Title: Ethanol consumption impacts adult neurogenesis in a sex, time, and region dependent manner as determined by genetic fate mapping

Authors: *E. L. MCGRATH, J. GAO, T. DUNN, B. S. KAPHALIA, K. T. DINELEY, K. A. CUNNINGHAM, P. WU;
UTMB, Galveston, TX

Abstract: Alcohol abuse is the third leading cause of preventable death in the United States, with more than 16.6 million adults over age 18 meeting the criteria for alcohol use disorders in 2013. It is well established that alcohol has detrimental effects on the brain and corresponds with deficits in cognitive and behavioral function. In many cases, damage incurred by long-term alcohol use is irreversible. Recently, alcohol has been shown to alter neural stem cells (NSCs) in the adult brain, however, little is known about how differences in brain region, sex, and duration of alcohol use can affect the response of NSCs. To better understand the full extent of these differences, we used an inducible transgenic mouse model to map the fate of adult endogenous NSCs following long-term alcohol treatment. Mice were ages 80-100 days at the start of the experiment and individually housed. They were fed a complete nutrient calorie-controlled liquid diet, which was measured daily, and were given *ad libitum* access to water. A subset of mice was harvested within the first two weeks and were used to evaluate the short term effects of alcohol use on NSCs. Short term was defined as maximum percent alcohol consumption for approximately 2 weeks or less, and long term treatment was defined as maximum percent alcohol consumption for greater than 3 weeks. At the experimental endpoint, mice were harvested and brain tissue underwent immunohistochemical staining, followed by confocal microscopy image analysis. We observed a distinct pattern of NSC behavior in the subventricular

zone of the lateral ventricle (SVZ), the sub-granular zone of the dentate gyrus (SGZ) and the tanycyte layer of the third ventricle (TL). Female mice display a significant decrease in NSC survival and neurogenesis over a shorter period of time in the SVZ when compared to male mice. In the TL, male mice exhibited a robust proliferation of NSCs with a unique morphological phenotype when consuming ethanol over a short period of time. This same effect was not seen in females. There was an increase in NSC proliferation and astrogliogensis in the SGZ following short and long term alcohol consumption in both male and female mice, which persisted through short-term into long-term consumption. We also observed that females tended to develop more severe symptoms, whereas males persisted with mild symptoms.

Title: ACE2 activity sustains serotonin levels that mediate the running-induced effect on adult neurogenesis

Authors: *F. C. KLEMPIN[1], M. BADER[1], R. SANTOS[2], N. ALENINA[1];
[1]Max-Delbruck-Centrum (MDC), Berlin, Germany; [2]UFMG, Belo Horizonte, Brazil

Abstract: Running is a strong external effector that induces precursor cell proliferation in the adult mouse hippocampus. We have recently established that serotonin is the signaling factor that transduces physical activity into adult neurogenesis. While direct pathways for serotonin activity in brain function is becoming understood, less focus has been given on many potential peripheral signals that may cause pro-mitotic running effect. The main system in the body that regulates cardiovascular homeostasis is the renin-angiotensin system (RAS). Here, we explore the effect of the acute running stimulus on adult neurogenesis in conditions of deregulated RAS. Specifically, we took advantage of mice with genetic deletion of the principle regulating enzyme of the RAS, angiotensin (Ang) - converting enzyme (ACE) 2, and the Ang-(1-7) receptor Mas, and measured proliferation and differentiation of dentate gyrus precursor cells. ACE2 controls the transition from Ang II signaling, which is vaso-constrictive and pro-inflammatory to that of Ang-(1-7),

which is vasodilatory and anti-inflammatory. Recent studies suggest an additional role for ACE2 as an amino acid transporter, facilitating the absorption of large dietary neutral amino acids in the gut. In ACE2-deficient mice impaired tryptophan (Trp) absorption has been described accompanied by decreased levels of Trp and serotonin in the blood and brain. Since L-Trp is the precursor of serotonin, ACE2 could indirectly modulate brain serotonin levels that are in turn known to affect adult neurogenesis. Indeed, we observed decreased brain serotonin levels and no increase in the number of BrdU-positive cells following physical exercise in ACE2-deficient mice. We demonstrate that experimentally increased levels of Trp and serotonin could not rescue the effect, and show how other components of the RAS such as the G-protein coupled receptor Mas maybe involved in central effects mediated by a local RAS. Our data identify ACE2 activity as a novel pathway that is serotonin-independent but required for exercise-dependent modulation of adult neurogenesis. These experiments will impact our understanding of the cardiovascular network and it's role in translating physical exercise with brain cell genesis.

Title: Expression and function of Sox Neuro in the development of the *Drosophila* adult nervous system

Authors: *S. SINGH, K. DAWSON-SCULLY, J. R. NAMBU;
Biol. Sci., Florida Atlantic Univ., Jupiter, FL

Abstract: The mammalian Sry gene, a sex determining Y chromosome was discovered in 1990 and encodes a transcription factor with single high mobility group DNA binding domain. More than 20 transcription factors in humans and 8 in *Drosophila* share a related HMG domain with at least 50% identity to that of Sry. These Sox (Sry box) proteins bind to the minor groove of DNA and induce 70° to 90° bends to regulate chromatin structure and transcription initiation. *Drosophila* possesses 4 highly related Group B Sox genes SoxNeuro, Dichaete, Sox21a and Sox21b. Previous study has shown that Dichaete has a strong role in development, affecting processes that include differentiation of specific neuronal and glial cells, segmentation, hindgut

development, differentiation of imaginal discs. Dichaete is expressed in several clusters of neurons in the brain, including intermingled olfactory LNs and central complex neurons and important for the elaboration of the adult olfactory system. SoxN function is important for the formation of neural progenitor cells in *Drosophila* and evidence suggests that loss of SoxN function results in defects in the neuroblast formation. Interestingly, both SoxN and Dichaete have region-specific functions in CNS development as they both regulate dorsal/ventral partitioning of the embryonic neuroectoderm into specific columns. Evidence also suggests that SoxN and Dichaete function in a redundant manner in neuroblast formation and other developmental processes including neuroectoderm formation, central nervous system development, and sensory trichome formation. However, little is known about the expression and function of SoxN in the adult brain. This study focuses on identifying the expression patterns and function of SoxN in the development of the adult nervous system. Our data shows SoxN is expressed both in neurons and glia of the adult central brain. SoxN expression overlaps with Dichaete in the adult central brain. We are currently determining the precise identity of SoxN brain expressing cells. The result of this study will lead to a better understanding of Sox gene functions in both conserved and specific aspects of development. Sox proteins have essential developmental functions in many species, including key roles in sex determination, segmentation, neural patterning, differentiation of neurons and glia, and formation of eyes, bone, cartilage, heart, and craniofacial structures. Furthermore, Sox gene mutations are associated with a wide array of human congenital disorders and cancer. Thus, these studies on *Drosophila* Sox genes may illuminate conserved developmental functions in mammals and are relevant for human health.

Title: Shedding light on serotonin in depression, and its linked role to adult neurogenesis

Authors: ***M. PETERMANN**[1], N. ALENINA[2], G. KRONENBERG[3], F. KLEMPIN[2];
[1]Max Delbrueck Ctr., Max Delbrueck Ctr. For Mol. Sci. In Helm, Berlin, Germany; [2]Max

Delbrueck Ctr. for Mol. Med., Berlin, Germany; [3]Dept. of Psychiatry and Psychotherapy, Charité - Univ. Med. Berlin, Berlin, Germany

Abstract: The fast progression of modern society is accompanied by a dreadful tribute - the risk to develop depression. Serotonin is well known as "molecule of happiness" and widely used in clinics. Yet, the neuromodulator is discussed to be the main target in major depression and studies into new mechanisms of antidepressants revived. By now, manipulation of serotonin is the preferred medical treatment with its flagship application of selective serotonin re-uptake inhibitors (SSRIs). However, not all patients respond to SSRIs, and SSR-enhancers (SSREs) attract clinical attention since it also improves the patient's mood. Yet, SSREs show inconsistency with the theory in that they decrease the availability of extracellular serotonin, a 'hypothesis' killer. Along with deregulation of central serotonin, a decline in hippocampal neurogenesis has been observed leading to depressive-like behavior. In turn, clinical improvement by antidepressant therapy goes along with a slow, temporal increase in adult neurogenesis. Whether antidepressant drugs act solely via manipulating serotonin levels it's on debate. In addition, drugs may affect other transmitter or brain functions. Recent studies even argue for placebo-mindset-changing actions. Current research is seeking to better define the mechanisms in the adult brain, and to target depression in more patients. We have recently developed a mouse model deficient in the central serotonin synthesizing enzyme tryptophan hydroxylase (TPH) 2 (Tph2-/- mice), and discovered no changes in baseline proliferation rates. Together with a second mouse model deficient in serotonin transporter (SERT mice), the supposedly main target for SSRIs, we tested antidepressant action in absence or altered serotonin signaling. The exciting genetic loss-of-function models are useful tools to unravel the underlying mechanisms of drugs targeting the serotonin system. The SSRI citalopram or fluoxetine, and the SSRE tianeptine were given over 21 days following BrdU injection to determine the effect on adult neurogenesis. Control wild type (WT) and littermates received no injection or were treated with saline solution. Our data confirm that chronic SSRI treatment increased the number of precursor cells in WT mice. Surprisingly, saline injection alone already increased BrdU-positive cells significantly in Tph2-/- mice, while no effect was observed in SERT animals compared to untreated Tph2-/-, and wild type groups, respectively. We further demonstrate distinct results following SSRE treatment. Our study sets an interesting point in depression research, and supports the development of alternative pathways other than via serotonin.

Title: The role of kainate receptors in regulating maturation of adult-born granule neurons

Authors: *Y. ZHU, A. CONTRACTOR;
Northwestern Univ., Chicago, IL

Abstract: The adult hippocampus generates continuous cohorts of newborn granule cells that undergo sequential neuronal maturation and incorporation into the existing network in the dentate gyrus. Increasing evidence has demonstrated that adult-born neurons in the dentate gyrus can impact numerous functions that involve learning and memory and other cognitive processes; therefore the mechanisms that regulate the maturation and synaptic integration of these neurons have been a subject of great interest. It is known that maturation of newborn neurons is dependent on neuronal activity and neurotransmitter signaling including both GABA and glutamate. Glutamate exerts its actions through both ionotropic and metabotropic receptors, and while there is evidence for some glutamate receptors affecting maturation and integration of newborn neurons, the role, if any, that the kainate receptor subfamily play in these processes is still unknown. However, it has been demonstrated that kainate receptors are present in neural progenitors harvested from the adult hippocampus, and kainic acid application induces an increase in cellular proliferation. Moreover, in the subventricular zone, kainate receptor activation decreases the migration speed of neuroblasts. Therefore, it is possible that kainate receptors may play a role in regulating newborn cell maturation in the dentate gyrus. In this study we employed retrovirus labeling of dividing neural progenitors to demonstrate that newly generated granule cells exhibited kainate receptor-mediated currents starting at 2-3 weeks. Comparison of the intrinsic properties of neurons from wild type and constitutive GluK2-/- mice, in which kainate receptor-mediated currents are completely eliminated, demonstrated that newborn neurons lacking GluK2 developed their mature-like intrinsic membrane properties at a faster rate than neurons recorded in littermate controls. A similar phenotype of accelerated maturation was also found in neurons subjected to retrovirus-mediated, conditional single cell deletion of the GluK2 subunit using a Cre recombinase dependent strategy. These data indicate that GluK2 signaling mediates a cell autonomous effect on inhibiting the development of mature intrinsic properties of adult-born neurons. Ongoing work is assessing how elimination of kainate receptors in newborn neurons affects the development of neuronal morphology and their integration into the hippocampal circuitry. Taken together these studies are beginning to reveal a novel role of kainate receptors in regulating neuronal maturation of adult-born granule cells in the hippocampus.

Title: The effect of intranasal manganese exposure on adult neurogenesis in the subventricular zone (svz)

Authors: ***V. LAI**[1], S. O'NEAL[1], W. ZHENG[2];
[2]Hlth. and Human Sci., [1]Zheng Lab., West Lafayette, IN

Abstract: Exposure to manganese (Mn) causes neurodegenerative manganism, with clinical signs and symptoms similar but not identical to idiopathic Parkinson's disease (IPD). In the healthy adult brain, neural stem/progenitor cells are produced in the subventricular zone (SVZ) and migrate towards the olfactory bulb (OB) along the rostral migratory stream (RMS). Cell migration following solvent exposure shows that these cells are capable of migrating to other areas of the brain in addition to the known destination of the OB. However, whether exposure to Mn, which is known to be mainly via the inhalation and accumulate in SVZ, causes any aberrant migration remained unknown. This study was designed to investigate the effect of intranasal Mn exposure on brain adult neurogenesis. Rats received intranasal instillations of 0.2 mg Mn/kg (low dose), 0.8 mg Mn/kg (high dose) as MnCl2, or equivalent volumes of saline (control), once daily for 14 days. During the last 4 days, animals received 100 mg BrdU/kg in order to label newly generated cells. Brain slices were then stained for BrdU and DCX, a marker of neuroblasts. Confocal quantification of BrdU signal in the selected regions of interest in the SVZ at 4x magnification revealed no significant differences between control (676.8± 260.9) and Mn treated groups; however, a significant difference between low dose (437.4 ± 168.8) and high dose (914.1 ± 371.2) groups was observed (n= 3-8; $p < 0.05$). Similar outcomes were also observed for DCX staining (243.1 ± 89.7 in the low-dose group vs. 463.2 ± 128.0 in the high dose group; n= 3-8; $p < 0.05$). In addition, BrdU signals were observed in the corpus callosum of three animals following intranasal Mn exposure. These data indicate that intranasal Mn exposure appears to alter the processes in the adult neurogenesis in SVZ and affect neural cell migration. Altered adult neurogenesis may contribute, at least partially, to the etiology of Mn-induced neurodegenerative disorder.

Title: Deletion of cohesin decreases adult neurogenesis in the subventricular zone

Authors: ***Y. FUJITA**, T. YAMASHITA;
Dept Mol Neurosci, Grad Sch. Med, Osaka Univ., Suita, Osaka, Japan

Abstract: Cohesin consists of four essential subunits, Smc1, Smc3, RAD21/Scc1 and Scc3. They hold sister chromatids together from the time of DNA replication to the onset of their segregation. This function is important for proper chromosomal segregation and DNA repair. These observations indicate that cohesin complex is essential for cell cycle progression and cellular proliferation. Loss of cohesin function results in 'cohesinopathies' such as Cornelia de Lange syndrome (CdLS). One of the major clinical features of CdLS is mental retardation, suggesting that cohesin has a crucial function in the central nervous system. Although cohesin function on chromosome segregation is studied intensively, its function in the central nervous system is poorly understood. To examine the function of cohesin in adult neurogenesis, we conducted loss of function analysis. We examined the consequences of deletion of cohesin function in the SVZ localized nestin-positive cells. We found that adult neurogenesis is inhibited when cohesin function is removed from the SVZ localized nestin-positive cells. Inhibition of cohesin function decreased the number of GFAP-positive cells and DCX-positive cells in subventricular zone. These results indicate that cohesin regulates adult neurogenesis in subventricular zone.

Title: The role of klotho in adult neurogenesis

Authors: *A. M. LASZCZYK, S. FOX, D. NETTLES, G. D. KING;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The age modulating protein klotho (KL) critically regulates pathways involved in both normal aging and disease pathogenesis. In mice, over-expression (KLOE) extends lifespan up to 30% while loss of protein expression in the knockout (KLKO) reduces lifespan 85%. KLKO mice exhibit rapid, premature onset of phenotypes typically associated with advanced human age including cognitive impairment. Brains of KLKO mice develop normally but hippocampal dependent cognitive impairment develops between the 6th and 7th week of life. New investigations reveal that increased KL expression enhances cognition. Reciprocal effects on cognition when KL expression level is up- or down- regulated validate the importance of KL brain function and suggest that KL plays an important role in the maintenance and/or function of hippocampal neurons. It remains unclear how KL acts to elicit these effects, however KL modulates signaling pathways in the periphery that are essential for neurogenesis. Age-related down-regulation of neurogenic signaling proteins results in decreased neurogenesis which contributes to cognitive decline; and we have identified altered performance in dentate-specific cognitive tasks in the KLKO. Thus, we hypothesize that KL regulates neurogenesis through modulation of neurogenic signaling pathways. We sought to determine how neurogenesis is modified by KL expression level, using KLKO and KLOE mice to identify which neurogenic cell populations are altered and how signaling pathway(s) in the neurogenic niche are modulated. Neuronal progenitor proliferation was assessed by Ki-67 immunohistochemistry (IHC) followed by stereological quantification. Changes in proliferation were detected dependent on level of KL expression. IHC for radial glia marker brain lipid binding protein identified changes to the number of stem cells. We examined doublecortin (DCX), in POMC-GFP/KLKO mice, as markers of early maturation and commitment to neural fate. IHC revealed that modulation of KL expression level affects maturation of immature neurons and profoundly alters both the number and the dendritic arborization of immature neurons. Investigations are ongoing to understand how maturation is changed by tracking cells from birth with 5-bromo-2-deoxyuridine (BrdU) to determine fate. Preliminary IHC for both BrdU and stage-specific markers support a maturation

deficit in the KLKO, suggesting new cells are capable of committing to the neuronal fate, but maturation is stalled before neurons fully mature. Studies are ongoing to examine the activity of several molecules in neurogenic signaling pathways to determine which pathways are modulated by KL.

Title: NGF regulates adult neurogenesis through a $p75^{NTR}$-ERK-miRNA-9 axis

Authors: ***J. SHI**, S. M. MASSA;
Dept. of Neurol., Dept. of Veterans Affairs Med. Ctr. and Univ. of California, San Francisco, CA

Abstract: Recent studies have suggested that loss or dysfunction of neuronal progenitor cells (NPCs) in the hippocampal dentate subgranular zone (SGZ) may contribute to post-traumatic memory deficits. We previously found that LM11A-31, a small-molecule non-peptide p75 neurotrophin receptor (NTR) modulator, which biases $p75^{NTR}$ signaling towards survival, mimicking NGF under some conditions, increased proliferation of polysialylated neural cell adhesion molecule (PSA-NCAM)-expressing cells, enhanced neurogenesis in the hippocampus, and improved spatial memory after traumatic brain injury in rats. Further, in hippocampal NPC cultures, NGF increased proliferation and differentiation, as well as survival and promoted $p75^{NTR}$-dependent PSA-NCAM expression in these cells (Shi *et al*. Stem Cells 2013; 31:2561-2574). To further investigate the mechanisms by which NGF promotes NPC proliferation and differentiation, we examined the roles of factors that have been implicated in the control of NPC growing, including extracellular-signal-regulated kinases (ERK1/2) and miRNA-9. With lentivirus-mediated over-expression of miRNA-9 and antisense miRNA-9 in NPC, we found that enforced miRNA-9 expression decreased the growth rate of NPC and PSA-NCAM-expressing cells *in vitro*. Antisense miRNA-9 increased the growth rate of NPC, beginning after several passages. Our studies have revealed relationships between miRNA-9 and NGF in the growth of NPC cells--NGF down-regulated miRNA-9 by up to 1000-fold and this was partially reversed by $p75^{NTR}$ antibody. Concordant with its effects on NPCs, NGF increased levels of phosphorylation

of ERK1/2 by up to ~80% compared to vehicle control, and the increase is blocked by a $p75^{NTR}$ N-terminal antibody. In contrast, brain-derived neurotrophic factor (BDNF) had no effect on ERK1/2 phosphorylation, but $p75^{NTR}$Ab together with BDNF increased phosphorylation as well as total expression of ERK1/2. Interestingly, *in vivo*, TBI increased miRNA-9 expression in SGZ PSA-NCAM-expressing cells and LM11A-31 partially reversed these effects, decreasing miRNA-9 expression. Together, these findings suggest that NGF may regulate the proliferation and differentiation of NPC cells through a p75NTR-ERK-miRNA-9 axis.

Title: Exogenous factors induce rod- and cone-specific progenitors from adult retinal stem cells

Authors: ***B. G. BALLIOS**[1], S. KHALILI[1], K. GRISÉ[1], L. DONALDSON[2], G. BERNIER[3], V. A. WALLACE[1], D. VAN DER KOOY[1];
[1]Univ. Toronto, Toronto, ON, Canada; [2]McMaster Univ., Hamilton, ON, Canada; [3]Maisonneuve-Rosemont Hospital, Ctr. de recherché, Univ. de Montréal, Montréal, QC, Canada

Abstract: Adult retinal stem cell (RSCs) derived from the ciliary epithelium (CE) of mice can give rise to all retinal cell types. Taurine, retinoic acid and FGF2/heparin (T+RA+FH) added to differentiating clonal RSC colonies increases the number of rods to 90% of all progeny. RSC progeny produce 10% rods when differentiated in 1%FBS+FH (pan-retinal conditions). We hypothesized that exogenous factors act on RSC progeny in an instructive, rather than permissive, manner to bias photoreceptor differentiation through the enrichment of photoreceptor lineage-specific progenitors. RSCs were clonally isolated from the CE of 4-6 week old mice. We used limiting dilutions (<1 clone / well) of a fluorescent retroviral construct to label individual

progenitor clones *in vitro*. Clonal retroviral labeling revealed enrichment in the percentage of rod-only clones between 1%FBS (13%) to T/RA (over 70%), without affecting clone size or overall cell survival. This strongly argues against selective survival of rod progenitors or differential survival of post-mitotic rods within a clone. Single cell sorting by fluorescence-activated cell sorting (FACS) for side-scatter intensity allowed isolation of non-pigmented and pigmented cells in wells, which were then treated for 28 d. Survival, clone size, and phenotype were assessed by immunocytochemistry. In 1%FBS, clones derived from single non-pigmented progenitors were distributed between non-rod and mixed clones, with a minority of rod-only clones (100% Rhodopsin-positive; n=4 of 28 clones). Clones derived from pigmented cells in 1%FBS never gave rise to rod-only clones. In T+RA conditions, all clones from non-pigmented progenitors (n=34) were rod-only clones, while those from pigmented progenitors (n=47 of 48) were almost all no-rod clones. Of note, one rod-only clone (the largest) was derived from a single pigmented cell in T+RA, suggesting potential neural lineage plasticity in a very early, pigmented progenitor. Survival rates of non-pigmented cell derived clones were similar in T+RA and 1%FBS. Similar experiments using Wnt, BMP4 and TGFβ inhibition increases the number of RSC-derived cones to >60% of all progeny. We have used similar clonal analysis to isolate cone-specific proliferative progenitors (100% cone arrestin+), as well as cone-specific reporter mice to purify populations of RSC-derived cones by FACS. This study marks an important step in the characterization of photoreceptor-specific progenitors - no markers exist and literature is divided on their existence *in vivo*. Our study suggests a critical role for exogenous signals instructing early lineage decisions between fate-restricted retinal progenitors.

Title: Effect of Aβ oligomers in adult mouse hippocampal neural precursor cells (NPCs)

Authors: M. SILVA-LUCERO[1], *M. CARDENAS-AGUAYO[1], G. RAMIREZ-RODRIGUEZ[2], M. MERAZ-RIOS[1];

[1]CINVESTAV-IPN, Mexico, Mexico; [2]Div. of Clin. Investigations, Natl. Inst. of Psychiatry "Ramón de la Fuente Muñiz", Mexico, Mexico

Abstract: Amyloid beta (Aβ) peptide is a product of Amyloid Precursor Protein (APP) processing, that is in low abundance and it is produced lifelong in the healthy brain. It is produced by sequential action of a β and a γ-secretase on APP, generating a sequence of 39 to 43 amino acids. Aβ40 and Aβ42 are composed for 40 and 42 amino acids, respectively; and they represent the majority peptides of Aβ found in plasma, cerebrospinal fluid and senile plaques. The functional properties of Aβ peptides to date have not been completely elucidated, although a number of studies suggest that the peptides have a number of neurotrophic and neurotoxic properties. Physiologically low concentrations of Aβ could play a key role in regulating synaptic plasticity and improving cognitive functions, however the accumulation of high concentrations of Aβ, combined with the effects of age, could cause dysregulation and loss of synaptic function, which is one of the characteristics of Alzheimer's disease. Neurogenesis is an active and dynamic process that involves the proliferation, migration and maturation of new neurons. This process is tightly regulated by several factors such as the niche, neurotransmitters, growth factors and hormones. Several studies suggest that Aβ peptides are involved in the process of neurogenesis, however the results are controversial. All existing data indicate a direct relationship between the physicochemical characteristics of the peptides and their effects. Here we evaluated the effect of Aβ oligomers on hippocampal neurogenesis. To this end we perform the characterization of Aβ oligomers 42 and 40 through atomic force microscopy and Western blotting (4G8 Antibody). NPCs isolated from the hippocampal dentate gyrus of adult rodents, were treated for 24, 48 and 72 hours with different concentrations of oligomeric forms obtained by Klein's protocol (2002) (Aβ 1-40 and 1-42), then evaluate the effect on viability (LDH Kit), proliferation (BrdU labeling) and the expression of differentiation markers: glial markers (GFAP) and neuronal markers (βIII-Tubulin). We found significant increase on cell viability in NPCs treated with oligomers Aβ40 (at 0.5, 1 and 5 μM) at 72 hours, however there was no effect on proliferation in NPCs treated neither with Aβ40 nor Aβ42 oligomers. Regarding differentiation markers, we found an increased expression of GFAP and βIII-Tubulin markers for cells that were treated with Aβ40. We conclude that Aβ could have an effect on NPCs survival, because it increases cell viability but not proliferation. Furthermore Aβ40 might be favoring neuronal differentiation.

Title: Global transcriptomic analysis of compensatory response to genetic perturbation of the notch signaling pathway

Authors: *A. HALLERAN, C. RATNAYAKE, C. GOLINO, B. RABE, M. MCDONOUGH, M. SAHA;
Col. of William and Mary, Williamsburg, VA

Abstract: As an organism progresses through development it encounters chemical, physical, environmental, and genetic stressors that it must overcome in order to develop appropriately. While the molecular mechanisms that govern normal embryonic development are relatively well understood, comparatively little is known about how embryos respond to perturbations over the course of development. However, knowledge of this process is critical for unraveling the embryonic origins of adult disease and for understanding the unique plasticity of embryonic tissues. Conserved across all metazoans, the Notch pathway is a juxtacrine signaling pathway that establishes a balance between differentiated and progenitor neural cells during neurogenesis. Overexpression of Notch signaling at the two-cell stage of Xenopus laevis embryos results in a severely reduced NBT expression phenotype by the early tailbud stage. However, as development progresses to the swimming tadpole stage, NBT expression approaches control levels. Through global transcriptome analysis of Xenopus laevis embryos in which Notch signaling was mis-expressed at the two-cell stage, we have identified potential regulators of this observed embryonic compensation.

Title: Regulation of Ptf1a to generate a balanced neural network in the spinal cord

Authors: ***B. MONA**, J. M. AVILA, D. M. MEREDITH, J. E. JOHNSON;
Neurosci., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Generating the correct balance of inhibitory and excitatory neurons in a neural network is essential for normal functioning of a nervous system. The neural network in the dorsal spinal cord functions in somatosensation where it modulates and relays sensory information from the periphery. PTF1A is a transcription factor expressed in a subset of neural progenitor cells that specifies an inhibitory neuronal fate while suppressing the excitatory neuronal fate in the dorsal spinal cord as well as in the cerebellum and retina. Thus, the regulation of Ptf1a expression is critical for determining mechanisms controlling neuronal diversity in these regions of the nervous system. We have identified multiple regulatory sequences in the Ptf1a gene locus that have distinct functions in directing Ptf1a expression. A highly conserved 2.3 kb auto-regulatory enhancer is present 13.4 kb upstream of the Ptf1a coding region that activates transcription in all Ptf1a expressing domains. A 1.2 kb enhancer located 11.2 kb 3' of the Ptf1a coding region is sufficient to direct expression to the chick and mouse dorsal neural tube. Activity of this 1.2 kb enhancer depends on the integrity of a sequence motif that matches the consensus binding site for a Paired - homeodomain family transcription factor. Furthermore, through bioinformatic analysis and subsequent experimentation, SOX3 was also found to regulate the 1.2 kb enhancer activity. Thus, multiple enhancer elements responding to a combination of transcription factors direct Ptf1a-domain expression. By mutating these motifs in mouse, individually and in combination using the CRISPR-Cas9 system, the *in vivo* contribution of these regulatory elements for Ptf1a expression and function in regulating the balance of inhibitory and excitatory neurons in the nervous system is being tested.

Title: Dual function of suppressor-of-fused in cortical progenitors during mammalian corticogenesis

Authors: *O. R. YABUT[1], K. YOON[2], G. FERNANDEZ[1], T. HUYNH[1], S. J. PLEASURE[1]; [1]Neurol., Univ. of California, San Francisco, San Francisco, CA; [2]Col. of Biotech. and Bioengineering, Sungkyunkwan Univ., Suwon, Gyeonggi-do, Korea, Republic of

Abstract: Cortical progenitors in the embryonic neocortex are tightly regulated to generate the correct number and subtypes of projection neurons that populate the mature mammalian neocortex. In our study, we found that the intracellular protein, Suppressor of Fused (Sufu), plays dual roles during corticogenesis to regulate the specification and proliferation of cortical progenitors at different timepoints. Conditional deletion of Sufu in cortical progenitors at early stages of corticogenesis (E10.5) result in the ectopic activation of Sonic Hedgehog (Shh) signaling leading to the abnormal specification of Pax6+ and Tbr2+ progenitors and the progressive loss of Tbr2+ progenitors as corticogenesis progressed. These defects result in the loss of upper layer projection neurons and the abnormal specification of the remaining projection neurons in the postnatal neocortex. In contrast, conditional deletion of Sufu at mid-corticogenesis (E13.5) does not disrupt the specification of cortical progenitors and the projection neurons they generate. Rather, our preliminary studies indicate that loss of Sufu primarily cause an increase in cortical progenitor proliferation, particularly the Tbr2+ population, and appears to be independent of Shh signaling activity. Collectively, our findings indicate that Sufu regulates cortical progenitor fate specification at early stages and proliferation at later stages of corticogenesis. The diverse role of Sufu is likely due to significant molecular changes in cortical progenitors as corticogenesis progress. Thus, our findings prompt the need to further dissect the spatial and temporal genetic changes in cortical progenitors to determine how specific molecular networks control fate specification and proliferation during the course of cortical development.

Title: Assessing the septal contribution to olfactory bulb interneuron diversity and the role of Gsx2 in septal progenitors

Authors: *S. QIN[1], H. CHAPMAN[3], S. M. WARE[4], R. R. WACLAW[2,1], K. CAMPBELL[1]; [1]Developmental Biol., [2]Exptl. Hematology and Cancer Biol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Dept. of Cell Biol. and Human Anat., Univ. of California, Davis, Davis, CA; [4]Pediatrics and Med. and Mol. Genet., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Earlier studies have shown lateral ganglionic eminence (LGE) progenitors generate a number of distinct neural cell types, including olfactory bulb (OB) interneurons. OB interneurons are thought to originate from the dorsal LGE (dLGE) and septum starting at embryonic time points. These cells migrate rostrally toward the OB, where they radially migrate to populate the different layers including the granule cell layer (GCL) and the glomerular layer (GL). Although some studies have attempted to investigate the contributions of dLGE versus septum to the OB interneuron subtypes, no genetic tool has been used to address this question. In this study, we utilize Zic3-LacZ BAC transgene, which is highly enriched in the septal ventricular zone (VZ) progenitor cells and serves as a short-term fate map of their OB derivatives. We find that β-galactosidase-positive septal progenitor cells give rise to a subpopulation of OB interneurons that express Sp8 and Calretinin (CR) but not Calbindin or TH, largely within the GL. The homeobox gene Gsx2 is expressed in VZ progenitors of the developing ventral telencephalon, including the LGE and septum. While a number of studies have examined the role of this factor in LGE progenitors, its function in septal progenitors remains unclear. To address this, we conditionally inactivated Gsx2 in the septum, leaving it largely intact in the dLGE progenitors, by recombining the Gsx2-floxed allele with Olig2-cre. Our results indicate that conditional inactivation of Gsx2 in the septum, results in impaired generation of Sp8-positive neuroblasts as well as reduced cell proliferation within the septal subventricular zone (SVZ). Accordingly, we observed decreased numbers of septum-derived (i.e. β-galactosidase-positive) Sp8- and CR-expressing OB interneurons within the GL. In summary, our results support the notions that septum (already at embryonic stages) is an important source of Sp8- and CR-expressing OB interneurons in the GL. Moreover, we show that Gsx2 is required within septal progenitors for the normal formation of the septal SVZ and subsequent generation of septum-derived Sp8- and CR-expressing OB interneurons.

Title: CoREST1 and CoREST2 express in primary culture of midbrain dopaminergic neurons

Authors: M. GONZÁLEZ, L. A. PEREIRA, *M. E. ANDRES;
Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: CoREST is a family of transcriptional co-repressors formed by CoREST1 (CoREST, RCOR1), CoREST2 (RCOR2) and CoREST3 (RCOR3). The CoREST proteins form part of a transcriptional regulator complex, also comprising the histone demethylase LSD1/ KDM1A and the histone deacetylases 1 and 2 (HDAC1/2), here referred as the LCH complex. A variety of transcription factors interacts with members of CoREST family to bring the LCH complex to repress target genes during differentiation, regulatory and pathological processes. Recent work has given evidence that CoREST1 regulates the expression of genes of the dopamine neuronal phenotype during development. For instance, it was shown that CoREST1 binds to the promoters of tyrosine hydroxylase (TH) and dopamine transporter (DAT) genes. Through this interaction, CoREST1 maintains repressive epigenetic features and lower transcription of these genes, during dopamine neurons development. We have wondered whether CoREST2 and CoREST3 play a role in dopamine phenotype acquisition and maintenance in adulthood. Previously, we showed that the 3 CoRESTs express widely in adult rat brain. Here, we have extended the study of CoRESTs expression to cultured mesencephalic cells to learn whether all CoRESTs express in dopamine neurons during *in vitro* maturation. Cultured mesencephalic cells, obtained from rat embryonic day 14-18th were maintained during different length periods until 14 days *in vitro*. After fixing, the cells were incubated with specific antibodies against CoREST1, CoREST2 and TH. The results show that CoREST1 and CoREST2 express in all TH-positive cells during *in vitro* maturation. In addition, the data show that the expression of both CoRESTs decreases during maturation, suggesting that both CoREST1 and CoREST2 play a role in dopamine neuronal maturation. Title: Ets factors regulate neural stem cell depletion and gliogenesis in perinatal development and glioma

Authors: H. PARK[1], R. LEVY[1], C. ANTONUK[1], J. MOLINA[1], M. DUTRA-CLARKE[1], A. AKHTAR[1], G. KIM[1], X. HU[2], S. BANNYKH[1], R. VERHAAK[2], M. DANIELPOUR[1], *J. J. BREUNIG[1];
[1]Regenerative Med. Inst., Cedars-Sinai Hosp., West Hollywood, CA; [2]MD Anderson, Houston, TX

Abstract: As the list of putative driver mutations in glioma grows, we are just beginning to elucidate the combined effects of unhinged signaling pathways on the transformation of CNS cells. We have created a mosaic, autochthonous, glioma model that captures the first hours and days of gliomagenesis in more resolution than conventional genetically engineered mouse models of cancer (GEMMs). We provide evidence that disruption of the Nf1-Ras pathway in the VZ compartment at multiple signaling nodes uniformly results in rapid NSC depletion, progenitor hyperproliferation, and gliogenic lineage restriction. Abrogation of Ets subfamily activity, which is upregulated downstream of Ras, rescues these phenotypes and blocks glioma initiation. Further, we demonstrate the influence of Ets factors on early cell fate decisions of NSCs in normal perinatal brain. Thus, the Nf1-Ras-Ets axis might be one of the select molecular pathways that is hijacked for initiation and maintenance in glioma.

Title: Understanding the role of Prdm13 in dorsal interneuron specification

Authors: *A. URUENA[1], J. CHANG[1], M. BORROMEO[1], R. KOLLIPARA[1], R. HAMMER[2], J. JOHNSON[1];
[1]Neurosci., [2]Biochem., UT Southwestern Med. Ctr., Dallas, TX

Abstract: After neural tube closure, there is an important stage of neurogenesis that is essential for producing the correct classes of neuronal populations. PTF1A is a transcription factor transiently expressed as neural progenitor cells become post-mitotic and begin to express neuronal specific gene programs. PTF1A specifies these cells to become GABAergic neurons (inhibitory neurons) while suppressing the glutamatergic neuronal program (excitatory neurons). A fundamental principle in bipotential cell fate decisions is the necessity to repress gene programs in the alternative fate. Recently, our lab identified PRDM13, a zinc finger containing transcription factor, as a direct downstream target of PTF1A that may serve this function in the inhibitory/excitatory neuron fate choice. Overexpression of PRDM13 in chick neural tube shows PRDM13 does indeed repress markers of the excitatory neuronal lineage. To explore PRDM13 function in more depth *in vivo*, and to expand these findings to regions outside the neural tube, a Prdm13GFP mutant mouse strain was generated that inserts a GFP coding region followed by a STOP codon. Prdm13GFP/GFP mice die neonatally, and at E10.5 show an increase in the dorsal neural tube excitatory neuron population at the expense of the inhibitory neurons. These phenotypes recapitulate that seen with Ptf1a null mice, and PRDM13 overexpression in chick neural tube. The Prdm13GFP mice have revealed additional insights into the function of PRDM13 and cell fate decisions in the developing spinal cord. First, PRDM13 negatively feedback regulates Ptf1a providing a mechanism for downregulating PTF1A as development progresses. Second, in contrast to the phenotype seen with Ptf1a mutants, late stage Prdm13 mutant embryos show only a partial loss of the inhibitory interneuron population, possibly due to the increased levels of PTF1A in these mutants. And finally, ChIP-Seq and RNA-Seq analysis of heterozygote versus homozygote Prdm13 mutants show that an important function of PRDM13 is to keep neuronal subtype specification genes for the ventral neural tube suppressed in the dorsal neural tube. Overall, this mouse model has placed PRDM13 in a pivotal role in the

specification of neuronal subtypes in the spinal cord, a function that will likely extend to the retina and cerebellum where PRDM13 is also present.

Abstract: In the developing vertebrate nervous system, neural stem cells generate neurons first and then glia (astrocytes). The timing of this cell fate switch is regulated by interplay of intrinsic and extrinsic cues. We focused on the key issue of how progenitors are restricted from making glia during the neurogenic period. A previous study from our lab reported that LIM-homeodomain transcription factor Lhx2 is necessary and sufficient to suppress astrogliogenesis in the embryonic hippocampus (Subramanian et al., 2011). Loss of Lhx2 produces astrocytes from progenitors that would otherwise produce neurons. Overexpression of Lhx2 prolongs neurogenesis to generate neurons from progenitors that would otherwise give rise to astrocytes. The mechanism of this regulation remains unknown. We hypothesized that Lhx2 may regulate this switch by directly binding to and activating or repressing genes in neurogenic and/or gliogenic pathways. We analyzed genome-wide occupancy of Lhx2 by performing ChIP-seq using embryonic hippocampal tissue to identify potential Lhx2 target genes. We have identified

genes involved in progenitor proliferation, neurogenesis and gliogenesis. Ongoing work is focused on validating potential target genes using multiple approaches.

Title: Genetic interactions of Lhx2, Pax6 and Foxg1 in early the patterning of telencephalic domains

Authors: *G. GODBOLE[1], A. SHETTY[2], B. CHEN[3], G. MIYOSHI[4], G. FISHELL[4], S. TOLE[1]; [1]DBS, TIFR, Mumbai, India; [2]Harvard Univ. Dept. of Stem Cell and Regenerative Biol., Harvard Univ. Dept. of Stem Cell and Regenerative Biol., Cambridge, MA; [3]Molecular, Cell and Developmental Biol., Univ. of California Santacruz, California, CA; [4]Dept. of Physiol. and Neuroscience,, NYU Neurosci. Institute, NYU Langone Med. Ctr., New York City, NY

Abstract: The early telencephalic neuroepithelium consists of the cortical primordium flanked by two non-cortical structures, the hem medially, and the antihem laterally (Grove et al 1998, Assimacopoulos et al 2003). Three transcription factors act as early regulators of telencephalic patterning and control the formation of these structures: LIM-homeodomain family member Lhx2; winged helix factor Foxg1; paired domain and homeodomain containing factor Pax6. Both Foxg1 and Lhx2 supress hem fate (Muzio and Mallamaci 2005, Mangale et al 2008). Lhx2 also suppresses antihem fate (Mangale et al 2008), whereas Pax6 is necessary for antihem formation (Assimacopoulos et al 2003). When Lhx2 function is disrupted, the cortical neuroepithelium taken on hem and antihem identity, as a result of which these two structures expand in the *Lhx2* mutant (Mangale et al 2008). We asked whether Pax6 is required for the expanded antihem in the *Lhx2* mutant. Furthermore, we tested whether Lhx2 and Foxg1 interact to restrict the hem to its

normal location. Finally, using *CreER* and low dose tamoxifen, we examined the critical period for each of these factors in regulating hem and antihem fate. Our results reveal interesting interactions between these three early regulators of dorsal telencephalic patterning, underscoring their importance in the development of the cortical primordium.

Title: Decoding subpallial neuronal diversity by single cell transcriptomic profiling

Authors: ***J. SYMMANK**[1], D. PENSOLD[1], N. HAAG[2], G. SALINAS-RIESTER[3], T. LINGNER[3], C. POMMERENKE[3], F. LUDEWIG[3], T. PIELER[3], G. ZIMMER[1];
[1]Inst. for Human Genet., [2]Inst. for Biochem. I, Univ. Hosp. Jena, Jena, Germany; [3]Dept. of Developmental Biochem., Univ. of Goettingen, Goettingen, Germany

Abstract: Most of the neuronal diversity in the mature telencephalon derives from progenitor cells of the subpallium giving rise to the astonishing variety of cells destined for the globus pallidus, septum, olfactory bulb, amygdala, striatum, hippocampus and the cerebral cortex. Despite a certain spatial and temporal bias regarding the generation of particular neuronal subtypes fated for the diverse destinations, most subpallial subdivisions like the medial and lateral ganglionic eminences (MGE and LGE), the caudoventral MGE (cvMGE), different regions of the preoptic area (POA) and septal anlagen represent mosaic structures contemporaneously generating various neuronal subpopulations. For the MGE and LGE molecular differences vastly correlate with the morphological appearance. In turn, subdivisions located ventrally of the MGE including pallidal septal domains, the cvMGE and the POA are partly continuous merging into each other. Moreover, the cvMGE, which is considered as a particular sub-domain, shares expression profiles with the MGE (like Lhx6 and Nkx2.1) as well as with septal subdivisions (Garcia-Lopez 2008). Similarly, the POA shares common features with septal and cvMGE-related tissue like Nkx2.1 expression (Flames et al., 2007). This complicates the exact demarcation of the different domains and the research on the fate of the

particular subdivisions. Additionally, the preoptic area consist of several subdomains like the POC, POB and lateral POA, which are suggested to distinctively give rise to certain neuronal subsets (Buspesh et al., 2011). The insufficient demarcation of the different domains complicates the research on the fate of the particular subdivisions. For this, we aimed to profile neuronal subsets generated in the POA and find candidate biomarker discriminating POA-derived cells from AEP and septal derivates by applying Nanostring nCounter based single cell transcriptome analysis.

Title: Nato3 is sufficient to drive Lmx1b expression in the developing neural tube

Authors: **N. HUISINGH**[1], D. MARTINEZ[2], J. STRAIGHT[2], *M. K. TAYLOR[3]; [1]Biomed. Sci., [2]Cell and Mol. Biol., Grand Valley State Univ., Allendale, MI; [3]Biomed. Sci., Grand Valley State Univ., Grand Rapids, MI

Abstract: The developing chick embryo has multiple organizing centers which are important for the correct development of the neural tube. Nato3 is a bHLH transcription factor that is endogenously expressed in one of these, the floor plate region. This region also gives rise to dopaminergic neurons which are affected in Parkinson's disease through the coordinated expression of multiple transcription factors, including Lmx1b. Nato3 has a broad and not fully understood role in the proliferation and differentiation of stem cells in the neural tube. Here, we show that overexpression of Nato3 promotes Lmx1b expression in the neural tube. Nato3 was transfected using in ovo electroporation and monitored using a bicistronic EGFP reporter expression vector and the observed effects were characterized using immunohistochemistry. These data demonstrate that Nato3 can drive Lmx1b expression in the neural tube.

Title: A NanoString-based single cell approach for transcriptomic profiling of embryonic interneuron subtypes

Authors: *D. PENSOLD[1], J. SYMMANK[1], N. HAAG[2], G. SALINAS-RIESTER[3], T. LINGNER[3], C. POMMERENKE[3], F. LUDEWIG[3], T. PIELER[3], G. ZIMMER[1];
[1]Inst. for Human Genet., [2]Inst. for Biochem. I, Univ. Hosp. Jena, Jena, Germany; [3]Dept. of Developmental Biochem., Univ. of Goettingen, Goettingen, Germany

Abstract: The inhibitory actions of GABAergic cortical interneurons are crucial for proper cerebral information processing and impairments in interneuron development contribute to the pathophysiology of neuropsychiatric disorders like epilepsy, autism and schizophrenia. As the reversal of disrupted molecular deficits of neurodevelopmental disorders restores proper function even by treatments in adults, decoding determinants of interneurons maturation holds great promise for therapy strategies. The interneuron generating tissue represent a mosaic, contemporaneously generating various neuronal subtypes destined for several brain regions. This requires single cell resolution to decode the transcriptional control of cortical interneuron diversity and development. Single cell transcriptome analysis presupposes the availability of robust, quantitative methods, combining the suitability for analysis of even low copy number transcripts with the processing of larger sample sizes in a short time. Here, we applied the direct and sensitive NanoString nCounter technology to establish and validate an improved PCR-based strategy for quantitative and qualitative global single cell transcriptome analysis, enabling multiple analytical runs. We were able to profile distinct progenitor and postmitotic subpopulations from the interneuron generating medial ganglionic eminence (MGE). We further found new candidate for MGE-derived neuronal subsets. The identification of such lineage-specific/defining molecular markers is crucial for fate-mapping studies of distinct interneuron subpopulations.

Abstract: Midbrain dopaminergic (mDA) neurons represent a heterogeneous pool of neurons that differ in their projection pattern, connectivity to target areas, synaptic inputs and outputs that impact on their function. Here, we report the identification and characterisation of a novel subset of mDA neurons of the VTA that expresses the basic helix-loop-helix transcription factor, neurogenic differentiation factor-6 (NeuroD6). By combining a *Cre* knock-in strategy and a loss-of-function approach in mice, we have characterised this mDA neuronal subset at late embryonic, early-postnatal and adult stages showing that they form a subset of the Calbindin$^+$ and Raldh1a$^+$ mDA subpopulation of the VTA. NeuroD6$^+$ mDA neurons are localised specifically in the interfasicular nucleus (IFN), dorsal and ventral paranigral nucleus (PN) and the lateral parabrachial nucleus (PBP) of the medial VTA. In NeuroD6 mutants, 32% of the total NeuroD6-expressing mDA cells are lost within the medial VTA due to cell death as shown by TUNEL analysis. Furthermore, retrograde tracing experiments using fluorogold injected into the septum have demonstrated that NeuroD6-expressing mDA neurons specifically project to two distinct septal regions, the dorsal lateral septum (LSD) and intermediate lateral septum (LSI). In the absence of NeuroD6, specific loss of mDA axonal projections occurs within the LSI, while, axon projections of mDA neurons to the LSD remain unaffected in NeuroD6 mutants. Altogether, our results demonstrate that NeuroD6 labels a unique population of mDA neurons projecting to the LSD and LSI, but is only required for the survival of the latter neurons.

Title: Comparison of the effects of mouse, chick and human nato3, a bhlh transcription factor, on floor plate marker expression in the developing neural tube

Authors: *D. DOYLE, N. HUISINGH, S. DURHAM, M. TAYLOR;
Grand Valley State Univ., Allendale, MI

Abstract: The Nato3 transcription factor from *Gallus gallus* has a unique sequence of 20 amino acids in its N-terminal domain when compared to highly conserved Nato3 sequences from seven other species. Due to this difference there may be unique effects from the *Gallus gallus* Nato3 as compared to the other species. In order to characterize differences between Nato3 from different species in the developing neural tube, we overexpressed Nato3 from *Mus musculus*, and did not see an upregulation of HNF3β, as reported with Nato3 from *Gallus gallus*. Currently we are testing the overexpression of Nato3 from the *Gallus gallus* and *Homo sapiens* to directly compare the effects of Nato3 from multiple different species.

Title: Epigenetic mechanisms in midbrain development

Authors: *H. V. HEESBEEN, M. P. SMIDT;
Mol. Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Keywords: midbrain development, histone modification, epigenetics Brain development depends on specifically regulated gene-expression and cases of neurodevelopmental disorders have been related to epigenetic aberrations. Genome wide expression profiling in time has shown that specific components of histone methylation complexes are temporary up-regulated during neuronal terminal differentiation and not equally distributed in the brain. In order to understand this epigenetic control in midbrain development we have developed a set of tools to pinpoint the consequences of altered histone methylation. These tools allow ablation of one specific histone mark in time during midbrain development *in vivo*. Initial analysis of the corresponding histone mark indicates that maintenance of this mark is essential through active methylation events even without a known demethylase. Moreover, our initial results indicate a role for histone methylation in regulating specific neurodevelopmental features, including neuronal outgrowth.

