=5 WT, $p<0.01$); additionally, WT social bout length decayed exponentially during the course of the test, while KO's did not (n=5 WT $R^2=0.88$, n=6 KO $R^2=0.10$). We further dissected real-time activity in mPFC by using fiber photometry to simultaneously record from PV and PYR neurons expressing ef1a-DIO-GCaMP6f and CKIIa-RCaMP2, respectively. Both types of neurons responded to novel social and object stimuli in a time-locked manner, with similar peak fluorescence changes (peak dF/F for social vs object; n=5 WT $p>0.05$, n=6 KO $p>0.05$). On the other hand, within-bout fluorescence changes were different for WT and KO mice during the initial bouts. Peak fluorescence signals were significantly different at the end of the bout compared to the beginning for WT social but not object interactions; in contrast these signals were similar for KOs (first vs last 0.25 s; n=5 WT $p<0.01$ for social, $p>0.01$ for object; n=6 KO $p>0.01$ for both social and object), suggesting that the KOs process social stimulus similarly to objects. Together these results illustrate the role of real-time balance between mPFC PV and PYR cells in modulating social behavior relevant to autism pathophysiology.

Abstract: Recent controversy regarding the diversity and connectivity of midbrain dopamine neurons has highlighted the importance, and the challenges, of defining cell types and roles in the mammalian brain. One promising idea is that brain cells are best defined, with their function most fully understood, using inclusive criteria spanning patterns of gene expression, biophysical properties, wiring of inputs, wiring of outputs, and activity during behavior; however linking all five of these measurements to cell types within the intact brain of living mammals has been difficult. Here, using an array of intact-brain circuit interrogation tools including CLARITY, optogenetics, viral tracing, and fiber photometry during behavior, we explore the complexity of dopaminergic cells within the mammalian substantia nigra pars compacta (SNc). We identify two parallel and largely non-overlapping nigrostriatal dopamine neuron subpopulations, separable by distinct biophysical properties (Ih current, DMS-projecting 296.2 ± 29.25 pA, n=21 vs. DLS-projecting 460.8 ± 49.69 pA, n=16, $p<0.01$), input wiring (using a viral tracing approach, TRIO, two-way ANOVA revealed a significant interaction between the starter cell projection target (DMS-projecting vs. DLS-projecting) and the input area to SNc ($p<0.001$, n=4 brains per group)), output wiring to dorsomedial striatum (DMS) versus dorsolateral striatum (DLS) (fraction of DMS-projecting axons located within the DMS 0.98 ± 0.01, n=2, fraction of DLS-projecting axons located within the DLS 0.86 ± 0.02, n=2), and natural activity patterns during free behavior (in this case, discriminated specifically by the nature of response to aversive stimuli; peak ΔF/F during shock, DMS-projecting -2.628 ± 0.513%, n=8 vs. DLS-projecting 1.527 ± 0.358%, n=9, $p<0.0001$). Together, these results reveal independently controlled information representations streaming through the SNc, with implications for understanding the logic of dopaminergic signaling to striatum and the diversity of cell types in the mammalian brain.

Title: Simultaneous multi-fiber photometry calcium recordings from deep brain regions using a single sensor

Authors: *C. K. KIM[1], S. J. YANG[2], N. PICHAMOORTHY[3], I. KAUVAR[2], T. N. LERNER[3], T. J. DAVIDSON[3], C. RAMAKRISHNAN[3], K. DEISSEROTH[4,3,5];
[1]Neurosci. Program, Stanford Univ., Stanford, CA; [2]Electrical Engin., [3]Bioengineering, [4]HHMI, [5]Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Fiber photometry is becoming a widely adopted technique for measuring the population activity of genetically- and anatomically-defined neurons during free behavior. Fiber photometry's simple instrumentation has the potential to permit simultaneous neural recordings from multiple deep brain regions. However, existing fiber photometry microscopes couple the emission from a single fiber to a single photodetector; this design makes multi-area recordings cumbersome, since every additional fiber requires an additional detector. Here we describe an sCMOS-based fiber photometry microscope capable of monitoring multiple regions simultaneously *in vivo* using only a single excitation source and camera sensor. On this new microscope, intracellular calcium signals (using nuclear-localized GCaMP6) could be readily detected from up to 7 different regions in a freely moving mouse. We considered that the high sensitivity of this system might also allow simultaneous recording of distinct axonal activity signals from multiple independent projection targets of ventral tegmental area dopamine (VTA-DA) neurons; indeed, we were able to record somatic VTA-DA signals while also recording independent axonal projection activity signals in medial prefrontal cortex, nucleus accumbens, and the basolateral amygdala, during administration of a reward or aversive tail shock (n=6 mice with at least two regions exhibiting responses to reward or shock, $p<0.05$ Wilcoxon's Signed-rank Test). This multi-fiber photometry system could also be readily adapted for multi-color observation, or for combined all-optical observation and perturbation of neural activity. Using an image splitter placed in front of the camera, we simultaneously imaged VTA-DA and VTA-non-DA neurons using GCaMP6 and RCaMP-2, and observed similar or opposite activity patterns between the two populations during administration of a reward or tail shock, respectively (n=12 and 10 trials, $p<0.05$ Wilcoxon's Signed-tank Test). Finally, we optogenetically stimulated VTA-DA neural activity with a novel red light-activated channelrhodopsin while measuring