Title: A novel role played by Mecp2 during early neocortical progenitors proliferation and differentiation

Authors: *C. COBOLLI GIGLI[1], F. BEDOGNI[1], L. SCARAMUZZA[1], R. ROSSI[2], C. KILSTRUP-NIELSEN[3], N. LANDSBERGER[1];
[1]Neurosci., San Raffaele Hosp., Milano, Italy; [2]Inst. Nazionale Genetica Molecolare "Romeo ed Enrica Invernizzi", Milan, Italy; [3]Univ. of Insubria, Varese, Italy

Abstract: Mutations in the X-linked Mecp2 gene cause the autism spectrum disorder Rett syndrome (RTT). RTT affected children experience a first phase of apparently normal development lasting 6-18 months, followed by a rapid regression after which RTT typical traits (autistic features, seizures, ataxia and stereotypical hand movements) become evident. Given the timing of RTT onset, most of the studies in the field investigated the role of Mecp2 in maturity, roughly considering the embryonic development phase normal. However, different evidences of

the presence of subtle symptoms already at birth have been recently produced, suggesting a possible role for Mecp2 even during the earliest phases of development. Starting from these observations, we investigated the consequences of lack of Mecp2 on the embryonic development of the cerebral cortex at E15, when cortical progenitors are still proliferating giving rise to other progenitors and neurons. First of all we highlighted that Mecp2 in the developing cortex is expressed not only by post-mitotic neurons, as previously demonstrated, but also by cycling progenitors. Moreover, a role for Mecp2 in cycling cells is strongly suggested by the fact that its absence alters different pathways related to cell cycle, as demonstrated by our transcriptional analysis on embryonic cortexes. Interestingly, we show that the proliferation of Mecp2 null progenitors cultivated *in vitro* is impaired as well as their post mitotic output. Given these evidences we analyzed the *in vivo* dynamics balancing apical (Pax6 positive) and basal progenitors (Tbr2 positive): our experiments show that the identity of the two populations is not properly defined in the Mecp2 null samples. Our data demonstrate that lack of Mecp2 affects the development of the cerebral cortex from early stages never so far analyzed in deep details. We therefore suggest that the etiopathogenesis of RTT includes early stages of development during which Mecp2 plays a role that precedes its documented involvement in maintenance of mature neuronal systems later in life.

Title: The role of Gsx2:Ascl1 protein-protein interactions on progenitor maturation in lateral ganglionic eminence (LGE) progenitors of the mouse

Authors: *K. ROYCHOUDHURY, M. NAKAFUKU, B. GEBELEIN, K. CAMPBELL; Developmental Biol., Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Homeobox and basic helix loop helix (bHLH) transcription factors play critical roles in Progenitor maintenance vs differentiation in the ventricular and subventricular zones of the embryonic telencephalon. Within progenitors of the lateral ganglionic eminence (LGE), Gsx2

helps maintain progenitors in an undifferentiated state while Ascl1 plays an important role in progenitor maturation and neurogenesis. In an effort to characterize the molecular mechanisms underlying progenitor maturation in the LGE, we studied the protein-protein interactions of Gsx2. We found that Gsx2 and Ascl1 directly interact with each other at the protein level in a yeast 2-hybrid assay and in the embryonic mouse telencephalon. Using proximity ligation techniques, we have identified a population of ventricular zone progenitors in the LGE where Ascl1 and Gsx2 directly interact, *in situ*. We mapped the interaction domains on each of these proteins and found that a region C-terminal of Gsx2's homeodomain interacts with amino acid residues in the second helix of the bHLH domain of Ascl1. This interaction with Gsx2 inhibits Ascl1's ability to bind the E-box sequence in EMSAs. Moreover, this interaction inhibits heterodimerization of Ascl1 with E-proteins that are critical for its transcriptional activity. We are currently studying the effects of deleting Gsx2 in Ascl1-expressing LGE cells (using Ascl1-creER) on progenitor maturation. Moreover, we plan to use single cell RNAseq techniques to analyze the transcriptome of LGE progenitors that either co-express Gsx2 and Ascl1 or only express one of these genes, to identify distinct downstream effectors of these factors within the LGE lineage.

Title: miRNA-pseudogenes interactions as a regulator of neural stem cell pluripotency and a target for ethanol teratogenesis

Authors: N. SALEM, S. BALARAMAN, R. HOLGATE, E. RAYMOND, *R. C. MIRANDA; Neurosci. & Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr, Col. of Med., Bryan, TX

Abstract: Fetal alcohol exposure is a leading non-genetic cause of neurodevelopmental disability. Neural stem cells (NSCs) that give rise to most neurons of the adult brain during the

first and second trimester are particularly vulnerable. We previously found that ethanol exposure did not result in NSC death, but rather, the loss of NSCs due to premature maturation. Moreover, we found that a class of small non-protein-coding regulatory microRNAs (miRNAs) was decreased following ethanol exposure. We recently found that the loss of miRNAs result in expression of a network of genes that support premature NSC maturation. However, the question that remains is whether ethanol also specifically prevents NSC renewal by interfering with miRNA-regulated processes. To address this question, we assessed the regulation of the homeobox transcription factor, Oct4/POU5F1, which is important for maintaining stem cell renewal and pluripotency. The Oct4 family includes a number of transcribed non-protein coding pseudogenes. We hypothesized that these pseudogenes serve as miRNA sponges. Immuno-precipitation studies with the miRNA binding protein, Ago-2, showed that several Oct4 pseudogenes bind miRNAs in both the nucleus and cytoplasm of NSCs, supporting their role as miRNA sponges. Ethanol exposure resulted in a decrease in expression of Ago2-binding pseudogene transcripts and also decreased expression of Oct4 mRNA and protein. These data suggest that pseudogenes-miRNAs interaction may protect pluripotency factors and facilitate NSC renewal. These data also advance a novel mechanism for ethanol teratology in that ethanol exposure may disrupt long non-coding RNA (lncRNA)-mediated protection resulting in miRNA-mediated loss of renewal capacity in fetal NSCs.

Title: A role for NOTCH pathway in the specification of glial precursors during hindbrain development

Authors: *M. S. DOMOWICZ, M. MCGOVERN, J. G. HENRY, D. SANTANA, D. VAVAL, N. B. SCHWARTZ;
Pediatrics, Univ. of Chicago, Chicago, IL

Abstract: After neurogenesis in the developing brain, radial glial cells (RGCs) have the potential to differentiate into the astrocytes or oligodendrocytes, but our knowledge of the signaling pathways governing this decision *in vivo* are limited. We study the influence of the NOTCH pathway in regulating the gliogenic fate of RGCs in an embryonic-day-8 chick hindbrain slice culture preparation in which astrocytes differentiate and migrate in a manner similar to *in vivo* timing and patterning. Inhibition of the NOTCH pathway with inhibitors of γ-secretase, DAPT or RO4929097, induces up-regulation of the oligodendrocyte marker proteolipid protein (PLP) mRNA in areas where the astrocyte precursors migrate, suggesting a switch from astrocytic to oligodendrocytic fate. In order to confirm this possibility, we analyzed a battery of astrocyte and oligodendrocyte markers by *in situ* hybridization and real-time qPCR and followed the morphological changes of RGCs over time after DAPT treatment. The level and distribution of SOX2, a marker of stem cells was not altered by inhibition of the NOTCH pathway. mRNA levels for GFAP, a marker of mature astrocytes, SOX9 and aggrecan, markers of astrocyte precursors, decreased in a DAPT-concentration-dependent manner. Using qPCR, the oligodendrocyte precursors markers PDGFRα and OLIG2, as well as MBP, a marker of mature oligodendrocytes, were up-regulated by DAPT treatment. Furthermore, after following the migration and morphology changes of RGCs labeled by transient transfection with a green fluorescent protein vector, an increase in ectopically localized oligodendrocyte-like cells in cultures treated with DAPT was observed. Taken together, these results indicate that NOTCH activation is required for RGCs commitment to the astrocytic fate and that inhibition of the NOTCH pathway in RGCs change their commitment towards the oligodendrocyte fate.

Title: Gas1 is present in the germinal niches of the developing dentate gyrus and cortex

Authors: *E. ESTUDILLO, P. ZAVALA, G. PEREZ-SANCHEZ, A. AYALA-SARMIENTO, J. SEGOVIA-VILA;
CINVESTAV, MEXICO CITY, Mexico

Abstract: Gas1 is a pleiotropic protein that inhibits tumor growth when overexpressed but during development acts as a co-receptor for sonic hedgehog to promote proliferation and survival of different developing organs and systems. Gas1 has been extensively studied during development in the cerebellum, however in other structures of the central nervous system the information is limited to *in situ* hybridization studies. We provide information about the pattern expression of Gas1 during different developmental stages of the cortex and dentate gyrus of the mouse. The levels of Gas1 decrease in the developing brain as mice grow and it is mainly in progenitor cells during the development of cortex and the dentate gyrus.

Title: Neurog2 and Ascl1 play a key role in development of mouse ventromedial hypothalamus

Authors: *S. ASLAN POUR KAL BOLANDI[1], G. WILKINSON[2], C. SCHUURMANS[2], D. M. KURRASCH[1];
[1]Neurosci., [2]Biochem. & Mol. Biol., Univ. of Calgary, Calgary, AB, Canada

Abstract: The hypothalamus is a small but powerful region of the brain that plays a key role in maintaining overall physiological homoeostasis. Despite this important role, the molecular programs that drive hypothalamic development are just starting to be explored. The ventromedial hypothalamus (VMH) is a hypothalamic nucleus important for controlling satiety and reproductive behaviours, and has been shown previously to require the proneural gene *Neurogenin 3* for proper neuronal terminal differentiation. Here, we asked whether other proneural genes, namely *Achaete-scute homolog1* (*Ascl1)* and *Neurogenin2 (Neurog2)* might also play a key role in VMH development, given their importance in specifying cortical neurons and that they are also expressed in hypothalamic progenitors. To investigate more fully the expression pattern of these genes in the embryonic hypothalamus, we conducted *In situ* Hybridization (ISH) assays on the brains of wild type (WT) mice at different embryonic stages from e10.5 to P0, a period that encompasses VMH development. Our results revealed that *Ascl1*

and *Neurog2* have distinct spatiotemporal expression profiles, suggesting that different proneural genes might play a role in establishing hypothalamic neuronal identities during development. Next, using *Neurog2*$^{-/-}$ and *Ascl1*$^{-/-}$ mice, we investigated whether loss of *Neurog2* and *Ascl1* affects VMH cell fate decisions. Specifically we immunostained *Neurog2*$^{-/-}$ and *Ascl1*$^{-/-}$ brain slices during VMH neuronal migration (e.g., e15.5-e16.5) and in the mature VMH nucleus (e17.5-P0). Our results demonstrate that while *Neurog2*-null mice at e15.5 lose cell-specific markers within the central and ventrolateral domains of the VMH nuclear structure, *Ascl1*-null mice at e16.5 lose marker expression complementarily within the dorsomedial and some of the central domains. In both *Neurog2*- and *Ascl1*-null neonatal (P0) animals, however, a significant decrease in overall VMH-positive neurons is observed throughout the entire nucleus regardless of subdomain localization. Lastly in *Neurog2*$^{-/-}$*;Ascl1*$^{-/-}$ double knock out mice at e17.5, expression of VMH markers in both the dorsomedial and central domains were lost while ventrolateral markers domain showed only a slight decrease in the number of VMH-positive cells. This phenotype was much severe compared to single knock out at e17.5. In conclusion, here we showed that *Neurog2* and *Ascl1* are necessary for proper VMH development.

Title: Increased dosage of DYRK1A enhances STAT activity and astrocytic differentiation of neocortical progenitors in a mouse model of Down's syndrome

Authors: *N. KURABAYASHI, K. SANADA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Down's syndrome (DS) occurs in approximately 1 in 700 live births and is caused by trisomy for human chromosome 21. The disorder is characterized by abnormalities in

neurological, skeletal, cardiovascular and immunological systems. Particularly, individuals with DS commonly exhibit mental retardation, which is associated with anomalies in brain development such as reduced neuronal production and increased astrocyte generation. Accumulating evidence suggests that differentiation of neural progenitors is deregulated in DS brains, and the deregulation contributes to brain developmental defect. Nevertheless, the molecular basis underlying the deregulation of progenitor cell fate decisions, particularly enhanced production of astrocytes in DS, is poorly understood. In this study, we demonstrate that differentiation of neocortical progenitors into astrocytes is enhanced by DYRK1A, a Ser/Thr kinase encoded on human chromosome 21. In the Ts1Cje mouse model of DS, overexpression of DYRK1A augments the propensity of progenitors to differentiate into astrocytes. We also found that increased dosage of DYRK1A is linked to deregulation of STAT, a transcription factor critical for astrogliogenesis. Overexpression of DYRK1A in wild-type progenitors increases STAT3 phosphorylation at Ser727, a regulatory site that enhances STAT3 activity. In addition, the STAT transcriptional activity is elevated upon increased dosage of DYRK1A in progenitors. On the other hand, STAT3 Ser727 phosphorylation and STAT activity are elevated in Ts1Cje progenitors and downregulating DYRK1A expression attenuates the deregulation of STAT. In sum, our work indicate that potentiation of the DYRK1A-STAT pathway in progenitors contributes to aberrant astrogliogenesis in DS.

Title: An assessment of the requirements for the Fgf receptor substrate (FRS) genes during early telencephalon development

Authors: ***S. NANDI**[1], G. GUTIN[1], N. KAMATKAR[1], K. W. LEE[2], F. WANG[3], G. FISHELL[4], M. GOLDFARB[2], J. M. HEBERT[1];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Hunter Col., NY, NY; [3]Texas A&M Hlth. Sci. Ctr., Houston, TX; [4]NYU Langone Med. Ctr., NY, NY

Abstract: FGF signaling is critical for forebrain development. Two FGF receptor substrate (FRS) proteins, FRS2 and FRS3, were proposed to play important roles in directly tranducing signal from the FGF receptors. However, their specific contributions in mediating FGF-dependent processes during early telencephalon development are unknown. Here, using a loss of function (LOF) approach we demonstrate that Frs3 is dispensable and that FRS2 protein is compensatorily upregulated in embryonic telencephalon of Frs3 mutants. In contrast, Frs3 is unable to fully compensate for the loss of Frs2 function during early telencephalon development. Moreover, we observe that Frs2 and Frs3 are together required for activation of MAPK and CREB1 in neural stem/progenitor cells and for differentiation of MGE neurons. We also propose that the Frs genes in contrast to their roles in stem/progenitor cells, may play an inhibitory role in CREB1 activation in the earliest-born neurons in a MAPK-dependent or -independent manner. Our LOF studies involving Fgf receptor 1 (Fgfr1) and Frs genes, together with analyses of Fgfr1 mutants with a deletion in the FRS-binding site of the FGFR1 further highlight a role for FRS proteins as primary if not the only modules of signal transduction downstream of FGFR1 during early telencephalon development. Thus our study demonstrates essential roles for FRS proteins relevant to FGF signaling *in vivo*. Since Foxg1-Cre-driven loss of three Fgfr (Fgfr1, Fgfr2 & Fgfr3) genes leads to a complete absence of telencephalon and that telencephalon although reduced in size is still present in the Frs2 and Frs3 double mutant, raise the possibility that FGF signaling in early telencephalon is mediated by non-FRS dependent mechanisms primarily involving FGFR2 & FGFR3.

Title: Identification of gene regulatory networks in cone development

Authors: *T. ELISEEVA[1], J. A. BRZEZINSKI[1], K. JONES[2], K. PARK[1];
[1]Ophthalmology, Univ. of Colorado Denver, Aurora, CO; [2]Biochem. and Mol. Genet., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Humans depend on their color-sensitive cone photoreceptors for high visual acuity. Loss of these photoreceptors in disease can result in blindness. It has been difficult to study cone development because they make up a small percentage of retinal cells in rodent and primate models and form asynchronously over an extended period. Treatment of cultured embryonic (E) day 14.5 mouse retinas with the Notch inhibitor DAPT causes progenitors to synchronously form a cone-dominant retina by two days of treatment. To identify the genes responsible for cone development, we used RNA-seq to compare the transcriptomes of DAPT-treated retinas with their control counterparts at several time-points between 6 and 48 hours of treatment. Our setup yielded over 20 million yields per sample on average. Statistical analysis reveals hundreds of differentially expressed genes between the treatment groups and how they change over time as the retinal cells become more cone-like. This dataset provides a valuable tool for studying the gene regulatory events that govern cone development. In addition, this technique will reveal early cone-specific markers that will help us evaluate early fate choice events in cone genesis, which are largely unknown.

Sch. of Med. and Hlth. Sci., Washington DC, DC

Abstract: After neural tube closure, amniotic fluid (AF) captured inside the neural tube forms the nascent cerebrospinal fluid (CSF). Stem cells of the neural plate contact CSF-filled ventricles, proliferate and differentiate to form the mammalian brain. Using *in vivo* ultrasound imaging, we quantified the dynamic expansion of the ventricular-CSF space from its time of inception. We then developed tools to obtain pure AF and nascent CSF, before and after neural tube closure. Using quantitative proteomics, we define how the AF and CSF proteomes diverge during the course of mouse development. Using embryonic neural explants, we demonstrate that age-matched fluids promote Sox2-positive neurogenic identity in the developing forebrain and olfactory epithelia. Nascent CSF also stimulates Sox2-positive self-renewal of forebrain progenitor cells, akin to LIF-mediated signaling. Taken together, our comprehensive proteomic resource should enable new approaches for the investigation of fluid-tissue interactions during this understudied, yet highly vulnerable stage of early brain development.

Abstract: The mammalian cerebral cortex is a remarkably complex structure, and establishment of cortical neural circuitries requires its unique laminar organization during neuronal migration. Accordingly, disruption in neural migration can lead to brain malformations with functional consequences on proper wiring of the neuronal network, as already described in neurodevelopmental disorders such as Autism Spectrum Disorders (ASD). Common knowledge indicates cell-adhesion molecules (CAMs) as essential for proper neural migration. Neuronal growth regulator 1 (Negr1) is a cell adhesion molecule, and NEGR1 gene mutations have been recently associated to autism spectrum disorders (ASD). So far, nothing is known about Negr1 function in *in vivo* neurodevelopment. By *in utero* electroporation coupled with RNA interference (siRNA), we downregulated Negr1 expression in late-born pyramidal neurons migrating to the superficial layers of the neocortex. We found that Negr1 siRNA caused ectopic positioning of neurons concentrated at the border between layer 5 and layer 4 in the somatosensory cortex. Downregulation of Negr1 did not cause migration defects in the motor or prefrontal cortices. Moreover, we found that FGFR2 and its partner NCAM physically interact with Negr1 to activate ERK signaling. Interestingly, downregulation of FGFR2 and NCAM *in utero* resulted in a strikingly similar phenotype on neuronal migration, as found for Negr1, but defective morphological maturation presented different characteristics in Negr1, FGFR2 or NCAM downregulated neurons. Accordingly, overexpression of FGFR2 as well as pharmacological activation of ERK signaling rescued the effect Negr1-downregulation on migration, but not on morphological maturation. In agreement with association of Negr1, FGFR2 and ERK signaling to autism, we found that downregulation of Negr1 or FGFR2 in the embryonic somatosensory cortex resulted in decreased number and complexity of ultrasound vocalizations in pups and that overexpression of FGFR2 as well as pharmacological activation of ERK signaling rescued the ultrasonic vocalization upon Negr1 downregulation. Finally, we further confirmed the above findings in Negr1 knock out mice, which showed defective cortical layering and reduced ultrasonic vocalizations. These data suggest that Negr1/FGFR2 complex is necessary for proper neuronal migration of pyramidal neurons in the somatosensory cortex and indicate a possible role for defective Negr1/FGFR2/ERK signaling and related migration impairment in autism.

Title: Reelin, ephs and ephrins: neuronal migration or synaptic plasticity?

Authors: *T. POHLKAMP[1], X. XIAN[1], L. XIAO[2], R. SULTANA[2], H. H. BOCK[6], M. HENKEMEYER[2], J. HERZ[1,3,4,5];

Ctr., Dallas, TX; [6]Clin. for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

Abstract: The greatest risk factor for Alzheimer's Disease (AD) today is advancing age and as life expectancy increases so does the number of new cases. The pathogenesis of AD is not well understood, nor is there a cure or effective treatment available. There is increasing evidence that the extracellular signaling protein Reelin as well as the cell-cell interaction receptors EphB/ephrin-B play important roles in the onset of AD. In addition to its important function in cortical layer formation during brain development, in the adult brain, Reelin by binding to lipoprotein receptors modulates synaptic functions and delays Aβ deposition, the hallmark feature of AD. Also EphB/ephrin-B signaling is protective against Aβ fibril formation and like Reelin acts on NMDA receptor signaling. Recently our lab and others found that Reelin can signal through a common complex containing EphB/ephrin-B and ApoE receptors (Senturk et al., 2011, Nature; Bouche et al., 2013, Cell Res), but the function of their interplay remains unclear. In contrast to published data (Senturk et al., 2011) we show that this interplay is not effective for radial pyramidal neuron migration during neocortical development. By using several techniques (NeuN, TBR1, and BRN1 immunoreactivity, Nissl, DAPI staining,

distribution of Thy1-GFP neurons) we examined knockout mice deficient in all three ephrin-B ligands (Efnb1;2;3-/-) or three EphB receptors (Ephb1;2;3-/-) as well as Ephb2-/-;Reln+/- and Efnb3-/-;Reln+/- compound mutant mice for layer malformation. We could not confirm the reported overmigration phenotype or any striking cortical layer malformations for Efnb1;2;3-/- and Efnb3-/-;Reln+/-. Reelin signaling induces Dab1 turnover, consequently in reeler mice Dab1 levels are elevated, which was not true for any of the mutants we analyzed, and serves as evidence that ephrin-Bs are not essential for canonical Reelin signaling. Understanding the interaction between Reelin and EphB/ephrin-B signaling will innovate targeted strategies to combat AD. In future studies we aim to understand how these signaling molecules interact in the complex machinery that controls synaptic function and how they influence the aging brain.

Title: Wnt signaling regulates multipolar-to-bipolar transition of migrating neurons in the cerebral cortex

Authors: *R. BOCCHI, M. BOITARD, K. EGERVARI, V. PETRENKO, B. VIALE, S. GREMAUD, E. ZGRAGGEN, P. SALMON, J. Z. KISS;
Dept. of Neurosciences - Fac. of Med., Geneva, Switzerland

Abstract: Radial migration of newborn excitatory neurons in the developing neocortex is a complex multistep process that is precisely regulated in space and time. It includes multipolar migration, multipolar-to-bipolar transition, radial glia-guided locomotion and terminal somal translocation. Increasing evidence suggests that different transition steps are regulated by distinct signaling pathways and mutations as well as deregulation of these molecular pathways could result in migration disorders. While it has been speculated that Wnt signaling might control neuronal migration, its direct role remains to be established. Using video time-lapse imaging and

reporter constructs for Wnt canonical and non-canonical signaling cascades, we now show that dynamically regulated activity states of canonical Wnt/ß-catenin as well as non-canonical signaling during specific migratory phases are crucial for proper polarization and migration of late generated pyramidal neurons. Transient down-regulation of canonical Wnt/ß-catenin signaling activity appears to be required for the proper transition of pyramidal precursors from multipolar into bipolar state. We found that time-dependent regulation of Wnt5A-mediated non-canonical signaling reduces canonical Wnt signaling in a cell-autonomous manner during the multipolar-to-bipolar transition. Down-regulation of canonical Wnt signaling by Wnt5A allows cells to express ephrin-B1, thereby enabling polarization and initiation of glia-guided locomotion. These findings highlight the role of a crosstalk between the Wnt5A/non-canonical and Wnt/ß-catenin signaling pathways in regulating pyramidal cell migration via multipolar-to-bipolar transition.

Title: Spontaneous neurodevelopmental malformations in rats and mice are visible with magnetic resonance histology

Authors: *R. L. RAMOS;
Biomed. Sci., NYIT-COM, Old Westbury, NY

Abstract: Several strains of mice and rats exhibit spontaneous neurodevelopmental malformations of the neocortex and/or cerebellum due to deficits in neuronal migration during pre- and postnatal periods, respectively. Several factors complicate the study of the development, anatomy, and physiology of malformations including: 1] malformations are not identifiable a priori in the living animal or *in situ*, 2] histological conformation of malformations is time- and labor-intensive, 3] histological analyses introduce limitations to quantitative descriptions of malformations such as a poor estimates of size, volume, spatial and areal extent, and 3D morphology. Therefore, methods to identify malformations *in vivo* or *in situ* would open new avenues to research associated with malformations. Using archival imaging data from the Duke University Center for *In vivo* Microscopy (an NIH/NIBIB Biomedical Technology Resource

Center - P41 EB015897), I will demonstrate that spontaneous neurodevelopmental malformations are visible in both mice and rats *in situ* with magnetic resonance histology. Moreover, several imaging modalities were found to be compatible for identifying malformations including T1, T2, and diffusion tensor imaging. The implications of these data will be discussed as well as the possible applications of magnetic resonance histology in the study of brain development and neuronal migration disorders in mouse models.

Title: Sp9 regulates MGE-derived cortical interneuron development

Authors: *Z. LIU, Y. YOU, Q. LIANG, Z. YANG;
Fudan Univ., Shanghai, China

Abstract: Interneurons in mammalian cortical structures (neocortex, hippocampus and olfactory bulb) are mainly generated from subcortical ganglionic eminence including medial, lateral and caudal ganglionic eminence (MGE, LGE and CGE). Here we explore the roles of the zinc finger transcription factor Sp9 in regulating neocortical interneuron development. We show that Sp9 is widely expressed in the MGE, LGE and CGE progenitors and postmitotic cells. Fate mapping studies using Sp9-Cre knockin mice suggest that virtually all cortical GABAergic interneurons are derived from Sp9-expressing cells. In Sp9 mutant embryos, MGE-derived interneurons tangentially migrate to the cortex, but exhibit defects in populating the marginal zone and superficial parts of the cortical plate. In P21 Sp9 mutant cortex, ~50% of MGE-derived cortical interneurons are lost, whereas CGE-derived cortical interneurons are mildly increased. RNA-Seq and ChIP-Seq experiments provide evidences that Sp9 mediates these effects in the MGE mainly through promoting expression of Lhx6 that regulates interneuron migration and through inhibiting the expression of Sox6 that is also controlling cortical interneuron development.

Title: Injectable biomaterials alter progenitor cell migration and inflammation after injury to the young adult brain

Authors: *R. MOTALLEB[1], E. J. BERNS[2], S. I. STUPP[3], G. H. KUHN[1];
[1]Neurosci. and Physiol., Goeteborg, Sweden; [2]Dept. of Biomed. Engin., Chicago, IL; [3]Dept. of Materials Sci. and Engineering. Dept. of Chemistry. Dept. of Med. and Inst. for BioNanotechnology in Med., Chicago, IL

Abstract: The regenerative capacity of the adult brain is insufficient when stroke or brain trauma occurs even though there is a proliferating population of neural stem cells capable of regenerating damaged tissue. However, the combination of stem cell research and biomaterials opens up new possibilities for regenerative medicine. Endogenous neuroblasts migrate from the subventricular zone along the rostral migratory stream (RMS) to the olfactory bulb, but as insult occurs to the brain, these cells can change path and migrate to the injured area, although not to the extent needed. By redirecting these cells we hope to increase the population of neural stem cells that reach the affected area and hence repopulate and regenerate the damaged tissue. Here we utilize a self-assembling peptide amphiphile (PA) with a Tenascin-C epitope to redirect the migration of endogenous neuroblasts from the rostral migratory stream to the cortex. Stereotactic injections of PA were performed in the RMS of young adult rats as the syringe is retracted, creating a tract of PA to the cortex. The PA material will polymerize forming nanotubular structure upon injection into the brain due to contact with Ca2+. PA is biodegradable lasting up to 4 weeks *in vivo*. Preliminary results show that the peptide amphiphile does not elicit an increased astrocytes or microglia response compared to the saline/vehicle injected controls. Neuroblasts (DCX+) are able to infiltrate the biomaterial and migrate to the cortex one week post-injection. Our results indicate that migrating neuroblasts can be redirected using an injectable biomaterial, which in turn can increase the number of neuroblasts reaching the damaged tissue. Injury also elicits an immune response resulting in scar tissue and inflammation, therefore we analyzed the effect of PA with the fibronectin-derived epitope RGDS on neuroinflammation using the same setup as previously described. Immunostaining shows significantly lower cell density for GFAP+ and Iba-1+ cells surrounding the needle tract after RGDS PA injection compared to vehicle. Intensity measurements using GFAP, Iba-1 and CD68

also show a significantly lower activation of astrocytes and microglia/macrophages up to 100 μm bordering the lesion site compared to vehicle, indicating a reduced glial scar and a smaller inflammatory response.

Title: Rapamycin can prevent, but not reverse, aberrant migration of pten knockout neurons

Authors: *S. A. GETZ[1], T. DESPENZA, Jr[2], M. LI[1], B. W. LUIKART[1];
[1]Geisel Sch. of Med. At Dartmouth, Lebanon, NH; [2]Icahn Sch. of Med. at Mount Sinai, New York City, NY

Abstract: The PI3K/Akt/mTor pathway is important in cell growth, survival and proliferation. Phosphatase and tensin homolog (PTEN) is a major negative regulator of that pathway through the dephosphorylation step of PIP3 into PIP2. *PTEN* mutations have been found in a subset of individuals with Autism and macrocephaly. To examine whether Pten knockout (KO) in granule neurons alters their migration, fluorescent protein linked cre- and non cre-expressing retroviruses were co-injected into the hippocampal dentate gyrus of *Pten* $^{Flox/Flox}$ mice at postnatal day 7. Animals were sacrificed at various days post-injection (DPI) to reveal Pten KO granule cell neurons migrate significantly further from the hilus compared to wild-type controls beginning at 12.5 DPI and remaining that way every timepoint thereafter. To test whether the migration phenotype could be prevented or reversed, we administered daily intraperitoneal injections (IP) of Rapamycin, an mTorC1 inhibitor. The preventative group received Rapamycin from 3-14 DPI, when the enhanced migratory phenotype of Pten KO neurons is being established. The reversal group received Rapamycin from 14-24 DPI, after the enhanced migratory phenotype has been established. Soma size and migration analysis reveals that Rapamycin can prevent and reverse somal hypertrophy seen in Pten KO neurons, but it can only prevent but not reverse the

enhanced migration of Pten KO neurons. This may have implications for the clinical use of Rapamycin in treating *PTEN*-mutation associated diseases.

Abstract: In this study we aimed to investigate the effect of ethanol exposure on the development of the GABAergic system in the telencephalon. We administered ethanol (2g/Kg) using a gavages cannula to pregnant swiss mice between E11 and E14. At E13, we collected blood to measure plasmatic concentrations at specific time points after ethanol gavages. At E14, animals were sacrificed, embryos removed and dissected. Brains were used for immunohistochemistry (GABA), western Blot (GAD65/67), or labeling for TUNEL. Some litters were kept after delivery and tested in the open field. Our results indicated that serum blood reached a pick (120±10mg/dl) after 1h and decreased until 3h. Roughly we did not identify macroscopic modifications, such as excencephaly or anencephaly. Quantification of the immunohistochemistry for GABA showed a decrease manly at the lateral ganglionic eminence (LGE), but no significant alterations in the medial ganglionic eminence (MGE) or in the developing cortical plate. We also found a significant increase in the GAD65/67 expression at the LGE but not in the MGE or in the cortex. In contrast, TUNEL labeling revealed a significant raise in the rate of neuronal death in the cortex and in the hippocampal anlagen. In the behavioral test no modification in animal's exploratory behavior was identified. We conclude that 2g/Kg ethanol during a short period at this specific developmental lag does not lead to significant alterations in the cortical GABAergic system, but leads to mild increase in GABA and GAD expression in the proliferative zones of the basal telencephalon and to cell death in the dorsal telencephalon.

Title: Cell migration of pituitary adenoma cells on collagen type I-III

Authors: ***D. AVILA**[1], A. ORTIZ-PLATA[2], C. SOLANO-AGAMA[1], M.-E. MENDOZA-GARRIDO[1];
[1]Ctr. For Res. and Advanced Studies, Mexico City, Mexico; [2]Natl. Inst. of Neurol. and Neurosurg., Mexico City, Mexico

Abstract: During the tumoral progression the composition and biomechanical properties of the extracellular matrix (ECM) are modified, and it influence the cells behavior, for example regulating the cell migration. In the pituitary adenomas it has been observed an up-regulation of ECM proteins; a higher deposition of fibrillary type I collagen was observed, particularly in invasive macroadenomas. Little is known about the regulatory mechanism of cell migration in pituitary adenomas. It has been suggested that the remodeling of collagen fibers in the pituitary capsule are important factors in the infiltration of the cavernous sinus by pituitary adenoma cells. The objective is to characterize the cell migration pattern that pituitary adenoma cells present on a mixture of type I and type III collagen. Using a rat derived pituitary adenoma cell line (GH3 cell line) we analyze the cell migration pattern that adenoma cells adopt on collagen type I-III, in a two-dimensional system, employing a pharmacological approach we also analyzed the participation of the myosin light chain kinase (MLCK) and Rho-associated protein kinase (ROCK) in the arrangement of the actin cytoskeleton, in the localization of the myosin light chain (MLC) phosphorylation and finally in the regulation of cell migration. GH3 cells present a rounded-shape with a cortical actin belt arrangement with small blebs. MLCK inhibition blocked MLC phosphorylation at the cell substrate level but not at the cell periphery. MLCK-inhibited cells migrate 3.7 times more distance and 3.6 times faster, without showing persistence in the migration direction. Meanwhile, ROCK inhibition blocked the MLC phosphorylation at the cell periphery but not at the substrate level. ROCK-inhibited cells present an elongated-shape with a 0.5 times more spreading, and a decrement of 1.6 times the distance and the migration velocity.

In summary, our results suggest that these two kinases perform two different functions in cell migration, MLCK controls cell spreading and directionality in the movement and ROCK controls the rounded-shape and increases the net cell translocation.

Title: ADP-ribosylation factor 6 controls the transition of migrating neurons from intermediate zone to cortical plate

Authors: *Y. HARA, H. SAKAGAMI;
Dept. of Anat., Kitasato Univ. Sch. of Med., Sagamihara-Shi, Japan

Abstract: Cortical layer formation in the cerebral cortex is one of the typical events in the mammalian brain. Neurons that are born in the ventricular zone (VZ) migrate to the pial surface with an inside-out manner along the fiber of radial glia. Recent studies revealed that transmembrane proteins such as N-cadherin, integrins, and connexins, regulate neuronal migration through cell-cell and/or cell-matrix interactions, and their expression on the plasma membrane is tightly regulated by vesicle trafficking factors that are involved in the process of secretion, endocytosis and recycling. Furthermore, some vesicle trafficking factors are identified as a responsible gene for periventricular heterotopia, and their dysfunction causes malformation of cortical layer. However, it largely remains unclear the mechanistic details of how vesicle trafficking factors regulate neuronal migration. In this study, we examined the expression and functional role of ADP-ribosylation factor 6 (Arf6), a critical regulator of endosomal trafficking, in the cortical layer formation. *In situ* hybridization analysis revealed that Arf6 mRNA was expressed in all layers including VZ, intermediate zone (IZ), and cortical plate (CP) in the dorsal pallium of embryonic cerebral cortex. Immunostaining analysis revealed that Arf6 appeared as puncta that partly colocalized with EEA1 and syntaxin12, markers for early and recycling endosomes, respectively, in migrating neurons. Knockdown (KD) of Arf6 by *in utero* electroporation revealed that Arf6 was required for transition from IZ to CP by controlling the recycling of N-cadherin in migrating neurons. Furthermore, mFIP3, a dual effector for both Arf6 and Rab11, also regulates neuronal migration, and knockdown of mFIP3 caused accumulation of

N-cadherin in perinuclear region of migrating neurons, as observed in Arf6 KD. These results implicate that N-cadherin recycling pathway through Arf6/mFIP3 regulates the transition from IZ to CP during the cortical layer formation.

Title: Conditional knockout of paxillin in the nervous system disrupts migrating neuron morphology and delays cortical lamination

Authors: *M. RASHID[1], J. BELMONT[2], D. CARPENTER[2], C. TURNER[3], E. OLSON[2]; [1]Dept. of Neurosci. and Physiol., [2]Neurosci. and Physiol., [3]Cell and Developmental Biol., SUNY Upstate Med. Univ., Syracuse, NY

Abstract: The paxillin family of focal adhesion adaptor proteins are known to regulate integrin-based cellular adhesion and migration, yet their roles in cortical development remain largely unknown. This is due, in part, to the early embryonic lethality of paxillin knockout mice. Two members of this family, paxillin and Hic-5, are expressed by neuronal precursors and differentiating neurons during early cortical development. Here, we characterize the cortical phenotypes of Hic-5 knockout mice and paxillin conditional knockout mice. Consistent with prior findings, we show that Hic-5 knockout mice are postnatal viable, fertile and have no overt abnormalities in cortical anatomy. In contrast, nestin-cre driven deletion of paxillin in the developing cortex produces a subtle cortical phenotype. While nestin-cre; paxillin$^{flox/flox}$ (paxillin cKO) mice are also postnatal viable and fertile, histological analyses of the neonatal cortex reveals a disruption in the lamination of Cux1^{+} upper-layer projection neurons compared to littermate controls. On postnatal day 1 (P1), Cux1^{+} neurons are normally localized to layer 2-4 in wildtype cortex, while significantly more Cux1^{+} neurons are found in ectopic deep positions in the paxillin cKO cortex (p=0.002). However, by P35 no difference is detected in the distribution of Cux1+ cortical neurons between mutant and control (p=0.68). To further characterize the P1 phenotype, cell-autonomous suppression and deletion of paxillin was performed using an *in utero* electroporation approach. Both shRNA-mediated suppression and cre-mediated deletion of

paxillin produced a migration delay and altered the morphology of migrating neurons. Compared to control, paxillin deficient migrating neurons have shorter leading processes and multiple swellings in their leading processes. This phenotype is remarkably similar to the reported phenotype produced by deletion of focal adhesion kinase (FAK), a critical signaling partner of paxillin. These results demonstrate that paxillin functions in a cell-autonomous manner to control the morphology of migrating neurons and the pace of cortical development.

Title: INM-like migration of newly born post-mitotic rod photoreceptors in the early post-natal mouse retinal neuroepithelium

Authors: *N. D. AGHAIZU[1], K. WARRE-CORNISH[2], M. R. ROBINSON[1], P. V. WALDRON[1], R. R. ALI[1], R. A. PEARSON[1];
[1]Dept. of Gene and Cell Therapy, UCL Inst. of Ophthalmology, London, United Kingdom;
[2]Basic & Clin. Neurosciences, Kings Col. London, London, United Kingdom

Abstract: Purpose: The developing retina is a pseudostratified neuroepithelium (NE) in which retinal progenitor cells (RPCs) span the radial tissue extent and mature stratification is yet to form. RPCs give rise to all major retinal cell types by mitosis. Cell cycle progression is

synchronised with the translocation of RPC nuclei within the radial cell extents, a process called interkinetic nuclear migration (INM). Nuclei are located at the apical edge of the NE during M-phase and nascent neurons must thus consequentially migrate radially to reach their designated layers. Rod cells eventually occupy a layer directly adjacent to the apical limit and it is often assumed, therefore, that there is limited requirement for migration. Nonetheless, in our preliminary investigations, post-mitotic rod precursor cells displayed marked motility during post-natal development. We therefore sought to determine the properties, kinetics, and mechanisms of this motility to help our understanding of retinal development. Methods: GFP under the control of the Nrl promoter labels post-mitotic rod photoreceptor precursor cells. The migration of GFP+ rod precursor cell bodies (RoPCBs) was assessed *ex vivo* by time-lapse 2-photon microscopy of live retinae from post-natal day 1, 3 and 7 Nrl.GFP+/+ mice and by software tracking (Imaris) of GFP+ rod precursor cell bodies. Results: RoPCBs were found dispersed within the NE, from directly adjacent to up to ~90 μm away from the apical limit. All observed cells extended a permanent apically attached process, but rarely extended a basal process. At all time points examined, RoPCBs underwent significant movement along the apico-basal axis. The majority of movements were stochastic with only limited net displacement. However, at least two further modes of migration, rapid apically directed jumps and slower basally directed migration were identified. Strikingly, RoPCBs were observed to oscillate between apical and basal positons using these three modes of migration with kinetics similar to INM. By means of pharmacology we demonstrated that migration was significantly impeded by inhibition of dynein I motor protein and microtubule dynamics, but not by inhibition of Myosin II motor protein. Conclusion: We report that the nucleus and surrounding RoPCBs engage in oscillatory apico-basal movements, highly reminiscent of the INM displayed by cortical neural progenitor cells. Similar to cortical neural progenitor cells but in contrast to lower vertebrate RPCs, these movements appear to be microtubule-dependent but Myosin II independent. To our knowledge, this is the first observation of an INM-like motility in a post-mitotic neuronal cell population.

Title: Deletion of Dcc results in mispositioning of spiral ganglion neurons during cochlear development

Authors: *Y. KIM, S.-Z. WANG, H. W. TAO, L. I. ZHANG;
USC, Los Angeles, CA

Abstract: The spiral ganglion neurons (SGNs) are the first neurons in the auditory pathway to fire action potentials to relay sound information up to the auditory cortex. These bipolar neurons send dendrites to innervate the base of hair cells in their cochlea and their axons to the cochlear nucleus through the auditory portion of eighth cranial nerves. Several axon guidance molecules have been reported responsible for the proper organization of SGN positioning and innervation patterns in the cochlea. Here, we show that disruption of Dcc results in mis-migrated SGNs towards the sensory epithelium. Specific patterns of positioning of mis-migrated SGNs were observed in different developmental time periods. Initial observation of mis-migrated SGNs at E16.5 suggests that it is not an initial migratory defect during delamination of SGNs but possibly a defect in rearrangement of SGNs during the convergent extension. Disruption of Dcc also caused SGNs to be mispositioned along the central auditory pathway towards the cochlear nucleus. In addition, a defect in fiber routing of SGNs in both peripheral and central sides has been observed. Our findings demonstrate that Dcc is required for the correct positioning of SGNs and routing of their processes during the auditory circuit development.

Title: N-cadherin and Astrotactin interact to regulate granule cell migration in the developing cerebellum

Authors: *Z. HORN, M. E. HATTEN;
Lab. of Developmental Neurobio., Rockefeller Univ., New York, NY

Abstract: The formation of a laminated cortex in the mammalian brain depends on directed migration of neuronal precursors. The neural cadherin, N-cadherin (Cdh2), is crucial for early development of the embryo and mediates neuron-glia attachment during glial-guided migration in the cerebral cortex. The role of Cdh2 in the development of the cerebellum is however still unclear. In this study, we assessed whether Cdh2 interacts with other adhesion proteins known to be involved in granule cell (GC) migration and maturation in the cerebellum. We found that Cdh2 co-immunoprecipitates with the two known members of the astrotactin family, Astn1 and Astn2, which regulate glial-guided migration of cerebellar GCs. This interaction is dependent on the MACPF, Fibronectin type III and EGF-like domains of the astrotactin protein. Interestingly, immunolabeling of GC/glia co-cultures showed that Cdh2 and Astn1 co-localize to the neuron-glia junctions of migrating GCs. Moreover, adhesion assays using *Drosophila* S2 cells indicated that Cdh2 and Astn1 interact in a heterophilic manner. To provide a genetic analysis of the role of *Cdh2* in GC development, floxed *Cdh2* mice were crossed with *NeuroD1-Cre* mice to delete *Cdh2* in migrating GCs. Structural studies showed that the cerebellum of *Cdh2* conditional mutant mice at P5 - P7 was 15 - 20% smaller than in control littermates, and BrdU/EdU labeling methods revealed a marked reduction in GC migration. In addition, the expression of the Astn1 protein was mislocalized in the GCs lacking *Cdh2*. Interestingly, Bergmann glial fibers were significantly decreased and misaligned in the mutants, indicating that homophilic and/or heterophilic interactions of Cdh2 function in Bergmann glial development. Taken together, our results suggest that Cdh2 regulates glial-guided migration of cerebellar GCs and may promote neuron-glia attachment by interacting with Astn1.

Title: Slit/Robo signals maintain motor neurons inside the spinal cord by regulating the integrity of the basement membrane

Authors: *M. KIM, H. LEE, G. S. MASTICK;
Biol., Univ. of Nevada, Reno, Reno, NV

Abstract: Spinal motor neurons are clustered in a well-organized pattern within the ventral spinal cord, and project axons out through the basement membrane to innervate their peripheral targets. The retention of motor neuron cell bodies within the spinal cord is critical to form their functional circuits. However, little is known about how spinal motor axons can exit, but not motor neuron cell bodies. The secreted Slit proteins are major repellents produced by the floor plate, and their Robo1 and Robo2 receptors mediate Slit repulsion. Importantly, Slit2 and both Robo receptors are expressed by spinal motor neurons. We found that some motor neurons migrated outside the spinal cord in Slit1/2 or Robo1/2 double knockout mouse embryos. More specifically, tests of single Slit or Robo alleles showed that Slit2 and Robo2 are necessary for maintaining motor neurons inside the spinal cord. We sought to test how abnormal Slit/Robo signals lead to emigrant phenotype in the spinal cord. Many reports suggest that the laminin-containing basement membrane is a substrate for neuron migration as well as a boundary that constrains motor neurons on a proper migratory path. We tested a major basement membrane protein, Dystroglycan (DG), a glycoprotein linking the extracellular matrix and the cytoskeleton. In the Slit1/2 knockout spinal cord, expression of DG was discontinuous, forming large gaps in the basement membrane. These gaps were associated with the ventral sites where motor neurons ectopically emigrate, suggesting that the basement membrane is critically required to prevent aberrant motor neuron migration. The fact that Robo1/2 mutants phenocopied Slit1/2 mutants suggests that the neuroepithelium of the wall of the neural tube produces or maintains the basement membrane in a Slit-dependent manner. Together, the findings from the present study suggest that Slit/Robo signals are required to retain spinal motor neurons inside the neural tube by regulating the integrity of the basement membrane. Further research will be needed to address a molecular basis on how, when and where the guidance signals are required for keeping spinal motor neurons on a proper position.

Title: Radial and tangential migration of telencephalic somatostatin neurons originated from the mouse diagonal area

Authors: ***J. L. FERRAN**[1], N. MORALES-DELGADO[1], P. MERCHÁN[2], B. CASTRO-ROBLES[3], M. MARTINEZ-DE-LA-TORRE[1], C. DÍAZ[4], L. PUELLES[1];
[1]Sch. of Medicine, Univ. of Murcia, Murcia, Spain; [2]Cincinnati Children's Hosp. Med. Center, Univ. of Cincinnati Col. of Med., Cincinnati, OH; [3]Inst. of Biomed. Res. of Lleida, Univ. of Lleida, Lleida,, Spain; [4]Sch. of Medicine, Univ. of Castilla-La Mancha, Albacete, Spain

Abstract: The telencephalic subpallium is the source of various GABAergic interneuron cohorts that invade the pallium via tangential migration. Based on genoarchitectonic studies, the subpallium has been subdivided into four major domains: striatum, pallidum, diagonal area and preoptic area (Puelles et al., 2013; Allen Developing Mouse Brain Atlas) and a larger set of molecularly distinct progenitor areas (Flames et al., 2007). *In utero* fate mapping and genetic lineage tracing studies have suggested that each subpallial subdivision produces specific sorts of inhibitory interneurons, distinguished by differential peptidic content, which are distributed tangentially to pallial and subpallial target territories (e.g., olfactory bulb, isocortex, hippocampus, pallial and subpallial amygdala, striatum, pallidum, septum). In this report we map descriptively the early differentiation and apparent migratory dispersion of mouse subpallial somatostatin-expressing (Sst) cells from E10.5 onwards, comparing their topography with the expression patterns of the genes Dlx5, Gbx2, Lhx7-8, Nkx2.1, Nkx5.1 (Hmx3), and Shh, which variously label parts of the subpallium. Whereas some experimental results suggest that Sst cells are pallidal, our data reveal that many, if not most, telencephalic Sst cells derive from de diagonal area (Dg). Sst-positive cells initially only present at the embryonic Dg selectively populate radially the medial part of the bed nucleus striae terminalis (from paraseptal to amygdaloid regions) and part of the central amygdala; they also invade tangentially the striatum, while eschewing the globus pallidum and the preoptic area, and integrate within most cortical and nuclear pallial areas between E10.5 and E16.5.

Abstract: Although interneurons play pivotal roles in the modulation of cortical function, the mechanisms that control interneuron development remain to be elucidated. This study aimed to explore a new role for Foxg1, a candidate gene for West syndrome and Rett syndrome, in interneuron development. By crossing Foxg1fl/fl mice with a Dlx5/6-Cre line, we determined that the conditional disruption of Foxg1 in the subpallium results in defects in interneuron differentiation and tangential migration. In developing interneurons, the expression levels of several receptors, including roundabout-1 (Robo1), Eph receptor A4 (EphA4) and (C-X-C motif) receptor 4/7 (Cxcr4/7), were strongly down-regulated, which led to migration defects after Foxg1 ablation. The transcription factors Dlx1/2 and Mash1, which have previously been reported to be involved in interneuron development, were significantly up-regulated at the mRNA levels. Notably, Prox1, which is a transcription factor that functions as a key regulator in the development of excitatory neurons, was also dramatically up-regulated at both the mRNA and protein levels. This result suggests that Prox1 is also important for interneuron development. Our work demonstrates that Foxg1 may act as a critical up-stream regulator of Dlx1/2, Mash1 and Prox1 to control interneuron development. These findings will improve our understanding of the molecular mechanisms of Foxg1-related diseases, including both West and Rett syndromes.