activity using GCaMP6. Using this approach, we could titrate the stimulation light power to elicit GCaMP6 transients of similar magnitude to physiological responses such as those evoked by reward delivery - a key goal of precision optogenetics (optogenetic responses with various light powers ranging from 2.27±0.57 to 22.29±0.28 %dF/F n=2-6 trials, reward response 8.27±1.63 %dF/F n=4 trials). Future modifications to our microscope may allow such combined dual-color imaging and optogenetic perturbation across all 7 fibers.

Title: Next-generation optogenetic chloride channels arising from crystal structure-guided molecular engineering

Authors: ***A. BERNDT**[1,2], S. LEE[2], J. WIETEK[5], C. RAMAKRISHNAN[2], S. IYER[2], S. PAK[3], S. DELP[2], P. HEGEMANN[5], K. DEISSEROTH[2,6,4];

Abstract: Chloride channel conductances are critical for the natural regulation of neuronal activity, and the recent development of light-gated chloride-conducting channelrhodopsins has enabled optogenetic inhibition of neurons using this physiologically relevant mechanism. Here we build upon our initial crystal structure-guided approach to engineer new enhanced chloride-conducting channelrhodopsins, in the process testing and extending our hypothesis for ion selectivity in channelrhodospin, by changing the surface potential of the ion conducting pore to enhance chloride flux. The best-performing of these new optogenetic tools, iC++, has near-

perfect chloride selectivity resulting in reversal potentials as hyperpolarized as - 78 mV ± 0.7 under physiological conditions, and with >5 times larger photocurrent compared to the first generation of chloride conducting light-activated channels iC1C2 ($P<0.0001$). As a result iC++ shows reliable spike inhibition in cultured neurons which significantly exceeds iC1C2 performance. To test applicability for *in vivo* application, we expressed iC++ in various cell types of the central and the peripheral nervous systems, and observed robust inhibition in fast-spiking hippocampal interneurons, dopaminergic neurons in substantia nigra, cells of the dorsal root ganglion, and cortical pyramidal neurons under controlled current injection-based stimulation conditions tuned to each cell's spike firing threshold. Next, since cytosolic chloride concentrations differ among cell types, subcellular compartments and even developmental stages, to test performance limits we characterized iC++ under widely varying chloride gradients and with extremely strong current injections. As expected, inhibition efficiency was tunable in this way; as with native inhibitory chloride channels, the reversal potential of iC++ was found to precisely follow varying chloride gradients. Under very strong current injections into cortical pyramidal cells (740 pA ± 84, 10 - 20 Hz, 10s), spike inhibition probabilities ranged from 71% ± 13 ([Cl-]int = 4 mM) to 23% ± 17 ([Cl-]int = 20 mM). However, in response to more moderate naturalistic levels of steady depolarizing current (229 pA ± 24, 10 s), iC++ performed at 100% successful spike inhibition even with internal chloride concentrations ranging from 4 mM up to 20 mM. We conclude that iC++ operates as an essentially pure chloride channel much like native inhibitory mechanisms involving endogenous chloride channels such as the GABA-A receptor. The design features of iC++ further illuminate electrostatic and steric structure-function relationships of the channelrhodopsin light-gated pore.

Title: Labeling membrane proteins *in vivo* and in PACT cleared tissue with genetically-encoded protein tag technologies

Authors: *C. BEDBROOK[1], M. KATO[2,4], S. KUMAR[2], A. LAKSHMANAN[2], N. FLYTZANIS[2], A. J. RICE[3], P. W. STERNBERG[2,4], F. H. ARNOLD[3,5], V. GRADINARU[2]; [1]Bioengineering, [2]Div. of Biol. and Biol. Enginneering, [3]Div. of Chem. and Chem. Engin., Caltech, Pasadena, CA; [4]Howard Hughes Med. Inst., Pasadena, CA; [5]Div. of Biol. and Biol. Engin., Pasadena, CA

Abstract: Many modern neuroscience methods rely on transgenic expression of membrane proteins for controlling or sensing neuronal activity. Visualizing membrane protein localization and trafficking in live cells can facilitate a greater understanding of the molecular basis of cellular dynamics. In addition, tracking projections from neurons with transgenic expression of membrane proteins can aid in understanding the architecture and circuitry of targeted cell populations, especially in the context of large tissue volumes. We present a method for specifically labeling the plasma membrane-localized fraction of heterologous membrane protein expression using channelrhodopsins as a case study. We show that the genetically encoded, covalent binding SpyTag and SpyCatcher pair from the Streptococcus pyogenes fibronectin-binding protein FbaB (Kato et al., 2012) can selectively label membrane-localized proteins in primary cultured neurons and *in vivo* in Caenorhabditis elegans. We use this system to develop a channelrhodopsin membrane localization assay in mammalian cells that is amenable to high-throughput screening for opsin discovery and engineering. We also describe a method for tagging and labeling opsin proteins in fixed, cleared tissue volumes using the SNAP-tag technology (Juillerat et al., 2003) and we validate this labeling technology for tracking neuronal morphologies in PACT / CLARITY cleared tissue. Both the SpyTag/SpyCatcher and SNAP-tag protein-labeling methods offer advantages for live cell and fixed tissue applications when compared with traditional antibody labeling methods. The SpyTag/SpyCatcher method is composed of all genetically encoded parts, which enables expression and labeling of two components within specific cells in live animals. The SpyCatcher labeling protein is inexpensive and easy to produce in bulk using standard protein expression methods. The SNAP-tag method uses small, bright chemical labeling probes, which are able to rapidly penetrate fixed, cleared tissue. Additionally, both the SpyTag/SpyCatcher and SNAP-tag methods allow for easy swapping of spectrally diverse fluorescent molecules enabling flexibility in fluorescence labelling to fit experimental needs.

Title: Deep brain mapping of functional connectivity in intact circuits via CaMPARI and PACT tissue clearing

Authors: *N. FLYTZANIS[1], C. CHALLIS[1], L. LOOGER[2], E. SCHREITER[2], V. GRADINARU[1];
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Mapping the functional connectivity within neural circuits of model organisms has been a longstanding goal of neuroscience. Efforts to develop tools for real-time imaging of neuronal activity *in vivo* through fluorescent indicators have been fruitful for mapping superficial cortical areas and the recent developments of endoscopes and fiber photometry have also enabled deep brain imaging. However, imaging activity across large brain volumes at depth remains a challenge. Although post hoc measures of neuronal activity such as the staining of cFos and other immediate early genes' (IEGs) products have been used throughout the brain, they are

limited by their poor temporal resolution. Therefore, to provide large-area functional mapping within temporally relevant periods locked to a stimulus or during behavior it is necessary to develop a method that combines the ability of IEG-like labelling to reveal activity changes in circuits across the brain with the temporal resolution of real-time sensors. CaMPARI is a recently developed neuronal activity integrator (Fosque et al., 2015) that uses a photoconvertible calcium indicator to label active circuits in a precise spatial, temporal, and cell type-specific manner. Building on our prior CLARITY work, we have further developed tissue clearing methods to image thick sections of deep brain structures. Here, we combine our passive CLARITY technique (PACT) (Yang et al., 2014) with CaMPARI to demonstrate a method for mapping network activity within deep brain regions in direct response to an excitatory stimulus. We first validate the compatibility of tissue clearing methods with retention of endogenous CaMPARI fluorescence by showing expression throughout thick (> 1 mm) cleared mouse brain sections. CaMPARI uses 405nm photoconversion light, which has poor tissue penetration, potentially limiting the effective volume that could be functionally mapped. Supporting the feasibility of a combined CaMPARI - PACT approach for deep brain circuit mapping, we achieved photoconverted fluorescence up to 1mm away from the fiber optic implant in anesthetized mice. Further development of this technique could be enabling for mapping the temporal progression of neuronal activity in response to stimuli or behavior throughout the brain.

Title: Retention and detection of RNAs in CLARITY

Authors: ***E. L. SYLWESTRAK**[1], P. RAJASETHUPATHY[1], M. WRIGHT[1,2], A. JAFFE[1], K. DEISSEROTH[1,2,3];

[1]Bioengineering, [2]Psychiatry & Behavioral Sci., [3]Howard Hughes Med. Inst., Stanford Univ., Stanford, CA

Abstract: Integrating information about the identity, function and connectivity of neural networks in intact 3D volumes is a fundamental aim in neuroscience. Recently, several tissue clearing techniques have emerged to enable the visualization and phenotyping of intact neural circuits, but most of these are not readily compatible with RNA labeling, and systematic methodologies to investigate the RNAs present in such volumes have not been described. The ability to reliably detect RNAs is critical for the investigation of cell activity (e.g. using temporally-tuned immediate early gene activity markers), cell identity and molecular signaling (e.g. using coding mRNAs for which antibodies may not exist or be practical, as well as small and large non-coding RNAs), and using RNAs differing in healthy and diseased states (e.g. in psychiatric conditions). Here, we characterize the extent of RNA retention in clarified tissue under varying CLARITY parameters and identify conditions in which RNAs can be preserved in clarified tissue and stably stored for many months. We further characterize the diffusion of different biomolecules into the tissue (DNA oligonucleotides diffuse significantly faster than RNA oligonucleotides, $p=0.04$), determine the rate-limiting steps (antibody-based amplification used in traditional ISH is slow and non-uniform), and implement an all-DNA based detection and amplification strategy for whole-brain RNA visualization. The resulting approach may enable labeling of several targets simultaneously, allowing for broad molecular phenotyping in which the robust structure of the CLARITY hydrogel would permit multiple rounds of hybridization. These advances in RNA detection highlight the versatility of the CLARITY technique and begin to allow for a more complete molecular characterization of intact neural networks.