Title: The essential role of RBM8a in brain development

Authors: *C. MCSWEENEY[1], D. REYNOLDS[2], A. SEBASTIAN[1], J. VITALE[1], Y. ZHOU[1], F. DONG[1], D. DENG[1], L. LIU[1], X. JIANG[1], J. JIANG[1], Y. WANG[3], I. ALBERT[1], Y. MAO[1]; [1]Penn State Univ., State College, PA; [2]Univ. of California Irvine, Irvine, CA; [3]Shanghai Jiaotong Univ., Shanghai, China

Abstract: Nonsense-mediated mRNA decay (NMD) is an RNA surveillance mechanism that ensures the degradation of mRNAs carrying premature termination codons (PTCs). This mechanism relies on several factors, which form a tetramer known as the exon junction complex (EJC). Mutations in multiple EJC factors have been reported to cause X-linked mental retardation and autism (Tarpey et al., 2009; Laumonnier et al., 2010; Addington et al., 2010). This strongly indicates a potential role for NMD in the pathogenesis of autism. Using the cre-loxp system, we selectively knocked out the protein RBM8a in neural stem cells. *Nes-Cre;RBM8a*$^{fl/+}$ mice presented with microcephaly (even after accounting for small body size), decreased body size, impaired mobility, and a life span of approximately 20 days. *Nes-Cre;RBM8a*$^{fl/+}$ mice have decreased cell density in the cortex, and throughout the CA regions of the hippocampus. The structural morphology of the hippocampus is also abnormal. The cortex of *Nes-Cre;RBM8a*$^{fl/+}$ mice is very thin, and the two hemispheres fail to meet on the midline. Interestingly, these mice also have disorganized cortices. Cux1, a marker for cortical layers 2/3 is present in cells all throughout the cortex of *Nes-Cre;RBM8a*$^{fl/+}$ mice, with the greatest density in layers 5/6. Foxp2, a marker for cortical layer 5/6, is also present in layer 4. This indicates either deficits in cell fate specification, or deficits in migration. Seeing as children with autism have been observed to have disorganized neocortices (using post mortem *in situ* hybridization), this phenotype further implicates RBM8a as a potential risk gene for autism (Stoner et al., 2014).

Title: Widespread neurodevelopmental malformations of the cerebellar vermis in genetically engineered mice

Authors: *J. A. CUOCO[1], A. ESPOSITO[1], S. SETH[1], S. O'MALLEY[1], Y. TANG[1], P. T. SMITH[2], R. L. RAMOS[1];

Abstract: C57BL/6 mice are among the most widely used mouse strains in neuroscience research. This strain is often used as a "control strain" in a wide range of behavioral, anatomical, and physiological studies and is often the background strain used in the production of knock-out and transgenic mouse lines. In addition, a significant amount of research funding from the NIH is supporting projects using C57BL/6 mice. Work in our laboratory has recently described the presence of spontaneous malformations of the cerebellar vermis in C57BL/6 mice (Mangaru et al. 2013; Van Dine et al. 2013). Malformations consist of heterotopia containing a diverse array of neuronal (Purkinje cells, granule cells, Golgi cells, etc) and glial (astrocytes, Bergmann glia, oligodendrocytes) cell-types located in the molecular layer between lobules VIII and IX. Heterotopia are associated with disruption of Bergmann glial radial fibers as well as breeches of the pia along the secondary fissure and are indicative of neuronal migration defect. In a previous study we tested the prediction that mutant and transgenic mouse models on a C57BL/6 background would also exhibit these same cerebellar malformations (Ramos et al. 2013). Consistent with our hypothesis, we found that spontaneous mutant mice and several genetically-engineered mouse lines did indeed exhibit molecular layer heterotopia. In the present study, we expand the list of genetically-engineered mice, developed on a C57BL/6 background, that display cerebellar heterotopia including numerous Cre-driver lines, reporter lines, and GCAMP/Channelrhodopsin transgenic lines. These data have implications for investigators wishing to use these mice in neuroscience research.

Title: Cdk12 regulates neurogenesis and late-born neuronal migration in the developing mouse cerebral cortex

Authors: *M.-J. FANN, H.-R. CHEN;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The DNA damage response (DDR) pathways are critical to ensure that replication stress and other types of DNA lesions do not perturb production of neural cells during development. Neural progenitors are particularly sensitive to DNA damage and their relative susceptibility may vary depending on the stage of development. Defective DDR is often associated with neurodevelopmental diseases. Cdk12 maintains genomic stability via regulation of expression of DDR genes. To define its role during neural development *in vivo*, we conditionally targeted Cdk12 using a Nestin-Cre mouse line. Nestin-Cdk12-cKO mice showed microcephaly and rarely survived beyond postnatal day 0 (P0). Results from cresyl violet-stained brain sections of Nestin-Cdk12-cKO at P0 showed reduced thickness of cortical plate layers in neocortex, and aberrant anterior commissure and corpus callosum. Nestin-Cdk12-cKO mice exhibited fewer neurons throughout the neocortex due to apoptosis of newborn progenitors. Furthermore, birthdating experiments with EdU showed that Cdk12 involved not only in survival of neural progenitor cells, but also in neuronal migration of late-born neurons in the developing neocortex. Although 6-cortical layer organization was preserved, misaligning of layers II-IV neurons marked with CUX1 expression was observed. An increase of ectopically localized CUX1+ cells in deeper layers was detected in Nestin-Cdk12-cKO neocortex. DiI tracing also showed a loss of the corpus callosum that is composed of axons of callosal projection neurons located in layer II/III. To further investigate effects of Cdk12 on neuronal migration without its confounding effect on neurogenesis, we used the Cdk12fx/fx mice that were electroporated *in utero* with Cre-expression plasmid between embryonic day 14 to 16. Migrating neurons are stagnant in the middle of the neocortex upon deletion of Cdk12. In short, Cdk12 function is crucial for two aspects of neuronal development, including neurogenesis and late-born neuronal migration. How deleting Cdk12 generates these effects is currently under investigation.

Title: Regulation of the actin cytoskeleton by the Ndel1-Tara complex is critical for cell migration and invasion

Authors: J.-H. HONG[1], Y.-D. KWAK[1], Y. WOO[1], S. KIM[1], C. PARK[1], S.-A. LEE[1], K. SANADA[2], M. NGUYEN[3], *S. PARK[1];

Abstract: Nuclear distribution element-like 1 (Ndel1) plays pivotal roles in diverse biological processes and is implicated in the etiology of multiple neurodevelopmental disorders. Ndel1 exerts its functions by regulating microtubules or intermediate filaments; however, its functional link to the actin cytoskeleton is largely unknown. Here, we show that Ndel1 interacts with TRIO-associated repeat on actin (Tara), an actin-bundling protein, to regulate cell movement. *In vitro* cell migration assays revealed that Ndel1- or Tara-deficient cells were defective in their migration and invasion. Moreover, Tara alters its intracellular distribution and this redistribution of Ndel1 was abolished by deletion of the Ndel1-interacting domain of Tara, suggesting that the altered localization pattern of Ndel1 requires a physical interaction with Tara. These findings uncover an interesting role of the Ndel1-Tara complex in actin reorganization during cell migration and invasion.

Abstract: Neuronal migration is a fundamental step during brain development, whose defects are consistently correlated with brain malformation and dysfunctions. An essential feature of neuronal migration is the nuclear translocation. When neurons migrate, they at first elongate a long and thick process, referred to as a leading process, toward their migrating direction and then the nucleus (and other organelles) translocates into the leading process, as if a soft ball moves in a thin tube. Mechanical forces generated by microtubule and/or actin motor proteins have been implicated in the nuclear translocation, yet the precise mechanism is still unclear; it remains controversial which of microtubule or actin motors generate the primary force driving the nuclear translocation and whether these motor proteins push or pull the nucleus. In order to elucidate the physical basis of nuclear migration, we carried out high-resolution time-lapse imaging of nuclear dynamics in migrating cerebellar granule neurons. Our time-lapse imaging studies demonstrate that the nucleus dynamically changes its morphology and sometimes rotates during neuronal migration. Considering the nucleus as a viscoelastic body in a fluid dynamic system, these dynamic behaviors should reflect the forces applied to the nucleus. Hence, we have established digital image analyses in order to quantify the deformation and rotation of the nucleus. In addition, we have also measured the traction force on the culture substrate exerted by migrating neurons, using a modified traction force microscopy technique. It has been revealed that the leading process frequently exerts bidirectional traction force, contrasting with the unidirectional force of the trailing process. Furthermore, the traction forces generated in the leading process often synchronize and counteract to the nuclear translocation, suggesting that the pulling force contributes to nuclear translocation. In this presentation, we would like to discuss the force driving nuclear translocation based on these quantitative image analyses.

Title: Identifying molecular mechanisms behind local cortical microcircuit assembly

Authors: *S. LODATO[1,2], L. GOFF[2,3], A. C. ZHANG[1], A. GROFF[1], E. J. STRONGE[1], A. SHETTY[1], J. RINN[1], P. ARLOTTA[1,2];
[1]Stem Cell and Regenerative Biol., Harvard Univ., Cambridge, MA; [2]The Broad Inst. of MIT and Harvard, Cambridge, MA; [3]John Hopkins University, Sch. of Medicine,, Baltimore, MD 21205, USA, MD

Abstract: The activity and function of the mammalian cerebral cortex rely on the precise assembly of specialized neuronal circuits involving an extraordinary diversity of excitatory projection neurons and inhibitory interneurons. Although they have different developmental origins, these two classes of neurons ultimately co-reside in the cortex, where they assemble into balanced local microcircuitry. The developmental events governing the proper interaction between excitatory projection neurons and inhibitory interneurons are poorly understood, in particular the cellular and molecular events that direct interneurons to position precisely within specific cortical layers. We recently reported that different subtypes of projection neurons uniquely and differentially determine the laminar distribution of cortical interneurons. We found that in Fezf2$^{-/-}$ cortex, the specific absence of subcerebral projection neurons and their replacement by commissural projection neurons causes abnormal lamination of interneurons and altered GABAergic inhibition. In addition, experimentally-induced ectopic corticofugal or callosal neurons selectively recruit distinct subtypes of cortical interneurons, based on the identity of the projection neuron. These data demonstrate that, in the cerebral cortex, individual populations of projection neurons cell-extrinsically control the laminar fate of interneurons and the assembly of local inhibitory circuitry (Lodato et al., Neuron, 2011). Here, we investigated the molecular mechanisms that mediate the precise pairing between distinct subtypes of projection neurons and interneurons in the early stages of radial migration of cortical interneurons. To address this question, we FACS-purified and transcriptionally profiled pairs of projection neuron and interneuron subtypes which preferentially reside in the same cortical layers, over multiple developmental time points. Using custom bioinformatic analysis, we have identified candidates that are functionally relevant for the lamination of interneurons within the cortex, and therefore crucial for the assembly of specialized cortical circuits. These molecules have potential roles in the etiology of neurological disorders such as autism and schizophrenia.

Title: Novel function of PIWIL1 in neuronal polarization and migration via regulation of microtubule-associated proteins

Authors: *P. ZHAO[1], M. YAO[1], S. CHANG[1], L. GOU[2], M. LIU[2], Z. QIU[1], X. YUAN[3]; [1]Inst. of Neuroscience, CAS, Shanghai, China; [2]Inst. of Biochem. and Cell Biology, CAS, Shanghai, China; [3]Hussman Inst. for Autism, Baltimore, MD

Abstract: Young neurons in the developing brain establish a polarized morphology for proper migration. The PIWI family of piRNA processing proteins are considered to be restrictively expressed in germline tissues and several types of cancer cells. They play important roles in spermatogenesis, stem cell maintenance, piRNA biogenesis, and transposon silencing. Interestingly a recent study showed that *de novo* mutations of PIWI family members are strongly associated with autism. Here, we report that PIWI-like 1 (PIWIL1), a PIWI family member known to be essential for the transition of round spermatid into elongated spermatid, plays a role in the polarization and radial migration of newborn neurons in the developing cerebral cortex. Knocking down PIWIL1 in newborn cortical neurons by *in utero* electroporation of specific siRNAs resulted in retardation of the transition of neurons from the multipolar stage to the bipolar stage followed by a defect in their radial migration to the proper destination. Domain analysis showed that both the RNA binding PAZ domain and the RNA processing PIWI domain in PIWIL1 were indispensable for its function in neuronal migration. Furthermore, we found that PIWIL1 unexpectedly regulates the expression of microtubule-associated proteins in cortical neurons. Our finding of PIWIL1's function in neuronal development implies conserved functions of molecules participating in morphogenesis of brain and germline tissue and provides a mechanism as to how mutations of PIWI may be associated with autism.

Title: Yes-associated protein (Yap) function in normal cerebellar development and medulloblastoma

Authors: *L. J. HUGHES;
Temple Univ., Philadelphia, PA

Abstract: The Hippo signaling pathway is known to be involved in the control of organ size by regulating proliferation and apoptosis. This well conserved pathway is activated by various signal inputs, including cell-cell contact, mechanotransduction, and G-protein coupled receptors, with the signals converging on the downstream effector protein Yap and its homologue Taz. Yap has also been implicated as a potential oncogene, as it is upregulated and transcriptionally active in several tumor types including medulloblastoma, a tumor that arises in the cerebellum. Furthermore, inhibiting Yap activity in various cancer models has been shown to revert tumorigenic properties. Although the role of Yap has been described in several organ systems, there is a paucity of information about its role in the central nervous system. Here we investigate the function of Yap/Taz in the cerebellum to determine its significance during both normal development and medulloblastoma. To date, we have identified the expression pattern of Yap from embryonic through adult stages in mice. Although Yap is highly expressed in granule neuron progenitors (GNPs) during the rapid postnatal expansion stage, it does not appear to play a major role in proliferation of these cells as conditionally knocking-out Yap/Taz in GNPs does not alter their proliferative capacity. However, Yap/Taz does play a significant role in cerebellar foliation: Yap has an important function in Bergmann glia (BG) cells for establishing normal cerebellar foliation patterns during development. Furthermore, Yap-deficient BGs exhibit migrational defects. To determine the role of Yap in medulloblastoma, we utilized mouse models with constitutively activated sonic hedgehog (SHH) signaling, a pathway known to be activated in about 25% of medulloblastomas, in various cerebellar cell types. Because GNPs proliferate in response to SHH during normal development, SHH-mediated medulloblastoma is believed to originate from GNPs with dysregulated SHH signaling. We found that knocking out Yap/Taz in SHH-mediated medulloblastoma does not rescue the phenotype, an unexpected finding amidst several reports of the significant function of Yap in several other cancer types. Our observations demonstrate Yap has a novel function in cerebellar glia that is required for the development of normal foliation and organization, but plays a minimal role in cerebellar tumorigenesis.

Title: ADAMTS-3 is the major protease that inactivates Reelin in brain

Authors: *H. OGINO, A. HISANAGA, Y. KONDO, H. TSUIJI, T. KOHNO, M. HATTORI; Biomed. Science, Grad. Sch. of Pharmaceut. Scienses, Nagoya City Univ., Nagoya, Japan

Abstract: Reelin is a secreted glycoprotein that is essential for normal brain development and function. Reelin exerts its function by inducing phosphorylation of an intracellular protein Dab1. Phosphorylated Dab1 is degraded promptly. In recent years, downregulation and/or hypoactivity of Reelin in adult brain has been suggested to be involved in the pathogenesis of neuropsychiatric diseases including Alzheimer's disease and schizophrenia. Reelin protein is specifically cleaved at three sites, called N-t, C-t and CTR sites. The N-t site cleavage virtually abolishes Reelin's ability to phosphorylate Dab1. Therefore, inhibition of N-t site cleavage can be a therapeutic strategy for neuropsychiatric diseases. We identified ADAMTS-3 (A Disintegrin And Metalloproteinase with Thrombospodin motifs-3) as the candidate protease in charge of N-t site cleavage by purification from the supernatant of cultured cortical neurons. Recombinant ADAMTS-3 has the ability to cleave N-t site of Reelin *in vitro*. In this study, we analyzed the knockout (KO) mice of ADAMTS-3 as well as conditional KO mice that lacks ADAMTS-3 only in the excitatory neurons of forebrain to verify its contribution to N-t site cleavage *in vivo* and to clarify the physiological significance of N-t site cleavage. It turned out that most of ADAMTS-3 KO mice die soon after birth. The amount of cleaved product of Reelin is significantly decreased in the embryonic ADAMTS-3 KO mice brain, indicating that ADAMTS-3 is the major enzyme that cleaves the N-t site in embryonic stages. Importantly, the amount of Dab1 is decreased in cerebral cortex of embryonic ADAMTS-3-KO mice, indicating that Reelin activity is enhanced. These results strongly suggest that ADAMTS-3 is the major protease that inactivates Reelin in embryonic mice brain. In order to analyze the contribution of ADAMTS-3 to N-t site cleavage in postnatal stages, we established conditional KO mice that lacks ADAMTS-3 only in the excitatory neurons of forebrain. This conditional KO mice lives to adulthood and does not show

obvious behavioral or growth abnormality. We are currently analyzing the brain of this ADAMTS-3 conditional KO mice. These studies will help us understand the physiological significance of N-t site cleavage *in vivo*, particularly in the pathogenesis of neuropsychiatric diseases.

Title: Prolonged hypoxia depletes SVZ neural stem/progenitor cell pools critical for cortical development in piglets

Authors: *P. D. MORTON[1,2], L. KOROTCOVA[1,2], B. LEWIS[3], V. KUMAR[1,2], F. SHAIKH[1,2], E. SHORT[1,2], J. ZHANG[4], S. MORI[4], J. A. FRANK[3], V. GALLO[2], R. A. JONAS[1,2], N. ISHIBASHI[1,2];

Abstract: Congenital heart disease (CHD) is the leading birth defect worldwide, affecting nearly 1 in every 100 infants. A majority of patients suffering from severe/complex CHD display significant neurological deficits, primarily due to a restricted oxygen supply to the brain during fetal life or early infancy. The subventricular zone (SVZ) generates neural stem/progenitor cells (NSPCs) that replenish damaged neurons and glia in the brain throughout the human lifespan. The structural and cellular properties of the well-studied rodent SVZ are dissimilar from its human counterpart. The piglet brain is a powerful tool to study human brain development as it shares more metabolic and physiological similarities to humans than other large mammals. In

addition, the porcine brain displays a highly evolved, gyrencephalic neocortex absent in many other mammals. Here we determine the contribution of SVZ NSPCs to cortical development in a human-like, gyrencephalic porcine brain under normal physiological conditions and after prolonged hypoxia. We found that the porcine SVZ shares significant anatomical/structural similarities to the human SVZ; including nearly identical laminar organization with an astrocyte ribbon. The dorsolateral-SVZ contained the largest number of NSPCs and was the predominant proliferative region in early postnatal development. A majority of NSPCs in the SVZ region generated immature neurons that migrated to the frontal cortices and olfactory bulb, indicating that the SVZ contributes to cortical development. Neurospheres generated from this cell population also displayed multipotency and a tendency for neuronal differentiation. Following hypoxia, our MRI studies demonstrated a reduction in cortical volume and folding of the frontal cortex; a phenomenon commonly seen in CHD patients. A reduction in cell proliferation and neurogenesis was also seen in the SVZ. In addition, results from *in vivo* cell labeling demonstrated that hypoxia limits the contribution of SVZ-derived neurons to postnatal cortical development. Finally, a decrease in the number of immature neurons was displayed within the frontal cortices with no changes in apoptosis. Our data indicate that chronic hypoxia reduces the generation of neuronal producing NSPCs in the SVZ, which delays/impairs corticogenesis. Future studies aimed at determining the underlying molecular signaling mechanisms coordinating the endogenous response of regenerating SVZ NSPCs will be invaluable in developing novel therapeutic targets and approaches to improve the neurological deficits exhibited in CHD patients.

Title: JNK signaling maintains the integrity of cortical interneuron migratory streams during corticogenesis

Authors: *A. K. MYERS, K. BAKER, J. P. SNOW, S. E. HICKLING, C. A. SMITH, E. S. TUCKER;
West Virginia Univ., Morgantown, WV

Abstract: Cortical interneurons assemble into streams of tangentially migrating cells as they enter the nascent cerebral cortex. As development proceeds, interneurons depart from migratory streams on diagonal or radial trajectories in order to populate the cortical plate, where they eventually segregate into layers and make synaptic connections with other cortical neurons. Errors in this process can lead to inappropriate cortical wiring and cause cortical circuit disorders such as schizophrenia, autism, and epilepsy. Therefore, elucidating cellular and molecular mechanisms underlying the transition from tangential to radial modes of migration is critical for understanding normal and pathological brain development. Our laboratory previously demonstrated that the c-Jun N-terminal kinase (JNK) intracellular signaling pathway is important for the initial entry of interneurons into the cerebral cortex. Jnk1/2 conditional double knockout mice, where Jnk1 is conditionally removed from interneurons of Jnk2 knockouts, exhibited significant delays in cortical interneuron entry as well as disruption in migratory streams at embryonic day (E) 13.5. In the present study, we explore the involvement of JNK signaling in the maintenance of cortical interneuron migratory streams between E14.5 and E15.5 when interneuron migratory streams are well formed. Time-lapse imaging of organotypic slice cultures treated with a pan pharmacological inhibitor of JNK signaling, SP600125, showed dramatic evacuation of cortical interneurons from the subventricular zone stream, while interneurons in the marginal zone stream slowed and extended leading processes into the cortical plate. Additionally, analyses of SP600125-treated slice cultures showed dose-dependent dispersion of interneurons from migratory streams and a tangential to radial re-orientation of leading processes. Washout experiments revealed that stream dispersion is partially reversible upon recovery of JNK signaling, indicating JNK-inhibition disrupts guided migration of cortical interneurons. Finally, Jnk1/2 conditional double knockout mice were evaluated to determine if interneuron-specific JNK-deficiency leads to migratory stream dispersion *in vivo* and in *ex vivo* slice cultures. Indeed, preliminary data indicate that long-lasting alterations in the radial distribution of cortical interneurons are evident in cortices of JNK-deficient mice. Completion of this work will further clarify the developmental mechanisms underlying appropriate migration and lamination of cortical interneurons and hopefully provide insight into the origins of detrimental disorders of cortical connectivity.

Title: Deciphering astrocyte spatial patterning cues

Authors: *V. M. PUNAL, F. BRECHA, J. KAY;
Duke Univ., Durham, NC

Abstract: A growing body of evidence demonstrates that astrocytes are critical players in neural circuit development, refinement, and function. To ensure all neurons have access to astrocytes, these glial cells become regularly distributed throughout neural tissue during development. The mechanisms that instruct the patterning of astrocytes into a uniformly-spaced network are not known. The objective of the current study is to elucidate the key cell biological events underlying the development of astrocyte patterning. In most regions of the nervous system, astrocytes are born in a particular location and migrate to fill adjacent tissue. Next they must adjust their local cell density, either by dividing, dying, or moving short distances, in order to produce the mature, uniform distribution. To assess the relative contributions of these cellular behaviors in astroctye patterning, we chose to focus on astrocytes of the retinal nerve fiber layer. The retina is an excellent model because in this tissue astrocytes arise from a point source (the optic nerve), exist in a monolayer, and can be easily manipulated *in vivo* or imaged *ex vivo*. Astrocytes are not the only retinal cells showing non-random distribution - each neuronal cell type is also distributed evenly over the retinal surface in a pattern known as a mosaic. Past work on neuronal mosaics provides us with quantitative tools to assess astrocyte spatial patterning. To begin our studies we used these tools to confirm that mouse astrocytes form a mosaic. We found that astrocytes are indeed non-randomly distributed in mature retina. Next we quantified the time course of astrocyte mosaic formation. We found that astrocytes pass through several developmental stages prior to arriving at a mature mosaic. These stages include periods of astrocyte chain migration (P1-P3), followed by the reorganization of astrocyte cell body position into honeycomb-like clusters (~P5), and finally an epoch of mosaic refinement (P5-10) that culminates in astrocyte somata regularity (P17). Additionally, during the course of mosaic development, there is a marked reduction in astrocyte density. These results indicate that both long- and short-distance migration, in addition to cell death, likely play roles in producing the astrocyte mosaic. Taken together, this work sets the stage for future experiments aimed at detailing the cellular and molecular mechanisms that astrocytes use to colonize neural tissues and to ensure their uniform distribution throughout those tissues.

Title: Effect of depleting microglia on developmental cell death in the mouse brain

Authors: *J. A. STRAHAN, N. G. FORGER;
Georgia State Univ., Atlanta, GA

Abstract: During the perinatal period, apoptotic cell death eliminates roughly fifty percent of the neurons originally generated in the mouse brain. We previously reported that for most forebrain regions, cell death peaks just after birth, then wanes by the end of the first week (Ahern et al., 2013). However, several forebrain regions have delayed peaks of cell death (P5-P7) and there are large (>10-fold) regional differences in the magnitude of cell death. It is not known what accounts for these differences in timing and magnitude of neuronal cell death. Microglia have recently been reported to play an active role in controlling neuronal cell death, although findings have been contradictory. While microglia apparently increase developmental neuronal death in the hippocampus and cerebellum (Marin-Teva et al., 2004; Wakselman et al. 2008), they are neuroprotective in primary sensory cortex (Ueno et al., 2013). We find that the density of microglia correlates with both the timing and magnitude of cell death in the mouse brain at P1 and P5. This is consistent with the interpretation that microglia cause cell death, but alternatively could simply reflect their role in phagocytosing dead neurons. To directly address whether microglia are required for neuronal cell death, we used clodronate liposomes (CL) to deplete microglia in the neonatal mouse brain. CL are lipid vesicles filled with clodronate. They are exclusively taken up by macrophages (microglia), and when accumulated, are cytotoxic. CL have been used extensively for *in vitro* and peripheral applications, but sparingly *in vivo* in the CNS. We injected a 1:1 dilution of a 5 mg/ml solution of CL, or control saline-filled liposomes, into the cerebral ventricles of mouse pups on P1. Brains were collected 24h later and alternate sections processed for immunohistochemical detection of Iba-1 (a microglial marker) or activated caspase-3 (AC3, a marker of cell death). CL markedly reduced the number of Iba1-stained cells throughout many regions of the brain. Based on thresholding of Iba1 immunoreactivity, we see a ~90% reduction in the septum and hippocampus, and a ~70% reduction in the hypothalamus. In adjacent sections stained for AC3, we did not see significant differences in the number of dying cells (counted stereologically) in the septum, hypothalamus or hippocampus. This suggests that microglia are *not* required for normal cell death, at least within

the time frame tested. We are currently testing shorter and longer time points after CL treatment, and performing AC3 counts on additional brain regions.

Title: Valproic acid exposure *in utero* causes neocortical dysgenesis: altered proliferation/differentiation pattern of neural progenitor cells

Authors: *K. FUJIMURA[1], T. MITSUHASHI[1], S. SHIBATA[2], S. SHIMOZATO[1], T. TAKAHASHI[1];
[1]Dept. of Pediatrics, [2]Dept. of Physiol., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Valproic acid (VPA), one of the first-line therapeutic agents for a wide spectrum of epileptic syndromes, inhibits histone deacetylases (HDACs) and hence modifies expression profiles of a variety of genes including cell-cycle related ones. An array of evidence strongly suggests that VPA exposure *in utero* increases the risk of congenital malformations, autism spectrum disorders, and lowers intelligence quotient scores in human offspring. Taken together, VPA exposure *in utero* may impair the cell cycle kinetics of neural progenitor cells (NPCs) through its HDAC-inhibitory activity leading to cerebral neocortical dysgenesis. We administered VPA to pregnant CD-1 mice through drinking water throughout the course of pregnancy. The following sets of experiments were conducted in the primary somatosensory area

of the neocortices of the postnatal day (P) 21 mice (experiments a and b) or in the dorsomedial cerebral walls of the embryos (experiments b and c): a) the thickness of neocortices and the number of GABAergic and non-GABAergic neurons, b) the number of neurons produced on the embryonic day (E) 16 and their final distribution in the neocortices, c) probability of cell cycle exit (quiescent or Q fraction) of the NPCs of the ventricular zone during the course of neuronogenesis. On P21, the thickness of the superficial neocortical layers (i.e., layers II-IV) was found to be increased in the VPA-exposed mice compared to that in the controls: this was exclusively attributable to an increased number of non-GABAergic neurons in those layers. The number of GABAergic neurons was indifferent between the two groups. Whereas neurons produced on E16 in the VPA-exposed mice were distributed in the layer II as in the controls, the number of those neurons was significantly increased. The Q fraction of the VPA-exposed NPCs was decreased by 10-40% during the early-middle phases of neuronogenesis compared to that of the controls. We infer that the fundamental effects of VPA exposure *in utero* are to decrease the Q fraction and to increase the number of NPCs during the early-middle phases of neuronogenesis. As a result, the number of non-GABAergic neurons, that are produced from the NPCs during the terminal phase of neuronogenesis (i.e., on E16 and later) and destined for the superficial neocortical layers, will be increased. It is of note that VPA exposure *in utero* may impair cell cycle regulation of the NPCs, possibly through its HDAC-inhibitory activity and leads to the neocortical dysgenesis.

Title: The transcription regulator Lmo3 is required for correct cell fate specification in the globus pallidus

Authors: *S. BISWAS, L. GAN;
Univ. of Rochester, Rochester, NY

Abstract: The external globus pallidus is an important nucleus of the basal ganglia; crucial for their function in health and disease. In Parkinson's disease, although the principal target of decreased midbrain dopaminergic neurons is the striatum, the most prominent pathophysiology in late-stage animal models of this disease and in human patients occurs in the GP, along with the STN (more correlated, synchronous patterns of neuronal firing as compared to healthy controls). Central to the function of the GP is its neuronal diversity. Recent studies have showed that while the functionally relevant neurons of the GP are all GABAergic, there are at least two non overlapping subtypes, based on their neurochemistry, anatomy and electrophysiological properties. "Prototypic" neurons can be identified by the expression of the transcription factors Nkx2.1 and Lhx6, and most of these neurons express the calcium binding protein parvalbumin (PV). Protypic neurons project to downstream basal ganglia nuclei like the subthalamic nucleus (STN). On the other hand, "arkypallidal" neurons can primarily be identified by their expression of the transcription factor FoxP2, and their axons arborize extensively across the striatum. Interestingly, the prototypic neurons, on an average, have higher firing rates while the arkypallidal neurons have lower firing rates. Lineage tracing has shown that the majority of PV+ neurons and about half of the non-PV+ neurons of the globus pallidus originate from the medial ganglionic eminence, while half of the non-PV+ neurons originate from the lateral ganglionic eminence. However, inspite of some inroads being made into the developmental origin of GP neurons, specific molecular factors that control cell fate specification and thus contribute to the neuronal diversity of this structure are so far, unknown. Our work shows that loss of the transcription regulator Lmo3, results in a dramatic reduction of PV+ neurons in the mouse GP. I am currently investigating changes in vesicular GABA transporter (vGAT) and gephyrin expression in the STN, a major downstream target of the PV-expressing globus pallidus neurons. As the GP forms the predominant inhibitory input of the STN, a decrease in the number of GP projections to the STN may have a significant impact on basal ganglia physiology and function.

Title: Characterizing the role of adhesion G protein-coupled receptor GPR56 in cortical lamination

Authors: *M. OKAMOTO, R. LUO, X. PIAO;
Newborn Med., Boston Children's Hospital, Harvard Med. Sch., Boston, MA

Abstract: Defects in neural migration and cortical lamination during development are among the leading causes of intellectual disabilities and epilepsy in humans. How post mitotic neurons reach and stop at their destined laminar position during cortical development remains one of the most fundamental questions in developmental neuroscience. There are many kinds of interactions between cortical cells (neurons and progenitor cells) and their surrounding environment to regulate cortical lamination. Previous studies have shown that mutations in adhesion G protein-coupled receptor 56 (GPR56) cause a devastating human brain malformation called bilateral frontoparietal polymictogria (BFPP) and deletion of GPR56 and its ligand Collagen III lead to the overmigration of neurons through a regionally breached pial basement membrane (BM) in mice, suggesting that the interaction between GPR56-expressing cortical cells and BM regulates the pial BM integrity and cortical lamination during cortical development. In this study, we investigated how interactions between cortical cells and microenvironment coordinate the cell dynamics underlying the cortical histogenesis via analysis of GPR56 signaling. We first detected GPR56 expression in earliest born preplate neurons at embryonic day (E) 10. Furthermore, we discovered that the overmigration, which is accompanied by disruption of the BM, is induced by the deletion of GPR56 between E9 and E12 with a gradually reduced severity of the defect along the development through the analysis of tamoxifen-inducible GPR56 (fl/fl); Nestin-cre mice. These results suggest that GPR56 might play a role in neuronal migration, cortical lamination and the maintenance of the pial BM in a stage dependent manner.

Title: Wntless is required for compartmentation and lamination in cerebellar development

Authors: *J. T. YEUNG[1,2], D. GOLDOWITZ[3,2];
[1]CMMT, Vancouver, BC, Canada; [2]Med. Genet., Univ. of British Columbia, Vancouver, BC, Canada; [3]Ctr. for Mol. Med. and Therapeut., Child and Family Res. Inst., Vancouver, BC, Canada

Abstract: The wnt signaling pathway involves a diversity of developmental processes in neural development. Previously, we demonstrated that Wntless (Wls), a transmembrane protein essential for the secretion of Wnt molecules, is expressed predominately in the cerebellar rhombic lip (RL) and isthmic organizer (ISO) during cerebellar development. Normally the expression of Wls is restricted to the interior face of the RL (iRL) by Pax6 expression, and we found that the Wls domain expands in the absence of Pax6. Together with the expression of Math1, Pax6, Lmx1a and Tbr2, Wls demarcates the RL into four molecularly distinct compartments. The fate of the cells from the Wls-positive compartment is unknown. The study of Wls in cerebellar development, however, is hindered by the early embryonic lethality of the conventional Wls-knockout. In this work, we employ the Cre-lox system to conditionally knockout *Wls* to circumvent the early requirement of Wls. By using Nestin-Cre, *Wls* is ablated conditionally from the cells of the RL at mid-gestation. With this *Wls*-cKO approach, Wls expression is deleted from the RL cells beginning at E12.5, while expression in the ISO is intact. The *Wls*-cKO mutant survives the embryonic period but dies within 6 hours after birth. Thus, this *Wls*-cKO allows for the study of Wls function in the RL and early cerebellar development. Examination of the *Wls*-cKO cerebellum at P0 reveals a significant reduction in the size of vermis, while the hemispheres are less affected. Across the whole cerebellum, the *Wls*-cKO lacks the formation of primary fissures and foliation is largely disrupted. The external granule layer (EGL) of the *Wls*-cKO is highly disorganized: at the medial region, gaps are observed between patches of granule cells, on the other hand, ectopic granule cells are observed in clusters that reside in the cerebellar core of the hemispheres. At the gaps in the EGL, we detected cells that are positive for Pax2, a marker of interneurons, or calbindin^{+}, a marker for Purkinje cells. Interneurons and Purkinje cells migrate through the gaps in the EGL and ectopically reach the surface of the cerebellum. The present work is the first to describe the cerebellar phenotype in the absence of Wls. Our findings indicate that Wls play a role in directing the proper placement of cerebellar cell types during development.

Title: Differential dependency of hindbrain serotonergic neuron development on transforming growth factor betas

Authors: *E. CHLEILAT, E. ROUSSA;
Mol. Embryology, Univ. of Freiburg, Freiburg, Germany

Abstract: Hindbrain serotonergic (5-hydroxytryptamine, 5-HT) neurons contribute to the regulation of a wide range of behaviors and their dysfunction may lead to neurological disorders. The 5-HT neurons of the hindbrain exist in two groups: rostral and caudal. These two groups can be further divided into various subpopulations of raphe nuclei later in development. Interestingly, 5-HT subpopulations are selectively affected in clinical disorders. A better understanding of the development of 5-HT neurons might contribute to the advancement of selective therapies for neurological disorders. The cytokines transforming growth factor betas (TGF-βs) may influence 5-HT neuron development. The double knockout mice for TGF-β 2/3 display a phenotype in midbrain dopaminergic neurons, a neuronal subpopulation that shares common developmental signals with hindbrain 5-HT neurons. The aim of the present study was to investigate the role of TGF-βs in the specification, development and survival of hindbrain 5-HT neurons. Using Cre-lox technology, we generated 3 conditional knockout mice lines with the deletion of TGF-β receptor 2 (TGFBR2) and the ligand TGF-β2 (TGF-β2) in cell-type specific hindbrain regions. In $TGF\text{-}\beta2^{flox/flox}::Krox20^{Cre/+}$ and $TGFBR2^{flox/flox}::Krox20^{Cre/+}$, TGF-β2 and TGFBR2 were knocked out in rhombomeres 3 and 5, respectively. In the $TGFBR2^{flox/flox}::En1^{Cre/+}$, TGFBR2 was knocked out in rhombomere 1. From these animals, 5-HT immunopositive neurons were counted in the hindbrain groups and subpopulations. The results show that in the $TGFBR2^{flox/flox}::Krox20^{Cre/+}$ mice, absence of TGFBR2 causes no statistically significant difference in the number of 5-HT neurons in the rostral and caudal groups at embryonic day (E) 14 compared to control. Similarly, at E18, where the 5-HT neurons are further developed, again no statistical difference was seen in the number of 5-HT neurons in the various raphe nuclei subpopulations. At E14 in the $TGFBR2^{flox/flox}::En1^{Cre/+}$ mice, no statistical difference in the 5-HT groups was observed. However, a statistical decrease in the number of 5-HT neurons was seen at E18 in the subpopulations compared to control. The most robust phenotype seen was in the $TGF\text{-}\beta2^{flox/flox}::Krox20^{Cre/+}$ mice which reveal statistically significant decrease in the number of 5-HT neurons in the caudal group in comparison to control at E14 and in every subpopulation except the rostral dorsal raphe nucleus at E18. The results propose a differential TGF-β2 (and TGFβ

signaling) dependency for proper 5-HT neuron development. This preliminary phenotypic characterization will be completed by investigating the molecular mechanism.

Title: Understanding the role of GABAergic signaling in larval zebrafish development

Authors: ***A. J. VANLEUVEN**[1], L. BEEBE[2], R. E. BALL[1], M. O'CONNOR[3], T. DORE[3], J. D. LAUDERDALE[1];
[1]Cell. Biol., [2]Genet., Univ. of Georgia, Athens, GA; [3]New York Univ., Abu Dhabi, United Arab Emirates

Abstract: γ-Aminobutyric Acid (GABA) is best known as the primary inhibitory neurotransmitter in the central nervous system of all vertebrates, but intriguing evidence has implicated GABA as a key signaling molecule in craniofacial development. Previous studies in mice show that *Gad1* mutants have severe cleft palates and do not live past birth, while *Gad2* mutants appear normal and viable, but exhibit stress-induced seizures. Due to neonatal lethality, the mechanism of *Gad1* activity in craniofacial development cannot be easily investigated in a mammalian model, but zebrafish provide an optimal system for such studies. Our work has focused on elucidating the function of the *gad1* and *gad2* genes in larval zebrafish through the use of morpholinos, novel photocaged morpholinos and CRISPR/Cas genome editing to alter GAD gene activity. In zebrafish, as in other vertebrates, there are two GAD genes, *gad1* and *gad2* that encode two isoforms of the GAD enzyme. Through the use of morpholinos, our lab has shown that *gad1* but not *gad2* morphants exhibit abnormal development of cranial neural crest cells. This phenotype can be bypassed using novel photocaged *gad1* morpholinos, when uncaging the morpholino at 1dpf. In these animals, craniofacial development appears largely normal, but electrophysiological recordings show increased and abnormal brain activity when compared to wild-type larvae. This evidence indicates that *gad1* is playing a role in early craniofacial development, which is independent of its role in GABA synthesis and

neurotransmission. We are currently validating these morpholino results with the several novel *gad1* and *gad2* alleles generated by the CRISPR/Cas method for targeted genome editing.

Title: Developmental control of cortical GABAergic interneuron number via Pten signaling

Authors: ***J. SEJOURNE**, D. T. PAGE;
Neurosci. department, The Scripps Res. Inst. Florida, Jupiter, FL

Abstract: GABAergic interneurons are crucial for establishing the functional balance and computational architecture of cortical circuits. Dysfunction of interneurons is linked with a variety of neuropsychiatric disorders, including autism and schizophrenia. Interneurons are generated in the ventral telencephalon and migrate to the cerebral cortex, where they undergo an intrinsic program of cell death during development to arrive at a mature population size. Recent findings indicate that interneuron cell death in the developing cortex is regulated by a cell- or population-autonomous mechanism, which has not yet been identified. Given the role of Pten phosphatase in regulating cell death, we hypothesize that its downstream signaling, particularly through Akt-FoxO, may play a role in this process within interneurons. To test this possibility, we generated mice carrying conditional heterozygous mutations in Pten restricted to GABAergic cell types (Gad2-Cre+; Pten[loxp/+]). In wild-type mice, we found that the number of GABAergic cells in the cortex decreased by approximately 25% between postnatal day 4 (P4) and P14, consistent with previous reports. In contrast, cortical GABAergic cell number in Gad2-Cre+; Pten[loxp/+] mice decreased by only 4%. Both wild-type and mutant animals had an equivalent number of cortical GABAergic cells at P4, but there was a net increase in mutants at P14 that persisted into adulthood, indicating that conditional mutation of Pten in GABAergic interneurons influences the postnatal survival of these neurons in a cell autonomous manner. Corresponding with this cellular phenotype, we observed deficits in social approach and open field behavior in Gad2-Cre+; Pten[loxp/+] animals. We are currently investigating alterations in

pro-apoptotic Akt-FoxO signaling downstream of Pten as a mechanistic explanation for this effect. Our results provide insight into the mechanism that controls the population size of GABAergic neurons during development and the importance of keeping a balanced ratio between excitation and inhibition in the brain for cognitive functions.

Title: Signaling centers that pattern developing cerebral cortex are conserved between mice and ferrets

Authors: *W. D. JONES, S. M. GUADIANA, E. A. GROVE;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: The mammalian cerebral cortex, including the neocortex and hippocampus, is responsible for higher cognitive functions such as decision-making, perception, and memory. Cortical regions that control these functions are specified in the developing embryo, when secreted factors from signaling centers in the brain direct cells in different regions of the developing cortex to adopt distinct fates. This model of cortical development, however, has been worked out in the lissencephalic mouse, and its relevance to cortical development in gyrencephalic species, including humans, is unknown. Differences between lissencephalic and gyrencephalic cortices suggest that patterning signals may contend with different spatial considerations in the two types of cortex. To begin to assess the relevance of area patterning mechanisms in the mouse to species with a gyrencephalic cortex, we used a gyrencephalic model, the ferret *Mustela putorius furo*. At various time-points of cortical development in the ferret, we characterized, with *in situ* hybridization, the expression patterns of several genes implicated in cortical patterning. These genes encode Fibroblast Growth Factors, Bone Morphogenetic Proteins, and Wnt proteins, along with Emx and Nr2f1 transcription factors. Comparison of the expression patterns in mice and ferrets at equivalent developmental stages

reveals strong similarities, providing evidence that highly similar signaling mechanisms could govern cortical area patterning in lissencephalic and gyrencephalic species. Furthermore, the ferret is more distantly related to rodents than are primates, making ferrets a good out-group for testing conservation of area patterning mechanisms. In particular, similar mechanisms shared by ferrets and rodents are likely to be conserved in humans and non-human primates.

Title: The role of PDK1 in the development of mice dentate gyrus

Authors: X. HAN[1], M. XU[2], B. LIU[1], T. TIAN[2], C. ZHAO[1], *J. GAO[3];
[1]Southeast Univ., Nanjing, China; [2]Nanjing Med. Univ., Nanjing, China; [3]Nanjing Med. Univ., Jiangsu, China

Abstract: Hippocampus is a crucial cortical region and administers learning and memory. Dentate gyrus is the first gateway receiving afferent input from the Entorhinal Cortex. The signal comes out from dentate gyrus to the CA zones then comes back to dentate gyrus which constitutes the classic circuit to form memories. Its substructure SGZ (subgranular zone) harbors the Tbr2 positive neuronal progenitors which can generate neurons throughout adulthood when occurs to enriched environment, stress and so on. Moreover these new born neurons can integrate into the existed neural circuit then perform the normal function. 3-phosphoinositide-dependent protein kinase-1 (PDK1) is a regulator of AGC kinases compromised with PKA, AKT (PKB) and S6K et al. PDK1 phosphorylates the highly conserved sequences on their T-loops by which to activate these protein kinases, and regulates cell apoptosis,survival,glucose uptake and storage and so on in mammals. There is no much research focused on the function of PDK1 in nervous

system. Just a few papers reported that ablation of PDK1 in nestin+ cells would result in the microcephaly. To learn more about the function of PDK1 in brain we used the Cre-Loxp approach to knock out PDK1 in Emx1 positive cells conditionally which are expressed in the dorsal telencephalon. We find the mutant mice have weaker capacity of learning and memory associated with hippocampus. Through morphology approaches the mutant postnatal hippocampus is found to have a smaller size than control. DG is the most severely impacted substructure with abnormal appearance more than decreased cell numbers. We use immunohistochemical method to detect the function of PDK1 before birth and find the ablation of PDK1 impacts the development of DG via reducing proliferation,increasing differentiation and hypogenetic radial glial scaffold. PDK1 could phosphorylate the Thr308 site of AKT whose Ser473 is phosphorylated by mTOR2. AKT is proved to be related with the survival and proliferation of neurons and mTORC2 is found to participate in the formation of dendritic of neurons. It is significant that if PDK1 modulate the development of DG via controlling these two signals.

Title: Activation of the mTOR pathway drives neurogenesis and alters neuronal fate in the olfactory bulb

Authors: ***N. W. HARTMAN**, A. GUBISTA, A. DECARLO, D. HELLTHALER;
Biol. Program, Stockton Univ., Galloway, NJ

Abstract: Neural stem cells (NSCs) of the subventricular zone (SVZ) give rise to inhibitory interneurons in the olfactory bulb based on their location in the SVZ. Recent studies have shown that activation of the mammalian target of rapamycin (mTOR) pathway can drive NSCs to differentiate and alter dendritic morphology. Here, we targeted NSCs either in the dorsal or

ventral SVZ by postnatal electroporation. Stem cells in the dorsal SVZ were more likely to produce periglomerular neurons, whereas ventral SVZ cells primarily gave rise to granule cells. In addition, activation of mTOR resulted in increased dendritic complexity in both periglomerular cells. Interestingly, driving mTOR increased overall neurogenesis only in the dorsal SVZ. In contrast, increased mTOR activity bolstered the production of periglomerular cells from the ventral SVZ, but did not the dorsal SVZ. Isolated dorsal NSCs in culture display increased mTOR pathway activity in addition to increased dorsal gene expression compared to their ventral counterparts. These results suggest that mTOR can affect regional identity of NSCs, either driving neurogenesis or altering the cell fate of progenitors.

Title: Identification of neurogenic S-nitrosylation targets in neural stem cells

Authors: *I. M. ARAUJO[1], A. I. SANTOS[2], D. M. SILVA[2], A. S. LOURENÇO[2], A. IZQUIERDO-ÁLVAREZ[3], E. RAMOS[3], C. M. CARVALHO[4], A. MARTÍNEZ-RUIZ[3]; [1]Dept. of Biomed. Abstract: Nitric oxide (NO) is a well-established regulator of neurogenesis. NO enhances proliferation of neural stem cells (NSC), and is essential for hippocampal injury-induced neurogenesis following an excitotoxic lesion. Although the main effects of NO on NSC proliferation are via activation of the ERK/MAPK and cGMP/sGC/PKG pathways, S-nitrosylation may have a substantial role in the activation and/or inhibition of several proteins involved in the neurogenic process. Protein S-nitrosylation is a post-translational modification that consists in the formation of a nitrosothiol group (R-SNO) in cysteine residues, which can promote formation of other oxidative modifications in those cysteine residues. It is one of the mechanisms underlying non-classical NO cell signaling that regulate many physiological processes, including neuronal plasticity. The aim of this work is to identify proteins modified by S-nitrosylation in conditions that promote cell proliferation in NSC derived from the subventricular zone, and that could take part in non-classical NO signaling. Treatment with S-nitroso-L-cysteine (CysSNO), a physiological permeable nitrosothiol, increased protein cysteine oxidation and S-nitrosylation in NSC, as assessed by a fluorescence switch assay. Separation by two-dimensional electrophoresis and analysis by mass spectrometry resulted in the identification of several proteins that were modified by treatment with CysSNO. From those, p21Ras, PEBP-1, PCNA, 14-3-3 proteins and hnRNP K, were the focus of further validation due to their relevance in the neurogenic context, including their involvement in the ERK/MAPK pathway. By using the biotin switch technique, we show a strong increase in oxidation and, specifically, in S-nitrosylation signal of p21Ras, PEBP-1, PCNA, 14-3-3 and hnRNP K in the presence of CysSNO. Overall, this work identifies several proteins as a target of S-nitrosylation in NSC and suggests new candidates for NO-induced regulation of neurogenesis.