Title: Quantitative assessment of alternative CLARITY procedures in mouse brain

Authors: *D. M. KROLEWSKI[1], V. KUMAR[1], B. MARTIN[1], R. TOMER[2], K. DEISSEROTH[2], H. AKIL[1], S. J. WATSON, Jr.[1];
[1]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA

Abstract: The CLARITY technique for visualizing 3-dimensional fluorescence immunohistochemistry (IHC) requires prior polymerization of a brain-infused acrylamide fixative to generate a hydrogel mesh through which lipid is subsequently removed with sodium dodecyl sulfate (SDS) detergent (Chung et al., 2013). The resulting linkage between hydrogel monomers, formaldehyde, and proteins using the original protocol proved challenging for achieving sufficient lipid clearing and antibody penetration in transparent tissue. More recently, these obstacles have been tempered by reducing and increasing acrylamide and SDS concentrations, respectively (Tomer et al., 2014; Yang et al., 2014). However, the degree of neuronal protein preservation related to such condition changes is still not completely understood. To address this, our laboratory has developed previously unpublished alternative acrylamide formulas and performed IHC experiments in passively cleared brain samples. Using both standard confocal microscopy and a CLARITY Optimized Light Sheet Microscopy (COLM) system, we employed multiple software packages and conducted quantitative analyses of neuronal and non-neuronal markers. The results of the present study will serve to further optimize CLARITY brain transparency methods.

Title: A novel adeno-associated viral vector based approach to deliver sparse multicolor labels to defined cell types for the mapping of intact neural circuits in PACT cleared tissue

Authors: *K. CHAN[1], B. DEVERMAN[1], A. GREENBAUM[1], J. CHO[2], C. XIAO[1], S. KUMAR[1], V. GRADINARU[1];
[1]Biol. and Biol. Engin., [2]Computation and Neural Syst., Caltech, Pasadena, CA

Abstract: The vast complexity of neuronal shapes and connections throughout the brain spurred the development of approaches (e.g. Brainbow) that use multicolor labeling to distinguish individual cells within dense genetically defined populations. We have expanded on this concept of multicolor labeling for single-cell analysis by building an adeno-associated viral (AAV) vector-based toolbox of constructs with modular promoters and floxed single monomeric fluorescent protein (XFP) cassettes. By coinjecting a mixture of XFP expressing viruses, we can achieve a wide range of hues that facilitates identification and tracing of single cells and their projections. However, even with multicolor labeling, individual cells can be difficult to discern from a dense population of labeled cells. Therefore, we have coupled our toolbox to a novel AAV capsid variant, AAV-PHP.B, which was engineered for efficient brain-wide neuron and glial transduction through the vasculature. By systemically delivering a low dose (~1e10 vector genomes/mouse) mixture of floxed XFP expressing genomes packaged into AAV-PHP.B, we are able to sparsely label genetically defined cell types for single-cell phenotyping and projection mapping. To facilitate mapping of intact circuits, we use the passive CLARITY technique (PACT) together with high-resolution light-microscopy (via a custom built system that can achieve up to 45 frames per second) to image through multi-millimeter thick tissue samples. We demonstrate the utility of this approach, which combines easily customizable genomes, a novel AAV capsid, tissue clearing, and light-sheet microscopy to trace select neural circuits within the brainstem and basal ganglia.

Title: Methods for generating hydrogel-stabilized transparent whole organs and organisms for single-cell phenotyping in both soft and osseous tissues

Authors: *J. B. TREWEEK[1], N. FLYTZANIS[1], K. CHAN[1], A. GREENBAUM[1], B. E. DEVERMAN[1], T.-F. HE[2], A. LIGNELL[2], L. CAI[2], C. C. FOWLKES[3], V. GRADINARU[1]; [1]Div. of Biol. and Biol. Engin., [2]Div. of Chem. and Chem. Engin., Caltech, Pasadena, CA; [3]Computer Sci., Univ. of California, Irvine, Irvine, CA