Title: Zinc transporter 3 gene deletion alters adult hippocampal neurogenesis

Authors: *B. CHOI[1], I. KIM[1], B. LEE[1], J. KIM[1], A. KHO[1], S. LEE[2], M. SOHN[3], S. SUH[1]; [1]Dept. of Physiol., [2]Dept. of Neurol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of; [3]Dept. of Nursing, Inha Univ., Incheon, Korea, Republic of

Abstract: The subgranular zone (SGZ) of the dentate gyrus (DG) is the most active neurogenic region and also contains highly concentrated synaptic zinc in the mossy fiber terminals. We therefore tested the hypothesis that vesicular zinc is an important mediator for neurogenesis in this system. In support of this hypothesis, our previous studies demonstrated that hippocampal zinc is an important factor for neurogenesis in the adult brain. Application of zinc chelator and zinc-deprived diet reduced progenitor cell proliferation and neurogenesis. In addition, evidence has accumulated from numerous studies indicating that zinc is an essential trace element required in cell division, proliferation, migration, and development and further suggests that zinc may have a critical role in neurogenesis and cognitive function. To determine whether synaptic zinc is important for modulating hippocampal neurogenesis, the present study used zinc transporter 3 (ZnT3) gene deletion mice. ZnT3 is a zinc transporter that is located in the synaptic vesicle membrane and regulates levels of ionic zinc within presynaptic terminals in the hippocampus. ZnT3 knockout (KO) mice show marked depletion of synaptic vesicular zinc. Here we report that endogenous ZnT3 regulates adult hippocampal neurogenesis. Neurogenesis was evaluated using BrdU, Ki67 and doublecortin (DCX) immunostaining. Genetic deletion of ZnT3 reduced the number of BrdU and Ki67 positive cells in the SGZ of the DG. Further, we found that ZnT3 deletion reduced the number of DCX positive cells. Our findings suggest a profound role of ZnT3 in the regulation of adult hippocampal neurogenesis under physiological conditions.

Title: A maturational transition of distict Wnt signals enables a stage-specific regulation of dentate granule cell neurogenesis

Authors: *S. T. SCHAFER, J. HAN, M. PENA, F. H. GAGE;
LOG-G, Salk Inst. For Biol. Studies, La Jolla, CA

Abstract: The dentate gyrus (DG) of the hippocampus is one of the stem cell housing niches in the adult mammalian brain. Canonical Wingless-type (Wnt) signals provided by the microenvironment are one of the major niche factors that regulate the differentiation of adult neural stem cells (aNSCs) towards the neuronal lineage. Wnts are part of a complex and diverse set of signaling pathways with a wide range of possible interactions. It remains unknown whether different canonical and non-canonical Wnt signals act in a stage-specific manner to regulate distinctive steps of adult hippocampal neurogenesis. Using *in vitro* assays on adult hippocampal NSCs, we identified an attenuation of canonical Wnt/ß-Catenin signaling responsiveness in the course of neuronal differentiation, while non-canonical Wnt/Planar Cell Polarity (PCP) signaling events progressively increased. Retroviral knockdown strategies against ATP6AP2, a recently discovered core protein involved in both signaling pathways, revealed that its dual role is critical for granule cell fate and morphogenesis. We were able to confirm its dual role in neurogenic Wnt signaling *in vitro* for both canonical Wnt signaling in proliferating aNSCs and non-canonical Wnt signaling in differentiating neuroblasts. While LRP6 appeared to be critical for granule cell fate determination, *in vivo* knockdown of PCP core proteins FZD3 and CELSR1-3 revealed severe maturational defects without changing the identity of newborn granule cells. Furthermore, we found that CELSR1-3 control distinctive aspects of PCP-mediated granule cell morphogenesis with CELSR1 regulating the direction of dendrite initiation sites and CELSR2/3 controlling radial migration and dendritic patterning. In summary, the data presented here characterize a transition of Wnt signaling responsiveness from Wnt/ß-Catenin signaling to non-canonical Wnt/PCP signaling in the course of granule cell fate that was also present in a human pluripotent stem cell (hPSC)-based model of dentate granule neurogenesis. Thus, our work reveals temporally distinct roles for different Wnt signaling pathways that may be achieved through a cell-autonomous mechanism to integrate niche-derived Wnt signals in a stage-specific manner.

Title: The interaction of neuronal Sema6D and microglial Plexin-A1 in developmental neuronal death in hippocampus

Authors: *T. ITO, K. YOSHIDA, T. NEGISHI, K. YUKAWA;
Meijo Univ., Nagoya / Aichi, Japan

Abstract: In the developing hippocampus, microglia actively promotes apoptotic neuronal death. The microglial DAP12 immunoreceptor and CD11b integrin cooperatively induce neuronal apoptosis by controlling the production of superoxide ions (Wakselman S et al, 2008). Our coimmunoprecipitation assay has disclosed the association of DAP12 with the Plexin-A1 semaphorin receptor and TREM2 in postnatal microglia. However, the role of Plexin-A1 in developmental neuronal death remains unknown. In the developing hippocampus, apoptotic neurons were in contact with microglia expressing DAP12, Plexin-A1 and TREM2. There was a significant decrease of apoptotic cells in the Plexin-A1-deficient hippocampus at postnatal day 1-3 (PND1-3) as compared with wild-type (WT). The production of superoxide ions was significantly decreased in Plexin-A1-deficient microglia reflecting the dependency on Plexin-A1 signaling. The expression level of Sema6D, one of Plexin-A1 ligands was significantly higher in hippocampi at PND1-3 compared with other developmental stages. Furthermore, activated caspase-3-positive neurons exhibited the increase of Sema6D expression in hippocampi at PND1-3. Addition of recombinant Sema6D significantly increased the production of reactive oxygen species (ROS) in cultured WT microglia, but not in Plexin-A1-deficient microglia. Sema6D induced a significant increase of neuronal apoptosis in cocultures of WT neurons and WT microglia as compared with the immunoglobulin G control, which was significantly inhibited by the free radical scavenger N-tert-butyl-phenylnitrone. In contrast, Sema6D did not induce a significant increase of neuronal apoptosis in cocultures of WT neurons and Plexin-A1-deficient microglia. The expression level of Sema6D also increased in cultured neurons in which the firing was lowered by tetrodotoxin (TTX). Microglial ROS production significantly increased in cocultures of WT neurons pretreated with TTX and WT microglia, but not in cocultures of WT neurons pretreated with TTX and Plexin-A1-deficient microglia. Cocultures of WT neurons pretreated with TTX and WT microglia displayed a significant increase of apoptotic neurons as compared with cocultures of WT neurons without TTX treatment and WT microglia. In contrast, there was no significant increase of neuronal apoptosis in cocultures of WT neurons pretreated with TTX and Plexin-A1-deficient microglia. Thus, Sema6D generated by dying neurons may function as a kill me signal to induce developmental neuronal apoptosis by activating microglial Plexin-A1-mediated signal which promotes ROS production.

Abstract: Stress is defined as a challenge to the homeostatic equilibrium of the organism and when long lasting it severely affects quality of life. In fact, stress maladaptation is considered to be an etiological factor in the emergence of mood disorders like 5depression and anxiety. Stress response elicits a cascade of hormonal and behavioral changes as an attempt to maintain homeostasis and at the level of the central nervous system (CNS), the hippocampus is considered to be a central target and executor of adaptative responses. Of interest, the hippocampus is unique in its structural and cellular plasticity, in the sense that, even in adulthood, stem cells reside and continuously give rise to new neurons. This adult neurogenesis is extremely dynamic and modulated by pharmacological, environmental and physiological stimuli and the newborn neurons are considered to highly contribute to the local network. Of interest, adult neurogenesis is well known to be regulated by stress and, conversely, to regulate stress responses. Of course there is no simple, linear relationship between stress hormones and adult neurogenesis. As an attempt to disclose putative factors in this crosstalk of stress modulation, in the present work we have assessed the modulation of hippocampal neurogenesis in an animal model with a targeted deletion of lipocalin-2 (LCN2). As part of the lipocalin protein family, LCN2 plays a critical role in the regulation of various phyisiological processess, such as inflammation and innate immune response. Several roles for cell proliferation and death have also been attributed to this protein, including during development, in hematopoiesis and even cancer, mainly recognized due to the capacity of LCN2 to traffic iron within cells. In addition, LCN2-null mice were described, at a physiological level, to present a sustained activation of the HPA axis translated into increased levels of corticosterone, accompanied by an anxious and depressive-like phenotypes. Also it was described to control anxiety and neuronal excitability upon stress. But specifically how is hippocampal neurogenesis being modulated upon LCN2 deletion and to which extent it contributes to animal's behavior and stress response is not quite known. Here we show that LCN2-null mice exhibit cell proliferation deficits, accompanied by impairments in adult neurogenesis progress and in contextual fear conditioning paradigms. The current observations will certainly contribute to the current interests on the role of hippocampal neurogenesis in the

etiology of mood, identifying LCN2 as a possible key regulator of executor of adaptative responses at the hippocampus.

Title: Sp8 and Sp9 coordinately regulate olfactory bulb interneuron development

Authors: ***J. LI**, C. WANG, D. QI, Y. YOU, Z. YANG;
Fudan Univ., Shanghai, China

Abstract: The zinc finger transcription factor Sp8 is wildly expressed in the subventricular zone, rostral migratory stream and olfactory bulb (SVZ-RMS-OB system). Conditional inactivation of Sp8 in the embryonic ventral telencephalon reveals that Sp8 is required for the normal generation of some OB interneuron subtypes. Herein, we show that Sp9 is also broadly expressed in the SVZ-RMS-OB system. Sp9 is not expressed in neural stem cells and transit-amplifying progenitors (type C cells) in the postnatal SVZ; however, all neuroblasts express Sp9. In Sp9 mutant OB, parvalbumin-expressing interneurons are lost. Only one amino acid residue differs between Sp8 and Sp9 within the zinc-finger domain. Thus, these two proteins might bind to same genes and serve several redundant roles. Indeed, we observed that, in Sp8/Sp9 double conditional mutant OB, nearly all migratory interneurons (neuroblasts) failed to exit the RMS. Accordingly, none of mature interneurons were observed in the granule cell layer, external plexiform layer and periglomerular layer of the OB. These results suggest that Sp8 and Sp9 have central roles in OB interneuron development. Diverse molecular mechanisms underlying these phonotypes are currently under study.

Title: Estrogen receptor-beta (ERβ) expression in the sexually dimorphic nucleus of preoptic area (SDN-POA) and the 3rd ventricle stem cell niche

Authors: *Z. HE, M. G. PAULE, S. A. FERGUSON;
Div. of Neurotoxicology, Natl. Ctr. For Toxicology Res., Jefferson, AR

Abstract: Perinatal exposure to estrogens leads to increased SDN-POA volumes in male and female weanling rats [He et al., 2012]. Proliferative activities of hypothalamic stem cells can be identified using Ki67 labeling within stem cell reservoirs (the 3rd ventricle stem cell niche (3VSCN) and the hypothalamic parenchyma which includes the SDN-POA [He et al., 2013a]) and indicate that stem cell activity is one of the driving forces in SDN-POA development. Here, we determined if the regulation of hypothalamic stem cell activity is mediated via an estrogen receptor-initiated pathway by examining ERβ expression in the 3VSCN and the SDN-POA. **Methods.** Hypothalamic slices containing the 3VSCN or SDN-POA from weanling (n=12) and adult (n=8) Sprague-Dawley rats were processed using a triple fluorescence labeling method: anti-ERβ (label #1); anti-calbindin D28K (CB28), -nestin, or -Ki67 (label #2) and DAPI (label #3, to delineate cellular nuclei). The SDN-POA was delineated using CB28 and DAPI since DAPI-labeling demarcates the SDN-POA similar to that of CB28 [He et al., 2013b]. The 3VSCN was delineated using nestin-immunoreactivity (ir) and adjacent slices were processed to determine whether proliferating cells (Ki67-ir positive) expressed ERβ. Traditional stem cell reservoirs such as the subventricular zone (SVZ) and subgranular zone (SGZ) served as reference or control areas. **Results.** Many cells within the SDN-POA exhibited ERβ-ir labeling which was irrespective of CB28-ir labeling. The majority of 3VSCN cells that expressed nestin also expressed ERβ. Interestingly, a few proliferating (Ki67 positive) cells within the 3VSCN and the hypothalamic parenchyma, including the SDN-POA, displayed ERβ-ir labeling. A subset of cells in the SVZ was double-labeled with nestin and ERβ and a few cells co-labeled with Ki67 and ERβ. There was little evidence that proliferating cells in the SGZ expressed ERβ. **In summary**, ERβ-ir may serve as a marker of estrogen-receptor associated pathways within the SDN-POA that subserve sexually-relevant behaviors and regulate cell regenerative cycles during proliferative periods (i.e., ERβ-Ki67 co-labeled cells). Because ERβ was heavily expressed in the 3VSCN in either nestin or Ki67-positive cells, ERβ may play a role in the development of sexual

dimorphism by regulating cellular proliferation in the sexually dimorphic structures surrounding the 3VSCN, including the SDN-POA. NCTR protocols P00710 and P00706 supported this project.

Title: Sustained increase of neuronal polysialic acid level does not affect the nervous system development and maintenance but induces a mild behavioral deficit that may be attributed to synaptic dysfunction

Authors: *S. NGAMLI FEWOU[1,2], I. RÖCKLE[4], H. HILDEBRANDT[5], K. HAASTERT[5], C. GROTHE[5], V. GIESELMANN[2], M. ECKHARDT[3];
[1]Fac. of Hlth. Sciences, Univ. Des Montagn, Bangangte, Cameroon; [2]Inst. of Biochem. and molecular biology, [3]Univ. of Bonn, Bonn, Germany; [4]Neuroglycobiochemistry, [5]Univ. of Hannover medical school, Hannover, Germany

Abstract: The polysialic acid (PSA) modification of the neural cell adhesion molecule (NCAM) is an abundant posttranslational modification during development. During postnatal development, PSA is rapidly down-regulated but remains expressed in certain brain regions that are involved in neurogenesis and display structural plasticity. This significant downregulation suggests that removal of PSA after modeling of the nervous system is an important task during postnatal development of the brain. In contrast, increase of PSA level is observed in some neurological disorder including multiple sclerosis and Alzheimer's diseases. We therefore hypothesized that prevention of postnatal downregulation of PSA will affects the structural and functional properties of the nervous system. To test our hypothesis, we generated transgenic mice overexpressing the polysialyltransferase (ST8SiaIV) in neurons under the control of Th1.2 promoter. The transgene expression prevented the postnatal downregulation of PSA in neuron and most NCAM-140 and NCAM-180 in the forebrain was polysialylated. Examination of the brain region such as the olfactory bulb, lamination of the mossy fiber tract in the hippocampal formation and the development of the corticospinal tract did not revealed any abnormality as

observed in NCAM- and PSA-deficient mice. In addition normal myelin structure and myelination was observed in transgenic mice compared to wild-type littermates. In general, morphological examinations of nervous system did not reveal structural abnormalities in transgenic mice as compared to wild-type controls. Behavioral studies revealed a reduced rearing activity and exploratory behavior, while parameters of motor activity like distance traveled and mean velocity in an open field or rotarod performance were not affected in transgenic mice. These results demonstrate that preventing the postnatal downregulation of PSA has a significant effect on exploratory behavior which may be attributed to some synaptic dysfunction in the brain. The absence of a neurodevelopmental phenotype makes the transgenic mouse a useful model system suited for further exploring the effects of sustained increased of PSA level in the brain homeostasis.

Title: Diazepam Binding Inhibitor (DBI) regulates the hippocampal stem cell pool

Authors: I. G. DUMITRU[1,2], A. NEITZ[1,2], J. ALFONSO[1,2], *H. MONYER[1,2];
[1]DKFZ / A230, Heidelberg, Germany; [2]Clin. Neurobio., Heidelberg Univ. Hosp., Heidelberg, Germany

Abstract: In the mammalian brain there are two areas where neurogenesis persists in the adult: the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the dentate gyrus. Diazepam Binding Inhibitor (DBI) is expressed by SVZ neural progenitors, and plays an important role in regulating adult SVZ neurogenesis by modulating the GABA regulatory signal (Alfonso et al., 2012). Here we present evidence that DBI is strongly expressed also in SGZ stem cells and its binding to the benzodiazepine binding site of the GABAA receptor leads to a reduction in GABA-induced currents. *In vivo* knockdown of DBI in the dentate gyrus via a lentiviral strategy reduces the stem cell and amplifying progenitor population, while the overexpression had the opposite effect. Our results indicate that DBI acts at the level of the SGZ stem cells and amplifying progenitors and promotes their proliferation at the expense of their differentiation. Furthermore, knocking down DBI in the dentate gyrus abolished the proliferative

effect of enriched environment, indicating that DBI might play a role in regulating the influence of external factors on the SGZ stem cell niche. In conclusion, our results suggest that DBI regulates the production of both inhibitory (SVZ) and excitatory neurons (SGZ) and modulates the environmentally induced changes of the niche dynamics.

Title: Synaptosomal Associated Protein-25 (SNAP-25) is not essential for the survival and morphological maturation of newborn dentate granule cells in adult hippocampus

Authors: *K. C. GUSTUS[1], L. LI[1], Y. GU[2], S. GE[2], L. CUNNINGHAM[1], M. C. WILSON[1]; [1]Neurosciences, Univ. of New Mexico, Albuquerque, NM; [2]Dept. of Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Adult hippocampal neurogenesis is critical for cognition and behavior, but the requirements for integration of immature neurons into a pre-existing mature dentate circuit have not been fully elucidated. In contrast to the widely held view that the survival and maintenance of neurons in the developing CNS is dependent on their ability for action potential (AP)-dependent synaptic communication, more recent studies have demonstrated considerable brain development in the absence of evoked neurotransmitter release. However, the role of AP-dependent synaptic transmission by adult-generated dentate granule cells (DGCs) for their survival within the existing circuitry has not been elucidated. Here, we utilized a unique SNAP-25 $^{fl/fl}$:Rosa dTomato bi-transgenic mouse to selectively inactivate AP-dependent synaptic transmission in adult hippocampal progenitors using retroviral delivery of Cre recombinase. SNAP-25 is a constituent of the presynaptic exocytosis complex that is specifically responsible for evoked synaptic transmission, but not for AP-independent, spontaneous neurotransmitter release. For these studies, retrovirus was stereotaxically delivered to adult hippocampal

progenitors in adult SNAP-25 $^{fl/fl}$:Rosa dTomato bi-transgenic mice or SNAP-25 $^{wt/wt}$:Rosa dTomato control mice, targeting the hilus/subgranular zone of the dorsal and ventral hippocampal dentate gyrus. Mice were sacrificed at 4 or 8 weeks post retroviral injection and dTomato+ DGCs were imaged using confocal microscopy. Adult generated dTomato+ DGCs were observed in both SNAP-25 $^{fl/fl}$:Rosa dTomato and control mice. Interestingly, SNAP-25 gene inactivation had no overt impact on dendritic or axonal growth by newborn DGCs. Newborn DGCs from both genotypes extended dendrites into the molecular layer and mossy fiber axons to the CA3/CA2 border. These initial studies suggest that AP-dependent neurotransmitter release by newborn DGCs is not essential for their survival or morphological integration into the adult hippocampal circuitry. Whether SNAP-25$^{-/-}$ newborn DGCs display more subtle deficits in dendritic and axonal complexity is currently under investigation.

Title: β1-integrin and BMP pathway interactions in the regulation of the adult hippocampal stem cell niche

Authors: ***S. M. BROOKER**, A. M. BOND, C.-Y. PENG, J. A. KESSLER;
Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: In the adult mammalian brain, neurogenesis persists throughout life in the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus. Ongoing hippocampal neurogenesis has been shown to play a key role in cognition and mood regulation. Diverse signaling molecules regulate the adult NSC

niche, including components of the extracellular matrix. Here we investigated the role of the extracellular matrix-interacting protein β1-integrin in regulating neural stem cell maintenance and fate commitment in the adult DG. We further examined how β1-integrin interacts with the bone morphogenetic protein (BMP) signaling pathway in adult NSCs. We used the Cre/LoxP system to genetically ablate β1-integrin in the dentate gyrus of adult β1-integrin floxed mice or from cultured NSCs derived from these mice. We also performed co-immunoprecipitation studies to investigate the interaction between β1-integrin and the BMP receptor subunits. Our results show that genetic ablation of β1-integrin in NSCs *in vitro* leads to a decrease in levels of stem and progenitor cell proliferation, as well as an increase in astrocytic differentiation, an effect which can be reversed by the addition of the BMP signaling inhibitor noggin. Conditional knockout of β1-integrin in the DG of adult mice leads to disruption of the structural integrity of the SGZ and granule cell layer. Knockout of β1-integrin in the DG also alters the size of the NSC pool and modulates cell fate commitment. Further, genetic ablation of β1-integrin in NSCs leads to an increase in overall levels of BMP signaling and β1-integrin physically interacts with the type I BMP receptors in both the wild type adult hippocampus and in cultured NSCs. We conclude that β1-integrin plays a dual role in the adult hippocampal niche, both maintaining the structural integrity of the DG and regulating NSC fate commitment via modulation of BMP signaling.

Title: The transcription factor NeuroD2 regulates synaptic integration in the postnatal olfactory bulb

Authors: ***S. BUGEON**[1], O. HARDT[2], A. BOSIO[2], H. CREMER[1], A. DE CHEVIGNY[1]; [1]Developmental Biol. Inst. of Marseille, Marseille Cedex 09, France; [2]Miltenyi Biotec GmbH, Bergisch Gladbach, Germany

Abstract: Integration of new neurons into an existing circuitry represents a prerequisite for effective cell therapy in CNS disease and trauma. Postnatal olfactory neurogenesis is a valid

system to study the molecular control of this process. Using a genetic screen to isolate genes whose expression peaks concomitantly with synaptogenesis of new neurons in the olfactory bulb, we identified the transcription factor NeuroD2 as a candidate regulator of synaptic integration in the postnatal olfactory bulb. Using mutant mice in concert with transplantation approaches and *in vivo* brain electroporation we studied NeuroD2 function in the OB. We find that in mice constitutively lacking NeuroD2 olfactory bulb interneurons show normal migration, integration and dendritic spine formation. However, in a competitive context, created either by transplantation of mutant cells into a WT environment or via sh-RNA induced knock-down, NeuroD2 loss-of-function leads to a strong decrease in synapse number of postnatally generated interneurons. These results suggest that inter-cellular differences of NeuroD2 expression between neurons, more than absolute levels of NeuroD2, impact on synaptic integration.

Title: Activity-dependent regulation of neurogenesis after stroke

Authors: *H. LIANG, S. T. CARMICHAEL;
Neurol., UCLA, Los Angeles, CA

Abstract: Stroke is the leading cause of death in America and a leading cause of adult disability. Post-stroke neurogenesis has been implicated in repair and functional recovery in brain injury; however the cellular and molecular mechanism that regulates neurogenesis after stroke remains unclear. Although activity has been shown to regulate neurogenesis during development in normal brain, how modulation of activity affects neurogenesis after stroke is not fully elucidated. In this study, we employed forced use of the paretic forelimb that mimics constraint-induced movement therapy (CIMT) as a physical modulation of activity after stroke. We found that forced use of forelimb that was associated with the stroke affected area enhanced neuroblast migration and neural progenitor proliferation in the peri-infarct cortex on post-stroke day 14 and neuronal differentiation was increased on post-stroke day 60. Interestingly, when forced use was

performed in the hindlimb that was associated with stroke non-affected motor cortex from the ipsilateral hemisphere, neurogenesis in peri-infarct cortex was largely abolished. These data suggested that activity-induced neurogenesis after stroke is circuit specific and is dependent on regions of modulation. To further demonstrate the role of activity in a cell type specific manner, we utilized the Designer Receptors Exclusively Activated by Designer Drugs (DREADD) as a pharmacological approach to modulate neuronal activity. Preliminary data suggests that activation of the CaMKII-expressing neurons in the peri-infarct cortex increased neurogenesis 14 days after stroke.

Title: The Wnt receptor Frizzled-1 regulates neurogenesis in the adult hippocampus

Authors: *L. VARELA-NALLAR[1], M. D. MARDONES[1], N. C. INESTROSA[2];
[1]Ctr. Inv. Biomedicas, Univ. Andres Bello, Santiago, Chile; [2]Ctr. Envejecimiento y Regeneracion (CARE), P. Univ. Catolica de Chile, Santiago, Chile

Abstract: In the adult hippocampus, new neurons are continuously generated from neural progenitor cells (NPCs) that reside in the subgranular zone of the dentate gyrus. This process is controlled by Wnts, a family of 19 secreted glycoproteins that bind to Frizzled (FZD) receptors and co-receptors to trigger the canonical Wnt/beta-catenin pathway or non-canonical Wnt signaling cascades. Wnts regulate different steps of adult neurogenesis such as proliferation and differentiation of NPCs, and maturation of newborn neurons. The regulation of the sequential steps of neurogenesis might be mediated by specific Wnt receptors. Here, we studied the potential role of FZD1 in the regulation of adult hippocampal neurogenesis. To evaluate *in vivo* the role of this receptor, we targeted FZD1 in newborn cells using retroviral-mediated RNA interference. Retroviruses expressing control or FZD1 shRNAs were injected stereotaxically into

the dentate gyrus of 2-month-old mice. First, we evaluated neuronal fate commitment, and determined that FZD1 knockdown resulted in a strong decrease in the differentiation of newborn cells into neurons. In cells that were able to differentiate into neurons, we evaluated migration within the granule cell layer (GCL). Adult-born neurons remain primarily positioned within the inner third of the GCL; in agreement, we observed that newborn neurons expressing control shRNA were located in the first third of the GCL. On the other hand, FZD1-deficient cells showed an extended migration and were also located in the middle and outer third of the GCL. Finally, no differences were observed in dendrite development between control and FZD1-deficient newborn granule neurons. Altogether, these results indicate that FZD1 regulates specific stages of neurogenesis being involved in neuronal differentiation and migration of newborn neurons.

Title: The role of post-translational modification of FOXP2 in brain development

Authors: ***N. USUI**[1], M. CO[1], M. HARPER[1], M. A. RIEGER[2], J. D. DOUGHERTY[2], G. KONOPKA[1];
[1]Dept. of Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Dept. of Genet. and Dept. of Psychiatry, Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Mutations in the gene encoding forkhead box P2, FOXP2 result in brain developmental phenotypes including altered cerebellar size in both human patients and rodent models. FOXP2 is a transcription factor expressed in the brain; however, the regional contribution of FOXP2-mediated signaling to brain development and function remains mostly uncharacterized. In addition, while prior studies have demonstrated an important role of post-translational modifications (PTMs) in regulating the function of transcription factors in the central nervous system (CNS), the importance of PTMs of FOXP2 is unknown. We uncovered that FOXP2 is sumoylated during brain development, and identified a consensus site responsible for FOXP2 sumoylation, which is evolutionally conserved from mouse to human. Furthermore, PIAS3 and SUMO-1/2 were also identified as the E3 SUMO ligase and SUMO proteins involved in the reaction of sumoylation respectively. To investigate the functional role of FOXP2 sumoylation, we overexpressed FOXP2 wild-type (WT) and a non-sumoylated mutant of FOXP2 (FOXP2 KR) in mouse neuronal progenitors. This resulted in neurite outgrowth being promoted by FOXP2 WT, but not FOXP2 KR. In addition, gene regulation by FOXP2 was also regulated by the sumoylation state of FOXP2. Taken together, sumoylation of FOXP2 has important roles in neuronal development and regulation of downstream targets of FOXP2.

Title: Granule neuron progenitors in the developing murine cerebellum exhibit asymmetric cell division

Authors: *A. CHATTERJEE[1], P. HALDIPUR[2], I. SIVAPRAKASAM[1], V. BABU[2], S. GOVINDAN[1], S. MANI[1,2];
[1]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India; [2]Natl. Brain Res. Ctr., Gurgaon, India

Abstract: Granule neurons found in the cerebellum make for the largest population of neurons in the human and murine brain. They are generated postnatally in the External Granule Layer (EGL) wherein granule neuron progenitors undergo extensive number of cell divisions. These progenitors subsequently exit the cell cycle and migrate ventrally to form the Inner Granule Layer (IGL) where they differentiate into mature granule neurons. However, it is not known whether granule progenitors exhibit bias in the orientation planes of cell division or they divide randomly. A biased orientation might imply sensing of directional cues by the progenitors either from the Purkinje cells ventrally or the pia dorsally. We found there to be an increase in number of divisions parallel to the pia from P5-P14 (BALB/c mice used for the study). We investigated the role of the classical mitogen Sonic hedgehog (Shh), which is secreted by Purkinje cells, in regulating the division plane. Significant number of granule progenitors underwent parallel divisions in cyclopamine (Smoothened antagonist) treated mice as opposed to more number of perpendicular divisions in SAG (Smoothened agonist) treated mice. This shows that Shh can regulate plane of division in granule progenitors. Moreover, on perturbation of Shh levels using cyclopamine it was seen that number of cells expressing NeuroD1 and β-III-tubulin increased while number of PCNA positive cells decreased in the EGL. The converse was noticed in mice treated with SAG. β-catenin is a putative cell fate determinant and has been causally implicated in maintaining cerebral and cerebellar ventricular zone progenitors in cell cycle. We checked for possible asymmetric distribution of β-catenin during progenitor divisions and observed increasing asymmetric distribution of the protein over the course of cerebellar development. Additionally, β-catenin was always found to be expressed more in the daughter cell in contact with printed Shh stripes. These results show that the general principles regulating progenitor expansion and neurogenesis might be conserved across different developing regions of the brain.

Title: The Akt-mtor pathway is a key regulator of neurogenesis in the subventricular zone

Authors: *G. PEZZANO, M. A. FINGER, J. MERCURIO, N. W. HARTMAN;
Sch. of Natural Sci. and Mathematics, Stockton Univ., Galloway, NJ

Abstract: The Akt-mTOR pathway is important for cellular growth, proliferation and differentiation. Dysregulation of this pathway in neural stem cells (NSCs) can lead to neurodevelopmental pathologies, such as Tuberous Sclerosis. It is unclear whether Akt and mTOR play roles independent of each other in NSC development. NSCs in the subventricular zone (SVZ) continually generate new daughter cells that migrate to the olfactory bulb (OB), differentiating into neurons. Here, we show that a constitutively active form of Akt resulted in a threefold increase in the number of newly born neurons in the OB. In contrast to driving mTOR alone, Akt activation did not result in any apparent aberrant migration in the SVZ or OB. Both Akt and mTOR activation resulted in increased dendrite length and complexity. We also observed that Akt induces proliferation of cells in the SVZ independent of mTOR activation. These data suggest that Akt controls NSC differentiation via mTOR but may exert proliferative effects independently.

Title: Regulation of adult neurogenesis by the hippocampal cholecystokinin network

Authors: *R. H. OLSEN[1], S.-A. LIM[2], I. HANIFF[3], J. SONG[4];
[2]Biol., [3]Biomechanical Engin., [4]Pharmacol., [1]UNC Chapel Hill, Chapel Hill, NC

Abstract: Adult neurogenesis is a unique and poorly understood form of neuroplasticity that in humans is essentially restricted to the dentate gyrus (DG) of the hippocampus. Unlike developmental neurogenesis, this enigmatic process is tightly regulated by the activity of local neuronal circuits and afferent projecting systems. The identity of specific cell types, neurotransmitters, and receptors that facilitate this regulation remains critically understudied. Studies utilizing animal and cell culture models suggest that the neuropeptide cholecystokinin

(CCK) serves as a survival signals for neural stem cells in the adult brain. We have therefore examined the hypothesis that CCK may regulate adult neurogenesis by promoting neural stem cell proliferation and asymmetric neuronal fate specification, neuronal progenitor survival, and integration of immature neurons into the surrounding circuitry. We have found that neural stem cells express mRNA for the Gq-coupled CCK2 receptor, and exhibit Ca2+ transients following stimulation with the CCK2-receptor selective form of CCK (CCK8) which can be blocked by the CCK2R antagonist YM022. Intravenous administration of CCK8 produces an increase in proliferating cells in the DG, and we have found that *in vivo* chemogenetic stimulation of CCK-releasing neurons in the DG produces an increase in stem cell proliferation. Moving forward we will identify whether this effect can be blocked by knocking down CCK synthesis. To further clarify the role of the CCK-network in activity-dependent adult neurogenesis, we will utilize retrograde transynaptic tracing to identify interacting local and distant and neuronal populations.

Title: CPEB4 regulates olfactory experience-dependent granule cell survival in the early postnatal olfactory bulbs

Authors: C.-S. TSENG[1,2], *Y.-S. HUANG[1,2];
[1]Academia Sinica/Institute of Biomed. Sci., Taipei, Taiwan; [2]Natl. Def. Med. Center/Graduate Inst. of Life Sci., Taipei, Taiwan

Abstract: Cytoplasmic polyadenylation element binding protein 4 (CPEB4) is a sequence-specific RNA-binding protein, which promotes polyadenylation-induced translation of target mRNAs. Although CPEB4 is distributed widely in the brain, the neuronal function of CPEB4 remains to be revealed. In this study, we found that 3-month-old CPEB4 knockout (KO) mice had smaller olfactory bulbs (OBs), in which the granule cell layer was significantly reduced. CPEB4 null mice with normal olfactory sensitivity and memory displayed impaired olfactory discrimination, which may result from the reduction of granule cells. Since OBs continue to replenish with new interneurons from adult neurogenesis to maintain its size, we first examined if any defect in this process. Unexpectedly, no difference in adult neurogenesis between wild-type (WT) and KO littermates was found. Instead, CPEB4 deficiency-induced OB hypoplasia

resulted from increased apoptosis in granule cells during the early (i.e. the first two weeks) postnatal OB development. Moreover, sensory deprivation by naris occlusion enhanced granule cell apoptosis and reduced OB size in WT but not CPEB4 KO mice, indicating that CPEB4 governs OB growth in an olfactory experience-dependent manner. Furthermore, using RNA immunoprecipitation coupled with microarray, several RNA candidates bound by CPEB4 were identified. Currently, we are investigating which RNA targets are indeed translationally regulated by CPEB4 to contribute to the granule cell survival during OB development.

Title: L-type voltage gated calcium channels Cav1.2 and Cav1.3 in adult neurogenesis

Authors: B. VOELKENING[1], T. WEBER[1,2], *D. BARTSCH[1];
[1]CIMH and Med. Fac. Mannheim, Heidelberg Univ., Mannheim, Germany; [2]AHG Klinik Wilhelmsheim, Oppenweiler, Germany

Abstract: Differentiation of adult neural progenitor cells (NPCs) into neurons is induced by a proneural gene expression program via electrical stimuli. NPCs directly sense these excitatory changes via L-type voltage gated calcium channels (LVGCC) and translate them into Ca2+-influx triggering cascade of gene expression. LVGCC Cav1.2 and Cav1.3 are expressed in the brain, but their expression and function in adult NPCs remains elusive due to a lack of specific antibodies or selective pharmacological tools. To define the role of LVGCCs in the dentate gyrus (DG) in neurogenesis, we used a transgenic mice mouse model with conditional, inducible knockout of alpha subunits (Cacna1c and Cacna1d) of Cav1.2 and Cav1.3 channels specifically in type-1 cells of the DG (directed by GLAST-CreERT2). To trace cells with ablated Cacna1c or Cacna1d genes and their progeny, we included in the mouse model a Cre inducible GFP transgene (GFPflox) which mirrors the deletion of the conditional Cacna1c and Cacna1d -alleles by GFP expression. We induced ablation of Cacna1c and Cacna1d in 8 weeks old mice and

compared the GFP expression to control mice (GLAST-CreERT2/GFPflox). The total amount of GFP+ cells was counted, along with the neuronal marker NeuN at 6 months of age. We found a significant decrease in GFP+ and GFP+/NeuN+ cells in both Cav1.2-/- and Cav1.3-/- mice in the DG, while the ratio of GFP+/NeuN+ neurons to all GFP+ cells did not differ compared to controls. Next, we dissected the hippocampus of adult mice, isolated the GFP positive cells by FACS few days after tamoxifen-induced LVGCCs ablation and established NPC lines. Likewise to results seen *in vivo*, both Cav1.2-/- and Cav1.3-/- NPC cells *in vitro* show much lower proliferation compared to control NPCs. These findings together show that the differentiation into adult neurons is not generally impaired, but rather a reduction of the precursor cell population occurs in the LVGCC knockouts. Our results indicate that ablation of both Cacna1c and Cacna1d in Type1 cells affect their proliferation *in vivo* and *in vitro*. Interestingly, this defect in both conditional mutants can be reversed by electroconvulsive seizures (ECS) *in vivo*, the mouse equivalent of electroconvulsive therapy (ECT) in humans. Studies to investigate this effect *in vitro* are in progress. Our results suggest an eminent role of LVGCCs on adult neurogenesis and will provide a novel insight into their effect on survival, proliferation and differentiation of NPCs.

Title: Down regulated necdin expression triggers proliferation of postmitotic neurons of the rat cortex

Authors: *S. LIU, R. LIU, H. QUE, J. YANG, Q. LIN, Y. LIU, S. JING, S. JING;
Beijing Inst. of Basic Med. Sci., Beijing, China

Abstract: Mature neurons have long being regarded as terminally differentiated cells and therefore can no longer enter the cell cycle or proliferate. Quite a number of the early reports showing evidence of adult animal brain neurogenesis are now believed to be actually a view of neurons derived from neural stem cells or neural progenitor cells. NeuN-positive neurons at layer VI of the cortex of adult rat were thought to be cells newly differentiated from stem cells in the

periventricle area. Despite of these facts, we found that the reduced level of necdin, which can be induced by either the tri-iodo-L-thyronine (T3) or the necdin RNAi treatment, is able to trigger the proliferation of primary neurons both *in vitro* and *in situ* of the adult rat cortex. The enriched primary neurons (purity up to 99.99%) were first treated with T3 at different concentrations. Substantial amount of dividing neurons at different mitosis phases were observed, Low dose of T3 made parvocellular neuron division and the high concentration of T3 resulted in magnocellular neuron proliferation. About 4.6±0.7% ShcC labeled primary neurons were analyzed at G2M with flow cytometry. We further demonstrated that the dividing neurons possess several characteristics of postmitotic neurons, evidenced by specific markers, electrophysiology, ultrastructural and typical synapses between the dividing neurons and others. When different concentration of T3 was reversely administrated into the cortex of adult rat by microdialysis, the substantial amount neurons *in situ* around the microdialysis areas were found to divide. The dividing neurons at different dividing phases were labeled by either both MAP2 and ShcC or MAP2 and NeuN. Further investigation suggested that T3 functions through the inhibition of necdin's expression, which leads to the alteration of the subcellular localization of E2F1 and ultimately triggers the expression of cyclin. This phenomena is further confirmed by necdin RNAi, during which the reduced expression of necdin triggers the division of several kinds of neurons *in vivo*. To be specifically, Necdin-RNAi-adenoviruses were injected into the layer II-V of the cortex, and a substantial amount of neurons at different mitosis phases, immunolabeled by either NeuN, ShcC or Map2 were observed and recorded around the injected areas. Even the pyramidal neurons labeled by NeuN and MAP2 at layer III and V were observed to divide. Postmitotic neurons still possess the ability for proliferation provides us an opportunity in neural regeneration and thereof, renews the hope in developing strategies for cure of neural degenerative diseases.

Abstract: In the postnatal mammalian brain, neural stem cells continuously generate new neurons in the ventricular-subventricular zone (V-SVZ). New neurons born in the rodent V-SVZ take the long journey to the olfactory bulb (OB), where they differentiate into interneurons. The intracellular mechanisms that precisely control the neurons' migration speed, enabling their well-organized movement, remain unclear. In this study, we performed a global proteomic search for proteins interacting with Girdin, an essential protein for postnatal neuronal migration, by combination of immunoprecipitation and liquid chromatography tandem mass spectrometry (LCMS/MS), and we identified Gem-interacting protein (Gmip), a RhoA-specific GTPase-activating protein, as a key factor in saltatory neuronal migration. Rho signalling is known to affect the morphology and movement of various cell types, including neurons. Using RNA interference (RNAi) and FRET imaging, we revealed that RhoA is activated at the proximal leading process of migrating neurons, where Gmip is also localized and negatively regulates RhoA. Gmip controls the saltatory movement of neurons that regulate their migration speed and 'stop' positions in the olfactory bulb, thereby altering the neural circuitry. This study demonstrates that Gmip serves as a brake for the RhoA-mediated movement of neuronal somata, and highlights the significance of speed control in the well-organized neuronal migration and the maintenance of neuronal circuits in the postnatal brain.

Title: Genetic deletion of intracellular fibroblast growth factor 14 (fgf14) disrupts transition of late immature to mature newly born granule neurons in the adult dentate gyrus

Authors: *M. A. ALSHAMMARI[1,2], T. K. ALSHAMMARI[1,2], F. SCALA[1], M. N. NENOV[1], F. LAEZZA[1];

Abstract: Growing evidence indicates that adult neurogenesis, the production of mature neurons from progenitor cells in the adult mammalian brain, is linked to the etiology of neurodegenerative and psychiatric disorders. However, a complete understanding of the molecular elements at the base of adult neurogenesis remains elusive. Here, we provide evidence for a previously undescribed function of fibroblast growth factor 14 (FGF14), a brain disease-associated factor that controls neuronal excitability and synaptic plasticity, in regulating adult neurogenesis in the dentate gyrus (DG). Through a combination of BrdU incorporation studies and confocal imaging, we show that FGF14 is dynamically expressed in DG at various developing states of neural progenitors. Genetic deletion of *Fgf14* in *Fgf14*$^{-/-}$ mice leads to a significant increase in the late immature and early mature population of doublecortin and calretinin positive neurons, while the number of early progenitor Sox2 positive stem cells and mature calbindin positive neurons remained constant. Caspase-3 activity is unaffected by deletion of *Fgf14* ruling out reduced survival as a major cause of the deficit. Ongoing studies are evaluating the impact of *Fgf14* genetic deletion in the functional integration of newly born neurons in the DG circuitry. Our results provide evidence for a novel signaling pathway associated with FGF14 expression controlling adult neurogenesis, providing insights into the biology of complex brain disorders

Title: EphA4-ephrin signaling regulates postnatal development of the rostral migratory stream

Authors: *M. EASTMAN, K. L. BAKER, N. B. GALLO, J. C. CONOVER;
Dept. of Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: The rostral migratory stream (RMS), the migratory pathway for neuronal precursors to transit through the mouse anterior forebrain from the subventricular zone to the olfactory bulb, undergoes significant cytoarchitectural rearrangement during the first few weeks of postnatal life. During this time, an astroglial meshwork is established to control neuronal precursor migration, restricting migrating cells to a tightly defined area via cell-cell contact-dependent signaling. Disruption of the postnatal astroglial meshwork can lead to atypical neuroblast orientation and escape from the RMS. Little is known about the molecular coordinators of RMS development, glial meshwork formation, or migratory control of neuroblasts. Receptor tyrosine kinase Ephs and their membrane-bound ephrin ligands are indispensable for normal embryonic development and have been shown to persist in regulating adult stem cell niches. Here, we provide evidence for the expression of EphA4 and its multiple ligand ephrins in the RMS from postnatal development through adulthood, and show that disruption of EphA4 intracellular signaling impairs the formation of the astroglial meshwork and neuronal precursor confinement within the RMS. Based on our studies, we propose a model for development of the postnatal RMS into the mature, adult RMS, and implicate EphA4/ephrin molecular mechanisms in regulating tangential neuronal precursor migration in the mature brain.

Abstract: Mutations of the ATP dependent chromatin-remodeling factor CHD7 are the major cause of CHARGE syndrome (Coloboma, Heart defects, Atresia of the choanae, Retarded growth and development, Genital-urinary anomalies and Ear defects). Symptoms attributable to neurodevelopmental defects including developmental delay, coordination problems and autistic traits are frequently identified. Furthermore we recently reported cerebellar vermis hypoplasia and abnormal foliation by magnetic resonance imaging (MRI) in a subset of patients. These neuroanatomical findings imply a role for CHD7 in post-natal cerebellar development, however, despite the frequency of clinical signs, mechanisms underlying neuropathology in patients remain unknown. Here, we report cerebellar hypoplasia, purkinje cell disorganization, motor deficits and developmental delay in a mouse model that conditionally deletes *Chd7* from granule cell precursors (GCps) and show that Chd7 is critical in regulating granule cell proliferation and differentiation *in vivo*. We report a crucial role for Chd7 in the regulation of *Reln* gene expression and identify a significant down regulation of *Reln* in GCps of the conditional mutants by RNA-seq and qPCR. Recessive mutations in RELN are associated with cerebellar hypoplasia and expression is down regulated in post-mortem cerebella from autistic patients. Despite these findings mechanisms that regulate RELN expression are not known. We provide functional evidence that Reln contributes to cerebellar hypoplasia *in vivo* by showing a partial rescue of the central lobule hypoplasia, which was most severely affected in the *Chd7* mutant, through the

ectopic expression of *Reln*. Finally, we report a mechanistic link between Chd7 and Reln and show that Chd7 is responsible for maintaining an open chromatin state at the Reln promoter. These findings outline a critical role for CHD7 in fine-tuning gene expression in the postnatal cerebellum and provide a link between CHD7 and a pathway associated with cerebellar hypoplasia, motor coordination deficits and autism.

Title: The role of camkiiα-expressing granule cells in the adult olfactory bulb

Authors: ***S. MALVAUT**[1], L. DAROLES[2], L. DAVID[1], S. GRIBAUDO[2], I. CAILLÉ[2], A. SAGHATELYAN[1];

Abstract: The olfactory bulb (OB) is one of few brain regions that constantly renews its interneuronal populations, periglomerular and granule cells (GCs). GCs play an important role in the odor information processing and different subtypes of GCs have been described through expression of neurochemical markers. It remains however completely unknown if different GCs subtypes play a distinct role in olfactory processing and odor behaviour. We demonstrate that 50% of both pre-existing and adult-born GCs express the Ca2+/calmodulin-dependent protein kinase IIα (CaMKIIα), independently of their age. CaMKIIα is a major actor of synaptic plasticity with numerous substrates. Morphological analysis of CaMKIIα immmunoreactive cells show that they are not distinguishable from their CaMKIIα negative counterparts in terms of localization in the granule cell layer, dendritic arborization and spine density. Intriguingly, however, 90% of the early immediate gene cfos expressing cells in the OB belonged to the CaMKIIα immunoreactive population. CaMKIIα positive cells receive less inhibition as compared to their CaMKIIα negative counterparts since displaying a lower amplitude of

spontaneous and miniature inhibitory postsynaptic currents (IPSCs). The smaller inhibitory drive onto the CaMKIIα positive cells could explain the preferential recruitment of this subpopulation of GCs in basal olfactory conditions. By contrast, associative odor memory and perceptual learning paradigms resulted in the increased percentage of cfos+/CaMKIIα- cells. Pharmacogenic inhibition of CaMKIIα immunoreactive GCs using DREADD approach affected the short-term memory of animals to odors. Our data suggest that CaMKIIα positive and negative GCs may be differentially recruited and play distinct roles during different odor tasks.

Title: Engrailed-2 plays a cell autonomous role in regulating proliferation and cell death in hippocampal neural stem cells *in vitro*

Authors: *M. DURENS[1], S. CHUNG[2], E. DICICCO-BLOOM[2];
[1]Rutgers Univ., Piscataway, NJ; [2]Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: Engrailed-2 (En2) is a homeodomain transcription factor that plays important roles in cerebellar development. En2 knockout (KO) mice display abnormalities in cerebellar size and foliation, and we have previously shown that En2 regulates the cell cycle in cerebellar granule precursors. However, our recent behavioral studies indicate abnormalities in forebrain-related behaviors in En2-KO mice, including deficits in social interaction, fear conditioning and learning. These deficits are accompanied by changes in forebrain structure, including reduced weight, size and cell number in several areas including hippocampus. Indeed, in previous En2-KO studies at P21 we found 17% less granule neurons in dentate gyrus, accompanied by 2-fold increase in stem cell proliferation and 70% increase in immature neuron apoptosis. These abnormalities in neurogenesis have been associated with deficiencies in monoamine levels and innervation in the KO hippocampus, consistent with non cell autonomous mechanisms. On the other hand, while major En2 expression is in the hindbrain, we have found low levels of En2

expression in the hippocampus, raising the possibility of cell autonomous functions. To examine this issue, neurosphere cultures were derived from hippocampus of wild type (WT) and KO mice. Expression of En2 mRNA was detected in WT neurospheres but was absent in KO cells. To examine cell autonomous effects, primary neurospheres from P7 WT and KO mice were incubated in defined media with FGF and EGF and assayed for neurosphere numbers and markers of proliferation (BrdU incorporation) and apoptosis (cleaved-caspase3, pyknosis). The assay revealed no change in numbers of primary spheres, but showed an increase in the frequency of larger spheres in En2-KO, suggesting potential effects on proliferation and/or survival. Compared to WT neurospheres, the KO exhibited a 2-fold increase in BrdU labeling ($p<0.005$) as well as apoptosis ($p<0.05$). We are examining whether proliferation and apoptosis are associated with early (Sox2, Tbr2) and late (Dcx) neural stem cells respectively. These studies suggest that En2 expression plays a role in regulating proliferation and apoptosis in hippocampal neural stem cells *in vitro*. While evidence of En2 expression in hippocampal subgranular zone cells *in vivo* remains uncertain, these *in vitro* studies support a functional role. In turn, the structural and behavioral deficits observed in the KO may reflect absence of local En2 expression, though further studies are warranted. More broadly, these studies indicate how developmental regulatory genes can impact brain structure and function through diverse region and time dependent activities.

Munich German Res. Ctr. for Envrn. Hlth. (GmbH), Neuherberg, Germany; [4]Physiological Genomics, Med. Faculty, Univ. of Munich, Munich, Germany

Abstract: Adult neurogenesis represents one form of non-synaptic neural plasticity critical for brain homeostasis and for adaptations to the ever-changing environment. In fact, several studies suggest a relevant role of newborn neurons in the adult brain for the pathogenesis and treatment of stress-related disorders including depression. Despite its relevance for both the physiological and pathological conditions, the molecular signature behind the neurogenic process occurring in the dentate gyrus of the adult hippocampus is still poorly described. Hence, it became clear the importance to better understand the mechanism and characterize the factors that regulate adult hippocampal neurogenesis. Furthermore, the understanding of important players in processes such as proliferation, maturation and specialization of neuronal precursors may reveal promising modulators of the adult neurogenic process with therapeutical potential. Herein, we described AP2gamma, a transcription factor known to display a role in neurodevelopmental processes, as a trigger for the generation and maturation of new glutamatergic neurons in the adult brain. Subsequently, we describe the mechanisms by which AP2gamma regulates glutamatergic neurogenesis *in vitro* (using transfected cell lines) and *in vivo* (using both AP2gamma knock-out and conditional AP2gamma mice and over-expressing retroviral vectors). Additionally, using structural, electrophysiological and behavioral end-points we demonstrated a critical role of AP2gamma in hippocampal and prefrontal cortex activity. To further clarify the importance of AP2gamma as an effective modulator of the adult hippocampal neurogenesis in a pathological context, wild-type (WT) and AP2gamma +/- mice were exposed to a chronic mild stress (CMS) protocol, which triggers depression-like features. Then, we accessed the molecular and behavioral impact of AP2gamma deletion in healthy and depressive-like animals. Results show that, under stress conditions, the heterozygous deletion of AP2gamma induces an increase of adult neurogenic progenitors consistent with a resilient effect to the CMS-induced deficits in cognitive tasks. Taken together, these evidences suggest a strong implication of AP2gamma to brain function both in physiological and pathological conditions.

Title: Mbd1- knockout alters the progression of adult neurogenesis *in vivo*

Authors: *E. JOBE, Y. GAO, J. MLADUCKY, X. ZHAO;
Univ. of Wisconsin, Madison, WI

Abstract: MBD1 is a nuclear protein that binds to both methylated and unmethylated DNA and is thought to repress gene expression by recruiting chromatin remodeling factors. Knocking out Mbd1 in mice causes learning and memory problems that are linked to hippocampal neurogenesis as well as behavioral phenotypes that are reminiscent of Autism. These mice generate fewer mature neurons in the hippocampus, a deficit which is likely a major contributor to their behavioral phenotypes. The present study investigates the role of MBD1 in adult neural stem cells (aNSCs or NSCs) located in the dentate gyrus, a population of cells that continuously gives rise to new neurons and astrocytes in the adult brain. To study aNSCs *in vivo*, Mbd1-KO mice were crossed with mice that express GFP under the control of the nestin promoter, a protein expressed in neural stem cells. Eight week old male mice were used for these studies; females were also examined for some experiments, but no significant differences between sexes were found. Using β-gal expression, which is under the control of the endogenous Mbd1 promoter in the KO allele, we determined that MBD1 has a bimodal expression pattern throughout the stages of neurogenesis: it is expressed in stem cells and mature neurons, but not in immature neurons, or astrocytes. Contrary to expectations, Mbd1-KO mice have more nestin-GFP positive cells, as determined by stereology and FACS sorting. Yet the proportion of activated and proliferating cells within the nestin-GFP+ population is the same between KO animals and WT controls. However, there are fewer DCX+ immature neurons but more DCX /Nestin-GFP double positive cells. RNA sequencing of nestin-GFP sorted cells reveals that there are significant changes in gene expression between WT and KO animals. *In vitro*, neuronal genes are upregulated in proliferating Mbd1-KO aNSCs, yet neuronal differentiation is reduced. These results show 1) a novel expression pattern for MBD1 and 2) reveal that the loss of MBD1 alters the progression of adult neurogenesis. Understanding the role of MBD1 in aNSCs will inform our understanding how subtle alterations in the epigenetic landscape during adult neurogenesis can lead to lasting changes in the brain.

Title: Neurodevelopmental effects of octopamine in isolation-induced social behaviors in Pheidole dentata

Authors: *R. S. GORE, M. A. SEID;
Biol., Univ. of Scranton, Scranton, PA

Abstract: Ants are eusocial insects that live in constant contact with their nestmates. Social behaviors like trophallaxis, allogrooming, and self-grooming function to transfer cuticular hydrocarbons onto other ants in the colony (Boulay et al. 2000a; Boulay et al. 1999, Lenoir and Hefetz, 2001; Boulay et al., 2000b). Hydrocarbon profile homogenization allows them to discriminate a nestmate from an intruder (Dahbi et al, 1999; Boulay et al. 2000a; Boulay and Lenoir, 2001). Given the importance of continuous contact with nestmates, prolonged periods of social isolation can be highly stressful and deadly (Boulay et al. 1999). Isolation increases the duration of social behaviors, and Octopamine (OA), a norepinephrine analog in invertebrates, modulates this process (Farooqui, 2012, Boulay et al. 2000a, Boulay et al. 2000b, Wada-Katsumata, 2011). The exact mechanism through which OA mediates isolation-induced social behaviors is unknown. To study the behavioral mechanism of OA on social behavior, we conducted two sets of experiments. We acutely treated adult Pheidole dentata workers with 15nL of 2.4% OA (in N,N-Dimethylformamide, DMF) following 5-day isolation, and recorded their social interactions. To determine the developmental effects of OA, we treated pupa with 15nL of 1.8% OA (in DMF) and allowed them to eclose and mature. The developed adults were then isolated for 5 days and behaviorally tested. We found an increase in duration of social behaviors, particularly allogrooming, in adults treated with OA. Surprisingly, DMF significantly lowered the duration of social behaviors compared to controls, but OA rescued these behaviors, such that OA treated ants did not significantly differ from controls or vehicle group. Therefore topical acute OA treatment had a behavior enhancing effect in adults (both isolated and non-isolated) and a protective effect during development. Detrimental effects of DMF due to chronic exposure has been well documents in mammals, however, we show that acute DMF treatment during development can be detrimental and OA may be protective against the damage.

Title: Global and site-specific epigenetic impact of alcohol on the developing brain and partial protection by S-adenosylmethionine

Authors: *M. RESENDIZ[1], J. REITER[2], F. ZHOU[3];
[2]Obstetrics and Gynecology, [3]Anat. and Cell Biol., [1]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Fetal alcohol spectrum disorder (FASD) affects approximately 1/100 children in the US. Symptoms range from severe facial dysmorphology to mild, undetectable cognitive impairment. Recent strategies such as choline and folate supplementation have shown ameliorating potential, particularly in the behavioral aspect. However, the molecular evidence informing how methionine metabolism may be involved in FASD is unclear. To assess the effects of alcohol and methionine supplementation on developing neural systems, we employed a stem cell model of neural differentiation where cells were exposed to 175 or 350mg/dL alcohol, 40mM S-adenosylmethionine (S-AMe, an active methyl donor), or all for three days. Here we report that alcohol negatively impacts DNA methyltransferase (DNMT) activity in a dose-dependent manner (2-fold decrease at 175mg/dL, $p<0.01$) and that this event is correlated with decreased DNA methylation and neural stem cell survival. Though S-AMe appeared to improve phenotypic properties, it did not significantly improve DNMT activity or global DNA methylation. Next, we extended the study to a developmental mouse model. C57 BL/6 mice were bred and introduced to an alcohol liquid diet (4% v/v), isocaloric parifed liquid diet, or alcohol liquid diet (4% v/v) supplemented with 10mM S-adenosylmethionine from embryonic days 7-16. At E17, embryonic tissues were dissected for analysis (n>4 litters/group). Examination of two DNA methylation markers abundant in the brain (5-methylcytosine, 5-meC; 5-hydroxymethylcytosine, 5-hmC) demonstrated that alcohol inhibits global DNA methylation (5-meC, cerebellum, $p< 0.05$; 5-hmC, cerebellum, $p<0.05$; 5-hmC, cortex, $p<0.05$) and that S-AMe may alleviate the negative effects of alcohol on methylation (5-meC, cerebellum, $P>0.05$; 5-hmC, cerebellum, $p<0.05$; 5-hmC, cortex, $p<0.05$). To address how alcohol-induced epigenetic inhibition may more-specifically be tied to the dysregulation of neural development, we used methylation-sensitive restriction enzyme digestion PCR and methylation-sensitive pyrosequencing to assess the effects of alcohol and S-AMe on transcriptionally-relevant sites on

the synaptic gene *Syt2* and the neural specification gene *Ngn1*. We describe that fetal exposure to alcohol decreases methylation at important CpG sites and that these can be at least partially rectified by S-AMe supplementation. This evidence supports a protective role for methionine supplementation in alcohol-related developmental outcomes and sheds greater light on the molecular basis of alcohol and epigenetics. Title: Role of adenosine A2A receptors on brain-derived neurotrophic factor (BDNF)-induced neurogenesis in the subventricular zone of Sprague-Dawley rats

Authors: *S. XAPELLI[1,2], F. FERREIRA[1,2], D. M. PEDRO[1,2], M. DUARTE-SAMARTINHO[1,2], F. F. RIBEIRO[1,2], A. M. SEBASTIÃO[1,2];

Abstract: Constitutive neurogenesis takes place in both adult mammalian subventricular zone (SVZ) and subgranular zone of the dentate gyrus. While BDNF is known to regulate SVZ neurogenesis, the role of A2A receptor (A2AR) is not known. SVZ neurospheres obtained from early postnatal (P1-3) Sprague-Dawley rats were prepared in serum-free medium (SFM) containing epidermal growth factor (EGF) and were subsequently seeded onto poly-D-lysine-coated coverslips and grown in differentiation conditions (removal of EGF). One day after plating, cells were treated with BDNF (30ng/mL), A2AR agonist CGS21680 (30nM) and/or antagonist ZM241385 (50nM). We observed that incubation with A2AR agonist or antagonist alone did not affect cell proliferation, as measured by BrdU incorporation (Control: 100.0±0.0%; CGS21680:107.8±7.2%; ZM241385: 94.3±9.5%) and neuronal differentiation, as evaluated by neuronal nuclei (NeuN) immunocytochemistry (Control: 100.0±0.0%; CGS21680:113.8±9.6%;

ZM241385: 112.8±5.2%). However, BDNF enhancement of cell proliferation (142.2±7.3%) and differentiation (162.0±10.4%) was completely prevented by A2AR antagonist (BDNF+ZM241385 (BrdU): 102.2±3.5%; BDNF+241385 (NeuN): 106.9±9.6%). For quantifying self-renewal capacity of stem/progenitor cells, SVZ dissociated cells obtained during the culture procedure were grown in SFM treated with BDNF and/or CGS21680. After 7 days, primary neurospheres were counted, collected, dissociated as single cells and grown in SFM without the drugs. After further 7 days, secondary neurospheres were counted. For the cell-fate study, dissociated SVZ cells, seeded in SFM and treated for 24 hours with the drugs, were stained for Sox2, a marker of neural stem/progenitor cells. Cell-pairs resulting from the division of a single SVZ stem/progenitor cell were counted and categorized in 3 groups according to their Sox2 expression: in both daughter cells (Sox2+/+), in only one of the daughter cell (Sox2+/-) and no expression (Sox2-/-). We showed that both A2AR activation and blockade did not change self-renewal capacity nor cell division type when comparing with control condition. Also, A2AR antagonist did not affect BDNF-mediated increase of Sox2+/+ cell-pairs. Data suggest that A2AR activation does not have a role on cell division type nor on self-renewal capacity of stem/progenitor cells. Nevertheless, besides the absence of A2ARs direct effect, the role of BDNF on cell proliferation and neuronal differentiation is dependent on the endogenous co-activation of A2ARs.

Title: Both inherent and acquired aerobic capacity protect against a chemotherapy-induced decline in cardiorespiratory and hippocampal fitness

Authors: *C. M. TOGNONI[1], N. S. NATH[1], S. M. LOOMIS[1], R. M. PEACE[2], E. A. BABB[3], E. F. O'STEEN[4], L. G. KOCH[5], S. L. BRITTON[5], L. W. JONES[6], C. L. WILLIAMS[1]; [1]Psychology & Neurosci., Duke Univ., Durham, NC; [2]Pathology, Duke Univ. Med. Abstract: Cardiotoxicity is one severe side effect of cancer treatments, such as anthracycline chemotherapy (doxorubicin), and can lead to congestive heart failure. Additionally, many patients experience progressive cognitive impairment following treatments for cancer − a phenomenon commonly referred to as "chemo brain." Cardiorespiratory fitness (CRF), often measured by aerobic capacity (or VO2 max) obtained from a fitness test, is thought to be one of the most powerful predictors of cardiovascular and all-cause mortality, as well as cancer survival. In rodents, voluntary wheel running has been shown to protect against the cancer treatment-induced decline in cognition and neurogenesis in the hippocampus of the adult brain, which might hint at the potential for increased CRF to be neuroprotective. However, measures of CRF are largely absent from rodent studies on the brain. To investigate whether a high level of CRF could protect against neurotoxicity as well as cardiotoxicity, four weekly rounds of doxorubicin chemotherapy were administered to rats that were selectively bred for 31 generations for low (LCR) and high (HCR) capacity for running (Koch & Britton Lab). At baseline, HCR rats have two- to three-fold higher aerobic capacity than LCR rats as measured by an incremental treadmill fitness test. We previously reported that, compared to LCR rats, HCR rats also had a two- to three-fold greater number of young neurons in the hippocampus that was correlated with highly accurate cognitive abilities. While doxorubicin induced a progressive decrease in aerobic capacity as well as neurogenesis, HCR rats remained at higher levels of aerobic capacity and neurogenesis compared to even saline-treated LCR rats. HCR and LCR rats that received individualized high-intensity interval treadmill training throughout doxorubicin treatment weeks demonstrated positive effects of exercise on both aerobic capacity and neurogenesis, regardless of inherent aerobic capacity. Overall, these findings demonstrate that inherently high CRF or increased CRF that is acquired by exercise training is protective against chemotherapy-induced damage to the heart and the brain.

Title: Maternal ingestion of artificial sweeteners and it's effect on the developing cerebellum

Authors: *Z. M. BAUCHI, R. A. KAREEM, A. ALHASSAN;
Ahmadu Bello Univ., Zaria, Nigeria

Abstract: Due to the proven link between consumption of sugar and tooth decay, nutritional deficiencies, diabetes, heart disease and obesity; manufacturers of many beverages and confectionaries have turned to artificial and non - nutritive sweeteners as an alternative to sugar. These sweeteners enhance the flavor of foods while reducing calories and the risk of disease. Saccharine is a non - nutritive sweetener. It is found in diet or sugar free sodas, diet coke, coke zero, desserts, sugar free gum, drink mixes, baking goods, cereal, breath mints, chewable vitamins and toothpaste. It is also one of the oldest artificial sweeteners available. Because of its health benefits and wide spread popularity, we decided to investigate the effect of maternal ingestion of saccharin on the developing cerebellum and compare it with maternal consumption of sugar. 15 pregnant female wistar rats were groups into 3, a control, sugar and saccharin group. The control group was administered distilled water, while the sugar and saccharin groups were administered with 14850mg/kg of sugar and 7100mg/kg of saccharin respectively daily throughout gestation and 2 weeks after delivery. The pups were sacrificed at birth, at 1 week and at 2 weeks of age, morphometric measurements taken and the brains harvested and processed for histological examination. Organ body weight ratio of the sugar and saccharin groups increased in comparison to the control, and the saccharin group were observed to have a greater brain weight than the sugar and control groups. Histological examinations revealed some cell damage in the saccharin group. **Keywords:** artificial sweeteners, cerebellum, development,

Title: Injury-induced neurogenesis in the adult mouse spinal cord

Authors: *L. WANG, C.-L. ZHANG;
Mol. biology, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Spinal cord injury (SCI) leads to permanent neuron loss and disruption of neural circuitry with a consequence of paralysis and long-term disability. Although neural progenitor cells exist in the adult mammalian spinal cord, they rarely produce neurons. In this study we examined whether endogenous neurogenesis can be stimulated by injuries. SCI was introduced by crush, contusion, hemi-section, or stab-wound in adult mice. Neurogenesis was analyzed by immunohistochemistry at various time points post injury. Interestingly, doublecortin (DCX)-positive neuroblasts/immature neuron-like cells were detected surrounding the lesion site at 7 dpi in all the above injury models. When compared to young (2-3 months) and middle aged (6-12 months) mice, the number of DCX-positive cells is much reduced in older (18 months) mice. Some of the DCX-positive cells found at 7 dpi are also Tuj1-positive suggesting a fate of neurons. Immunohistochemistry showed that a fraction of DCX-positive cells are proliferative. A time course analysis revealed that the number of DCX-positive cells declines rapidly with time. Ongoing experiments are aimed at examining survival and maturation of the injury-induced DCX-positive cells. Lineage mapping experiments are also conducted to determine their origin and fate. We hope to provide new insights into the injury-induced neural response and define ways for promoting intrinsic regeneration in the adult injured spinal cord.

Title: An investigation of the early cellular responses associated with an ischemic event: cortical and hippocampal profile of cellular markers EGFR, CD133, NeuN and Nestin

Authors: *G. WEMHOFF, R. SWEAZEY, B. HONG-GOKA, S. TOPALOV, F.-L. CHANG; Med. Educ., Indiana Med. Sch., Fort Wayne, IN

Abstract: Routinely, investigations centered on examining neuronal injury and recovery initiate following several hours to days after reperfusion. While these studies continue to build the large database of information regarding cellular responses, infiltrating cell populations, and potential

treatments to reduce hypoxic impact, investigations focused on examining the more immediate cellular responses to an ischemic event are limited. Central to this work is our attempting to gain insight as to why models systems that demonstrate a positive effect following exogeneous agent administration, fail to demonstrate any positive response when applied to human trials. It is established that reducing secondary responses such as immune infiltration lead to an apparent decrease in the core ischemic region. We want to look early following the ischemic event in order to eventually identify approaches that maximize the preservation and recovery of the penumbra. To this end we initiated a series of studies to examine the cellular profile/response of the cortical and hippocampal cells immediately upon the conclusion of a limited, two hour, ischemic event. Using the intraluminal suture technique, rats were exposed to two hours of ischemia without reperfusion. Animals were sacrificed and cell suspensions prepared from ischemic and nonischemic cortical and hippocampal regions and single cell suspensions were stained and subjected to flow cytometric analysis. In this study, epidermal growth factor receptor, prominin-1, the neuronal nuclear antigen and nestin were the initial targets. Early results suggest a differential expression in the percentage of EGFR and CD133 expressing cells when nonischemic naïve regions and ischemic regions were compared: EGFR naïve: cortex - 3%/hippocampus - 9%; EGFR ischemic: cortex - 12%/hippocampus - 13%, and CD133 naïve: cortex - 8%/hippocampus - 26%; CD133 ischemic: cortex - 43%/hippocampus - 33%.

Title: Periodic Fasting Mimicking Diet reverses age-dependent decline in neurogenesis and enhance cognitive performance

Authors: ***I. CHOI**, P. CHILDRESS, G. NAVARRE, S. BRANDHORST, V. LONGO; USC, Los Angeles, CA

Abstract: Prolonged fasting promotes resistance to multiple stress and cause changes in aging biomarkers but its effects on longevity are poorly understood. We developed a simple diet that

mimics the effects of fasting (Fasting Mimicking Diet; FMD), and found that maintenance of the young (12 weeks old), middle age (6 months old) or the old (18 months old) mice on either a single FMD or cycles of FMD regimen resulted in a significant increase in number of proliferating cells in the dentate gyrus and the cycles of fasting mimicking diet reduces the age-dependent decline in adult neurogenesis. Furthermore, these mice also showed enhanced hippocampal dependent learning and memory performances. We demonstrated that the increase in the neurogenesis is associated with a decrease in hippocampal IGF-1 level and PKA activity as well as an increase in the neuronal differentiating and surviving factor, NeruoD1. We propose that FMD cycles can enhance cognitive performance and delay age-dependent cognitive decline in part by promoting neurogenesis.

Title: The effects of synaptic zinc, fluoxetine and stress on adult hippocampal neurogenesis

Authors: *J. M. BOON[1], M. J. CHRUSCH[2], R. H. DYCK[1];
[1]Psychology, [2]Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Adult neurogenesis has been observed in the dentate gyrus of the hippocampus and the olfactory bulbs. In adult hippocampal neurogenesis (AHN), newly formed cells migrate into the granule cell layer of the dentate gyrus where they express neuronal markers, elaborate axons, make functional synaptic connections, and improve hippocampal-dependent behaviours. The level of AHN can be modulated by a variety of factors - it is increased by exercise, environmental enrichment and exposure to selective serotonin reuptake inhibitors and decreased

by stress and ageing. We recently showed that environmental enrichment-induced increases in AHN, and improvements in hippocampal-dependent behavioural tasks were ablated in animals lacking synaptic zinc (ZnT3-knockout (KO) mice). Here, we examine whether synaptic zinc is also essential for modulation of AHN by other factors, specifically, exposure to fluoxetine and/or to stress. Female ZnT3-WT and -KO mice were chronically exposed to fluoxetine or vehicle, while in stressed (single-housed) or non-stressed (pair-housed) conditions for 6 weeks. All animals then underwent behavioural testing (elevated plus maze, novelty-suppressed feeding, pattern separation), and levels of AHN were assessed. We found that synaptic zinc is necessary for fluoxetine-induced increases in AHN, in both stressed and non-stressed mice. We also found that behavioural benefits associated with fluoxetine-induced increases in AHN are ablated in all stressed animals. In non-stressed animals, only WT animals demonstrate the behavioural benefits of fluoxetine thus indicating that synaptic zinc is necessary for the behavioural benefits of fluoxetine. These data implicate synaptic zinc as an essential modulator of AHN, acting upstream of the effects of environmental enrichment and fluoxetine.

Title: Long-term impact of neonatal ethanol exposure on hippocampal adult neurogenesis, BDNF expression, and bdnf DNA methylation in rats

Authors: *K. E. BOSCHEN[1], K. J. CRISS[2], T. L. ROTH[1], A. Y. KLINTSOVA[1];
[1]Psychology, Univ. of Delaware, Newark, DE; [2]Psychological and Brain Sci., Univ. of Delaware, NEWARK, DE

Abstract: Exposure to ethanol *in utero* in humans may result in neuroanatomical, cognitive, behavioral, and physiological deficits. Certain brain structures, including the hippocampus, are particularly sensitive to teratogenic insult during the “brain growth spurt” (occurring during the third trimester in humans and first two postnatal weeks in rodents), potentially contributing to the memory and behavioral deficits observed in models of developmental ethanol exposure. Ethanol

exposure during the third trimester-equivalent has been shown to negatively impact hippocampal neuroplasticity, increase apoptosis, decrease dendritic morphology, and impair adult neurogenesis and LTP. The current study investigates the effects of a binge ethanol exposure during neonatal development on expression of brain-derived neurotrophic factor (BDNF) and exon-specific BDNF mRNA transcripts in adulthood. On postnatal days (PD) 4-9, ethanol-exposed rat pups (AE) were intragastrically intubated 2x daily with 5.25 g/kg/day ethanol. Sham-intubated (SI) animals were intubated alongside AE pups without liquid and suckle control (SC) animals were undisturbed. Animals were assigned to one of three housing conditions from PD30-72: social housing (SH), wheel running only (WRWR), or twelve days of WR followed by living in a complex environment (WREC), and sacrificed on PD72. Current data suggests that ethanol exposure does not have a long-term effect on new cell proliferation at PD72 (as measured by Ki-67 and doublecortin immunocytochemistry), but impacts long-term cell survival and dendritic complexity of dentate gyrus granule cells, resulting in less total dendritic material. Basal BDNF mRNA and protein expression does not seem to be affected by ethanol exposure at PD72, suggesting that maintaining changes to dendritic complexity occurs through other mechanisms. A differential effect of WRWR and WREC on BDNF gene expression was found, with WRWR increasing gene expression while WREC did not. Previous work from our lab shows that ethanol exposure affects BDNF expression and DNA methylation shortly following the ethanol exposure (PD10), however the current data suggest that these alterations become more subtle across the lifespan. Impairments to adult neurogenesis suggest that ethanol-induced alterations to expression of other plasticity-related factors may play a role as well. Title: Voluntary exercise mediated enhanced neurogenesis does not impair the recall of retrograde memory

Authors: *A. K. SHETTY[1,2], M. KODALI[1,2], T. MEGAHED[1], V. MISHRA[1], B. SHUAI[1,2], X. RAO[1,2], B. HATTIANGADY[1,2];
[1]Mol. and Cell. Med., Inst. for Regenerative Med, TAMHSC Col. of Med., Temple, TX; [2]Res. Service, Olin E. Teague Veterans' Med. Center, Central Texas Veterans Hlth. Care Syst., Temple, TX

Abstract: Physical exercise is beneficial for boosting cognitive and mood function as well as for easing neuropsychiatric disorders. Many studies have implied that enhanced neurogenesis in the hippocampus is one of the substrates mediating these favorable effects. Yet, a recent study using mouse model has shown that running-induced increased neurogenesis impairs the recall of hippocampus-dependent memories that were made prior to the exercise regimen (Akers et al., Science 344: 598-602, 2014). The study also proposed that reconfiguration of the DG-CA3 circuitry through addition of greater numbers of granule cells reduces the ability of a given set of cues to re-invoke the same pattern of activity that occurred at the time of memory formation as a possible reason for the degradation of retrograde memories. This interesting finding raised a vital question whether such forgetting induced by running (via enhanced neurogenesis) is applicable to all mammals. Hence, we ascertained whether voluntary running exercise would promote forgetting in young male F344 rats. Animals were first subjected to 8 sessions of water maze training followed by a probe test (PT) at 24 hrs after the last training session. Animals displaying similar memory recall ability were next assigned randomly to two groups: an exercise group in which rats were individually housed in larger cages with access to running wheels (n=14) and a sedentary group where rats were housed in standard cages (n=15). Animals also received 5'-bromodeoxyuridine injections on days 15-17 of the running/sedantary period. Animals in the exercise group ran an average of 1.2 Kms/day and 31 kms for the entire 28-day duration. A second PT conducted after 28-day housing as above revealed similar ability for memory recall between the exercise and sedentary groups, evidenced through increased dwell times in the platform quadrant vis-à-vis other quadrants. Comparison of additional parameters of memory recall revealed the same. Analyses of the DG in animals euthanized a week after the 2nd PT using doublecortin immunostaining revealed that neurogenesis was increased by ~1.5 folds in the exercise group. A similar increase was seen when net neurogenesis was quantified in animals euthanized 4 weeks after the 2nd PT. These results are in sharp contrast to findings in the previous mouse study. The discrepancy likely reflects differences in kilometers ran, the extent of exercise-induced increase in neurogenesis and the type of memory test employed. Nonetheless, our results provide novel evidence that moderate physical exercise induced increases in neurogenesis do not interefere with the recall of memory that was formed prior to the exercise regimen.

Title: Curcumin improves memory and mood with enhanced neurogenesis and alleviation of inflammation and oxidative stress in a model of gulf war illness

Authors: *M. KODALI[1,2], B. HATTIANGADY[1,2], G. SHETTY[1,2], B. SHUAI[1,2], X. RAO[1,2], A. K. SHETTY[1,2];
[1]Inst. for Regenerative Med, TAMHSC Col. of Med., Temple, TX; [2]Res. Service, Olin E. Teague Veterans' Med. Center, Central Texas Veterans Hlth. Care Syst., Temple, TX

Abstract: Brain dysfunction in Gulf War Illness (GWI) mainly includes memory and mood impairments. Based on epidemiological studies, exposures to anti nerve gas agent pyridostigmine bromide (PB), pesticides and stress during the war have caused GWI in a major fraction of Persian Gulf War-1 veterans. Indeed, our studies in a rat model have shown that exposures to GWI-related chemicals (GWIR-Cs) and mild stress for 4 weeks cause persistent memory and mood dysfunction linked with declined neurogenesis, increased oxidative stress, and low-grade inflammation in the hippocampus. Hence, drugs and compounds capable of improving memory and mood function through increases in neurogenesis and/or suppression of oxidative stress and inflammation are of great interest for treating GWI. Curcumin (CUR), a polyphenol derived from the rhizome of curcuma longa, has neurogenic and antiinflammatory properties. Administration of CUR is also considered safe in humans and has minimal side effects. Therefore, we tested the usefulness of curcumin therapy in a rat model of GWI. Male SD rats were exposed daily to GWIR-Cs, DEET (40 mg/kg), permethrin (0.13 mg/kg) and PB (1.3 mg/kg) and 5-minutes of restraint stress for 4 weeks. A week later, a group of rats received daily CUR (30 mg/kg, i.p) for 4 weeks while another group received vehicle (VEH). Animals also received 5'-bromodeoxyuridine (BrdU) during the last 7 days of treatment for analysis of neurogenesis. Behavioral tests performed 4 weeks later revealed improved memory function in CUR treated GWI-rats, which was evidenced through their preference to explore an object that was displaced to a novel location in object location test or to explore a novel object over a familiar object in novel object recognition test. Performance in a novelty suppressed feeding test implied improved mood function as well. These rats also displayed three-fold increase in hippocampus neurogenesis (measured via BrdU, BrdU-NeuN, and doublecortin+ cell counts). Moreover, CUR-treated GWI-rats exhibited reduced inflammation, typified by diminished astrocyte

hypertrophy and ED-1+ activated microglia in the hippocampus. Besides, the hippocampus of these animals displayed diminished concentration of oxidative stress markers 4-HNE and 3-NT, and increased expression of antioxidant genes. Thus, CUR therapy is efficient for alleviating memory and mood dysfunction in GWI. In view of the role of neurogenesis, inflammation and oxidative stress in altering memory and mood function, it is likely that CUR-induced enhanced neurogenesis, and repressed inflammation and oxidative stress triggered the beneficial effects.

Title: The 5-HT3 receptor is essential for exercise-induced hippocampal neurogenesis and antidepressant effects

Authors: M. KONDO, Y. NAKAMURA, Y. ISHIDA, *S. SHIMADA;
Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan

Abstract: Exercise has a variety of effects on the animal brain at many levels. At the cellular level, exercise enhances hippocampal neurogenesis. At the behavioral level, exercise induces antidepressant effects and improves learning behavior. It has been suggested that neurotransmitters and neurotrophic factors, such as serotonin (5-hydroxytryptamine, 5-HT),

BDNF (brain-derived neurotrophic factor), IGF-1 (insulin like growth factor-1) and VEGF (vascular endothelial-derived growth factor), are candidate factors that mediate these exercise effects on the brain. 5-HT has attracted much attention in the context of the functional link between major depression and adult neurogenesis in the hippocampal dentate gyrus. Actually, the dentate gyrus is highly enriched with serotonergic fibers, and the 5-HT system regulates neuronal plasticity in the dentate gyrus. Additionally, the beneficial effects of antidepressant drugs that primarily target the central 5-HT system have been shown to require the generation of new hippocampal granule neurons. Previous studies have shown that both 5-HT and exercise have neurogenic and antidepressant effcts, and have significant effects on learning and memory. Furthermore, exercise increases the levels of 5-HT in the hippocampus, which could affect learning and affective processes. However, the precise mechanism of action of 5-HT in neurogenic and behavioral effects induced by exercise is unknown. The 5-HT3 receptor is the only ionotropic receptor in the 5-HT receptor subfamilies. The 5-HT3 receptor is expressed on interneurons in the limbic region, including the hippocampus, amygdala and prefrontal cortex. However, its possible role in hippocampal neurogenesis has not been defined. Previous studies have indicated that the 5-HT3 receptor plays important roles in mood and memory. Thus, we have investigated the possible relationship of the 5-HT3 receptor with exercise-induced hippocampal neurogenesis and behavioral changes. In this study, analysis of the 5-HT3A receptor subunit-deficient (htr3a-/-) mice revealed that lack of the 5-HT3 receptor resulted in loss of exercise-induced hippocampal neurogenesis and antidepressant effects, but not of learning enhancement. Furthermore, stimulation of the 5-HT3 receptor promoted neurogenesis. These findings demonstrate that the 5-HT3 receptor is the critical target of 5-HT action in the brain following exercise, and is indispensable for hippocampal neurogenesis and antidepressant effects induced by exercise. This is the first report of a pivotal 5-HT receptor subtype that plays a fundamental role in exercise-induced morphological changes and psychological effects.

Title: Vitamin C deficiency disrupts normal cellular composition within the subventricular zone neurogenic niche

Authors: *N. A. JARA[1], M. CIFUENTES[2], F. MARTÍNEZ[1], K. SALAZAR[1], F. NUALART[1]; [1]Univ. De Concepción, Concepción, Chile; [2]Univ. de Málaga, Málaga, Spain

Abstract: The subventricular zone (SVZ) is the largest neurogenic niche in the adult brain. It is mainly formed by: SVZ astrocytes (B cells), which correspond to the adult neural stem cells; neuroblasts (A cells); type C cells; and ependymal cells (E cells). In the guinea pig brain, neuroblasts born in the SVZ migrate to the olfactory bulb (OB), where they surround a continuous open ventricle known as the lateral ventricle extension (LVE), which reaches the OB. Previous studies suggest that vitamin C could modulate neurogenesis. In the embryonic brain, vitamin C induces the differentiation of precursor cells into neurons and astrocytes. In the adult brain, guinea pigs subjected to vitamin C deficiency show a lower number of hippocampal neurons. However, no studies have assessed the effect of a vitamin C deficiency on the adult SVZ. Therefore, we analyzed the effect of this condition in the SVZ and LVE of the adult guinea pig brain. Guinea pigs consumed a vitamin C-deficient diet for 0, 2, and 3 weeks. Cell proliferation was analyzed using BrdU-labeling. Immunohistochemical analysis, confocal spectral microscopy, and transmission electron microscopy were used to compare the different cell populations within the SVZ and LVE of control and vitamin C-deficient animals. We identified neuroblasts (βIII-tubulin+), SVZ astrocytes (vimentin+), type C cells (BrdU+), and ependymal cells (vimentin+ and isolectin B4+) in the SVZ and LVE of control and vitamin C-deficient animals. Neuroblasts were reduced as the days of deficiency increased. We demonstrated a significant and progressive reduction that reached about 50% in the SVZ and LVE with 21 days of deficiency. This reduction in neuroblasts was correlated with the reduction of BrdU+ cells in the SVZ and LVE. In the ultrastructure analysis, the SVZ looked similar in deficient and control animals; however, the deficient animals had fewer neuroblasts and, therefore, the subependymal cells were mainly astrocytes. In addition, the ultrastructure of the LVE revealed that the cellular and nuclear morphology of the ependymal cells was different in deficient versus control animals and the former had fewer neuroblasts; however, the same or even more astrocytes were observed. We showed that vitamin C is essential for the maintenance of the SVZ cell populations required for normal activity of the SVZ neurogenic niche in the adult guinea pig brain. Moreover, we observed similar results in the LVE, suggesting that a vitamin C deficiency may modify the normal OB structure and neuronal composition. Finally, vitamin C may be modulating the neurogenic activity and potential of the SVZ neurogenic niche.

Title: Retinoids attenuate neonatal hyperoxia-induced neurodevelopmental impairment in mice

Authors: ***M. RAMANI**[1], N. AMBALAVANAN[2], T. VAN GROEN[3], I. KADISHA[3]; [1]Pediatrics, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Pediatrics, [3]Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Background: Extremely preterm infants exposed to supraphysiological oxygen exposure during a critical developmental period often have poor executive and memory function during later life associated with reductions in hippocampal volume. We recently showed that adult mice exposed to neonatal hyperoxia had deficits in spatial and recognition memory associated with smaller hippocampal volumes. Retinoids have been shown to attenuate hyperoxia induced lung injury in animal models and reduce neonatal chronic lung disease in human preterm infants. We hypothesized that retinoid administration during neonatal hyperoxia exposure would also inhibit hyperoxia-induced brain injury. Methods: C57BL/6 mouse pups (n = 2 litters per condition; at least 10/group) were exposed to hyperoxia (85% oxygen) or air, in combination with either Vitamin A+ Retinoic Acid (VARA) or canola oil (vehicle) from postnatal day 2 to 14 (P2-P14; roughly corresponding from early preterm to early infancy in human brain development) and then returned to air. Neurobehavioral and structural assessments were done at 12-14 weeks of age. Results: Neonatal hyperoxia induced spatial navigation deficits and increased exploratory behavior in adult mice, and these changes were attenuated by the administration of VARA (Figure A, B, C). Neonatal hyperoxia also reduced adult right hippocampal size, and this effect was also attenuated by VARA administration (Figure D). Brain sections stained for white matter (CNPase), astrocytes (GFAP) and synaptic density (synaptophysin) were qualitatively similar among the groups. Conclusion: Administration of VARA during neonatal hyperoxia attenuates adult neurodevelopmental deficits and associated reduction in hippocampal size in mice. This animal model suggests retinoids may be a neuroprotective agent in extremely preterm infants at high risk of neurodevelopmental impairment.

Title: Effects of perinatal exposure to PCBs on thyroid hormones, spinogenesis and neurogenesis in mice dentate gyrus

Authors: ***A. PINSON**[1], A. S. PARENT[1], N. WOODS[2], C. CHRISTINA[2], A. BENSEN[2], A. GERARD[1], E. NAVEAU[1], J. P. THOME[3], J. P. BOURGUIGNON[1], G. L. WESTBROOK[2]; [1]unit of neuroendocrinology, Univ. of Liege, Giga Neurosciences, Liege, Belgium; [2]Vollum Institute, Oregon Hlth. and Sci. Univ., Portland, OR; [3]Lab. of Animal Ecology and Ecotoxicology (LEAE, CART), Univ. of Liège, liege, Belgium

Abstract: Perinatal exposure to polychlorinated biphenyls (PCBs), an endocrine disruptor, is associated with relative hypothyroidism and learning and memory deficits in children and rodents. We hypothesized that perinatal exposure to Aroclor 1254 (A1254), a mixture of PCBs, from gestational day 6 (E6) to postnatal day 21 (P21) could impair neurogenesis in the dentate gyrus in C57BL/6J WT and proopiomelanocortin-enhanced green protein (POMC-EGFP) mice, the latter of which transiently and selectively express EGFP in newborn neurons in the dentate gyrus. Total thyroxin concentration was decreased in serum of A1254-exposed mice at P7 and P21 but not at P56. Despite the decreased thyroxin levels, early exposure did not affect the proliferation or survival of newborn neurons at P7 as assessed using POMC-EGFP mice as well as BrdU pulse labeling. However, 5 weeks after the end of the exposure (P56), the number of POMC-EGFP+ cells was moderately but significantly reduced in the dentate gyrus of exposed mice (105±8.41 vs 81±3.58 cells/section; control vs exposed). This effect was compensated by 2 weeks of voluntary running (138.6±17.07 vs 142±7.29 cells/section; control vs exposed). In mice exposed to PCBs, dendritic spine density of 2 weeks post-mitosis neurons labeled by a stereotaxic injection of a retrovirus expressing EGFP was transiently increased on P21 (1.17±0.09 spines/µm vs. 0.86±0.07; exposed vs control). This effect was not observed in mature neurons labeled by Golgi staining at P21. Exposure to A1254 prevented the normal increase in frequency of spontaneous excitatory postsynaptic currents (sEPSC) in newborn neurons between14 and 21 days post-mitosis. The mean amplitude of sEPSC was not affected by A1254 exposure but A1254 significantly increased the variability of sEPSC amplitudes, which may suggest a disruption of normal synaptic maturation. Our results suggest that early exposure to PCBs can alter excitatory synapse development during a period of active synaptogenesis.

Title: 12-deoxyphorbols isolated from Euphorbia resinifera promote neural stem cell proliferation and adult neurogenesis via PKC activation

Authors: N. GERIBALDI-DOLDÁN[1], E. FLORES-GIUBI[2], M. MURILLO-CARRETERO[1], F. GARCÍA-BERNAL[1], M. CARRASCO[1], A. J. MACÍAS-SÁNCHEZ[2], J. DOMÍNGUEZ-RISCART[1], C. VERÁSTEGUI[1], R. HERNÁNDEZ-GALÁN[2], *C. CASTRO[1];

Abstract: Generation of new neurons from neural stem cells is induced in the central nervous system in response to different types of injuries. Strategies aimed to facilitate neuronal renewal by promoting neurogenesis constitute a promising therapeutic option to treat brain damage associated with neuronal death. It is well known that cell proliferation is increased by Protein Kinase C (PKC) activated mechanism. In this contex, we have found that PKC activation by phorbol 12-myristate 13-acetate promotes neural progenitor cell (NPC) proliferation. In addition, the capacity of the non-tumorigenic PKC activator prostratin, as well as other 12-deoxyphorbols isolated from *Euphorbia resinifera* sharing structural similarities with prostratin were tested for their capacity to affect NPC proliferation. Our results showed that prostratin promoted NPC proliferation and this effect was reverted by the general PKC inhibitor G06850. Additionally, we analyzed the molecular mechanisms involved showing that prostratin activated the expression of cyclin D, E and A. Similar proliferative effects were obtained with all the 12-deoxyphorbols tested, which induced NPC proliferation in a PKC-dependent fashion. Most of the 12-deoxyphorbols evaluated were significantly more potent than prostratin in inducing NPC proliferation. Additionally, we show that treatment with several 12-deoxyphorbols *in vivo* induces proliferation of NPCs within the main neurogenic areas of the adult brain: the dentate gyrus of the hippocampus and the subventricular zone. We suggest that PKC activation might be a promising strategy to expand the endogenous NPC population to promote neurogenesis. Our results support the potential of 12-deoxyphorbols as new pharmaceutical agents to facilitate neuronal renewal. Title: Social isolation, ethanol, and golgi in planarians

Authors: B. LOVELL, T. MCCHARLES, N. LANDRY, *A. D. STILLAR, A. WEEKS, M. SAARI;
Nipissing Univ., North Bay, ON, Canada

Abstract: We have recently developed a method of Golgi staining of planarians (Dugesia dorotocephala) based on a combination of methods used in mammalian brains. This method allows for observation of neural plasticity associated with environmental toxins or manipulation of the social environment in planaria. In order to examine the potential toxic effects of ethanol (EtOH) at low dosages and the effect of social isolation, planarians were placed into isolation, exposed to EtOH, and neuron counts as well as other anatomical measures were taken. Isolated or control (housed in groups of ten) planarians were placed in one of four conditions of EtOH: vehicle (30ml dechlorinated H2O), 1.0%, 1.5%, or 2.0% for five minutes and then stained. The EtOH concentrations were chosen based on a pilot study to confirm EtOH thresholds that cause complete immobility of the planarians. MANOVA of the 2 X 4 design revealed significant EtOH effects on the length of the anterior to posterior axis, eye spot to tip and a few other effects. The neural count approached significance as a function of social condition. Although the multivariate interaction was not significant (p. = .175) examination of the associated univariate F values suggested that some measures may be sensitive to the combined effects of EtOH and the social manipulation. (Supported by Nipissing University).

Title: Early alterations in the mouse brain following an exposure to shock waves of a single blast

Authors: *D. UPADHYA[1,2], A. B. ROBBINS[3], B. HATTIANGADY[1,2], M. KODALI[1,2], B. SHUAI[1,2], G. A. SHETTY[1,2], M. MORENO[3], A. K. SHETTY[1,2];

Abstract: Exposure to blast shock waves (BSWs) causes mild traumatic brain injury (mTBI) and diverse neurological deficits varying on the severity of shock waves (SWs) and the site of brain affected by SWs. Exposure to BSWs underlies a significant fraction of combat related mTBI incurred by Operation Iraqi Freedom and Operation Enduring Freedom veterans. Although brain imaging studies do not typically reveal sites of brain injury at early post-exposure time points, blast-related mTBI can lead to memory and mood dysfunction several years after the incident. Indeed, our previous study using a mouse model has shown that exposure to shock waves of a single blast can cause impairments in memory, mood and hippocampus neurogenesis, when examined six months after the exposure. Here, we examined early changes in the mouse brain after an exposure to SWs of a single blast. We wrapped each anesthetized C57BL/6 mouse in a flexible Kevlar and placed inside a Schedule 80 PVC container designed to leave only the head exposed. The container was then fixed to the distal end of the shock tube apparatus, and the head was exposed once to BSWs (12 psi) via restrained rupture of a Mylar membrane. Age-matched mice served as sham controls, which were anesthetized and placed near the shock tube to receive only the sound. Analyses of brains at 24 hrs and 14 days post-exposure suggested increased activity of GFAP+ astrocytes, IBA-1+ microglia and/or NG2+ oligodendrocyte progenitors in the cerebral cortex, corpus callosum and internal capsule. The hippocampus did not show noticeable changes in GFAP+ or IBA-1+ elements in most areas but microscopic patches of injury and inflammatory reaction could be observed in the CA1 region, where long IBA-1+ microglial processes were concentrated at high density. Characterization of the subgranular zone (SGZ) of the hippocampus with Ki-67 revealed increased proliferation of cells at both 24 hrs and 14 days after exposure to BSWs. Quantification of putative neural stem cells (NSCs) in the SGZ via Sox-2 and Ki-67 dual immunofluorescence did not show differences in proliferation between sham- and BSW-exposed animals, suggesting that cells other than NSCs may be proliferating in the SGZ after exposure to BSWs. Moreover, stereological measurement of newly born neurons positive for doublecortin at 14 days post-exposure revealed no differences in the overall status of neurogenesis between sham- and BSW-exposed animals. Thus, exposure of the brain to SWs of a single blast causes modest changes in astrocytes, microglia and oligodendrocyte progenitor cells in several brain regions but does not alter the extent of hippocampus neurogenesis at early time-points after the exposure.

Title: Methamphetamine promotes neuronal differentiation and strengthens long-term potentiation of immature dentate granule neurons

Authors: *S. BAPTISTA[1], F. BORGES[2], N. MILHAZES[2], A. SILVA[3], A. BACCI[4]; [1]Lab. of Pharmacol. and Exptl. Paris 06, UMR S 1127, Paris, France, 7Inserm U 1127, Paris, France, 8CNRS UMR 7225, Paris, France

Abstract: Methamphetamine (METH) is a psychostimulant drug of abuse, whose consumption has been increasing worldwide. Several studies report that METH causes irreversible brain abnormalities that may reflect cognitive deficits. Despite the fact that the underlying mechanisms are still not well characterized, it has been suggested that alterations of dentate gyrus (DG) neurogenesis may contribute to these deficits. Accordingly, several pieces of evidence have suggested that METH impairs hippocampal neurogenesis, which can in part justify memory

deficits observed in METH abusers. However, little is known about the effect of METH on synaptic plasticity of DG neurons. Here, we aimed at investigating the impact of METH on neurogenesis and synaptic plasticity of immature and mature dentate granule cells. We used the GAD67-GFP (line G42) mice, in which GFP is transiently expressed in maturating newborn neurons. Male G42 mice were administered with 2 mg/kg/day METH (i.p.) once a day for 7 days. 24 h after the last METH injection, immature neuronal phenotype, synaptic plasticity, dendritic and spine morphology were assessed. We found that METH treatment enhanced the differentiation of immature GFP+ cells shifting from DCX- to a more mature NeuN-expressing GFP+ cells. Electrophysiologically, GFP+ neurons showed three different profiles, reflecting specific stages of differentiation. We found that METH treatment had little effect on long-term potentiation (LTP) of synaptic transmission onto very young neurons but facilitated and strengthened LTP in more differentiated GFP+ neurons and mature GFP- DG neurons, respectively. Interestingly, despite METH did not induce any change dendritic morphology, it differently altered spine morphology in GFP+ DG cells at specific maturation stages. In conclusion, METH interferes with DG neurogenesis by accelerating differentiation of immature neurons and tends to facilitate LTP more differentiated GFP+ and in mature GFP- DG neurons. These results might have important implications towards the understanding of the synaptic basis of METH-induced cognitive deficits.