Abstract: To aid in mapping cellular connectivity and studying tissue microenvironments at the whole-organ level, many tissue clearing protocols have been described over the last decade, including CLARITY, CUBIC, 3DISCO, iDISCO, ScaleA2, and SeeDB. Although these techniques circumvent the need to section, individually process, and digitally reconstruct single-plane images from thin-sliced samples, as in traditional histology, the ability to image and interpret data from intact, transparent samples encounters two major bottlenecks. First, obtaining high-resolution image stacks for thick tissue sections requires lengthy acquisitions. Second, analysis of the corresponding terabytes of raw image data is computationally demanding. Thus, in addition to optimizing clearing protocols for a wide variety of tissues (e.g. bone), our recent work has been aimed at addressing these barriers to the high-throughput analysis of large tissue volumes. Entailing four general steps of fixation, hydrogel embedding, chemomechanical removal of light scattering moieties, and refractive index matching, PACT (PAssive CLARITY Technique), PACT-deCal (PACT deCalcification for bone) and PARS (Perfusion-assisted Agent Release *in situ*), and RIMS (Refractive Index Matching Solution) mounting transform excised organs and whole organisms into optically transparent samples within 1-2 weeks. Aside from granting long-range tract tracing through the rodent brain and body, these clearing methods may also be applied to the super-resolution detection of single-molecule transcripts in smFISH. Since the amine-containing macromolecules and nucleic acid transcripts within a sample are locked into place via their hybridization to a size-adjustable hydrogel scaffold, the tissue-hydrogel

matrix can withstand rounds of delipidation, decalcification, enzymatic digestion, histological labeling, and size fluctuations during clearing and mounting. To more efficiently image the resulting samples at high resolution, we built an affordable light-sheet microscope that allows fast imaging (~ 45 frames/sec), and an immersion chamber that accommodates cleared samples. Finally, we delineated a workflow for handling gigabyte-sized raw data files, wherein we highlight image analysis software packages that we found most capable of performing basic functions for cleared tissue data analysis (e.g., semi-automated tract-tracing, cell-mapping and quantification). We anticipate that, with future advances in automated 3D image analysis and registration for terabyte-sized datasets, tissue clearing will enable whole-body anatomical maps to be rewritten with nanoscale resolution.

Abstract: A major challenge in modern neuroscience is to map brain architecture and activity together, with both datastreams collected at high (wiring-level) resolution while maintaining broad (brain-wide) perspective. Light microscopy-based approaches are emerging as important tools for achieving this goal, largely fueled by developments in tissue clearing, genetic labeling and fast high-resolution microscopy. We recently developed CLARITY and CLARITY Optimized Light-sheet Microscopy (COLM), two methods that together allow rapid high-resolution imaging of entire intact adult mammalian brains. While this integrated approach has already provided unprecedented access to the underlying neuronal architecture of mouse brains, many new challenges have emerged for larger brain samples. Here we report three key advances to address these challenges. First, we report development of second-generation COLM (using multiplexed synchronized image detection and illumination optics), which is up to an order of magnitude faster, while maintaining or improving the imaging resolution, and increased (up to two-fold) imaging depth. This new COLM framework reduces the imaging time of an entire mouse brain from hours to minutes, and make intact tissues twice as large along any or all dimensions accessible for imaging in a practical timeframe; we present a complete characterization of this system with large brain examples from rodent and primate. Second, we report a computational tool and data management framework for analyzing the immense data streams that result. The pipeline includes efficient image registration (using B-splines-based multi-resolution strategies), segmentation (for cell detection and tracing), statistical analysis and visualization for (terabyte-scale) data. Third, we report application of these tools for integrated structural and functional mapping of rodent and fish CNS, in which wiring-level anatomy and functional activity are collected on the same COLM system, enabling highly accurate merging of the two modalities. Together, these tools may provide a robust platform for an integrative brain-wide understanding of nervous system structural and functional architecture.

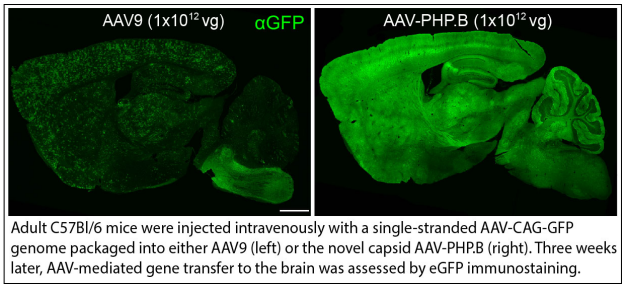
Title: Adeno-associated viruses capable of efficient global transduction of the adult central nervous system identified by *in vivo* cell type-specific capsid selection

Authors: *B. E. DEVERMAN[1], P. L. PRAVDO[2], B. P. SIMPSON[2], A. BANERJEE[2], K. Y. CHAN[2], W.-L. WU[2], S. R. KUMAR[2], B. YANG[2], V. GRADINARU[2];
[1]Caltech, Pasadena, CA; [2]California Inst. Tech., Pasadena, CA