Title: Calorie restriction protects against age-related dysregulation of neural stem cells in the murine subventricular zone

Authors: *D. M. APPLE[1], R. SOLANO FONSECA[1], M. C. TEXIERA DOS SANTOS[2], S. MAHESULA[2], C. ZHU[1], E. KOKOVAY[2];
[1]Dept. of Cell. and Structural Biol., [2]Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Aging is a major risk factor for increased susceptibility to damage from brain insults like stroke, inflammation, and disease. Calorie restriction (CR) can improve physiological markers of health during aging, including extending lifespan and protecting against age-related damage to the brain. The largest source of neural stem cells in the adult brain is the subventricular zone (SVZ). We sought to determine the effect of long-term CR on neurogenesis and the neural stem cell niche in the SVZ of young and aged mice. Here, we show that aged mice fed standard control chow have fewer SVZ-derived neurons in the olfactory bulb, indicating that aging impairs neural stem cell function. Long-term CR preserved neural stem cell function and resulted in a significant increase in neurogenesis in aged mice compared with ad libitum- fed controls. Paradoxically, we have observed that proliferation of neural stem cells is decreased in aged CR mice. This is in the presence of increased neuroblast formation and increased neurogenesis. These data indicate either a change in cell fate or a change in the survival of transit amplifying cells as they mature into neuroblasts, suggesting an altered regulatory mechanism. Confocal imaging and fluorescent staining of SVZ wholemounts revealed an increase in both the total number and reactivity of microglia in the aged control mouse, suggesting increased inflammation in the neural stem cell niche during aging. Remarkably, these age-related inflammatory markers were not observed in the long-term CR aged mice, which appeared no different from young control and young CR mice included in the study. We have found that the neural stem cell chemoattractant mechanism CXCL12, secreted by endothelial cells, and its receptor expressed on neural stem cells, CXCR4, are dysregulated in the aged mouse fed ad libitum, but not in the aged CR mouse. Further, the recently identified rejuvenation factor GDF11 was found to be decreased in the aged SVZ, but not in the aged CR SVZ. These initial experiments have revealed a protective role for CR in the aging SVZ, and are an important first step in understanding how CR may be an effective therapeutic intervention for the aging or damaged brain.

Title: Subventricular zone NSC grafting into the hippocampus after status epilepticus modifies disease by curtailing epileptogenesis and inflammation

Authors: *G. ZANIRATI[1,2,3], B. HATTIANGADY[1,2,3], B. SHUAI[1,2,3], J. BLAIR[1,2], A. K. SHETTY[1,2,3];

Abstract: Status epilepticus (SE) evolves into chronic temporal lobe epilepsy (TLE) through epileptogenic changes and persistent inflammation in the hippocampus. The features of TLE include complex partial seizures and impaired memory and mood function. Several evolving epileptogenic changes are believed to contribute to these impairments, which include aberrant and reduced neurogenesis, abnormal mossy fiber sprouting, and diminished numbers of inhibitory interneurons. Persistent inflammation is another alteration contributing to the disease. Subventricular zone neural stem cells (SVZ-NSCs) have shown ability to promote brain repair in several neurological disease prototypes with neuroprotective and antiinflammatory effects. Hence, using an animal model of SE, we rigorously examined whether grafting of SVZ-NSCs early after SE would provide lasting control over spontaneous recurrent seizures (SRS), and whether such alleviation of SRS would be linked with curbs on epileptogenesis and inflammation. We induced SE in young male rats via graded intraperitoneal injections of kainic acid and terminated acute seizures two hrs after SE induction by diazepam injection. Four days after SE, a group of animals received SVZ-NSC grafts into the hippocampus (4 grafts/side, ~90,000 live cells/site). Another group was maintained as epilepsy-only controls. Analyses at 6-months after SE using video-electroencephalographic recordings revealed that animals receiving NSC grafts displayed reduced frequency and intensity of SRS, in comparison to epilepsy-only controls. The reductions were ~60% for the frequency of all SRS, ~97% for Stage-V SRS and ~72% for the percentage of time spent in seizure activity. Grafted animals also displayed preserved object recognition memory function and reduced depressive-like behavior. Analyses of the hippocampus in these animals revealed persistence of NSC-graft derived cells (equivalent to ~89% of injected cells) and their differentiation into GABA-ergic interneurons (~20%) and astrocytes (~60%). Moreover, NSC grafting promoted lasting restraint on several epileptogenic changes and inflammation in the hippocampus. In contrast to epilepsy-only controls, the hippocampus of grafted animals displayed normal pattern and greater level of neurogenesis, greater numbers of neuropeptide Y and parvalbumin positive interneurons, diminished aberrant

mossy fiber sprouting, and reduced hypertrophy of astrocytes and activated microglia. Thus, SVZ-NSC grafting early after SE into the hippocampus promotes enduring control of SRS and co-morbidities with curbs on multiple epileptogenic changes and inflammation that ensue SE.

Title: The effects of caloric restriction on neurogenesis

Authors: *A. CARBAJAL[1], M. Y. CALAMUCHA[2], M. FUSE[2], C. MOFFATT[2], C. DULDULAU[2];
[2]Biol., [1]San Francisco State Univ., San Francisco, CA

Abstract: Adult neurogenesis occurs throughout the lifespan of many species, including vertebrates and invertebrates. The factors that regulate this process are comparatively poorly understood. To this end, the goal of this project was to determine how caloric restriction affected the rate of cell proliferation in the brain of an invertebrate, the house cricket, Acheta domesticus. Adult neurogenesis in this species occurs mushroom bodies, the insect analog of the hippocampus. Blocking neurogenesis in mushroom bodies impairs the performance of crickets in olfactory learning and memory tasks. Our studies determined how acute caloric restriction affected the rate of cell proliferation in the mushroom bodies. Crickets were starved for four days and then injected with bromodeoxyuridine (BrdU) to label proliferating cells and were then euthanized two hours later. We found that four days of starvation did not affect the rate of cell proliferation: The number of BrdU-immunoreactive cells present in the mushroom bodies did not differ significantly between freely feeding crickets and those that had been starved. Continuing experiments are replicating this observation and are determining whether or not starvation affects the survival of newly generated neurons. Elucidating how neurogenesis is regulated in crickets, and understanding the ways in which it is similar and different from that in mammals, has great potential to improve our understanding of a process that plays such an important role in learning and memory, as well in some neuropathologies.

Title: Chronic intermittent hypoxia suppresses adult neurogenesis and disrupts synaptic plasticity in the dentate gyrus of the hippocampus

Authors: ***M. A. KHUU**[1], C. M. PAGAN[1,2], M. LESLIE[1], J. M. RAMIREZ[1,2,3], A. J. GARCIA, III[1];
[1]Seattle Childrens Res. Inst., Seattle, WA; [2]Dept. of Pathology, [3]Dept. of Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstract: When left untreated, sleep disordered breathing (SDB) leads to significant cognitive decline. SDB is associated with chronic intermittent hypoxia (CIH), which is known to cause cognitive deficits and impaired synaptic plasticity in the CA1 neuronal population of the hippocampus. Here we studied the impact of CIH on neurophysiological processes within the dentate gyrus (DG) another key neuronal population within the hippocampal network important for integrating limbic information. Experiments were conducted in the DG of hippocampal brain slices from mice (P60-P80) left unexposed or exposed to CIH for 30days. Using immunohistological analyses, CIH did not alter structural volumes within the DG. However, CIH significantly stimulated the number of intermediate progenitors as represented by the increased number of Ki-67 positive cells within the DG region. Interestingly, the number of doublecortin positive granule neurons was significantly smaller following CIH. Thus, while CIH appears to stimulate the neuroprogenitor pool, it suppresses the transition of neuroprogenitors to newly born DG neurons. Electrophysiological studies demonstrate that CIH affects synaptic plasticity expressed in the DG. Specifically, CIH (1) decreased the degree of paired pulse facilitation and (2) disrupts LTP evoked by high frequency stimulation. We conclude that unlike many other conditions associated with disturbed oxygen homeostasis, CIH differentially influences adult neurogenesis during specific stages of development and leads to impaired synaptic plasticity. We hypothesize that these cellular effects contribute to memory deficits associated with SDB.

Title: Low-level manganese and nanosilver alter adult neural stem cell morphology and gene expression during differentiation

Authors: R. J. COOPER, A. PARSONS-WHITE, A. RAMIREZ, *N. SPITZER;
Dept of Biol. Sci., Marshall Univ. - Biol. Sci., Huntington, WV

Abstract: Heavy metals are well known for their cytotoxic and neurotoxic effects. Often, however, exposures at environmentally relevant levels are lower than those resulting in cell death. The changes in cellular mechanisms resulting from such exposure are poorly understood for two emerging environmental contaminants, manganese (Mn) and silver nanoparticles (AgNPs). Excessive environmental exposure to Mn, a micronutrient, results in cognitive deficits and neuropsychological abnormalities. AgNPs, are increasingly incorporated in industrial and consumer products due to their antimicrobial properties; they persist in the environment, bioaccumulate, and are toxic to eukaryotic systems at high concentrations. Though symptoms of over-exposure are well defined, the mechanisms underlying these effects are not as well understood. Cultured adult neural stem cells (NSC) from the subventricular zone (SVZ) of young-adult rats provide an accessible model to investigate the responses of cellular mechanisms underlying proliferation, migration, and neural differentiation to Mn or AgNP. Adult neurogenesis contributes to learning, memory consolidation, and repair, in addition to recapitulating cellular processes occurring during neurodevelopment. Previously, we found that exposure to low-level (1μg/mL) AgNPs induced the formation of f-actin inclusions in differentiating NSCs, indicating disruption of the cytoskeleton. Further, neurite extension and arborization, cytoskeleton-driven processes vital for neurogenesis, were significantly impaired. In our current study, we cultured NSC from the SVZ of rats as neurospheres and exposed them to $MnCl_2$ (10-200μM) or AgNP (1μg/mL). Cells were allowed to differentiate for 48 hours and then fixed and stained for morphology or collected for analysis of gene expression patterns by RT-PCR. We found a dose-dependent decrease in the ratio of neural to glial morphotypes following

exposure to Mn. Further, Mn upregulated GPx1, an antioxidant enzyme, and down-regulated MAP2, a neural fate marker. These data suggest that Mn exposure inhibits neuronal differentiation, and indicate oxidative stress as a possible mechanism for these effects. AgNP exposure, caused a down-regulation of DCX and Nestin, both markers of NSC proliferation. Together, these results indicate that both Mn and AgNPs, at environmentally relevant concentrations, disrupt neurogenesis by interfering with proliferation and differentiation of NSCs. Environmental exposure to these heavy metals could therefore lead to losses in learning and memory and interfere with normal neural development.

Title: Galactic cosmic radiation (28Si) reduces dentate gyrus neurogenesis in the long-term in a dose-dependent manner

Authors: *A. K. WALKER[1], C. W. WHOOLERY[1], D. R. RICHARDSON[1], R. P. REYNOLDS[1], P. D. RIVERA[1], H.-Y. SHIH[2], R. L. REDFIELD[1], M. J. LUCERO[1], D. H. BEDDOW[1], S. MUKHERJEE[1], B. P. C. CHEN[2], A. J. EISCH[1];
[1]Dept. of Psychiatry, [2]Dept. of Radiation Oncology, Univ. of Texas Southwestern, Dallas, TX

Abstract: Astronauts undertaking future voyages to Mars will be exposed to chronic low doses of cosmic galactic space radiation containing many different high-energy, high-charge (HZE) particles. Certain HZE particles, such as ^{56}Fe, have previously been shown to reduce the

generation of new neurons in the adult hippocampus dentate gyrus (DG), a brain region involved in memory and mood control. Diminished levels of DG neurogenesis could therefore negatively influence astronaut cognitive abilities and pose a risk to mission success. While significant data support that ^{56}Fe particles damage mouse brain and behavior, less is known about whether additional HZE particles, such as ^{28}Si, are similarly damaging. In order to fill this knowledge gap, 9-week old mice were exposed to whole-body ^{28}Si particle ground-based radiation at doses of 0 cGy (SHAM), 20 cGy, and 100 cGy at Brookhaven National Laboratories. DG neurogenesis was evaluated at two time points after irradiation (IRR) in order to assess short-term (24-hours) versus long-term (3-months) effects. To label dividing cells, mice were given a single BrdU injection 22 hours post-IRR and perfused either 2 hours or 3 months later. Using immunohistochemistry (IHC) and sterological approaches, tissue from the 24-hour group was labeled for markers of proliferation (BrdU and Ki67), and immunoreactive cells were quantified. In the 24-hour group, mice exposed to 100 cGy had fewer DG BrdU+ and Ki67+ cells as compared to SHAM, revealing a significant decrease in proliferation. Additionally, in both the 24-hour group and 3-month group, quantification of doublecortin immunoreactive (DCX+) cells was performed to assess levels of neurogenesis. In the 24-hour group, mice exposed to 20cGy and 100cGy IRR displayed a dose-dependent reduction in DG DCX+ cells compared to SHAM. However, in the 3-month group, only mice exposed to 100cGy IRR had fewer DG DCX+ cells compared to SHAM. These data suggest ^{28}Si radiation dose-dependently decreases neurogenesis in the short-term, but that there may be recovery of neurogenesis in the long-term in mice that received the lower dose of IRR. Additional studies on the long-term influence of ^{28}Si IRR on neurogenesis, cell morphology and death, and behavior are underway. This work is part of a broader effort to gain better understanding of whether space radiation is detrimental to the brains of future deep space faring astronauts.

Title: Effects of castration on adult hippocampal neurogenesis

Authors: *K. ATKINSON[1], T. ALKAM[1], S. DIAZ[2], A. ROBBINS[3], R. N. PECHNICK[1]; [1]Western Univ. of Hlth. Sci., Pomona, CA; [2]California State Polytechnic Univ., Pomona, CA; [3]Pitzer Col., Claremont, CA

Abstract: Androgen-deprivation therapy is a common treatment for prostate cancer. Its goal is to lower the level and/or effects of testosterone, a critical factor driving the progression of the disease. However, patients subjected to these treatments frequently exhibit symptoms of cognitive impairment. The relationship between androgen-deprivation and cognitive impairment is poorly understood. We propose that the cognitive impairment is due to deficits in hippocampal neurogenesis. The purpose of this study was to test the hypothesis that adult hippocampal neurogenesis is disrupted after castration-induced decreases in plasma testosterone levels in mice. Seven week-old, male C57/BL6 mice underwent either castration or sham surgery. In the castration surgery, both testes were removed, whereas in the sham surgery the mice received an incision in the same area but the testes were not removed. The survival of the proliferating neurons was assessed using 5-bromo-2-deoxyuridine (BrdU). One week after surgery, mice were injected with BrdU (50 mg/kg i.p.) every 2h for a total of four times. Four weeks later, the mice were anesthetized and sacrificed by cardiac perfusion, fixed with 4% paraformaldehyde, the brains sremoved and immunohistochemical studies were carried out. We found that there was a decrease in the number of BrdU-labeled cells in the dentate gyrus of the hippocampus in the castrated mice compared to the sham mice. We also found that there was a decrease in the number of cells expressing Ki-67, a marker for cell proliferation. The results suggest that testosterone is critical for normal neuronal proliferation and survival in the hippocampus and support our contention that cognitive impairment after androgen-deprivation therapy might be a consequence of disruption of hippocampal neurogenesis.

Title: Effects of prenatal and/or adolescent exposure to nicotine on hippocampal neurogenesis in adult rats

Authors: *T. ALKAM, S. O'DONNELL, R. N. PECHNICK;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Exposure to tobacco smoke (nicotine) prenatally or during adolescence increases the likelihood of suffering cognitive impairment in adult life. Some drugs of abuse are known to affect adult hippocampal neurogenesis; however, the relationship between developmental exposure to nicotine and adult hippocampal neurogenesis is poorly understood. The purpose of the current study was to define the effects of prenatal or/and adolescent nicotine exposure on hippocampal neurogenesis and begin to identify molecular pathways underlying the effects. On day 4 of pregnancy the dams were implanted with subcutaneous osmotic mini-pumps containing either vehicle (sodium bitartrate in saline) or nicotine bitartrate (6.0 mg/kg/day). During the adolescent period (postnatal days 33-40) male pups from the vehicle- and nicotine-treated dam received injections of either saline or nicotine (0.4 mg/kg/s.c.) for 8 consecutive days. On postnatal day 150, the rats were sacrificed and brains were collected for Western blot and immunohistochemistry studies. Analysis of Western blots showed that the expression of Ki67, a marker of cellular proliferation, and doublecortin, a microtubule-associated protein expressed by neuronal precursor cells and immature neurons, were significantly increased in the hippocampus of the rats that received both prenatal and adolescent nicotine exposure. On the other hand, the protein level of calbindin, a marker for mature neurons, was significantly down-regulated. The current results show that combined prenatal and adolescent nicotine exposure might have long-term effects on adult hippocampal neurogenesis.

Title: Role of systemic and local insulin-like growth factor-I in the regulation of the sequential stages of postnatal/adult hippocampal neurogenesis

Authors: *C. VICARIO-ABEJON[1], V. NIETO-ESTEVEZ[1], C. O. OUESLATI-MORALES[1], J. PICKEL[2];
[1]Cajal Institute, CSIC, Madrid, Spain; [2]NIMH, Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: Insulin-like growth factor-I (IGF-I) is involved in the regulation of adult hippocampal neurogenesis, although its specific actions have not been fully defined. Moreover, the role of locally-produced IGF-I in adult neurogenesis has not been addressed. We show that both IGF-I and IGF-IR are expressed in the postnatal/adult dentate gyrus (DG). To study the influence of IGF-I on the stages of DG neurogenesis, we analyzed sections from postnatal/adult global Igf-I KO mice (Igf-I-/- and Igf-I+/+ mice) and from a nervous system specific Igf-I conditional KO (Igf-IΔ/Δ and Igf-ICtrl mice). In both KO mice we found an accumulation of progenitor cells, some of which were situated ectopically in the outer granule cell layer (GCL) and in the molecular layer (ML). Indeed, the GCL was disorganized in both KO animals, with significantly more Prox1+ granule neurons outside this layer than in WT mice. Dividing progenitors were also generated in higher numbers in clonal neural stem cell cultures prepared from the Igf-I-/- hippocampus. To determine the impact of Igf-I deletion on newly formed neurons *in vivo*, dividing progenitors in P21 Igf-I-/- and Igf-I+/+ mice were labeled with GFP-expressing retroviral particles. This revealed that in the Igf-I-/- mice more GFP+ cells expressed markers of immature neurons and they had less complex dendritic trees. Consequently, there were fewer mature granule (calbindin+ cells) in the Igf-I-/- animals. Our findings indicate that IGF-I plays critical roles during postnatal/adult DG neurogenesis, regulating in a paracrine manner the number of progenitors as well as the positioning and the molecular and morphological differentiation of newly formed neurons.

Abstract: Aberrant synaptic transmission mediated by N-methyl-D-aspartate receptors (NMDARs) has been implicated in various neuropathological conditions ranging from psychiatric to neurodegenerative disorders. Previous efforts to develop novel modulators of NMDARs utilizing heterologous expression systems, however, have led to little success in developing clinically tolerable, efficacious chemical matter. To assess the utility of human induced pluripotent stem cell (hiPSC)-derived neurons developed by Cellular Dynamics International (hereafter, iCell® Neurons) for *in vitro* validation of NMDAR modulators, we initially confirmed the expected electrophysiological responses of iCell® Neurons to glutamate and NMDA by using manual patch-clamp recordings. Assessment of the relative expression of NMDAR subunits by qRT-PCR revealed the highest expression of NR2B, medium expression of NR1 and NR2D, and low or no expression of NR2A and NR2C transcripts in these cells. The relative abundance of NR2 transcripts did not markedly change from Day 3 to Day 15 post-plating, which was confirmed by Western blot analysis. Manual patch-clamp assessment of iCell® Neurons using various pharmacological tools also pointed out the predominance of NR2B among the other NR2 subunits; IC50 determination of the NR2B selective antagonist ifenprodil against NMDA-induced currents revealed a similar potency of ifenprodil in iCell® Neurons and human NR2B-expressing recombinant cell lines. Taken together, these findings suggest that iCell® Neurons predominantly express functional NR2B-containing NMDARs and could serve as a valuable system for development and validation of NR2B-modulating pharmaceutical agents.

Title: Topographical influence on differentiation of pluripotent stem cells into regionalized dopaminergic neurons

Authors: ***K. K. TAN**[1], W. LIM[2], C. CHAI[2], K. LIM[2], E. L. K. GOH[2], E. K. F. YIM[1]; [1]Mechanobiology Inst., Singapore, Singapore; [2]Duke-NUS Grad. Med. Sch. Singapore, Singapore, Singapore

Abstract: Parkinson's disease is a neurodegenerative disease attributed to the loss of midbrain dopaminergic (DA) neurons. Pluripotent stem cells hold great promise in the study and clinical treatment for this neurodegenerative disease but progress has been hampered by the acquirement of robust cells, posing a major barrier to drug development. Appropriate biophysical cues can direct stem cell fate but the role of topography in differentiating stem cells into subtype specific cells has hitherto not been well understood. We aim to develop an *in vitro* substrate that will accelerate the derivation of midbrain dopaminergic (DA) neurons from human pluripotent stem cells (hPSCs). By using human induced pluripotent stem cells (iPSCs), we have examined the ability of topographical patterns to influence the differentiation of hPSCs into subtype-specific and regionalized dopaminergic (DA) neurons. We have made minor modifications to the protocol based on dual SMAD inhibition method and optimized on patterned substrates to further improve the efficiency for DA neuron derivation. The size of embryoid bodies was standardized on fabricated PDMS chambers consisting of microwells. We have also optimized the use of region specific markers to study regionalized specification of DA neurons on patterned substrates. Our current progress in using patterned substrates for DA differentiation will be presented here. It is hoped that this will also provide novel insights into mechanisms underlying DA neuronal development and ultimately discover new therapeutic approaches for this neurodegenerative disease.

Title: Influence of carbonyl stress on neural cells derived from induced pluripotent stem cell

Authors: ***Y. HORIUCHI**, N. OBATA, I. NOHARA, A. KOBORI, K. TORIUMI, M. ITOKAWA, M. ARAI;
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Schizophrenia (SZ) is a devastating mental illness in which initial and major risks of the disease during neurodevelopment may disturb postnatal brain maturation, which results in the onset after puberty. However, mechanistic understanding of mental disorders, such as schizophrenia and bipolar disorder, is not well developed. One major limitation that has blocked the progress is the difficulty of accessing relevant tissues/cells for the investigation. First, although mental disorders affect the brain, it is almost impossible to obtain biopsied brains or neurons of central nervous system origin that are relevant to the diseases. Second, because the onset of these disorders is relatively young (adolescence or young adulthood), there is no guarantee that autopsied brains from aged patients with long-term medication reflect disease pathologies. For these reasons, there is expectation that induced pluripotent stem cells (iPS cells) will be a major advance for understanding of mental disorders. Astrocytes facilitate neuronal maturation by regulating exogenous stress. Antioxidant defense is one example of this type of astrocyte function. Previous study from our laboratory reported that the carbonyl stress in a subpopulation of SZ patients, leading to a failure of metabolic systems with plasma pentosidine accumulation and serum pyridoxal depletion. However the molecular mechanisms of the relationship between carbonyl stress and SZ are still unknown. We hypothesize that astrocytes may have a deficit in energy metabolism resulting in neuronal damage in SZ, which might be involved in SZ pathology in carbonyl stress context. As a first step of the study, we examined how pentosidine accumulation affects to neuron and astrocyte using human iPS cells. We generated TUJ1 positive neurons and GFAP positive astrocyte via neurosphere formation from human iPS cells of normal control subjects. And then we measured the energy metabolism such as glycolysis and mitochondrial respiration in the cells. Our strategy will provide important clues for understanding of SZ.

Abstract: Human cortical development consists of intricate cellular processes that are coordinated across time and space. Protocols for inducing neural differentiation from pluripotent stem cells *in vitro* have provided unique opportunities to study features of normal and abnormal corticogenesis, but current techniques are largely limited to two-dimensional systems that lack the cellular maturity and three-dimensional (3D) cytoarchitecture typically found in the developing cortex. Here, we present a simple and reproducible 3D culture approach for generating a laminated cerebral cortex-like structure, named human cortical spheroids (hCS), from human pluripotent stem cells. hCS are easy to maintain in culture and are reproducible within and across differentiations. hCS contain both deep and superficial layer cortical neurons and can be mapped transcriptionally to *in vivo* human cortical developmental stages up to late mid-fetal periods. Neurons are electrophysiologically mature, display spontaneous activity, are surrounded by non-reactive astrocytes, and form functional synapses. Experiments in acute slices of hCS demonstrate that cortical neurons participate in network activity and produce complex synaptic events. These 3D cultures allow a detailed interrogation of human cortical development,

function and disease, and represent a versatile platform for generating other neuronal and glial subtypes *in vitro*.

Title: Induction of neural stem cell migration through transposon-mediated reprogramming

Authors: *F. SIDDIQI[1], A. L. TRAKIMAS[2], R. RISBUD[2], E. D. MARSH[3], J. H. WOLFE[3]; [1]Dept. of Neurol., [3]Neurol., [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Neural stem cell (NSC) transplantation therapy can serve as a therapeutic model in damaged or diseased brains. Often NSC lines have been selected based upon their endogenous ability to engraft into host tissue. In contrast, when primary immune-compatible NSCs are used, their ability to migrate is significantly attenuated. However, subsets of primary neural progenitor cells (NPCs) show extensive migration during brain development, such as neural crest and medial ganglionic eminence (MGE) cells. It is currently unknown whether or not NSCs can be reprogrammed from non-migratory into migratory states using upstream transcription factors (TFs). In the current study, we conducted a meta-analysis of micro-array data sets comparing these cell populations at active stages of migration to identify transcription factors (TFs) associated with migratory pathways. We conducted DAVID functional clustering analysis and identified several candidate genes that were differentially expressed during migratory stages. To functionally test candidate TFs, we generated piggyBac (PB) vectors for 5 TF conditions, which allowed for ectopic expression of candidate TFs in non-migratory NSCs. Our results showed that at least 2 candidate TFs were able to induce migration in *in vitro* scratch assays compared to

control condition. These cells gained bipolar morphologies with dynamic growth cones consistent with cell motility. *In vivo* transplantation of 1 TF condition into neonatal mice brains resulted in increased engraftment. Our results suggest upstream TFs are able to induce NSC migration for utility in transplantation therapy.

Title: Differentiation of midbrain floor plate progenitors and dopaminergic neurons from human pluripotent stem cells

Authors: *S. SHIN, M. DERR, Y. YAN, L. SANGENARIO, K. VEDVIK, A. HANNAY, D. KUNINGER;
Primary and Stem Cell Systems, Thermo Fisher Scientific, Frederick, MD

Abstract: Midbrain dopaminergic (DA) neurons derived from human pluripotent stem cells (hPSCs) provide an excellent source for disease modeling and drug screening for Parkinson's disease. During brain development, midbrain floor plate (mFP) is formed during 21-28 days of gestation along the ventral midline of developing neural tube and it has been shown that midbrain DA neurons are differentiated from mFP cells. Recent reports have focused on identifying the appropriate *in vitro* conditions to differentiate hPSCs to properly regionalized floor plate precursors, rather than a more general neural stem cell population, in order to create authentic DA neurons. However, published protocols are quite lengthy and complicated leading to increased variability in differentiation efficiencies. Also, few reports describe whether specified progenitors can be expanded and cryopreserved. Our objective is to develop a culture media system designed to simplify and standardize this process while compressing timelines and adding increased flexibility in this complex differentiation workflow. Here we describe our results which have broken the process down into 3 distinct steps: (1) specification of hPSC to midbrain floor plate (mFP) cells, (2) expansion and cryopreservation of derived mFP cells, and (3) maturation to DA neurons. Characterization of floor plate cells and mature DA neurons was performed by immunostaining for the presence of specific markers including Lmx1, Otx2, FoxA2 and TH, additional qPCR analysis included expanded lists of genes to help define these

cell populations. Electrophysiological characteristics of differentiated neurons were assessed by Multi-electrode array and spontaneous and depolarization induced dopamine release was measured with HPLC. In comparison to published protocols, our new system has several advantages including ease of use, significant expansion and preservation of progenitors in relatively short culture duration. This efficient system will benefit researchers with increased scale and flexibility in targeted studies.

Title: Human iPSC-derived neurons: ideal for electrophysiological and toxicological assays

Authors: *B. MURPHY[1], G. LUERMAN[1], A. EHLICH[2], T. PALM[2], A. DUENBOSTELL[2], R. KETTENHOFEN[2], A. NICOLINI[3], B. BADER[4], A.-M. PIELKA[4], C. EHNERT[4], A. VOSS[4], O. SCHRÖDER[4], H. BOHLEN[2];
[1]Axiogenesis Inc, Plymouth Meeting, PA; [2]Axiogenesis AG, Cologne, Germany; [3]Axion Biosystems, Atlanta, GA; [4]NeuroProof GmbH, Rostock, Germany

Abstract: New standards are needed to address drug development for neurological degenerative diseases and neurotoxicological liability screens. Current drug development and toxicology screens employ classical animal derived *in vitro* and *in vivo* models, but lack true human neuronal cells. Axiogenesis developed different types of human induced pluripotent stem cell (iPSC) derived neurons (dopaminergic and peripheral neurons) to address the lack of relevant human central nervous as well as peripheral cellular systems. Here we demonstrate the suitability of these models in various neurotoxicological assays, such as: 1) Functional synaptic network activity of dopaminergic and peripheral neurons plated in 12 well microelectrode arrays. While dopaminergic neurons showed burst patterns similar to primary midbrain neurons from mouse,

peripheral neurons demonstrated increased thermal sensitivity; 2) Within a neurite outgrowth assay, our peripheral neurons highlighted enhanced sensitivity to chemotherapeutics (e.g. Vinblastine) than the gold-standard rat PC12 “neurite” cell model. Together, these data show that Axiogenesis human iPSC-derived neuronal subtypes are relevant human cell models and are ideal for a variety of well-established toxicological assays.

Title: Selective stimulation of AT2 angiotensin II receptor subtype increases neural stem cell proliferation

Authors: B. BLANCO[1,2], L. COULING[3], P. PATEL[4], S. KAMISETTY[4], M. TRIVEDI[3], J. MUNOZ[4], *R. C. SPETH[3,4,5];

Sciences, Col. of Pharm., Nova Southeastern Univ., Davie, FL; [4]Farquhar Col. of Arts and Sci., Nova Southeastern Univ., Fort Lauderdale, FL; [5]Dept. Pharmacol. and Physiology, Col. of Med., Georgetown Univ., Washington, DC

Abstract: Activation or inhibition of the renin-angiotensin system (RAS) affects neuronal function and viability. To assess the effect of angiotensin II (Ang II) receptor stimulation on neuronal growth and development, human neuronal stem cells (H-9 derived, Life Technologies), which were shown by qRT-PCR to express detectable levels of mRNA for components of the RAS, were seeded in chamber slides and cultured under proliferation (with EGF and FGF-2) or differentiation (no added growth factors) conditions with chronic exposure to AT1 and AT2 selective agonists. Conditions included 14 days treatment with once daily addition of the AT2 selective agonist CGP42112 (final concentration 100 nM); once daily treatment with the non-selective Ang II receptor agonist Sar1 angiotensin II (100 nM) plus the AT2 receptor selective antagonist PD123319 (10 μM) for selective AT1 receptor stimulation; once daily treatment with PD123319 (10 μM) alone; or once daily treatment with vehicle. Following treatment, cells were immunostained for the proliferation marker PCNA; the neural stem/progenitor cell marker Nestin; the neuroblast marker doublecortin; the astrocyte marker GFAP; the neuronal marker HuCD, and the DNA counterstain DAPI. Two-way ANOVA assessment of DAPI counts of cells revealed that there was a higher density of cells, as revealed by DAPI staining, in the proliferation medium compared to the differentiation medium ($p<0.0001$). There was a significant treatment effect ($p=0.0026$). The AT2 selective agonist CGP42112 significantly increased the density of cells compared to the AT1, PD1123319 and control groups ($p<0.05$) regardless of growth conditions. There were no significant differences between AT1 stimulated, PD123319 treated and the control groups, regardless of growth conditions. Preliminary results from immunostaining are consistent with an increase in cell growth with AT2 treatment with CGP42112. These results suggest that AT2 receptor stimulation can promote neural stem cell proliferation in both proliferation and differentiation conditions.

Title: Cell type and species specific toxicity screen of human neural stem cells and rat cortical neurons

Authors: *J. P. STEINER[1], A. G. EFTHYMIOU[2], K. MATHER[1], N. CHESTER[1], X. WANG[2], M. RAO[2], N. MALIK[2], A. NATH[1];

Abstract: Human primary neural tissue is a vital component for the quick and simple determination of chemical compound neurotoxicity *in vitro*. In particular, such tissue would be ideal for high-throughput screens that can be used to identify novel neurotoxic or neurotherapeutic compounds. We have previously established a high-throughput screening platform using human induced pluripotent stem cell (iPSC)-derived neural stem cells (NSCs) and neurons. In this study, we conducted a 2000 compound screen with human NSCs and rat cortical neuronal cells to identify compounds that are selectively toxic to each group. Approximately 100 of the tested compounds showed specific toxicity to human NSCs when screened at a concentration of 10 micromolar. A confirmatory and secondary screen of a small subset of compounds from the primary screen on human iPSCs, NSC-derived neurons, and fetal astrocytes validated the results from more than 80% of these compounds, with some showing cell specific toxicity. Amongst those toxic compounds were several cardiac glycosides, all of which were selectively toxic to the human cells. As the screen was able to reliably identify neurotoxicants, many with species and cell-type specificity, this study demonstrates the feasibility of this NSC-driven platform for higher-throughput neurotoxicity screens.

Title: Exploring the role of estrogen in early corticogenesis using human induced pluripotent stem cells

Authors: *C. SHUM[1], S. MACEDO[2], K. WARRE-CORNISH[2], D. P. SRIVASTAVA[2]; [2]Basic and Clin. Neurosci., [1]King's Col. London, London, United Kingdom

Abstract: Estrogens have a mechanistic influence during critical periods of prenatal brain development. The actions of estrogens are mediated by multiple neuronal signalling pathways, involving classical and non-classical estrogen receptors (ERs). The “classical” pathway involves estrogens binding to ERα and ERβ, transcription factors that regulate target gene transcription via binding to estrogen response element sequences and recruitment of other regulatory proteins. The “non-classical” pathway involves estrogens binding to membrane-bound ERα and ERβ, as well as the G protein-coupled receptor GPER1. Activation of these receptors results in the activation of multiple effectors, leading to various downstream effects. The activation of these pathways in neurons has been shown to promote survival, neuritogenesis and modulation of synaptic function. Interestingly, sex differences have been observed in the distribution of estrogen receptors in some brain regions and males and females and males respond differently to estrogen treatment in the brain. The expression and function of ERs and related genes in neurodevelopment are not well known. In addition, it is not clear which cellular and subcellular targets of estrogens are mediating its neuroprotective and neuroreparative actions, and whether there are sex differences in these and other components of the estrogen signalling pathway. We have used human induced pluripotent stem cells (iPSCs) to explore the role of estrogens in corticogenesis. Real time PCR and luciferase assays were used to examine the expression and function of estrogen receptors and related genes during the differentiation of iPSCs to cortical

projection neurons. Immunocytochemistry and live cell imaging were also used to characterise the effect of estradiol and estrogen receptor agonists on neuronal morphology and the expression of synaptic proteins in cortical projection neurons differentiated from iPSCs. We observed expression of estrogen receptors during neural induction and maturation. We have found that estradiol and estrogen receptor agonists have differential effects on neurite outgrowth. Our findings show that the neuritogenic actions of estrogen are mediated by specific components of the estrogen signalling pathway and support the use of human induced pluripotent stem cells for the study of the molecular mechanisms underlying the mechanistic influence of estrogen.

Abstract: In 2014 Japanese government launched three Acts in the field to promote and secure regenerative medicine. Therefore, the 2014 is called the first year of regenerative medicine in Japan. Acceleration of stem cell sciences and realization of their outcomes to benefit patients, efficient exchange of stem cells information and inspiring database for science are indispensable. This database also aims to bridge science and patients and citizens to facilitate their participation in clinical research. SKIP is an initiative to promote the exchange of information and facilitate joint research between researchers by providing one stop database of information of stem cells (iPS cells, original diseased fibroblasts, lymphoblast cells, etc.), data include cell types, ownership, characters, culture and preservation conditions, literature, etc.. SKIP also aims to offer information on stem cells to the general public, including patients, in order to promote societal understanding and enhance participation of medical research using stem cells. SKIP

(http://www.skip.med.keio.ac.jp/) is administrated by an operating committee ("SKIP Operating Committee") of Keio University as Human Stem Cells Informatization Project, the Ministry of Health, Labour and Welfare. To date, we have had more than 550 cell information without duplication. The information is registered from published papers and open resources, and also from original establishers of their culture. We also create and provide secure database to share stem cell information between different institutions at collaborations. We are calling you to register your own cell lines to SKIP to promote your collaboration. Accession reached more than 300 per day and is increasing. Researchers can reach disease iPS cells of their interest from the name of disease or ICD-10 code. Visibility of the database increase and we are trying to add detailed relational information of cells and make the database more fruitful. SKIP is developing to be a powerful tool for researchers to liberate their ideas and promote stem cell sciences involving public and commercial entities.

Title: Long-term electrophysiological activities and drug responses in cultured human iPSC derived neurons

Authors: ***A. ODAWARA**[1], Y. SHI[2], H. JIKO[3], I. SUZUKI[1];
[1]Tohoku Inst. of Technol., Sendai, Japan; [2]Axol Biosci. Ltd, Cambridge, United Kingdom;
[3]Alpha MED Scientific Inc., Osaka, Japan

Abstract: Neuronal cells can be generated from Human induced pluripotent stem cells (hiPSCs), providing a very important alternative to studies of humans and model organisms, to facilitate a better understanding of the mechanisms of neurological diseases and identifying novel therapeutic avenues. However, the long-term electrophysiological futures of cultured human iPSC-derived neurons have not been investigated. Here, we used the multi-electrode array system to investigate the functional characteristics of hiPSC-derived neurons on their long-term spontaneous activity and drug responsiveness. We demonstrated that hiPSC-derived neurons allowed the culture to be maintained for >260 days with long-term spontaneous activity. After 2

months of culture, we observed synchronous burst firing activity due to synapse transmission within neuronal networks. Compared with rat neurons, hiPSC-derived neurons required longer time to mature functionally. In drug responsiveness, addition of the synapse antagonist bicuculline, CNQX, AP5 and agonist a kainic acid, L-gulutamate induced significant changes of the firing rate. Furthermore, administration of pentylentetrazole (PTZ) induced epilepsy phenomenon. Anti-epilepsy drug phenytoin and sodium valproate reduced epilepsy phenomenon. These results suggested that long-term electrophysiological measurements in hiPSC-derived neurons using a MEA system may be beneficial for clarifying the functions of human neuronal circuits and for drug screening applications.

Title: Development and integration of engrafted induced pluripotent stem cells-derived 3-dimensional cerebral organoids

Authors: *N. DAVIAUD, H. ZOU;
Lab. of axonal growth & neuronal regeneration, Mount Sinai Sch. of Medecine, New York, NY

Abstract: Stem cells hold great promise for modeling brain disorders and promoting neural repair, but are limited by the lack of 3-dimensional (3D) organization. Recently, 3D cerebral-organoid (C-organoid) culture system was developed, containing discrete brain structures, such as forebrain cortical plate with stereotypical inside-out stratification and regional specifications. However, C-organoids stop progressing due to nutritional limitation. To overcome this obstacle, we propose to transplant C-organoids into neonatal mouse brains to achieve *in vivo* vascularization, which may further promote morphological maturation and advance neural differentiation of the grafted organoids. In addition, formation of *in vivo* vasculature may also orchestrate signals between endothelial cells and neural progenitors, recapitulating the interaction of cells and tissues during corticogenesis. In a recent pilot study, we transplanted *in vitro* derived C-organoids and demonstrated good survival and robust *in vivo* vascularization in neonatal mouse cortex (Fig. 1). We also observed the expression of stem cell, intermediate progenitor and preplate markers. Importantly, at 1 month post-transplant, the engrafted C-organoid maintained a ventricle-like cavity, an important structure for maintaining polarity of the

germinal zone and stem cell niche. Further analysis will be performed to study proliferation and differentiation state of the implanted tissue. We propose an innovative approach using *in vitro* 3D C-organoid culture as a unique platform to model human cortical development. Once established, engraftment-based cerebral organoid studies will have far-reaching implications in illuminating human brain evolution and in advancing CNS repair strategies. Fig. 1. Grafts in motor cortex of P14 mouse after 1 month. (A, B) Immunofluorescence shows abundant vasculature (CD31, red) in grafted organoids labeled by anti-human mitochondria antibody (green). (C, D) A ventricle-like cavity (V) is preserved in the graft. Inset of A and C are enlarged in B and D. Scale: 100 μm (A), 25 μm (B-D).

Title: Probing network dynamics in an *in vitro* model of human cortex development

Authors: *M. PETER, P. KIRWAN, F. J. LIVESEY;
Gurdon Inst., Cambridge, United Kingdom

Abstract: One fundamental question in neuroscience is how neurons form specific connections and functional neuronal networks. During development, neurons typically undergo a phase of over-connectivity followed by synaptic pruning and a reduction in neuronal connectivity. Furthermore, network activity undergoes different phases of synchronous oscillatory firing before complex firing pattern emerge. The functional role of this oscillatory activity is not fully understood, however it is believed that synchronous network activity is important to shape neuronal connectivity and the development of mature neuronal networks. Due to the limitations of studying human fetal material, later aspects of cerebral cortex development has largely been studied in rodents. Our lab has previously published a method to replay cortical development, generating human cortical neurons from pluripotent stem cells. These neurons express markers from all cortical layers and develop excitatory neuronal networks that recapitulate rodent network development over months in culture. Network activity is sensitive to tetrodotoxin, and is AMPA and NMDA receptor-dependent. Therefore human stem cell derived neurons serve as an ideal model system to study human cortical network development *in vitro*. Currently I am combining imaging of neuronal network activity using GCaMP6 and tracing of neuronal connectivity with a modified rabies virus to link activity with a connectivity analysis. I am also combining trans-synaptic rabies tracing with a histological analysis of connected neurons to test if late born neurons integrate into existing neuronal networks. In the future I will further explore the contribution of inhibition on network activity development by co-culturing neurons with stem cell derived interneurons. These experiments will allow me to better understand how different activity pattern shape neuronal connectivity during human cortex development.

Abstract: Neuronal differentiation for *in vitro* disease modeling and translational regenerative medicine applications is facilitated by the availability of somatic cell-derived induced pluripotent stem cells (iPSCs). In that regard, the common marmoset monkey (Callithrix jacchus) has been identified as an ideal species for modeling age-related disorders, such as Parkinson's disease (PD), due to their shorter lifespan compared to larger nonhuman primates. While neuronal differentiation has been achieved from marmoset embryonic stem cells (Cj-ESCs) and iPSCs derived from fetal tissues, production of patterned midbrain floorplate (FP) neuroprogenitors (NPs) from adult marmoset fibroblast derived iPSCs have not been reported. The aim of this study was to fill this gap by producing a Cj-iPSC line from adult marmoset skin fibroblasts, generate a differentiation protocol to pattern FP-derived midbrain NPs, and characterize the expression of pluripotent, neural ectoderm, NP, and mature neuronal subtype genes throughout the differentiation process of both Cj-ESCs (Cj367) and Cj-iPSCs (M8). To reprogram the marmoset skin fibroblasts, skin punch biopsy tissue obtained from an adult marmoset was cut to smaller samples and explanted to 35 mm wells. Non-integrating pluripotency-inducing plasmids were then electroporated into the outgrown fibroblasts. To verify pluripotency of colonies selected by morphological criteria, RT-PCR was performed using primers for marmoset OCT4, SOX2, NANOG, KLF4, LIN28, and C-MYC genes. For ventral patterning, sonic hedgehog (SHH) was added at 500 ng/mL for the first 16 days, then reduced to 20 ng/mL until day 28. FP derivation was confirmed by a shift of expression from PAX6 to FOXA2. Anterior-posterior patterning was accomplished using CHIR99021 (0.4 μM). Colocalization of OTX2 and EN-1 confirmed midbrain identity. For neuronal differentiation, suspension neurospheres were transferred to adherent culture on day 28 and exposed to BDNF, GDNF, TGF-β3, cAMP, and Ascorbic Acid in neural basal media. Immunocytochemistry for nestin and βIII-tubulin confirmed NP and mature neural fates respectively. Our results demonstrate that the M8 line reprogrammed from adult marmoset fibroblasts is morphologically identical to the Cj367 ESC line, and pluripotent mRNA expression was similar between the two cell lines, each expressing all 6 endogenous genes mentioned above. We also observed that both M8 and Cj367 cell lines patterned to midbrain FP NPs under ventral-posterior patterning parameters and produced βIII-

tubulin positive neurons. We conclude that adult marmoset fibroblast-derived iPSCs can be patterned towards midbrain FP NPs.

Title: Using neural stem cells to evaluate the potential developmental neurotoxic effects of silver nanoparticles

Authors: *F. LIU[1], M. MAHMOOD[2], Y. XU[2], F. WATANABE[2], A. S. BIRIS[2], D. K. HANSEN[1], A. INSELMAN[1], D. CASCIANO[2], T. A. PATTERSON[1], M. G. PAULE[1], W. SLIKKER, Jr.[1], C. WANG[1];
[1]Natl. Ctr. For Toxicological Research/FDA, Jefferson, AR; [2]Ctr. for Integrative Nanotechnology Sci., Univ. of Arkansas at Little Rock, Little Rock, AR

Abstract: Silver nano-particles (Ag-NPs) are becoming increasingly prevalent in consumer products as antibacterial agents. The increased use of Ag NP-enhanced products will almost certainly increase environmental silver levels, resulting in increased exposures and the potential for increased adverse reactions including neurotoxic effects. In the present study, embryonic neural stem cells (NSCs) from human and rat fetuses (gestational day-16) were used to determine whether Ag-NPs are capable of causing developmental neurotoxicity. The NSCs were cultured in serum free medium supplemented with appropriate growth factors. On the eighth day *in vitro* (DIV 8), the cells were exposed to Ag-NPs at concentrations of 1, 5, 10, and 20 μg/ml for 24 h. The cultured cells then were characterized by NSC markers including nestin and SOX2 and a variety of assays were utilized to determine the effects of Ag-NPs on NSC proliferation and viability and the underlying mechanisms associated with these effects. The results indicate that mitochondrial viability (MTT metabolism) was substantially attenuated and LDH release was increased significantly in a dose-dependent manner. Ag-NPs-induced neurotoxicity was further confirmed by up-regulated Bax protein expression, an increased number of TUNEL-positively

stained cells, and elevated reactive oxygen species (ROS). NSC proliferation was also significantly decreased by Ag-NPs. Co-administration of acetyl-L-carnitine, an antioxidant agent, effectively blocked the adverse effects associated with Ag-NP exposure.

Title: Positive biocompatibility of several graphene derivatives with dopaminergic cells at long term culture

Authors: N. RODRIGUEZ-LOSADA[1], R. WENDELBO[2], E. ARENAS[3], *J. A. AGUIRRE[1]; [1]Dept. of Physiology. Fac. of Med., Malaga, Spain; [2]Abalonyx AS, Oslo, Norway; [3]Dept. of Med. Biochem. and Biophysics, Karolinska Institutet, Stockholm, Sweden

Abstract: The emerging carbon nanomaterial graphene (G) and its oxidized derivative graphene oxide (GO) have recently gained considerable attention in biomedical applications such as cancer therapy or biosensors. It has for example been demonstrated that G has an efficient bioconjugation with common biomolecules and activates cell differentiation of neuronal stem cells (Li et al., 2013). This way, G could acts as a physical support or scaffold to promote differentiation and axonal sprouting of dopaminergic (DA) cells derived from neural stem cells. Since GO in its multilayer form and with multiple carboxylate and epoxy groups seems to show interesting biological properties (Yang et al., 2013) the aim of the present work has been to test different graphene derivatives searching for the best scaffold to be used in stem cell differentiation. For this purpose we have tested the cytotoxicity of GO and reduced GO, and specifically its biocompatibility with SN4741, a dopaminergic cell line derived from mouse substance nigra, measuring the effect on long term culture. The cells were cultured in Dulbecco's

modified Eagle's medium 10% FCS (Gibco) to about 80% confluence. Cells (1.000) were plated onto 96-well microliter plates with graphene using three chemically different types of GO as powders and films: 1) hydrophilic GO; 2) partially reduced GO (PRGO) which is hydrophobic and 3) fully reduced GO (FRGO), also hydrophobic, each of them in five concentrations: 1 mg/ml; 0.1 mg/ml; 0.05 mg/ml; 0.02 mg/ml and 0.01 mg/ml. Cells were cultured with GO and cell viability was determined after 24 hours, 1 week and 2 weeks using the MTT assay (Roche) and cytotoxicity was determined by the lactate dehydrogenase (LDH) assay (Roche). Our results show positive biocompatibility between the G-derivatives and SN4741 cells. We conclude that the use of our G-derivative scaffolds can enhance the morphological differentiation towards DA neurons (TH positive) providing microenvironments appropriate for neural differentiation and axon guidance. These findings suggest that biocompatible scaffolds can contribute to the future generation of successful clinical applications of G. Future experiments will examine whether G could offer a platform for neural stem cell and neural regeneration for neurological diseases such as PD. Abstract: Strategies that exploit induced pluripotent stem cells (iPSCs) to derive neurons have relied on cocktails of cytokines and/or growth factors to bias cell signaling events in the course of fate choice. These are often costly and inefficient, involving multiple steps. In this study, we took an alternative approach and selected five small-molecule inhibitors of key signaling pathways to improve efficiency in derivation of sensory neurons from human iPSCs. Within 8 days of the differentiation protocol, iPSC-derived sensory neurons were achieved as denoted by marker expression, >80% being immuno-positive for Tuj1, NeuN and NF200, Islet1, peripherin and Brn3a but immuno-negative for neural progenitor markers (Pax6 and nestin) as well as neural crest cell markers (AP2, HNK1 and p75). Patch-clamp recordings on the derived neurons revealed healthy resting membrane potentials averaging -60 mV. Single action potentials were elicited in response to depolarizing step currents whereas multiple action potentials could be evoked with increasing intensity of the depolarizing current. Spiking was blocked by bath administration of tetrodotoxin. The derived cells therefore demonstrated electrophysiological properties characteristic of functional neurons. Neurite bundles that extended from the derived neurons were amenable to myelination in co-culture with rat Schwann cells, showing internodal segments that were immuno-positive for myelin-related proteins, P0, MBP and GALC. The phenotype of the iPSC-derived neurons was sustainable in Neurobasal medium supplemented with maintenance growth factors but without the small-molecule inhibitors. With this rapid and efficient induction protocol, we expect production of sensory neurons from human iPSCs on demand for developmental studies and disease modeling.