Abstract: Recombinant adeno-associated virus (rAAV) vectors have emerged as essential tools for gene transfer to the central nervous system (CNS). rAAVs are widely used to deliver genetically encoded elements (e.g., opsins, sensors, and RNAi) with high efficiency to discrete CNS regions via intraparenchymal injections. Alternatively, intravascular (IV) administration of certain AAV serotypes, most notably AAV9, can be used for CNS-wide delivery, but the resulting gene transfer efficiency is insufficient for applications requiring transduction of a large fraction of neurons and/or glia, especially in the adult. To achieve efficient gene delivery throughout the CNS, we developed a novel cell type-specific selection platform and used it to identify variants from an AAV capsid library that transverse the vasculature and transduce cells within the CNS. One AAV capsid variant, AAV-PHP.B, when administered IV to adult mice, delivers genes to the brain and spinal cord 40- to 92-fold more efficiently (depending on the CNS region) than the current standard, AAV9. Importantly, AAV-PHP.B efficiently transduces neurons, astrocytes, and oligodendrocytes, making AAV-PHP.B useful as a vehicle for global gene transfer to the brain and spinal cord for a wide variety of applications. We identified AAV-PHP.B, as well as an additional vector AAV-PHP.A, which exhibits enhanced tropism for CNS astrocytes and reduced tropism for non-CNS organs, after only two rounds of *in vivo* selection validating of our novel vector development platform as a powerful approach to customize gene delivery vectors for biomedical applications.



Adult C57Bl/6 mice were injected intravenously with a single-stranded AAV-CAG-GFP genome packaged into either AAV9 (left) or the novel capsid AAV-PHP.B (right). Three weeks later, AAV-mediated gene transfer to the brain was assessed by eGFP immunostaining.

Title: Head-motion modulation of the activity of optogenetically tagged neurons in the vibrissal thalamus

Authors: ***T. B. ORAM**, E. AHISSAR, O. YIZHAR;
Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The vibrissal system evolved to function in freely-moving animals that explore and interact with their environment. There are two major afferent sensory pathways in the vibrissal system, the lemniscal pathway, which passes through the ventro-posterior-medial nucleus of the thalamus (VPM), and the paralemniscal pathway, which passes through the posterior medial nucleus of the thalamus (POm). To date, it is unclear what the perceptual functions of these pathways are and what type of perceptual information is primarily processed by each. Fortunately, the optogenetic and tracking tools necessary to study the system in a natural-like environment now exist. Conveniently, the lemniscal and paralemniscal pathways are functionally and anatomically segregated at the level of the thalamus. Taking advantage of this segregation, we used a Cre-ON/Cre-OFF genetic targeting strategy to selectively target the expression of channelrhodopsin fused to yellow-fluorescent protein (ChR2-eYFP) to either the VPM or the POm of GPR26-Cre mice, which strongly express Cre in the POm but only sparsely in the VPM. A chronic multi-site optrode was then implanted in the ChR2-eYFP expressing nucleus enabling

(1) recording of the multi-unit and single-unit activity, and the local field potential of awake, freely-moving mice and (2) the assignment of nucleus affiliation to recorded units through "optogenetic tagging". We then recorded the exploratory behavior of freely-moving mice in a walled arena containing a cylindrical object while collecting neural data from nucleus-affiliated single units. Our preliminary data show that the activity of units recorded in both the lemniscal and the paralemniscal pathways (n=10) was modulated by head-motion variables. Modulations depths varied between 0.21 and 0.94 for the different variables (the linear and angular velocity and acceleration of the head, and head orientation), where the strongest modulations were due to the velocity variables (0.94±0.50 for linear velocity, and 0.70±0.36 for angular velocity). Additionally, the firing rate of VPM units was strongly modulated by vibrissal touch events. On average, there were no significant interactions between head- and touch-induced modulations. We are currently collecting data to clarify the sensitivity of identified VPM and POm units to whisking phase and to touch-related variables. Collectively, these data are expected to elucidate the perceptual functions of the lemniscal and paralemniscal pathways in awake, freely-moving mice.

Title: Controlling fear associations through optogenetic modulation of amygdala to prefrontal connectivity

Authors: *O. KLAVIR, M. PRIGGE, R. PAZ, O. YIZHAR;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Post-Traumatic stress Disorder (PTSD) is thought to reflect strong and persistent learned fear associations resulting from aberrant synaptic plasticity processes. Despite the extensive study of the neural circuits involved in fear learning, interventions that could reverse pathological associations and ameliorate the debilitating symptoms of PTSD have not been defined. The basolateral amygdala (BLA) and the medial prefrontal cortex (mPFC) play a key role in the acquisition and extinction of fear memories. Here, we establish an optogenetic stimulation protocol for manipulating the synaptic strength of the BLA to mPFC projection, and use this approach to explore this pathway's role in fear learning. Using acute slice recordings and extracellular single-unit recordings in behaving mice, we found that high frequency stimulation (HFS) of BLA projections in the mPFC induced long term depression (LTD) of synaptic strength. This stimulation protocol dramatically reduced the response of mPFC neurons to BLA input without altering the intrinsic properties of mPFC cells or their spontaneous firing rates. We then sought to utilize the unique response to repetitive stimulation of the BLA->mPFC projection to modulate learned fear. We found that depotentiation of BLA->mPFC synapses prior to conditioning leads to impaired fear learning. However, effective treatment should be capable of alleviating the fear response after it had already been acquired. We therefore performed experiments in mice that have already undergone fear learning. In these animals, inducing LTD prior to exposure to the fear-associated cues facilitates extinction learning. Our combined findings suggest a new role for the BLA->mPFC pathway not only in the in the acquisition but also the maintenance of learned fear associations. We also provide an effective way to specifically target and alter the connectivity of the pathway creating a time window for enhanced efficiency of fear extinction.

Title: Strategies for optogenetic silencing of axonal terminals

Authors: *M. MAHN, M. PRIGGE, S. RON, O. YIZHAR;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Light-driven ion pumps are commonly used for temporally precise and effective inhibition of neural activity. The use of such optogenetic tools can potentially allow fast and reversible inhibition of defined projection pathways through illumination of presynaptic terminals. However, the use of optogenetic silencing tools in axonal terminals has not been mechanistically validated. We used two-photon imaging and whole-cell patch clamp recordings in cultured neurons and acute brain slices to evaluate the impact of optogenetic light-driven ion fluxes on the excitability and function of presynaptic terminals. Surprisingly, we found that extended (minutes-long) light-driven activation of a proton pump at presynaptic terminals can lead to accumulation of intracellular calcium and to an increase in synaptic vesicle release. The rate of miniature excitatory postsynaptic currents (mEPSC) increased six-fold within 3 minutes of proton pump activation using moderate light power (2 mW/mm^2), surpassing the average EPSC rate recorded in spontaneously active hippocampal neuron cultures nearly 2-fold. Removal of extracellular calcium during ion pump activation was sufficient to reduce the presynaptic calcium signal, reported by SyGCaMP6s, back to baseline levels. Whole-cell patch clamp recording in acute brain slices from mice transduced with eArch3.0-mCherry revealed an increase in EPSC rate after light application to axonal terminals originating from eArch3.0-expressing cells. These results stress the importance of understanding the unique impact of light-driven ion pumps on the physiology of the presynaptic compartment.

Title: Behavioral effects of partial unilateral optogenetic inhibition of the nigrostriatal pathway

Authors: *V. IYER[1], N. PATEL[1], K. VENKITESWARAN[1], E. HANDLY[1], N. IQBAL[1], C. WHITE[1], P. SRIDHAR[1], K. THIAGARAJAN[1], Z. LIU[2], C. RAMAKRISHNAN[3], K. DEISSEROTH[3], T. SUBRAMANIAN[1];
[1]Neurol. and Neural and Behavioral Sci., Pennsylvania State Univ. Col. of Med., Hershey, PA; [2]Electrical Engin., Pennsylvania State Univ., University Park, PA; [3]Bioengineering and Psychiatry, Stanford Univ., Stanford, CA

Abstract: A completely reversible animal model of Parkinson's disease (PD) that is specific to a single neural pathway may benefit our understanding of the pathophysiology of parkinsonism. To test this concept we assessed the effects of unilateral optogenetic inhibition of the nigrostriatal pathway in 18 adult rats. AAV2-Ef1a-mCherry-IRES-WGA-Cre was injected into the left striatum of 14 adult rats while 2 animals served as no virus controls. AAV5-Ef1a-DIO-eNpHR3.0-EYFP was then injected into both left and right substantia nigra (SN) or left SN alone in 11 of the WGA-Cre injected animals while the remaining 3 were WGA-Cre controls. Two animals received only eNpHR3.0-EYFP viral vector into both SN to serve as NpHR controls. Trans-synaptic retrograde transport of WGA-Cre allowed expression of the double floxed eNpHR 3.0 and EYFP and enabled specific targeting of nigrostriatal neurons. A 589 nm laser source and a tethered fiber optic system allowed awake animal behavioral assessments using a rodent behavioral battery of tests (RBBT) comprising the cylinder test, the elevated body swing test, the stepping test and the vibrissae evoked forelimb placement test. The animals were tested with laser intensities ranging from 1.5mW to 5mW. The duration of laser exposure varied from 30 seconds to several hours and was performed both intermittently and continuously. The RBBT was performed at time points ranging from 1 minute after laser exposure to 5 days post laser testing. Experiments were repeated multiple times and compared between pre-laser vs. laser exposure vs. post laser behavioral data on all RBBT tests. Histological examination completed in 9 animals showed excellent targeting and expression of mCherry in medium spiny neurons in the entire left striatum in animals that received WGA-Cre injections. The left SN in test animals showed complete labeling of all tyrosine hydroxylase (TH) positive neurons that project to the left striatum with EYFP and eNpHR. In the same animals the right SN showed a small percentage of interhemispheric neurons expressing EYFP and eNpHR. No EYFP or eNpHR expression was seen in control animals. These techniques allowed differentiation of extrastriatal projections of the SN from its striatal projections. The laser cannula was accurately positioned just above the SN. Remaining histology is ongoing. Our data provides proof of principle that specific Cre mediated eNpHR3.0 and EYFP expression can be achieved in all left SN neurons and all interhemispheric projections from the right SN neurons that make synaptic connections to the left striatum. It also demonstrates the technical feasibility of optogenetic inhibition of the nigrostriatal pathway in rats.