Abstract: Parkinson's disease (PD) is a chronic progressive disorder with motor symptoms characterized by tremor, bradykinesia, rigidity and postural instability. Currently there are nearly one million diagnosed cases in the US. Clinical studies have shown that patients can gain improved motor function with transplantation of cell preparations derived from fetal ventral midbrain. However, fetal cell sources are too limited and require immunosuppression. Induced pluripotent stem cells (iPSCs) can be generated from affected PD patients or HLA-matched individuals and differentiated to midbrain dopaminergic cells, providing opportunities for low-rejection risk or autologous transplantations. We have recently shown that dopaminergic neurons derived from iPSCs from an MPTP-lesioned cynomolgus monkey survived two years after autologous transplantation, re-innervated the host putamen and provided improved motor function (Hallett et al. Cell Stem Cell. 2015 Mar 5;16(3):269-74). We did not observe any graft-derived proliferating cells two years after transplantation, which is encouraging from a clinical standpoint. We are now in pre-clinical experiments improving our cell differentiation and transplantation paradigms in order to outline requirements and conditions for potential clinical trials. Using a xeno-free differentiation protocol (modified from Cooper et al., 2010, Mol Cell Neurosci;45(3):258-66) and feeder-free and foot-print-free human iPSC lines derived using episomal reprogramming technology, we are defining positive and negative cell-marker expression criteria of cell-preparations and cell-sorting requirements. We are also determining cell freezing and thawing strategies and pre-transplantation cell-viability criteria. For safety purposes we are preparing for scale-up and cell-dosing studies. Functional recovery and graft survival is studied in xeno-grafted rodents. These data and experiments are IND enabling efforts to establish future clinical trials.

Title: HESX1 regulates neural induction from human embryonic stem cells

Authors: ***C. T.-L. HUANG**[1,2], J. LU[1], L. FOWLER[1], Y. CHEN[1], J. CAO[1], S.-C. ZHANG[1,2,3]; [1]Waisman Center/University of Wiscosin, Madison, Madison, WI; [2]Dept. of Neurosci., [3]Dept. of Neurol., Univ. of Wiscosin, Madison,, Madison, WI

Abstract: The precise coordination of signaling pathways and transcriptional regulation is required for neural development. However, how the neural induction process is coordinated remains unknown. Here we use the *in vitro* neural induction model from human embryonic stem cells (hESCs) and show that HESX1, a homeodomain transcription factor, is transiently expressed right before a neural determinant marker, PAX6, is expressed. Knockout (KO) of HESX1 does not affect the self-renewal and pluripotency of hESCs. It, however, results in early neural induction, indicated by the earlier and faster downregulation of pluripotent markers, such as OCT4 and NANOG, and the accelerated upregulation of neural induction markers, such as PAX6 and ZEB2. In addition, the structure of neural tissue in the teratoma from the HESX1-KO hESCs is disorganized. Interestingly, non-physiological overexpression of HESX1 under the HESX1 KO background promotes neural induction. Our findings suggest that HESX1 plays a role as a gate-keeper in human neural induction.

Abstract: Pluripotent stem cells (PSCs) including embryonic stem cells and induced pluripotent stem cells (iPSCs) proliferate infinitely and differentiate into multiple cell types. Neuronal progenitor cells (NPCs) and functional mature neurons derived from human PSCs can be useful in regenerative medicine and drug discovery. However, human PSCs under a conventional culture, growing as colonies on feeder cells, often differentiate into undesired cells that interrupt reproducible experiments and the large-scale preparation of functional neurons. Here we report the robust differentiation into highly pure NPCs and neurons from human iPSCs maintained in a single-cell and feeder-free (SFF) culture using an original chemically defined medium containing bFGF and Activin, by which human PSCs serve as a practical cell source. Differentiated cells formed rosette-like structures and expressed neuronal markers such as β3-tubulin and microtubule-associated protein 2. In addition, we have established the techniques for cryopreservation of the NPCs, which enable highly reproducible functional analysis and drug screening practices. To characterize functional properties of the neurons, we performed whole-cell patch-clamp recording at 1-4 weeks after re-plating. In current clamp-mode, depolarizing current injection revealed the generation of action potentials. In voltage clamp-mode, depolarizing voltage steps from a holding potential of -60 mV elicited fast inward Na^+ currents that were blocked by application of tetrodotoxin (TTX). Moreover, application of both glutamate and gamma-aminobutyric acid (GABA) elicited inward currents at a holding potential of -60 mV. The electrophysiological analysis revealed essential functional properties such as TTX-sensitive voltage-dependent Na^+ currents, glutamate- and GABA-induced currents in the neurons. Thus, the functional human iPSC-derived neurons are expected to be a powerful tool for disease investigation and drug development. Furthermore, it is suggested that the SFF culture for human iPSCs is an outstanding versatile platform to prepare several functional cells including neurons.

Abstract: Background Neurogranin (Ng), a post-synaptic, brain specific protein kinase C substrate, is expressed in neuronal cell bodies and dendrites. Ng has a role in synaptic plasticity, long term potentiation, spatial memory and learning. Much research has been done on the expression of Ng during development in rodent models, while little is still known about the expression of Ng in the human brain. Due to differences in the development and maturation of the human brain compared with the rodent brain, rodent brain models are inadequate to address some specific scientific questions. One example is expression of Ng during cortical development. Therefore, cells of human origin were used here to study the expression of Ng during cortical development. Methods Human induced pluripotent stem cells (hiPS cells) of chondrocyte and fibroblast origin were differentiated towards cortical neurons following Shi et al., 2012 protocol. Cell conditioned media was collected continuously during the 125 days long differentiation and secreted levels of Ng were measured in the media using ELISA and immunoprecipitation-mass spectrometry (IP-MS). Expression of Ng was assessed with immunocytochemistry (ICC) at different days of differentiation. Results ICC results showed that cellular expression of Ng appears at approximately 40 to 50 days of differentiation from hiPS cells towards cortical neurons. During differentiation Ng was observed to translocate from nuclei to neurites. ELISA results indicated that Ng was secreted to the cell conditioned media throughout differentiation. Further, it was possible to detect Ng peptide (53-78) in the cell conditioned media via IP-MS. Conclusions To the best of our knowledge, cellular expression of Ng from cells of human origin was illustrated for the first time during differentiation. Furthermore, detection of Ng peptide (58-78) and secretion of Ng in cell conditioned media throughout differentiation are also novel findings in this study. Taken together, this study provides a promising platform for elucidating the role of Ng in human cortical development.

Title: Treatment with gamma–secretase inhibitor for neural stem/progenitor cells derived from tumorigenic human induced pluripotent stem cells

Authors: ***T. OKUBO**[1,2], A. IWANAMI[2], J. KOHYAMA[3], G. ITAKURA[2], M. MASTUMOTO[2], M. NAKAMURA[2], H. OKANO[3];

Abstract: [Introduction] Recently we reported that transplantation of neural stem/progenitor cells derived from human induced pluripotent stem cells (hiPS-NSC) promoted functional recovery in animal models of spinal cord injury (SCI). However, some cell line of hiPS-NSC occurred deterioration of motor function due to tumor formation after transplantation. Since Notch signaling controls the induction of definitive neural stem cells, its inhibition with Gamma-secretase inhibitor (GSI) may induce hiPS-NSC to differentiate into a more mature state with limited proliferation. Here we present the effects of GSI on proliferation and differentiation of hiPS-NSC. [Method] hiPS-NSC (253G1), a potentially tumorigenic cell line (Nori et al, Stem Cell Reports 2015), were cultured with GSI for 1 day in GSI-1d group, 4 days in GSI-4d group, and without GSI in no GSI treatment group. Then the characterizations of these cells were evaluated by immunocytochemistry and the neuronal maturation was also assessed by micro electrode array (MEA). Cell cycle/apoptosis analysis was performed using flow cytometry, and the gene expression related to pluripotency, self-renewal and neural differentiation were analyzed using RT-PCRs. All of these data were statistically analyzed and compared among three groups. [Result] In the GSI-4d group, the number of cells significantly decreased compared to the other groups. In the no GSI treatment group, the sizes of spheres were significantly larger than those of both GSI groups. Compared to the no GSI treatment group, the percentage of G0/G1 phase significantly increased, and the percentage of S phase significantly decreased in both the GSI groups, although there was no significant difference in AnnexinV/7-AAD apoptosis assay. The percentages of Ki67-and Nestin-positive cells also significantly decreased compared

with no GSI treatment group, whereas the percentage of Tuj-1-positive cells significantly increased. In both GSI groups, neuronal maturation was significantly enhanced compared to the no GSI treatment group. RT-PCRs showed that the expression of Notch signaling target genes, such as HES5, Notch1 were almost abolished by GSI, indicating that Notch signaling was efficiently inhibited. Gene expression of the mature neuronal markers, such as Neurog2, ASCL1, NeuroD1, but not glial markers, such as GFAP, Olig2, were up-regulated in accordance with the down-regulation of gene expression of pluripotency/self renewal markers, such as Nanog, Lin28, Oct3/4, Nestin. [Conclusion] In conclusions, pretreating with GSI promoted neuronal differentiation and maturation, inhibited glial differentiation of hiPS-NSC *in vitro*.

Title: Study on the cell transplantation and differeniation of retinal progenitor derived from human embroynic stem cells

Authors: ***S. WANG**, X. WANG, K. XIONG, D. GU, G. ZHOU;
Fudan Univ., Shanghai, China

Abstract: Human embryonic stem cells (hESCs) have been reported to serve as an excellent source for obtaining various specialized cell types and could be used in cell replacement therapy. Here we demonstrate the potential of hESCs-GFP to differentiation into retinal progenitor by using our novel differentiation system. The neural optic cup-like structures can be formed within 4-5 weeks. Most of the cells were pax6 and math5 positive, and $Math5^{+}$/$Brn3b^{+}$ ganglion cell progenitor were deceted in the hESC-derived optic cup-like structures at 8 weeks. When these cells were transplanted into the vitreous cavity of mice that were damaged by N-methyl-D-aspartate (NMDA) before, at 30 days past transplantation, the transplanted cells could survive and integrate into the host retina, located in the ganglion cell layer. At 35 days, some of them were Brn3a positive. These findings suggests that retinal progenitor cells derived from hESCs can differentiate into retinal ganglion cells under the host retinal microenvironment. Our results

provide insights that hESCs can serve an excellent renewable source for generating retinal progenitor that can be used to treat neurodegenerative disease like glaucoma.

Abstract: Genetic epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant disorder associated with mutations in *SCN1A,* encoding the $Na_v1.1$ voltage-gated sodium channel. Our lab has used a *Drosophila* knock-in model to explore the cellular mechanisms contributing to hyperthermia-induced seizures characteristic of GEFS+ patients. These data suggest that the K1270T mutation causes hyperthermia-induced seizures through a conditional gain-of-function alteration in sodium channels that reduces excitability of GABAergic neurons (Sun *et al.*, 2012). To determine whether this mutation causes similar changes in sodium channels and excitability in human neurons, we generated induced pluripotent stem cell (iPSC)

lines from three siblings, two with the GEFS+ K1270T mutation and one without (Control). We used a recently published strategy for directed differentiation of iPSCs into medial ganglionic eminence (MGE) progenitors that had been shown to enrich cultures for GABAergic neurons (Liu *et al.*, 2013). Three weeks after plating MGE progenitors onto mouse astrocyte feeder layers, approximately 30% of the MGE derived neurons arising from Control iPSCs were GABAergic and nearly all recorded cells were capable of firing action potentials. Single action potentials were observed as early as ten days after neuronal differentiation was begun. Functional maturation continued steadily and by five weeks in culture the majority of neurons examined fired spontaneous action potentials and had GABAergic and/or glutamatergic synaptic inputs. The time course and degree of functional differentiation was similar from plating to plating, allowing quantitative analysis of currents, firing properties and synaptic transmission. Therefore comparison of cultures prepared from Control and GEFS+ iPSCs will allow us to identify alterations in sodium currents, firing properties and synaptic function associated with the K1270T mutation in human neurons. This differentiation protocol will also be useful in determining how other genetically induced neurological disorders affect neuronal maturation and function, facilitating development and testing of novel therapies.

Title: *In vitro* modeling of early retinogenesis with human pluripotent stem cells

Authors: ***A. SRIDHAR**[1], S. K. OHLEMACHER[1], J. S. MEYER[1,2];
[1]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Stark Neurosciences Res. Inst., Indiana Univ., Indianapolis, IN

Abstract: Human pluripotent stem cells (hPSCs) provide a unique ability to study some of the earliest events of human development, particularly some of the earliest events in human retinogenesis such as the establishment of a definitive retinal fate from a more primitive neural progenitor source. In this role, hPSCs may provide an *in vitro* model for understanding the complex interplay of transcription factors involved in the acquisition of a retinal fate from an unspecified pluripotent cell population. hPSCs were differentiated as previously described and samples were collected every two days, starting from the undifferentiated state through when cells acquired either retinal or non-retinal forebrain identities. Immunocytochemistry and qRT-PCR approaches were undertaken to identify candidate transcription involved in retinal fate establishment. Candidate transcription factors were identified underlying the establishment of a retinal fate apart from other neural lineages. Neural transcription factors including PAX6 and OTX2 were expressed early while retinal-associated transcription factors such as SIX6 were expressed at slightly later timepoints. Upon establishment of an anterior neural identity, the expression pattern of the RAX transcription factor became more restricted to subpopulations of cells, presumably indicative of the emergence of retinal population apart from related forebrain populations from the same primitive anterior neural population. Gene overexpression and knockdown experiments investigated the mechanism of action of these candidate transcription factors. Furthermore, epigenetic analysis demonstrated that DNA methylation could potentially account for differential gene expression in the establishment of retinal phenotypes apart from alternate neural lineages. Preliminary results begin to elucidate the complex interplay of transcription factors involved in the specification of a retinal fate from differentiating hPSCs. Overall, these results will help to better establish hPSCs as a valuable *in vitro* system with which to study some of the earliest events of human retinogenesis.

Title: Self-organization of polarized cerebellar tissue in 3D culture of human pluripotent stem cells

Authors: *K. MUGURUMA[1], H. KAWAKAMI[2], K. HASHIMOTO[2], Y. SASAI[3];
[1]Cell Asymmetry RIKEN CDB, Kobe, Japan; [2]Hiroshima Univ., Hiroshima, Japan; [3]RIKEN CDB, Kobe, Japan

Abstract: The cerebellum (CB) has been considered as a major component of the motor system. It is well known that the damage in the CB leads impairments in motor and postural control. In human, the CB develops over a long period of time, from the early embryonic days to the first postnatal year. Such protracted development could be the source of vulnerability and the cause of broad spectrum of developmental disorders. Cellular and molecular studies on the cerebellar development have been done mostly in model animas. However, it is not known whether the mechanisms revealed in model animals are simply applicable or not. Thus the studies in human have been long awaited for elucidation of functions of the human CB. The CB is a highly ordered brain structure with several well-defined types of cells. The initial phase of cerebellar development is the formation of the isthmic organizer. Under its inductive influence, the cerebellar anlage arises in the dorsal region of rhombomere 1 (r1). Cerebellar cells are generated in the two distinct germinal zones in the r1. One is the ventricular zone of the cerebellar plate (CP), which expresses Ptf1a. The Ptf1a progenitors produce GABAergic neurons of the cerebellar cortex (Purkinje cells and interneurons) and of the deep cerebellar nuclei (DCN). The other one is the upper rhombic lip (RL), which expressed Atoh1. The Atoh1 progenitors generate cerebellar glutamatergic neurons, including granule cells (GC) and large DCN projection neurons. We previously reported that cerebellar neurons could be generated from mouse embryonic stem cells (mESCs). mESCs have the potential to form isthmic organizer tissue in response to FGF2 and Insulin. Here, we apply the self-formation principle to human ESC/iPSC culture for the generation of human cerebellar tissues *in vitro*. Using modified culture condition, we show *in vitro* production of major cerebellar types such as Purkinje cells and GCs. In the course of optimizing 3D culture we identified two factors, FGF19 and SDF1 that promotes self-formation of ordered CP-like tissues in distinct manners. FGF19 promotes spontaneous generation of dorsoventrally polarized neural tube-like structures at the level of the CB. Furthermore, addition of SDF1 and FGF19 promotes the generation of a continuous CP neuroepithelium with RL-like structure at one end a three-layer cytoarchitecture similar to the embryonic CB. Thus, human pluripotent stem cell-derived cerebellar progenitors exhibit substantial self-organizing potential for generating a polarized structure reminiscent of the early human CB at the first trimester.

Title: Improved differentiation of mouse embryonic stem cells into Purkinje Neurons

Authors: *C. J. ALEXANDER, J. A. HAMMER, III;
Lab. of Cell Biol., NHLBI, NIH, Bethesda, MD

Abstract: The use of embryonic mixed primary cerebellar cultures has been invaluable for dissecting detailed structure: function studies in Purkinje Neurons (PNs), however this technique is technically challenging and can yield few cells. Recently, mouse embryonic stem cells (mESCs) have been successfully differentiated into PNs, however these methods are equally as challenging as primary cultures. The focus of this study was to determine if we can simplify differentiation of mESCs into PNs. Using specific extrinsic factors, we have successfully differentiated mESCs into PNs without the requirement for a postnatal feeder-layer. We have characterized the morphology of mESC derived PNs and show that they are indistinguishable from PNs grown in primary culture with similar gross morphology, spine length and spine density. Further to this we have demonstrated that mESC derived PNs express Calbindin D28K, IP3R1, PLCb4 and GRID2, all of which are PN-specific markers. Finally, using collagen, poly-l-lysine and gelatin as the extra cellular matrix has allowed us to grow mESC derived PNs in monolayers, which will be critical for live cell imaging. Future directions will be to determine if we can express exogenous DNA specifically in the mESC derived PNs using the PCP2/L7 PN-specific promoter. If this is possible, we will be able to gene edit stem cells using CRISPR and compliment with exogenous DNA. Together, this will allow for a scalable, high throughput approach that will be important in dissecting specific molecular mechanisms in PNs, especially in currently unobtainable genotypes.

[2]California Stem Cell, Inc. (since acquired by Neostem, Inc.), Irvine, CA

Abstract: Age-related macular degeneration and other retinal disorders affect millions of people worldwide. Current treatments can delay the degradation, but few can restore function and visual acuity. The challenge is how best to create and introduce fresh, healthy tissue to replace damaged host retinal cells. We used human embryonic stem cells (hESC) to produce transplantable sheets of retinal and retinal pigmented epithelium (RPE) and are now testing the use of induced pluripotent stem cells (iPSC). It is hoped that the new iPSC derived tissue will create fresh photoreceptors for the host, generate new synaptic connections for phototransduction, and a new RPE monolayer critical for photoreceptor maintenance. Human stem cells were differentiated into retinal tissue by creating 3D neurospheres, following a protocol modeled after Zhong et al. 2014 (Nature Communications 5:4047) which results in laminated 3D structures (neurospheres). Quantitative polymerase chain reaction (qPCR) analysis of genes characteristic for neuronal (Pax6) and retinal development (Chx10, Rax, CRALBP, CRX, recoverin), and RPE (MITF) was performed on retinal neurospheres between d27 and d73 of differentiation and human stem cell-derived RPE monolayers. For comparison, d84 and d110 human fetal retina (HFR) and RPE were also analyzed and used as control tissues. In parallel, immunofluorescence (IF) experiments on fixed differentiated neurospheres looked for the expression of important neuro-retinal proteins found in the human eye (e.g. Rax, CRX, Recoverin, CRALBP, MITF). Immunohistochemical H+E staining confirmed the developing lamination and retinal maturation of the neurospheres at progressive time points. Taken together, the data demonstrates a neurosphere expression pattern similar to that seen in the developing human fetal eye with early commitment progenitor markers like PAX6 and CHX10 coming up first during the culture time course and more mature photoreceptor and RPE proteins (i.e. recoverin and CRALBP) coming up late. The 3D neurospheres are clearly undergoing retinogenesis and the use of this system to produce transplantable tissue is promising. Transplantation experiments into a nude S334ter-line 3 retinal degenerate rat strain are ongoing.

Title: Visualization of photoreceptors derived from human iPSC by using CRISPR/Cas9 system

Authors: *K. HOMMA, M. KANEDA;
Nippon Med. Sch., Tokyo, Japan

Abstract: Genome engineering tools, such as ZFN, TALEN, and CRISPR/Cas9 systems enable us to efficiently insert fluorescent reporter gene(s) into the genome. The cell lineage specific reporter gene knock-in induced-pluripotent stem cell (iPSC) lines are used to evaluate the efficiency of differentiation/maturation in physiological experiment or live cell imaging. Here, we introduced CRISPR/Cas9 system to insert fluorescent protein gene into the C-terminal of photoreceptor specific transcriptional factor. Photoreceptor specific genes were linked with fluorescent protein gene by the gene of 2A-peptide, which was to be cleaved off after the translation. Another target site is the adeno-associated virus integration site 1 (AAVS1), which is enclosed by insulators, thus is thought as “safe harbor” for gene insertion. The guide-RNA expression vectors, the Cas9 expression vectors, and the donor vector, which contains puromycin or blasticidine resistance gene, were electroporated into human iPSCs (454E2 line from RIKEN BRC). Electropolated human iPSCs were plated on Matrigel-coated 6 well plates. On day 2 after the electroporation, antibiotic, such as puromycin or blasticidine was added to the culture medium. After the selection culture, around the day 10, possible single colonies were picked and amplified on culture plate. Genomic PCR showed that the donor gene was inserted into target sites in 19 lines / 20 lines (95.0 %). Also, genomic sequencing confirmed correct gene insertion in these hiPSC lines. After the 3D retinal differentiation culture, retinal laminar formation was observed and some cells showed fluorescence in expected layer. These photoreceptor-specific reporter gene knock-in human iPSC lines are useful for identifying the developmental stage at which derived photoreceptors were applicable to retinal cell-based therapy.

Title: Skilled grasping requires non-apoptotic Bax/Bak-mediated corticospinal circuit refinement

Authors: ***Z. GU**[1], N. SARRAD[2], M. L. BACCEI[3], J. LI[3], M. UENO[1], M. LIANG[1], J. H. MARTIN[2], Y. YOSHIDA[1];

Abstract: During mammalian development including humans, early postnatal animals are only capable of performing motor behaviors that are critical for survival, whereas fine motor skills are acquired later during postnatal developmentrefs. Therefore, reorganization of motor circuits, including corticospinal (CS) circuits, for skilled movements has been postulated to occur during postnatal development in an activity-dependent manner. However, it remains unknown how CS (or any other motor) circuits underlying skilled movements are refined during development to control appropriate patterns of muscle activation, and how neuronal activity controls the CS circuit refinement. Here we explored connectivity between CS neurons and functionally related muscle pairs in juvenile and adult mice by injecting two color variants of retrograde, trans-synaptic pseudorabies viruses (PRVs) to various functionally-related (synergistic or antagonistic) muscle pairs. We find that relatively distinct populations of CS neurons form circuits with antagonistic muscle pairs in juvenile mice, whereas similar populations do in adults, suggesting that antagonistic CS circuits undergo synaptic refinement during development. In contrast, we do not find synaptic refinement of synergistic muscle pairs. The circuit rearrangement of antagonistic muscle pairs does not occur in the absence of the activity-dependent, non-apoptotic Bax/Bak-caspase signaling pathway. Moreover, recording muscle activity in response to cortical stimulation reveals aberrant co-activation of antagonistic muscle pairs in adult Bax/Bak double mutant mice, likely due to defects in synaptic refinement of CS circuits. Finally these mutant mice show deficits in skilled grasping without affecting reaching behaviors. Our findings therefore reveal that acquisition of proper flexor and extensor activation during skilled

movements requires Bax/Bak-mediated synaptic refinement of antagonistic CS circuits during development. Since up to 6% of all children suffer from developmental motor disabilities affecting motor skill movements, these studies provide the potential mechanisms underlying skilled movement disorders related to CS circuits.

Title: Activity-dependent synapse refinement requires the cytoskeleton regulator CRMP

Authors: ***S. CASPER**, T. HERMAN;
Biol., Univ. of Oregon, Eugene, OR

Abstract: Neuronal activity is a critical regulator of synapse specificity during development. We are using *Drosophila* R7 photoreceptor neurons to understand how activity prevents the formation of ectopic synapses. Wild-type R7s in the retina extend axons to a specific layer in the brain and assemble synapses within their terminal boutons. We have found that R7s lacking voltage-gated calcium channels (VGCCs) extend their axons normally and form terminal boutons in the correct layer, but later these boutons sprout thin projections that extend deeper into the brain and contain presynaptic markers. This defect resembles that caused by loss of VGCCs from vertebrate photoreceptors. We found that disrupting the calcium-dependent kinase CaMKII in R7s causes an identical defect, suggesting that prevention of these ectopic projections requires the influx of calcium. Although the projections form around the time that R7s are able to detect light, we found that animals reared in the dark have wild-type R7s, indicating that the VGCCs prevent ectopic projections by opening in response to spontaneous voltage changes and not in response to light. After establishing this model of activity-dependent synapse refinement, we performed an EMS screen to identify the genes that act downstream of VGCCs. Among others, we identified Collapsin Response Mediator Protein (CRMP), a cytosolic phosphoprotein

that has previously been shown to regulate axon growth via its effects on microtubules. *CRMP* mutants are viable and have normal locomotory activity, yet 30% of *CRMP* mutant R7 boutons sprout ectopic projections that phenocopy loss of VGCCs. *CRMP* is well-studied in vertebrates and *C. elegans*, yet nothing is known about its role in presynaptic development. We generated individual *CRMP* mutant R7s and found that they initially assemble synapses in the correct locations and only later extend ectopic projections. The conserved RhoGEF Trio has previously been shown to mediate presynaptic development in both R7s and motor neurons. We have found that loss of *trio* also causes R7 ectopic projections and that *CRMP* is partially rescued by over-expression of Trio, indicating that *CRMP* functions either upstream of or in parallel to the Trio pathway. We are currently testing a model in which CRMP acts downstream of VGCCs and CaMKII to regulate microtubule assembly, thereby localizing Trio and preventing the formation of ectopic projections.

Abstract: The long-term impact of early life anesthesia exposure on neurocognitive function is a potential public health issue. Administration of general anesthetics in the early postnatal period can lead to developmental stage-dependent life-long changes in synapse number in the central nervous system. The present study aimed to test the hypothesis that the effect of general

anesthetics on synaptogenesis depends upon the efficacy of GABAA receptor-mediated inhibition controlled by the developmental up-regulation of the potassium-chloride cotransporter KCC2. *In utero* electroporation of KCC2 or the inward-rectifier potassium channel Kir2.1 in timed-pregnant rats was used to prematurely increase the efficacy of GABAergic inhibition or to reduce neuronal excitability in layer 2/3 pyramidal neurons in the immature rat somatosensory cortex. The effects of these genetic manipulations on propofol anesthesia-induced changes in dendritic spine densities were evaluated using iontophoretic injection of Lucifer Yellow. We found a robust correlation between the developmental up-regulation of KCC2-mediated Cl- extrusion and the age-dependent effects of propofol on dendritic spines of pyramidal neurons. Early overexpression of KCC2 but not of its transport-deficient N-terminal deletion construct, KCC2-ΔNTD, completely prevented propofol-induced dendritic spine loss. Overexpression of Kir2.1, which dampens neuronal excitability, also protected against the impact of propofol on dendritic spines. These data demonstrate that the KCC2-dependent developmental increase in the efficacy of GABAA receptor-mediated inhibition is a major determinant of the age-dependent actions of propofol on dendritic spinogenesis in the developing cerebral cortex.

Title: Astrocyte-derived ATP mediates synapse eliminaton in the thalamus

Authors: ***J. YANG**, H. YANG, D. ZHOU, X. LI, L. QIN, H. LOU, S. DUAN, H. WANG; Dept. of Neurobio., Zhejiang, China

Abstract: The selective elimination of unwanted synapses is a key mechanism for the precise formation of neuronal circuits during development, but the underlying mechanisms remain unclear. Using mice deficient in the inositol 1,4,5-trisphosphate receptor type 2 (Itpr2−/−) to specifically disturb intracellular Ca2+ signaling in astrocytes, we showed that developmental elimination of the ventral posteromedial nucleus (VPm) relay synapse was impaired. Interestingly, intraperitoneal injection of ATP, but not adenosine, rescued the deficit in synapse elimination in Itpr2−/− mice. We next found that ATP activated P2Y1 receptors to mediate long-term depression and thus may serve as a "punishment" signal for synapse elimination. This hypothesis was further supported by the finding that developmental synapse elimination was also impaired in P2ry1−/− mice and was not rescued by ATP. Our results have uncovered a novel mechanism suggesting that astrocytes release ATP in an IP3R2-dependent manner to regulate synapse elimination by activating P2Y1 receptors.

Title: Glial cells control synaptic plasticity of competing nerve terminals and alter synaptic connectivity at mammalian neuromuscular junctions

Authors: *H. DARABID[1,2], R. ROBITAILLE[1,2];
[1]Neurosci., Univ. de Montreal, Montreal, QC, Canada; [2]Groupe de recherche sur le systeme nerveux central, Univ. de Montreal, Montreal, QC, Canada

Abstract: The precise wiring of synaptic connections requires the elimination of supernumerary inputs competing for innervation of the same target cell. At the neuromuscular junction (NMJ), this competition depends on the synaptic efficacy of competing terminals which strengthens one

input whilst others are weakened and eventually eliminated. Little is known about the synaptic activity and plasticity of these competing terminals. Moreover, the role of glial cells during synaptic competition remains ill-defined despite their known importance in the modulation of synaptic efficacy and plasticity at adult NMJs. Therefore, the goal of this work was to study the regulation by perisynaptic Schwann cells (PSCs), the glial cells at NMJs, of synaptic plasticity of nerve terminals during synaptic competition and their influence on synaptic elimination. We performed intracellular recordings from dually innervated P7-8 mouse Soleus muscle fibres to assess synaptic activity and we monitored PSC activity using confocal Ca^{2+} imaging. PSCs were loaded with the Ca^{2+} indicator Fluo-4 by single cell electroporation. We observed a tight relationship between the size of PSC's Ca^{2+} responses and the synaptic strength of each input (i.e. weak input generated smaller Ca^{2+} responses than the strong one). Moreover, at the same NMJ, the strong input showed a long-lasting potentiation of neurotransmission while the weak one displayed only a small transient potentiation. This differential plasticity of competing terminals depends on PSCs Ca^{2+} signalling since inhibiting PSCs Ca^{2+} activity, by photoactivation of Diazo-2 (photoactivable BAPTA loaded into PSCs by single cell electroporation), blocked PSCs Ca^{2+}-responses and resulted in the prevention of synaptic plasticity. The controlled raise of Ca^{2+} in PSCs using the caged-compound NP-EGTA was sufficient to induce synaptic plasticity. Furthermore, bath application of the purinergic P2Y1 receptors antagonist MRS2179 blocked both PSCs Ca^{2+} responses and synaptic plasticity of terminals. This indicates that PSCs detect synaptic transmission of competing terminals trough P2Y1Rs and, in turn, control synaptic plasticity. This plasticity is mediated by adenosine A_2A receptors as revealed by the use of the specific $A2_ARs$ antagonist SCH58261. Finally, chronic *in vivo* blockade of PSCs P2Y1 receptors resulted in an increased proportion of poly-innervated NMJs and delayed synaptic elimination at different post-natal ages. These results suggest that PSCs Ca^{2+} responses are required for synaptic plasticity of competing terminals and may influence the outcome of synaptic competition and connectivity.

Title: NMDA receptor signaling at the neuromuscular junction accelerates developmental synapse elimination

Authors: *K. E. PERSONIUS[1], S. B. UDIN[2];
[1]Rehabil. Sci., [2]Physiol. and Biophysics, Univ. at Buffalo, Buffalo, NY

Abstract: During normal development, motor neurons form superfluous synaptic connections with muscle fibers. After birth, this multiple innervation is pared until each muscle fiber is innervated by a single motor neuron. The elimination of extraneous synapses is controlled by differential activity levels, with the less active input being eliminated. Acetylcholine has previously been thought to be the primary mediator of this activity, but here we show that N-methyl-D-aspartate (NMDA) receptors at the neuromuscular junction are pivotal modulators of synapse elimination. We have previously reported that synapse elimination is slowed by reducing glutamate receptor activation; thus we now tested whether the converse is true - that synapse elimination could be accelerated by increasing glutamate receptor activation. We implanted slices of a slow-release polymer (Elvax) infused with NMDA (0.1 mM) within the leg of P4 mice. The contralateral hindlimb was implanted with saline-infused Elvax to serve as an internal control. At P8, immunostaining revealed a significant increase in the rate of synapse elimination in the NMDA- vs saline-infused muscles. For the extensor digitorum longus (EDL) muscle the percentage of multiply innervated junctions was 37.5 ± 3.9 vs. 47.5 ± 3.4% for NMDA and saline treated legs, respectively ($n = 8$, $p < 0.05$; t-test). The soleus muscle showed a similar result (48.9 ± 4.2 vs. 63.5 ± 2.3% for NMDA and saline treated legs, respectively; $n = 9$, $p < 0.01$; t-test). We used calcium imaging to assess neuromuscular responses to NMDA (0.5 mM) in P4-to-adult mice. Bath application of NMDA resulted in increased neuromuscular calcium signaling in pups up to 3 weeks of age. Calcium signaling was blocked by APV (0.2 mM). Taken together, these results point to a role for NMDA receptor signaling during the activity-dependent phase of developmental synapse elimination at the neuromuscular junction.

Title: Activity-dependent molecular mechanisms underlying synaptic refinement at the *Drosophila* NMJ

Authors: *F. J. VONHOFF[1], H. KESHISHIAN[2];
[1]Molecular, Cellular, and Developmental Biol., [2]MCDB Dept., Yale Univ., New Haven, CT

Abstract: Precise connectivity in neural networks relies on the strengthening of correct synaptic contacts and the removal of off-target synapses. Neural activity plays a crucial role in the refinement of neural circuits in vertebrates and invertebrates. For example, in the vertebrate visual system, low frequency calcium (Ca) and cyclic nucleotide oscillations are involved in the refinement of early projection maps. At the *Drosophila* neuromuscular junction (NMJ) synaptic refinement also occurs in an activity-dependent manner, where oscillatory neural activity and presynaptic Ca signaling modulate the motoneuron's response to the retrograde chemorepellent Sema2a for the removal of off-target contacts in a CaMKII-dependent fashion. We previously showed that mutations in the Ca-dependent adenylyl cyclase rutabaga as well as the cAMP-dependent phosphodiesterase dunce increase the frequency of miswired, ectopic neuromuscular synapses. Targeted RNAi knockdown and rescue experiments indicate a presynaptic role of these two genes, which regulate intracellular cAMP levels. Using the photoactivatable adenylyl cyclase bPAC, we show that presynaptic cAMP levels are required to oscillate within an optimal range. Activation of bPAC in an oscillatory pattern of 15 s light followed by a rest period of 150s darkness suppresses the miswiring phenotype observed in rut1 mutants. No rescue is observed using activation patterns of shorter cycles of 8s light: 80s darkness or longer cycles of 30s light:300s darkness. We tested the role PKA as a downstream target of cAMP. PKAIIR homozygous mutants show an increased frequency of ectopic contacts of 24% as compared to a frequency of 14% observed in controls. A similar miswiring phenotype is observed by the panneuronal expression of PKAIIR-RNAi. We are now testing the role of the protein-phosphatase1 (pp1) family in synaptic refinement, which serves as a molecular link between CaMKII and PKA in mammalian cells. We find that heterozygous double mutants for the pp1-87B and pp1a-96A genes show an increased ectopic frequency of 21.5%. Panneuronal RNAi knockdown of either gene phenocopies the observed effect. In order to monitor Ca activity during synaptic refinement, we used paralyzed embryos expressing the Ca reporter GCaMP5. Low frequency Ca oscillations are evident in native and ectopic contacts during synapse development. We are now using different FRET-based cAMP sensors for live imaging of cyclic nucleotide levels at motoneuron growth cones. Our results show that as in vertebrates, synaptic refinement in *Drosophila* is dependent on dynamic second messenger signaling pathways that engage both Ca and cyclic nucleotide oscillations

Title: Target-dependent retrograde signaling mediates synaptic plasticity at the *Drosophila* neuromuscular junction

Authors: *B. A. BERKE[1,2], H. KESHISHIAN[2];
[1]MCDB Dept., [2]Molecular, Cellular, and Developmental Biol. Dept., Yale Univ., New Haven, CT

Abstract: Neurons often innervate multiple postsynaptic cells with distinct synaptic strengths and expressions of activity-dependent plasticity. How can neural activity strengthen one synapse while leaving the innervation of other cells unaffected? Here we describe differential target-specific synaptic plasticity in *Drosophila* 'common exciter' (CE) motoneurons, which synapse onto multiple larval muscle fibers. By driving transgenes in only one of the CE-innervated muscle fibers, the other target muscles acted as controls to compare responses to elevated CE activity. Control NMJs expanded in the expected activity-dependent fashion (boutons increased in number by 15%, $p<0.005$). However, when the level of functional postsynaptic glutamate receptors (GluR, GluRC and GluRIIA) was reduced by RNAi or a dominant-negative transgene, the manipulated NMJ failed to expand ($p=0.3$), despite showing comparably robust spontaneous activity (8 Hz, $p=0.4$ with respect to control NMJs). This suggests that each muscle fiber can independently influence the growth and plasticity of its NMJ through a putative retrograde signal. A key retrograde transynaptic molecule necessary for growth and plasticity is the Bone Morphogenetic Protein (BMP) Glass bottom boat (Gbb). When Gbb was expressed in a single CE-innervated muscle fiber in a gbb mutant background, synaptic growth was rescued only for that NMJ (boutons reached 94% of WT, compared to 30% in non-rescued muscle fibers). Conversely, RNAi-mediated suppression of Gbb in that same muscle fiber blocked activity-dependent growth plasticity compared to other CE-innervated muscle fibers ($p<0.005$). This is intriguing, as Gbb promotes NMJ growth and plasticity through transcriptional regulation by the downstream SMAD1 transcription factor Mad. Activated Mad (pMad) is, however, found both in motoneuron nuclei and in presynaptic boutons at the NMJ. pMad immuolabeling was reduced at the CE-NMJ of the RNAi treated muscle fiber, yet no apparent change in pMad levels was observed in nuclei. Thus synaptic pMad may have a non-canonical function in tagging the NMJ to permit local growth and plasticity. Preliminary data also indicate that activity-dependent Ca signaling and Ca-dependent regulation of phosphorylation by CaMKII and Calcineurin play a role in this differential plasticity. We are currently examining the link between BMP signaling

and postsynaptic Ca and identifying additional molecules that are differentially expressed between manipulated and control presynaptic terminals.

Title: Quantifying synaptic reorganization in the developing cerebellum using serial section scanning electron microscopy data

Authors: ***A. M. WILSON**, R. SCHALEK, A. SUISSA-PELEG, T. R. JONES, S. KNOWLES-BARLEY, J. W. LICHTMAN;
Harvard Univ., Cambridge, MA

Abstract: Neurons undergo dramatic changes in connectivity during development. In both the peripheral and central nervous system some axons prune branches to innervate fewer postsynaptic target cells and each postsynaptic target cell is innervated by fewer axons. As synaptic connections are removed, surviving inputs are strengthened by additional synapses, resulting in a more focused connectivity with smaller numbers of neurons driving smaller numbers of target cells. This process, called synapse elimination, is thought to be regulated by synaptic activity and therefore experience. This phenomenon has been studied in parts of the peripheral nervous system using optical microscopy, but the small sizes and dense, tenuous arrangements of cells in the central nervous system has prevented identification of the neuronal branches or synapses of single inputs during development. In order to overcome this barrier to exploration of synaptic rewiring in the central nervous system, we have used serial section

scanning electron microscopy to produce 3D volumes of high-resolution images from cerebella of CD1 mice in early postnatal development. Unlike other methods, the resolution of electron microscopy is sufficient to clearly identify all synapses in a tissue sample. We use a recent adaptation of this technique in which a long series of thin sections is cut, collected on tape, and automatically imaged with scanning electron microscopy to generate images of thousands of thin sections with minimal loss and reasonably quickly. We have focused on the developing cerebellum because it undergoes a large scale change in connectivity and is intrinsically simpler than cerebral cortex. We have reconstructed neonatal Purkinje cells and their climbing fiber inputs at several developmental ages. We show that climbing fibers form many synapses onto somatic spines of immature Purkinje cells during the first week of life, and many synapses from parallel fibers and other cerebellar cell types are present at this same time. We also see that climbing fibers innervate immediately adjacent Purkinje cells during development, unlike the more distributed connections in adults. We see that synapses from single climbing fibers occupy territories on Purkinje cells that are largely segregated to different somatic regions by postnatal day 7.

Title: Neuroligin-2 regulates postnatal development of climbing fiber-Purkinje cell synapses in the cerebellum

Authors: ***E. LAI**, N. UESAKA, M. KANO;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Formation of mature functional neural circuits depends on proper elimination of early-formed redundant synapses during postnatal development. It is also known that proper balance of excitation and inhibition is essential for establishing functional neural circuits. Neuroligin 2 (NL2) is an inhibitory synapse-specific cell adhesion molecule that functions in GABAergic synapse formation and stabilization through binding to presynaptic neurexins. Mice lacking NL2

have been reported to exhibit a selective perturbation of inhibitory synaptic transmission, but it remains unclear whether the NL2 deficient mice show any abnormality in developmental refinement of neural circuits. In the present work, we examined the effects of NL2 deletion on synapse elimination of redundant climbing fiber (CF) to Purkinje cell (PC) synapses in developing mouse cerebellum, a representative model of developmental refinement of neural circuits. We found that global NL2 knockout (KO) mice displayed both an increased expression of NL3 and a significantly decreased expression of GABAA receptor α1 subunit in the cerebellum. The amplitude of miniature inhibitory synaptic currents (mIPSCs) in PCs was reduced from P7 to adulthood, but excitatory synaptic transmission was normal. Because of this enhanced excitation/inhibition ratio, dendritic Ca2+ transients elicited by stimulating weaker CFs in individual PCs were significantly larger in NL2 KO than in wild-type mice, whereas dendritic Ca2+ transients by stimulating the strongest CFs were the same between the two genotypes. Importantly, elimination of redundant CF synapses was significantly impaired at P10 and thereafter in NL2 KO mice. In addition, PC-specific knockdown of NL2 by RNA interference significantly impaired CF synapse elimination, which was very similar to the phenotype of NL2 KO mice. These results strongly suggest that NL2 in PCs maintains functional balance between excitatory and inhibitory synapses and that this balance is crucial for properly eliminating redundant CF synapses from P10 and for establishing mature CF innervation of PCs.

Title: Cotinine, the major metabolite of nicotine, alters trafficking and assembly of nicotinic acetylcholine receptors

Authors: *A. M. FOX, F. H. MOONSCHI, C. I. RICHARDS;
Chem., Univ. of Kentucky, Lexington, KY

Abstract: Nicotinic acetylcholine receptors (nAChRs) are pentameric ligand-gated ion channels consisting of a combination of alpha (α2-10) and beta (β2-4) subunits. Regulated subcellular localization and stoichiometry are crucial for correct intracellular processing and function.

Exposure to nicotine alters the trafficking and assembly of nAChRs, resulting in an upregulation of number of receptors on the plasma membrane and a shift in the distribution of stoichiometry to favor the high sensitivity $(\alpha4)_2(\beta2)_3$ version. Although the mechanism of these processes is not fully understood, nicotine-induced upregulation is believed to contribute to nicotine addiction. We have found that cotinine, the primary metabolite of nicotine, also effects nAChR trafficking and assembly, meaning nicotine metabolites may have a previously unacknowledged role in the mechanism of nicotine addiction. We utilize a pH sensitive variant of GFP, super ecliptic pHluorin (SEP), to differentiate between intracellular nAChRs and those expressed on the plasma membrane to quantify changes resulting from cotinine and nicotine exposure. SEP is fluorescent at physiological extracellular pH 7.4, but off at a pH of less than 6. This allows us utilize pH differences in the cell to pinpoint receptor location, number, and resolve single vesicle insertion events at the membrane. Similar to nicotine, exposure to cotinine increases the number of α4β2 receptors on the plasma membrane and causes a redistribution of intracellular receptors. This can be partially attributed to an increase in number of insertion events when exposed to cotinine. In contrast to this, cotinine exposure down regulates α6β2β3. In addition to subcellular location, determining individual receptor stoichiometry is an important aspect in the development of diagnostics and therapeutics for smoking cessation. We used single molecule fluorescence studies to evaluate stoichiometry differences under nicotine or cotinine exposure. In these studies, a GFP that undergoes bleaching when exposed to continuous excitation is encoded in each alpha subunit sequence. Therefore, the number of single molecule bleaching steps detected corresponds to the number of alpha subunits in a nAChR pentamer, and thus the stoichiometry. We found that both nicotine and cotinine alter the assembly of α4β2 receptors to favor the high sensitivity $(\alpha4)_2(\beta2)_3$ stoichiometry. In conclusion, the nicotine metabolite, cotinine, also alters trafficking and assembly of nAChRs. Since cotinine's half-life is approximately ten times longer than nicotine, a potential role in nicotine addiction is feasible but not explored.

Title: Nocturnal frontal lobe epilepsy-associated intracellular-loop mutant subunits alter single-channel properties of alpha4beta2-nicotinic receptor isoforms

Authors: *M. M. WELTZIN, A. A. GEORGE, R. J. LUKAS, P. WHITEAKER;
The Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Nocturnal frontal lobe epilepsy (NFLE) is a group of familial seizure disorders associated with mutations in nicotinic acetylcholine receptor (nAChR) subunits. alpha4beta2-nAChRs are the most prevalent central nervous system subtype. They exist as two isoforms with distinctive subunit stoichiometries and high or low sensitivity to nicotinic agonists [HS (alpha4)2(beta2)3- and LS (alpha4)3(beta2)2-nAChR, respectively]. They are abundantly expressed in the thalamocortical network, an area highly implicated in epilepsy. Two novel NFLE-associated mutations have been identified in the alpha4 and beta2 subunit cytoplasmic loop 2 (C2) domains. The C2 domain is an under-studied region of nAChR subunits, and mutations in this region have previously not been linked to NFLE. We expressed either alpha4beta2-nAChR isoform by injecting Xenopus oocytes at alpha4:beta2 unlinked subunit cRNA ratios of 1:10 or 30:1 (HS or LS receptors, respectively) or as concatenated (linked subunit), pentameric receptors (HSP or LSP). Concatenated subunits ensure pure expression of a single isoform, enabling comparison to results collected using biased ratio injections of unlinked subunit cRNAs. There is close resemblance of receptor isoform properties whether expressed from linked or unlinked subunits. Single-channel patch-clamp recordings were used to define unitary responses to acetylcholine (ACh) at specific concentrations. Parameters examined include unitary amplitude, channel conductance, open and closed dwell times, probability of the channel being open, event lifetimes and events per burst. We found significant parameter differences between alpha4beta2-isoforms and effects of alpha4 or beta2 C2 domain mutant subunit incorporation. We determined that wildtype loose subunit and concatenated LS-isoform receptors have two unitary amplitudes (LSP: 0.98 ± 0.03 and 1.76 ± 0.06 pA), while wildtype HS and HSP receptors have one unitary amplitude (HSP: 1.51 ± 0.04 pA). NFLE C2 domain mutations minimally altered the unitary amplitudes with the exception of the beta2 mutant subunit reducing the HS-isoform amplitude (1.13 ± 0.09 pA). Expression of the beta2 mutant subunit in the LS-isoform significantly increased the open-dwell time of the longest component (wildtype: $\tau 2 = 1.48 \pm 0.13$ vs. beta2 mutant: $\tau 2 = 2.40 \pm 0.10$ ms). Other single channel parameters were also affected by the mutant subunits. These studies indicate the functional consequences of NFLE-associated mutations at the single-channel level that illuminate bases for C2 domain-mediated alterations in receptor function and may help explain how those changes relate to disease pathology.