Title: Control of bladder function by optogentic modulation on membrane potential of smooth muscle

Authors: ***J. PARK**[1], J. JANG[1,2], J. HONG[1,3], H.-J. MOON[1], H. LEE[1], H. SHIN[1,3], J.-K. SUH[1]; [1]Korea Inst. of Sci. and Techonology, Seoul-City, Korea, Republic of; [2]Dept. of Electronics Engineering, Col. of Engin., Ewha Womans Univ., Seoul, Korea, Republic of; [3]Dept. of Biomed. Engin., Univ. of Sci. and Technol., Daejoen, Korea, Republic of

Abstract: The function of lower urinary tract which is regulated by a complex neural circuit with smooth and striated muscle is subject to be disrupted by various disease and injuries. Conventional treatments for lower urinary tract disorder (LUTD) such as pharmacological agents and electrical stimulation have a limitation in application, due to lack of spatial and temporal accuracy of the treatments. In this study, we show an approach that addresses the two issues of the treatments for LUTD by using optogenetics to modulate membrane potential of smooth muscle cells. Channelrhodopsin (ChR2) and halorhodopsin (Halo) were expressed in smooth muscle cells of mouse bladder through cre-loxp transgenic system. In order to test the feasibility of optogenetic modulation on bladder function, we set up a laser stimulation and pressure recording system for the whole bladder. Whole bladder connected to a pressure transducer via a polyethylene tube was submerged in carbonated (5% CO_2 and 95% O_2) physiological saline solution (pH 7.3~7.4) maintained at 37℃. Each of blue (473nm, ~1mW/mm^2) and yellow laser (589nm, ~3mW/mm^2) was uniformly illuminated to the bladder lumen using a spherical lens. We observed that ChR2 activation by blue illumination evoked bladder contraction and Halo activation by yellow illumination suppressed both electrically induced bladder contraction and

overactive bladder symptom induced by PGE_2 treatment (50μM). We first demonstrated that optogenetic control of membrane potential of smooth muscle cells can bi-directionally regulate bladder function. Considering a fine spatio-temporal resolution of our approach, the optogenetic modulation on bladder may be an effective strategy to restore bladder dysfunction.

Title: Immunological response to optogenetic laser stimulation of fetal ventral mesencephalic transplants

Authors: R. E. THOMAS[1], *K. VENKITESWARAN[1], E. HANDLEY[1], M. DAWSON[1], C. WHITE[1], A. HARRIS[1], A. STULL[1], C. RAMAKRISHNAN[2], K. DEISSEROTH[2], T. SUBRAMANIAN[1];
[1]Neurol & Neural & Behav Sci., Penn St Hershey Med. Ctr. & Col. Med., Hershey, PA; [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA

Abstract: Optogenetics can potentially be used for precise neuromodulation of central nervous system (CNS) grafts and to control any deleterious consequences of CNS transplants. One potential optogenetic method to precisely control CNS graft function is by the use of a dual vector system that requires graft host synaptic connectivity. We tested the effects of the dual vector system AAV2- Ef1a-mCherry-IRES-WGA-Cre and AAV5-Ef1a-DIO-eNpHR3.0-EYFP in CNS grafts. The WGA-Cre vector was injected to striatum of adult hemiparkinsonian rats and eNpHR3.0-EYFP vector was introduced into E13.5 mouse fetal ventral mesencephalic (mFVM) tissue prior to stereotactic transplantation into the left striatum. Control grafts did not receive any

viral vectors. All animals were treated with cyclosporine post transplantation for a 3-month period. Behavioral effects of these transplantation experiments have been previously reported (Subramanian, T., et. al., SfN Program 295.08/A29. 2014). Detailed histology was performed on all animals at the end of behavioral experiments. Excellent mCherry expression was seen in the entire left striatum indicating exceptional transduction of WGA-Cre vector. Excellent survival of mFVM grafts was also confirmed with TH immunohistochemistry and the cell survival of grafts was quantified using design based unbiased stereology. Graft host connectivity was confirmed by the presence of EYFP and eNpHR positive grafted neurons and in their newly formed axons making synaptic contact with mCherry positive medium spiny neurons in the host striatum. The immune response to these transplants were assessed immunohistochemically using antibodies against glial fibrillary acid protein (GFAP), Ox-42, a marker for activated rat microglia and Ox-6, a marker for MHC class II expression. Our results showed mild immune response as evidenced by GFAP positive activated astroglia, and Ox-42 and Ox-6 positive activated microglia in the vicinity of the grafts. The contralateral hemisphere, showed no expression of these immune markers indicating a mild localized immune response that did not negatively impact graft survival or maturation. Densitometry results showed no significant differences in immune response between control animals that did not receive any optogenetic viral vectors and test animals that received dual optogenetic viral vector exposure. Laser use in these animals also had no apparent negative immune response. These data provide support to the notion that optogenetic viral vectors can be safely used in CNS transplantation experiments and these methods can potentially have application in translational research for PD.