Title: Characterization of nicotinic acetylcholine receptors formed by gain of function α6 subunit

Authors: ***L. AZAM**[1], J. M. MCINTOSH[2];
[1]Biol., Univ. of Utah, Salt Lake City, UT; [2]Biol. & Psychiatry, Univ. of Utah and George E. Wahlen Veterans Affair Med. Ctr., Salt Lake City, UT

Abstract: α6* nAChRs (* denotes presence of other subunits) have gained recent attention due to their role in dopamine release that is a hallmark of substance use reinforcement and addiction. α6* nAChRs are also preferentially lost in striatal regions of animal models of Parkinson's and in humans with Parkinson's disease. In the dopaminergic system, the α6 subunit combines with the β2 and β3 subunits and in some instances the α4 subunit to form a functional receptor. Unique chaperones may allow in-vivo assembly of α6β2β3* nAChRs. Obtaining adequate expression levels of functional α6β2* nAChRs in heterologous systems such as Xenopus oocytes and transfected cell lines has proven extremely difficult. Progress has been made by using subunit chimeras, point mutants of the α6 or β3 subunit or concatameric subunits. Gain-of-function mutations in the α6 and/ or β3 subunit have also been employed with some success. In this study, we are investigating mutations of residues in the TM2 region of the human and rat α6 subunits. The human α6L9'A subunit forms functional nAChRs in Xenopus oocytes when expressed with the β2 and β3 subunits. A panel of α-conotoxins showed a pharmacology consistent with that obtained when using chimeric α6/α3 subunit. The use of minimally altered but functional α6 subunits may prove useful in efficient expression of heterologously expressed α6* nAChRs and subsequent development of α6β2* drugs.

Title: Modulation of nicotine reward-associated behaviors by mir-542-3p

Authors: *A. CASSERLY, L. LIU, R. ZHAO-SHEA, E. HOGAN, M. SCOFIELD, A. R. TAPPER, P. D. GARDNER;
Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Nicotine binds to and activates a family of ligand-gated ion channels, neuronal nicotinic acetylcholine receptors (nAChRs). Chronic nicotine exposure alters the expression of various nAChR subtypes, which likely contributes to nicotine dependence; however, the underlying mechanisms regulating these changes remain unclear. A growing body of evidence indicates that microRNAs (miRNAs) may be involved in nAChR regulation. Using bioinformatics, miRNA library screening, site-directed mutagenesis and gene expression analysis, we have identified a limited number of miRNAs that functionally interact with the 3′-untranslated regions (3′-UTRs) of mammalian nAChR subunit genes. miRNAs typically regulate gene expression via direct interactions with specific, evolutionarily conserved sites (miRNA recognition elements [MREs]) within the 3′-UTRs of their targets. In silico analysis identified a number of MREs within the 3′-UTRs of the nAChR subunit genes. Mutating these sites disrupted miRNA regulation thereby confirming the in silico predictions. Through this screen we identified the β2 nAChR subunit as a target of miR-542-3p and confirmed that miR-542-3p down-regulates its expression *in vitro* and *in vivo*. We show that miR-542-3p is expressed in the mouse ventral tegmental area (VTA), a component of the mesocorticolimbic reward circuitry. In addition, miR-542-3p expression in the VTA is regulated by chronic nicotine exposure. Finally, overexpression of miR-542-3p in the VTA blocks a conditioned place preference to nicotine. Our results provide evidence for a novel mode of regulation of β2 nAChR subunit expression by

nicotine. Furthermore, our data suggest a key role for miRNAs in the modulation of nicotine-reward associated behaviors.

Title: Differential modulation of α3β4 and α3β4α5 nAChR isoforms by the endogenous neuromodulator lynx1

Authors: ***A. A. GEORGE**, B. EATON, R. J. LUKAS, P. WHITEAKER;
Neurobio., The Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Nicotinic acetylcholine receptors (nAChRs) exist as pentameric complexes of homologous, but genetically-distinct subunits. Recent studies have demonstrated that α3β4* nAChRs (*indicating the presence of additional subunits) mediate mechanisms in the medial habenula (MHb) circuitry that regulate negative reward processing. The α5 nAChR subunit can integrate into these complexes, and the α5 subunit D398N variant has been implicated in increased susceptibility to nicotine dependence, perhaps by lowering nicotine aversion. Endogenous neuropeptides, such as lynx1, can influence subunit stoichiometry, cell-surface expression and function of α4β2-containing nAChRs. However, the functional consequences of lynx1 interaction with α3β4* or α3β4α5* nAChRs are poorly understood. In the current study, we used a concatenated (i.e. linked) subunit approach to ensure consistent subunit incorporation while probing the functional modulation of α3β4* and α3β4α5* nAChRs by lynx1. Using two-electrode voltage clamp (TEVC) electrophysiology, we demonstrate that lynx1 attenuates macroscopic receptor peak currents for (α3β4)2α3, (α3β4)2β4, (α3β4)2α5[D398] and (α3β4)2α5[N398] subtypes when expressed in Xenopus oocytes. Radio-immmunolabeling reveals that lynx1 also significantly reduces cell surface levels of (α3β4)2β4, (α3β4)2α5[D398]

and (α3β4)2α5[N398] nAChR cell-surface expression but not of (α3β4)2α3 nAChRs. Single-channel recordings confirm preferential functional effects of lynx1 on (α3β4)2α3-containing nAChRs, reducing single-channel conductance and burst percentage. Significant temporal shifts in single-channel closed dwell-times were also observed for (α3β4)2α3 nAChRs, indicating the ability of lynx1 to enhance (α3β4)2α3 single-channel desensitization. No statistically-significant changes in single-channel parameters were observed for any other α3β4* or α3β4α5* nAChR isoform. Given the established role of α3β4* and α3β4α5* nAChR function in the habenulo-peduncular pathway, it seems likely that selective modulation of α3β4* nAChRs by lynx1 could represent a valuable strategy in modulating neuronal activity in brain areas involved in reward processing. This work was supported the Arizona Biomedical Research Commission's Early Investigator Award (A.A.G) and by NIH grants R21 DA027070 and R21 DA036059S (to P.W).

Title: Functional impact of 13 single nucleotide polymorphisms causing missense mutations of human α7 nicotinic receptor

Authors: *Y. CHANG[1], Q. ZHANG[2], Y. DU[3], Y. HUANG[4], R. J. LUKAS[1];
[1]Barrow Neurolog. Inst., St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ; [2]Neurobio., St. Joseph's Hosp. & Med. Center/Sichuan Univ., Phoenix, AZ; [3]Univ. of California at Los Angeles, Los Angeles, CA; [4]St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ

Abstract: The α7 nicotinic receptor (nAChR) is a major subtype of the nAChRs in the central nervous system, and the receptor plays an important role in brain function. In the dbSNP database, there are 55 single nucleotide polymorphisms (SNPs) that cause missense mutations of the human α7nAChR in the coding region. In this study, we tested the impact of 13 SNPs that cause missense mutations in the agonist binding site or the coupling region between binding site and channel gate on the receptor function. The wild type or mutant receptors were expressed or co-expressed in *Xenopus* oocytes, and the agonist-induced currents were tested using two-electrode voltage clamp. Our results demonstrated that 6 mutants were nonfunctional, 5 mutants

had reduced current expression, and some of them had slightly reduced agonist sensitivity. Interestingly, the function of 4 out of 6 nonfunctional mutants could be rescued by α7nAChR positive allosteric modulator PNU-120596. Finally, when coexpressed with the wild type, the nonfunctional mutants could also influence the receptor function. These changes of the receptor properties by the mutations could potentially have impact on physiological function of the α7nAChR-mediated cholinergic synaptic transmission and anti-inflammatory effects in the human SNP carriers. Rescuing the nonfunctional mutants could provide a novel way to treat the related disorders.

Title: The prototoxin LYPD6B modulates heteromeric alpha3 beta4 containing nicotinic acetylcholine receptors (nAChRs) but not alpha7 homomers

Authors: *V. OCHOA[1], P. WHITEAKER[2], A. A. GEORGE[2], R. NISHI[1];
[1]Univ. Vermont, Burlington, VT; [2]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Prototoxins are a diverse family of membrane-tethered molecules expressed in the nervous system. Several prototoxins modulate nicotinic signaling, but the functional significance of this is not clear. We identified a new prototoxin, LYPD6B, and tested its selectivity and efficacy on α3(α5)β4 versus α7-containing nicotinic acetylcholine receptors (nAChRs). To constrain stoichiometry, fusion proteins encoding human α3, β4, and α5 (D and N variants) heteromers were expressed in Xenopus oocytes with LYPD6B. Controls lacked LYPD6B. We used two-electrode voltage-clamp to quantify responses to ACh: sensitivity (EC50), maximum current induced (Imax), and rate of desensitization (τ). LYPD6B acts selectively on (α3)3(β4)2 and (α3)2(α5D)(β4)2 leaving unaffected (α3)2(β4)3, α7 and (α3)2(α5N)(β4)2 nAChRs. For β4α3α3β4α3 and β4α3β4α3α3, LYPD6B decreases EC50 from >631 μM to approximately 100 μM, reduces Imax significantly by at least 59%, and decreases τ. For β4α3α5Dβ4α3 and β4α3β4α3α5D, LYPD6B decreases Imax by 63% and 32% respectively. For β4α3α5Dβ4α3 and β4α3β4α3α5D, LYPD6B decreases Imax by 63% and 32% respectively. Thus, LYPD6B is a

positive modulator of (α3)3(β4)2 at low [ACh] but a negative modulator at high [ACh]. LYPD6B also negatively modulates α3β4 nAChRs that include the α5 D variant, but not the N variant associated with smoking dependence.

Title: Chimeras of first transmembrane domain identify important residues for expressing extracellular domain α4β2 nicotinic acetylcholine receptors

Authors: *G. B. WELLS, A. M. GALVAN, A. M. PERSON;
Mol. & Cell. Med., Texas A&M Univ. Hlth. Sci. Ctr., College Station, TX

Abstract: Background: Extracellular domain receptors formed from truncated Cys-loop subunits are potentially valuable for structural and functional studies. Their smaller size and reduced transmembrane content focuses investigations on properties of ligand-binding extracellular domain and might lead to higher resolution X-ray crystallographic structures than can be achieved with full length receptors. Uncertainty persists about how the first transmembrane domain (M1) and specific residues in M1 contribute to expressing extracellular domain Cys-loop receptors. What is the best sequence for M1 for expressing a given extracellular domain Cys-loop receptor? **Objective**: To help answer this question, the goal was to identify important residues in M1 through chimeric constructs of M1 from α7 nicotinic acetylcholine receptor (nAChR) and serotonin 5-HT3A receptor (5-HT3AR) subunits. These chimeras were designed in the background of extracellular domain α4M1/β2M1 nAChRs. **Methods**: Human α4 and β2 cDNAs were truncated after M1 (α4M1 and β2M1). M1 sequences from chicken α7 nAChR and mouse 5-HT3AR subunits were swapped into α4M1 and β2M1. Roles of specific residues in M1 were probed by changing residues from the α7 nAChR subunit into residues from the 5-HT3AR subunit based on side chain properties and conservation that was evident through multiple sequence comparisons. Subunits were expressed as cRNA in *Xenopus laevis* oocytes. Immunoblotting and yield of [^{3}H]epibatidine binding sites assessed effects of the changes. **Results**: The α7 chimera of α4M1/β2M1 according to [^{3}H]epibatidine binding showed high structural fidelity to extracellular domain α4M1/β2M1 and full length α4β2 nAChRs. The α7 chimera had significantly higher expression than the 5-HT3AR chimera.

Swapping at positions in M1 with different hydrophobic side chains, which were expected to be freely interchangeable, instead decreased expression of [^{3}H]epibatidine binding sites. Swapping at positions of M1 with side chains of different polarity, ionization properties, chemical reactivity, or bulk decreased expression of [^{3}H]epibatidine binding sites. Swapping residues along nearly the entire M1 affected expression of [^{3}H]epibatidine binding sites. **Conclusions:** M1 functions as more than a nonspecific, transmembrane tether for the extracellular domains of α4M1/β2M1 nAChRs. These results suggest that specific residues of M1 might have specific structural and functional roles for extracellular domain Cys-loop receptors. These results help refine the concept of an optimally designed M1 sequence for expressing a given extracellular domain Cys-loop receptor.

Title: Differential effects of varenicline and nicotine on endogenous α3β4* nicotinic acetylcholine receptors in human adrenal chromaffin cells

Authors: *A. ALBILLOS[1], L. RUEDA-RUZAFA[1], J. M. MCINTOSH[2], J. PASSAS[3], C. DE CASTRO-GUERIN[4], J. BLAZQUEZ[5], C. GONZALEZ-ENGUITA[6], A. J. HONE[1]; [1]DEPARTAMENTO DE FARMACOLOGÍA (L6), UNIVERSIDAD AUTONOMA DE MADRID, MADRID, Spain; [2]UNIVERSITY OF UTAH, SALT LAKE CITY, UT; [3]HOSPITAL DOCE DE OCTUBRE, MADRID, Spain; [4]HOSPITAL LA PAZ, MADRID, Spain; [5]HOSPITAL CLINICO SAN CARLOS, MADRID, Spain; [6]FUNDACION JIMENEZ DIAZ, MADRID, Spain

Abstract: Nicotine and varenicline are known to activate heterologously expressed human α3β4 nicotinic acetylcholine receptors (nAChRs) but very little information is available concerning their activities on endogenously expressed receptors in native human cells. We used patch-clamp electrophysiology to assess the activities of nicotine and varenicline on α3β4 nAChRs expressed in human adrenal chromaffin cells. Under voltage-clamp conditions both nicotine and varenicline evoked whole-cell currents in these cells but varenicline was more potent than either nicotine or acetylcholine (ACh). In current-clamp mode, continuous perfusion of EC_{50} concentrations of nicotine (20 μM) and varenicline (4 μM) initially increased the number of ACh-evoked action potentials (APs) and were capable of evoking APs in the absence of ACh stimulation. Perfusion of varenicline (50-100 nM) at concentrations achieved in humans robustly increased the number of ACh-evoked APs whereas nicotine (50-250 nM) did not. Higher concentrations of varenicline (250-500 nM) further increased the number of ACh-evoked APs whereas nicotine (500 nM) inhibited them. Our results suggest that nicotine and varenicline may both activate and desensitize human adrenal chromaffin cell α3β4 nAChRs which may alter the release of catecholamines from adrenal chromaffin cells. These results provide valuable information concerning the pharmacology of endogenously expressed human adrenal chromaffin cell α3β4 nAChRs and may help guide the development of therapeutic compounds used in the treatment of nicotine addiction.

Title: Exploiting ligand selectivity to understand allosteric receptor opening upon agonist binding

Authors: *D. INDURTHI, T. BALLE, P. AHRING, M. CHEBIB, N. ABSALOM;
Univ. of Sydney, Camperdown, Australia

Abstract: Introduction: Nicotinic acetylcholine receptors (nAChR) are cation ion channels and are implicated in several mental illnesses. α4β2 nAChR exists in two stoichiometries, (α4)2(β2)3 and (α4)3(β2)2, with distinct pharmacological properties, due to the presence of additional agonist binding site at α4-α4 interface on (α4)3(β2)2 receptor. Although very little is known, determining molecular mechanism of receptor opening is important for understanding receptor functioning. Methodology: Using two-electrode voltage clamp technique we measured responses of sazatidine-A and TC-2559 on both wild-type and mutant α4β2 nAChRs, to test ligand selectivity for different binding interface. Kinetic modelling was used to determine mechanism of receptor opening.<br Result and discussion: Sazatidine-A and TC-2559 acted as partial agonists on (α4)3(β2)2 but as full agonists on (α4)2(β2)3 wild-type receptors. When tested on (α43m)3(β2)2 mutant receptor that is engineered to only have the α4-β2 agonist binding site, both compounds act as full agonists, suggesting their interaction at α4-β2 interface on α4β2. However, no activity was observed on (α4)3(β23m)2 mutant receptor that is engineered to have only α4-α4 binding interface, therefore demonstrating ligand selectivity for α4-β2 and not at α4-α4 binding interface. When these compounds were co-applied with NS9283 that binds only at the α4-α4 binding interface, full activation was observed on wild-type (α4)3(β2)2 receptors. This activation profiles were used to propose a kinetic model that best represents an activation model for heteromeric nAChRs.

Title: Critical determinants of alpha7 nAChR allosteric activation and modulation: pharmacological agents and structural epitopes that separate those activities

Authors: *G. A. THAKUR[1], R. PAPKE[2], A. KULKARNI[1], N. HORENSTEIN[3]; [1]Dept. of Pharmaceut. Sci., Northeastern Univ., Boston, MA; [2]Dept. of Pharmacol. and Therapeut., [3]Dept. of Chem., Univ. of Florida, Gainesville, FL

Abstract: Critical determinants of α7 nAChR allosteric activation and modulation: pharmacological agents and structural epitopes that separate those activities. The α7 nicotinic acetylcholine receptor is of current interest as a drug target for indications ranging from

cognitive disorders to inflammation. Under normal conditions, α7 nicotinic acetylcholine receptor (nAChR) ion channels activate less readily than do those of other nAChR subtypes. However, the unique properties of α7 receptors render them sensitive to selective positive allosteric modulators (PAMs), which increase the efficiency of channel activation to a level greater than that of other nAChR. By definition, PAMs must work in concert with "orthosteric" agonists such as ACh, while compounds such as GAT107, the active isomer of 4BP-TQS, have the combined properties of agonists and PAMs, able to function as single agents to produce very effective channel activation (ago-PAMs). Ago-PAMs activate α7 nAChR ion channels far more effectively than ACh, or other orthosteric agonists working at the same binding site as ACh, in the absence of a PAM. The direct activation of receptors by ago-PAMs arises from the effects of these agents at two different sites. One site, likely to be within the receptor's transmembrane domains, is likely to be the same as where PAMs like PNU-120596 function to promote the enhanced activation by orthosteric agonists, destabilizing nonconducting states associated with orthosteric desensitization by reducing the barrier for transition into a novel conductive state. The other site, likely to be solvent accessible in the extracellular domains, is a unique site for allosteric activation (AA) of PAM-potentiated receptors. One phenomenological distinction we observe for the two sites is that more rapid washout and exchange with solution tends to be observed for the AA site. Low GAT107 concentrations, are relatively ineffective at the PAM site, however, activity at the AA site can be increased by PNU-120596 binding to the PAM site. We identify key attributes of GAT107 required for activity at the AA site through the characterization of two different classes of competitive antagonists of AA that do not inhibit PAM activity. We have also identified several mutations in α7 which disable activation by orthosteric agonists These mutants remain sensitive to allosteric activation by GAT107 and that activity is also blocked by the same antagonists which block the allosteric activation of wild-type α7. Analysis of key molecular features of effective allosteric agonists and antagonists allows us to propose a model for recognition features within the AA site and identify putative binding sites.

Title: Modulation of the alpha 7 nicotinic acetylcholine receptor by ibuprofen

Authors: *J. C. RODRIGUEZ, J. O. COLON-SAEZ, J. A. LASALDE DOMINICCI;
Biol., Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstract: Members of the nicotinic acetylcholine receptor family (nAChR) like the α7 nAChR have been linked to the inflammatory process making it a possible target for anti-inflammatory treatments. Recent studies have shown that inflammation is related to the development of various diseases like cancer, diabetes, asthma and Alzheimer's disease. Ibuprofen is a nonsteroidal anti-inflammatory drug (NSAID) commonly used to treat inflammation, fever and pain. The objective of these experiments was to determine whether ibuprofen can modulate the activity of the α7 nAChR. This was achieved by using Xenopus oocytes injected with mRNA coding for the α7 nAChR. The oocytes were incubated for a 48 hours period to allow for channel expression. The functionality and the amplitude of the response of the α7 nAChR was determined using the two electrode voltage clamp technique on Xenopus oocytes. The amplitude of the responses was determined in the presence and absence of ibuprofen. In the presence of ibuprofen, the amplitude of the α7 nAChR's response was significantly reduced. This suggests a possible role for ibuprofen in the modulation of the α7 nAChR function. Further studies will be directed at determining ibuprofen's mechanism of action and whether other members of the nAChRs family are also modulated by it. Also, we will determine if other common drugs used to treat inflammation and pain, like acetaminophen and naproxen, are also able to modulate the function of neuronal nAChRs.

Title: Nicotinic acetylcholine receptor subtypes expressed in the rodent habenula

Authors: *R. VENKATESH, R. P. YASUDA, T. H. GUPTA-GOLDENBERG, B. B. WOLFE, K. J. KELLAR;
Dept. of Pharmacol. and Physiol., Georgetown Univ., Washington, DC

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) play a critical role in nicotine addiction. In mammalian nervous systems, heteromeric nAChRs are composed of combinations of 8 alpha and 3 beta subunits. These combinations constitute receptor subtypes, each of which has distinct biophysical and pharmacological properties. nAChRs are highly expressed in the habenula, and are of particular interest because the subtypes expressed there may be associated with sensitivity/tolerance to nicotine in animals allowed to freely self-administer the drug (Fowler et al., Nature, 2011,) and with symptoms of withdrawal in animals treated chronically with nicotine (Salas et al., J Neurosci, 2009.) Although the rat habenula expresses several nAChR subunits (Grady et al., J Neurosci, 2009; Scholze, J Neurochem, 2012,) the receptor subtypes they form are not entirely clear. In this study, we used immunoprecipitation and radioligand binding methods to investigate the nAChR subtypes expressed in the rat habenula. In particular, we used sequential immunoprecipitation assays to determine the extent to which two subunits are associated. Our data indicate that both β2 and β4 subunits are highly expressed in the habenula (at about 50% and 60%, respectively) and that they are associated with each other in about 20% of receptors. Additionally, both the β2 and β4 subunits are associated with α3, α4, and α5 subunits. Our study also indicated a significant population of α3α5β2β4* receptors; however, in contrast to several other brain regions, we found no associations between the α4 and α5 subunits in the rat habenula. [3H]-Epibatidine saturation binding in habenular tissue fit a single site with a Kd of 78 pM, but competition binding assays with nicotine in habenular tissue fit a two-site model. The nAChR subtypes in the habenula are likely to be important. In agreement with Grady et al. (2009), our studies show that the habenula is rich in “uncommon” nAChR subtypes; consistent with this, immunoprecipitation and competition binding studies indicate a diverse population of receptors. These data may help identify the habenula nAChRs involved in nicotine addiction and withdrawal, which may aid in the development of more effective smoking cessation drugs.

Title: The role of calcium and calcium-sensitive signaling pathways in nicotine-induced upregulation of alpha 7 receptors expressed in xenopus oocytes

Authors: *K. DEBOEUF[1], M. ISLAM[2], J. PANCHAL[3], J. ROSE[4], J. FARLEY[2]; [1]Psychology, [2]Neurosci., [3]Biol., Indiana Univ., Bloomington, IN; [4]Ctr. for Smoking Cessation, Duke Univ. Med. Ctr., Durham, NC

Abstract: The α7 neuronal nicotinic-acetylcholine receptors (α7 nAChRs) play important roles in learning, memory, nicotine-addiction/withdrawal, and many other neurological conditions. Nicotine-produced upregulation of α7 Rs is believed to be involved innicotine-addiction and relapse, but reliable upregulation of α7 and its underlying mechanism(s) are poorly characterized. In our recent studies of α7 Rs heterologously expressed in Xenopus oocytes (see accompanying abstract), we have described the procedural determinants that lead to reliable, 2-fold increases of α7 currents by 12-14 hrs of exposure to 100 μM nicotine followed by extensive washout. Because of the large Ca2+ conductance of α7 Rs, intra- and/or extracellular Ca2+ and Ca2+ -sensitive signaling pathways might play a critical role in such upregulation. In our studies, nicotine-upregulation of α7 Rs was unaffected by elimination of extracellular Ca2+ (zero Ca2+ plus EGTA). However, intracellular Ca2+ chelation (by BAPTA-AM) completely blocked nicotine-upregulation, without affecting basal α7 current expression, or de novo expression of Kv1.1 channels. Several Ca2+ -dependent signaling pathways were critical for nicotine-upregulation: PP2B/calcineurin (inhibited by cyclosporin A), Ser/Thr protein kinase-activity (inhibited by H7), and possibly PKC isozymes (activated by PMA). 12-14 hr incubation with 10 μM CsA + 100 μM nicotine, yielded a mean current of 756.46 ± 137.66 nA (n=15), which was significantly greater ($p < 0.05$) than control currents of 307.65 ± 59.40 nA (n=15), but clearly sub-additive for the CsA alone controls (512.04 ± 142.0 nA, n=20) and nicotine alone oocytes (501.43 ± 99.04 nA, n=23). Similarly, a combination of H7 +nicotine produced significant ($p < .05$) upregulation (511.09 ± 91.14 nA, n=16), that did not exceed that produced by 25 μM H7 alone (560.79 ± 121.17 nA, n=15), nor that produced by nicotine alone. Thus, both CsA and H7 largely occluded nicotine-upregulation of α7.12-14 hr exposure to 100 nM PMA + 100 μM nicotine strongly suppressed α7 currents [24.94 ± 5.54 nA (n=5)], vs same-batch controls and nicotine alone oocytes (679.28 ± 99.05 nA, n=10), suggesting that PKC-inhibition by nicotine might be involved in upregulation. However, PMA's strong suppression of α7 currents precluded a clear interpretation of PKC's involvement. In contrast, although protein tyrosine kinase (PTK) activity (inhibited by genistein) had large effects on basal α7 currents (via both PAM- and non-PAM effects), PTKs did not seem to participate in nicotine-upregulation. Our results suggest that Ca2+-dependent inhibition of PP2B and one or more Ser/Thr kinases underlies nicotine-upregulation.

Title: 3-(2-chlorophenyl)-5-(5-methyl-1-(piperidin-4-yl)-1H-pyrrazol-4-yl)isoxazole is a selective positive allosteric modulator of low-sensitivity (α4)3(β2)2 nicotinic acetylcholine receptor

Authors: *A. K. HAMOUDA[1,2], Z.-J. WANG[1], T. S. MOHAMED[1], A. B. ALASKARI[1]; [1]Pharmaceut. Sci., Texas A&M Hlth. Sci. Ctr., Kingsville, TX; [2]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Positive allosteric modulators (PAM) of nicotinic acetylcholine receptors (nAChR) are a class of drugs that allow selective modulation of a subpopulation of brain nAChRs. However, structural information necessary for the design of nAChR subtype-selective PAMs is lacking and studies are needed to identify binding sites for nAChR PAMs and to define the molecular determinants of PAMs nAChR-subtype selectivity. To this end, we use site-directed mutagenesis coupled with *in-vitro* electrophysiological recording to identify binding site(s) for a novel α4β2 nAChR PAM, 3-(2-chlorophenyl)-5-(5-methyl-1-(piperidin-4-yl)-1H-pyrrazol-4-yl)isoxazole (CMPI); Albrecht et al. 2008, Biorg. Med. Chem. Lett. 18: 5209). Recording from *Xenopus* oocytes injected with low-sensitivity $(\alpha4)_3(\beta2)_2$ or high-sensitivity $(\alpha4)_2(\beta2)_3$ nAChRs, we found that CMPI selectively potentiates ACh-induced current of $(\alpha4)_3(\beta2)_2$ but not $(\alpha4)_2(\beta2)_3$ nAChR. For $(\alpha4)_3(\beta2)_2$ nAChR, CMPI produced a left-shift of ACh dose-response curve without altering ACh efficacy. At 10 μM ACh, CMPI potentiated the response of $(\alpha4)_3(\beta2)_2$ maximally by ~400% with an EC50 of ~1 μM. For $(\alpha4)_2(\beta2)_3$ nAChRs, CMPI produced a dose-dependent inhibition of ACh response with a maximal inhibition of 30% at 10 μM CPMI. Mutational analyses of amino acids contributing to the α4:α4 interface, which is present in the $(\alpha4)_3(\beta2)_2$ but not the $(\alpha4)_2(\beta2)_3$ nAChR, identified amino acids necessary for CMPI potentiation that are distinct from those identified as determinants of potentiation by NS9283, another $(\alpha4)_3(\beta2)_2$ nAChR selective PAM (Olsen et al 2013, *JBC 288*: 35977). CPMI potentiation was not affected by α4H114V substitution (α4H142V when numbering with signal peptide included) that reduced potentiation by NS9283. On the other hand, substitutions at α4K62 and α4E64 abolished potentiation by CMPI without affecting NS9283 potentiation. Further mutational analyses are ongoing to refine the definition of the location of PAM binding site(s) at the α4:α4 interface.

Title: Expression and purification of the intracellular domain of an anionic pentameric ligand-gated ion channel

Authors: A. PANDHARE, *M. JANSEN;
Cell Physiol. Mol. Biophys., TTUHSC, Lubbock, TX

Abstract: Anionic pentameric ligand-gated ion channels (pLGIC) of the Cys-loop superfamily are receptors for neurotransmitters such as gamma-aminobutyric acid (GABA) and glycine. These receptors are the targets for a number of currently used clinical drugs including general anesthetics, anti-epileptics (anti-convulsants), sedatives, anxiolytics, and muscle relaxants. Towards developing new improved drugs as well as improving current treatments, it is imperative to determine how each of these pLGICs functions, more specifically, to identify and characterize the different structural elements that mediate each aspect of receptor function. All Cys-loop receptor subunits in metazoans contain three domains: an extracellular domain (ECD), a transmembrane domain (TMD), and an intracellular domain (ICD). The functional roles of ECD and TMD have been extensively studied and their three-dimensional structures have been determined. The identification of prokaryotic pLGICs, e.g. *Gloeobacter violaceus* ligand-gated ion channel (GLIC), lead to structural information at atomic resolution. However, the prokaryotic members lack the ICD. Interestingly, the ICD of Cys-loop receptors from the animal kingdom is the most diverse domain with respect to both length and amino-acid composition. The ICD, therefore, represents an attractive target for developing subtype-selective drugs with the promise of fewer side effects than current drugs, which all target the highly-conserved extracellular or transmembrane domains. Therefore, the main goal of our project was to develop a large-scale protein expression and purification strategy to produce the ICD of an anionic pLGIC. To this end, we have generated chimeras by inserting the ICD of the $GABA_A\rho1$ receptor into proteins of known X-ray structures. We have optimized conditions for expression in *E. coli* culture, as well as purification to homogeneity, yielding 10-15 mg of purified protein per L

culture. Thus, our results are consistent with the successful large-scale expression and purification of the $GABA_A\rho$1-ICD chimera which is now amenable to structural studies.

Title: Species difference pharmacology of native α3β4* nicotinic acetylcholine receptors in rat, cow, and human adrenal chromaffin cells

Authors: *L. RUEDA[1], A. J.HONE[2], J. MCINTOSH[3], J. PASSAS[4], A. ALBILLOS[2];
[1]Univ. Autónoma De Madrid, Madrid, Spain; [2]Univ. Autónoma de Madrid, Madrid, Spain; [3]Univ. of Utah, Salt Lake, UT; [4]Hosp. 12 de Octubre, Madrid, Spain

Abstract: Adrenal chromaffin cells from rat and cow have previously been reported to express α3β4 nicotinic acetylcholine receptors (nAChRs) yet debate surrounds the functional expression of β2-containing nAChRs in these cells. Here we present pharmacological evidence demonstrating that adrenal chromaffin cells from these two species express few functional nAChR that contain β2 ligand-binding sites and that the predominant subtype expressed is α3β4. Patch-clamp electrophysiology was used to evaluate the activites of several subtype-selective α-conotoxins (α-Ctxs) on the ACh-evoked currents. The α3β4 and α6β4 selective α-Ctx TxID completely blocked ACh-evoked currents in both rat and cow cells indicating that the nAChRs mediating these currents contain the β4 subunit. Furthermore, the ACh-evoked currents were insensitive to α-Ctxs selective for either α6- or β2-containing nAChRs suggesting that there were few receptors present with these subunits. Together, these results demonstrate that the predominant nAChR expressed in these cells is the α3β4 subtype. Subsequent experiments were performed using rat, cow, and human cells to evaluate the potencies and efficacies of several nAChR agonists. Potencies for ACh, nicotine, varenicline, cytisine, and dimethyl-piperazinium were all similar among the three species however agonist efficacies were strikingly different.

Cytisine was a low efficacy agonist in bovine cells but a full agonist in rat and human. Varenicline behaved as a full agonist in human cells but a partial agonist in rat and cow cells. Finally, nicotine was a full agonist in cow cells but a partial agonist in human and rat cells. These studies highlight the importance of species difference considerations when evaluating the activities of both agonists and antagonists of α3β4 nAChRs.

Title: The β2/β2 interface of the (α4β2)2β2 nicotinic acetylcholine receptor does not bind competitive ligands

Authors: K. NEW, *I. BERMUDEZ, S. MAZZAFERRO;
Oxford Brookes Univ., Oxford OX3 0BP, United Kingdom

Abstract: Nicotinic acetylcholine receptors (nAChRs) containing α4 and β2 subunits (α4β2 nAChRs) are the most abundant heteromeric nAChRs in the brain. These are of particular interest due to converging evidence indicating that α4β2 nAChRs are a key mediator of the reinforcing effects of nicotine. α4β2 nAChRs have also been implicated in a wide range of brain functions, including cognition, mood and nociception. α4 and β2 nAChR subunits assemble into alternate stoichiometries (α4β2)2α4 and (α4β2)2β2 that display remarkable differing sensitivity to activation by agonists and allosteric modulators. Recently, it has been shown that an additional operational agonist site is present in the α4/α4 interface of the (α4β2)2α4 nAChR, and this site accounts for the ligand-selectivity and desensitisation pattern of this receptor stoichiometry. To probe whether a competitive ligand binding site is present in the β2/β2 subunit interface of the (α4β2)2β2 nAChR, we have alanine substituted conserved aromatic residues that contribute to competitive ligand binding in canonical agonist binding sites in nAChRs. To avoid uncertainties in data interpretation due to potential assembly and expression of multiple receptor forms, we carried out these studies on fully linked (α4β2)2β2 nAChRs. We find that mutations expected to impair competitive ligand binding in canonical agonist sites have no impact on receptor function.

We conclude from these findings that competitive ligands do not bind the β2/β2 interface, in contrast to what has been demonstrated for the α4/α4 interface in the (α4β2)2α4 nAChR.

Title: ACR-16 nAChRs are actively transported to synapses by a CDC-42 dependent pathway

Authors: *A. J. KALLARACKAL, J. MELLEM, D. MADSEN, A. MARICQ;
Dept Biol., Univ. of Utah, Salt Lake City, UT

Abstract: The delivery of nicotinic acetylcholine receptors (nAChRs) to synapses is essential for the proper formation, maintenance, and plasticity of cholinergic neural circuits. Using an *in vivo* approach in the model organism *C. elegans*, our lab has previous shown that α7-type nAChRs are dependent on a non-canonical Wnt signaling pathway for translocation to the cell surface from subsynaptic stores. This pathway is specific to ACR-16/ α7 nAChRs in that mutations in Wnt signaling components result in decreased nicotine-gated current and subsynaptic accumulations of ACR-16::GFP but do not affect neighboring levamisole-gated AChRs or GABA receptors. Little is known however, about how receptors are transported to these subsynaptic stores following synthesis. We now have evidence that actin polymerization is necessary for the trafficking of ACR-16/ α7 nAChRs to muscle arms. Using real-time *in vivo* imaging and fluorescence recovery after photobleaching (FRAP) experiments, we can dissociate between receptors that move to synapses through passive diffusion versus those that are transported actively in an ATP-dependent manner. We find that this process is dependent on a myosin 1D motor and is regulated by the Rho GTPase CDC-42. This work outlines a pathway for efficient delivery of nAChRs to synapses that may be regulated by activity and disrupted in diseases that affect cholinergic signaling.

Title: Nicotine induced upregulation of alpha 7 nicotinic acetylcholine receptor expressed in xenopus oocytes: key factors and determinants of upregulation

Authors: *M. ISLAM[1], K. DEBOEUF[1], P. B. SCHWARTZ[2], T. MURUGESAN[3], J. ROSE[3], J. FARLEY[1];
[1]Neurosci., [2]Sch. of Med., Indiana Univ. Bloomington, Bloomington, IN; [3]Ctr. for Smoking Cessation, Duke Univ. Med. Ctr., Durham, NC

Abstract: Alpha 7 (α7 Rs), a major subtype of nAChRs appear to play critical roles in learning, memory, and various neuropathologies including nicotine addiction. Nicotine-upregulation of α7 Rs is thought to play significant roles in these phenomena. But whether nicotine-upregulation of α7 Rs reliably occurs, and the nature of its underlying mechanism(s), are largely unknown. Previous *in vitro* studies of α7 nAChRs heterologously expressed in Xenopus oocytes failed to observe nicotine-upregulation. These failures might have been due to incomplete removal of nicotine from the recording media, as a result of its intracellular accumulation and subsequent slow release from the oocytes, resulting in desensitization of α7 Rs during functional assays. In our experiments, 12-14 hr exposure to nicotine (100 μM) 4-5 days post cRNA-injection (PI), followed by extensive washout yielded statistically-significant ~2-fold increases in α7 currents [614.25 ± 53.44 (mean ± SEM) nA, n=95; $t(200) = 5.97$, $p < 0.001$] as compared to controls (294.36 ± 19.6 nA, n= 107), as determined by TEVC and α7-protein (by Western blot). Net charge was also ~ 2X bigger in nicotine-treated cells vs. controls, but the kinetic indices (net charge/peak) were similar. Less-extensive washout, as well as 100 nM nicotine incubation, failed to produce upregulation. Instead, inactivated/desensitized currents were observed. Direct GC/MS measurement of nicotine in the washout fluid confirmed that nicotine was continually released from oocytes and the concentration was ~20 nM at 3-4 hr following onset of washout, well in excess of the ~ 3nM IC50 value. Exposure of α7 oocytes to cumulative washout fluid produced suppressed α7 currents (23.59 ± 10.35 nA, n=9) as compared to controls (295.58 ± 25.53 nA, n=14). Nicotine-upregulation did not depend on new protein synthesis, as cycloheximide (1 μM) affected neither the maintained expression of 4-5th day α7 currents nor nicotine- upregulation. On the 5th day PI, the magnitude of the nicotine-upregulated currents was correlated with the level of basal expression of α7 Rs, but the extent of upregulation was remarkably consistent: ~2X. However, early in the course of expression (2-3 days PI cRNA), 100 μM nicotine failed to produce upregulation. Similar to nicotine, methyllycaconitine, a cell-permeable competitive

antagonist of α7 Rs, and carbachol, a stable membrane-impermeable agonist, also produced ~ 2X-upregulation. However, ACh incubation (which can be hydrolyzed by the oocytes) failed to produce upregulation. These results suggest that a persistent ligand-binding to α7 Rs (but not necessarily gating of the ion channels) was critical for α7 Rs upregulation.

Title: Antiallodynic effects of substituted N-aryl piperidinium salts: alpha7 nAChR silent agonists

Authors: N. HORENSTEIN[1], D. BAGDAS[3], M. QUADRI[1], *M. DAMAJ[3], R. L. PAPKE[2]; [1]Chem., [2]Pharmacol. and Therapeut., Univ. of Florida, Gainesville, FL; [3]Dept. of Pharmacol. & Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The α7 nicotinic acetylcholine receptor (nAChR) is an emerging target for treatment of conditions associated with inflammatory processes. In a number of cases, ligands that are active in this way do not mediate observable ion currents, but are desensitizers of ionotropic activity. We term compounds of this type “silent agonists”, and have previously shown that the silent agonist NS6740 has α7-dependent analgetic activity in several pain models (Papke et al., 2015). The MQ series of substituted analogs of N,N-diethyl N’-phenylpiperazinium (diEPP) have been generated (see presentation by Horenstein et al. at this meeting). In this study we evaluated the antiallodynic activity of several MQ compounds that were silent agonists of α7 nAChR in the CFA mouse model, a model of chronic inflammatory pain. When applied alone, none of these compounds activated either heteromeric nAChR or α7 expressed in Xenopus oocytes. To varying degrees they were able to activate α7-mediated currents when co-applied with the positive allosteric modulator (PAM) PNU-120596, identifying them as silent agonists. In regards to their efficacy for stimulating PAM-dependent currents we found the following trend: 2.MQ.95 > 2.MQ.79 > 2.MQ.75. The compound 2.MQ.75 is a tertiary amine while the other two are quaternary amines, likely to have limited blood brain permeability. After systemic

administration (i.p.) in male ICR mice treated with CFA, 2.MQ.95 and 2.MQ.75 were active in reversing CFA-induced allodynia in a dose-related manner. However, 2.MQ.79 failed to show any antiallodynic effect in the mouse. These results suggest that a hard charge on the piperidine nitrogen is not a critical feature for antiallodynic activity.

Abstract: The α7 nicotinic acetylcholine receptor (nAChR) is a ligand gated ion channel widely distributed in the nervous system and peripheral tissues, even in leukocytes. It is a potential target in a number of processes ranging from neurocognition to inflammation. Conventional pharmacological thought places emphasis on control of this receptor via agonists, partial agonists and antagonists. Interestingly, α7 desensitization can be converted to a conductive state with a positive allosteric modulator (PAM) such as PNU-120596, and we have identified compounds that are selective in their ability to place the receptor in a PAM sensitive desensitized state (Ds) without significant channel activation. We define these compounds silent agonists (Papke et al., 2014), and they are associated with anti-inflammatory effects (see posters by Gould et al, Damaj, et al). The MQ series of compounds are substituted analogs of diethylphenylpiperazinium (diEPP) which itself is an analog of the ganglionic agonist dimethylphenylpiperazinium (diMPP). While diMPP is an efficacious orthosteric agonist of ganglionic (α3β4) heteromeric nAChR and homomeric α7 nAChR, when applied alone, diEPP will not activate these receptors, but places them into Ds. We synthesized a number of compounds in the MQ series with the key reaction being Pd-catalyzed coupling of piperazines with aryl compounds. The substituent on the

phenyl ring was varied in both identity and position and we assayed the compounds on the α7 and α3β4 nAChRs as expressed in the Xenopus oocyte using TEVC methodology. Across the series we observed variations in the ability of compounds to activate α7 as partial agonists with most exhibiting barely detectable activity while many produced robust responses when co-applied with PNU-120596 indicating they were selective for desensitization. The emergent four most probative compounds featured electron dense grouping at the para position of the phenyl ring including fluoro, trifluoromethyl and carboxamide groups. We hypothesize that polar interactions at the para position are key to silent agonism by favoring conversion of the bound complex into a PAM-sensitive desensitized state. A subpopulation of the receptors will also to varying degree reside in a PAM insensitive desensitized state (Di). The relative induction of these states may be probative for functional aspects of these compounds. Additionally, some compounds in the series exhibited noncompetitive inhibition of α3β4 nAChRs. The data presented here are part of a larger picture in which we seek to define the design features required for silent agonists, define state distributions, and apply them for control of the α7 nAChR *in vivo*.

Title: Insights into an emerging class of α7 nAChR silent agonists and NF-κB signaling mechanisms in immune cells

Authors: *T. M. GOULD[1], M. QUADRI[1], N. A. HORENSTEIN[1], R. L. PAPKE[2];
[1]Chem., [2]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL

Abstract: Compounds that preferentially stabilize non-conducting, desensitized α7 nicotinic acetylcholine receptor (nAChR) conformations (e.g. silent agonists) are potential therapeutic candidates for inflammatory and pain-related disorders. We have identified a new class of α7 nAChR silent agonists (the MQ series) with *in vitro* anti-inflammatory activity. The MQ compounds are derived from diethylphenylpiperazinium (diEPP), the parent α7 nAChR silent agonist. The lead MQ compounds inhibited stimulus-induced NF-κB activation in Jurkat and THP-1 cells, most with an approximate IC50 of 50 μM and some with no significant effects on

cell viability at concentrations up to 1 mM. Collaborative studies on the MQ series are also described in abstracts by Horenstein et al. and Damaj et al., which characterize the synthesis, electrophysiological properties, and *in vivo* efficacy of these agents. We also studied the mechanism(s) by which drugs targeting α7 nAChR impact the regulatory state of NF-κB in THP-1 cells. We tested whether drugs that differentially impact LPS-stimulated NF-κB activity (GTS-21 and NS6740) can affect the phosphorylation and degradation of IκBα, a protein that binds to cytosolic NF-κB thereby inhibiting its transcriptional activity. GTS-21 and NS6740 also differentially altered the phosphorylation state and level of IκBα, consistent with the reciprocal effects the drugs had on NF-κB activity. We conclude that these drugs modulate NF-κB activity by altering the phosphorylation state and (presumably) degradation of IκBα at the NF-κB/IκBα complex. We hypothesize that α7 drug-mediated regulation of NF-κB is catalyzed by drug-induced perturbations to receptor conformation, which could facilitate transient protein-protein interactions at intracellular domains, and may involve the recruitment of signaling proteins with SH2 domains (e.g. Src kinases, PI3K, JAK2). We speculate that such interactions either alter transmission of the canonical LPS/TLR4/NF-κB signal transduction pathway, or activate other pathways that can impact the regulatory state of IκBα. Together these studies provide insights into a novel class of α7 nAChR silent agonists with anti-inflammatory activity and the molecular mechanism(s) of nAChR drug-mediated NF-κB signaling.

Title: Chimeric acetylcholine binding protein for structure-guided insecticide design

Authors: *J. BOBANGO, T. T. TALLEY;
Dept. of Biomed. and Pharmaceut. Sci., Idaho State Univ., Meridian, ID

Abstract: The biological target of the fastest growing class of insecticides worldwide are the nicotinic acetylcholine receptors (nAChRs). Structural characterization of the binding interactions of insecticides with target and off-target species has not yet been examined. This is potentially a concern due to selectivity and resistance issues. Further, insect nAChRs to date have been notoriously difficult to heterologously express. Current expression and assay techniques use truly hybrid receptors or a heterogeneous mix of the binding target from crude tissue preparations. Here we present the soluble acetylcholine binding protein (AChBP) from the mollusk *Aplysia* californica as an alternative means for exploring insecticidal structural characterization. This soluble protein has been established as a structural surrogate for the native receptor and has the potential to be utilized for high-throughput screening. Additionally, this protein is amenable to the development of chimeric binding proteins relative to species of interest. These chimeras are generated by introducing mutations in key loops in the ligand binding domain. In the current study, we have produced chimeric AChBPs to mimic specific insect species nAChRs with mutations introduced in the integral loop C region and in the loop D region. The insect species we have completed mutations for include: the model organism *Drosophila* melanogaster (fruit fly), Myzus persicae (green peach aphid), Heliothis virescens (moth), Anopheles gambiae (mosquito), and the off-target honey bee Apis mellifera. In addition, we have completed chimeric constructs relative to humans. This will allow the comparison of binding interactions elucidated by x-ray crystallography between target and off-target species and provide data to drive structure-guided drug design. This combined with radioligand competition binding assays will aid the development of novel, selective, and safer insecticides.

Title: Structure-activity guided design and analysis of arylidene anabaseines and myosmines reveal two distinct binding modes with the acetylcholine binding protein

Authors: *T. T. DENTON[1], T. T. TALLEY[2], J. BOBANGO[2];
[1]Washington State Univ. Col. of Pharm., Spokane, WA; [2]Biomed. and Pharmaceut. Sci., Idaho State Univ. Col. of Pharm., Meridian, ID

Abstract: Nicotinic acetylcholine receptors (nAChRs) are recognized for playing a pivotal role in cognitive function. For more than a decade now, the acetylcholine binding proteins (AChBPs), soluble surrogates of the membrane bound nAChRs, have been extensively used as screening tools and for the X-ray crystallographic determination of ligand-binding interactions between natural products and synthetic compounds with the AChBPs. In an effort to identify new potential therapeutics, that may ultimately serve as leads in the development of new compounds to aid in the treatment of cognitive disorders, a number of arylidene anabaseines and myosmines were synthesized and screened using competition assays with the AChBPs. The most potent compounds were selected for co-crystallization and X-ray structural analysis. Most of the compound structures examined demonstrated protein ligand interactions similar to those seen in the structures of AChBPs with 2,4-dimethoxybenzylidene anabaseine (DMXBA). In these structures, as well as most examined to date, the basic nitrogen of the imine forms a hydrogen bond with the carbonyl of Trp143 (Ls numbering) deep within the binding pocket. Further, the distal ring of most of the compounds was oriented out of the binding packet often demonstrating pi - thio interactions with the vicinal cysteines at the tip of loop C. However, there was one significant outlier. The X-ray structure of (1-methyl-1H-imidazol-2-yl)methylidene myosmine uncovered a novel binding pose where the distal imidazole ring is twisted deep within the binding site. The nitrogen of the imidazole ring forms a hydrogen bond with both Trp143 and Ser142. In addition, a new hydrogen bond between the protonated imine nitrogen of the compounds central ring and the hydroxyl group of Tyr192 is observed. This novel binding pose has led to the development of a second generation of these compounds now in development.

Title: A survey of high resolution acetylcholine binding protein X-ray structures reveals details of tertiary and quaternary movements of the protein, both real and imagined, upon ligand binding

Authors: *T. T. TALLEY[1], T. T. DENTON[2], J. BOBANGO[1];
[1]Dept. of Biomed. and Pharmaceut. Sci., Idaho State Univ. Col. of Pharm., Meridian, ID; [2]Col. of Pharm, Washington State Univ., Spokane,, WA

Abstract: The acetylcholine binding proteins (AChBPs) have provided a wealth of information about the molecular organization of nicotinic receptors since the initial report by Sixma and colleagues in 2001. Currently there are more than 90 structures of the AChBPs deposited in the PDB. This impressive compilation of endeavors by many groups globally demonstrates the importance of the AChBPs in both increasing our understanding of protein/ligand interactions and in the development of novel compounds. During the past year our group has deposited a number of high resolution (better than 2.5 Å) structures of the AChBPs from both *Lymnaea stagnalis* (*Ls*) and *Aplysia californica* (*Ac*). In addition we have deposited a number chimeric entities in which specific segments of the proteins have been modified to resemble the corresponding regions of specific human receptor subtypes. Included in this set are examples of natural products, peptide toxins, and novel synthetic entities as well as the highest resolution

structure to date of the WT AChBP from *Ls*. A comparison of the higher resolution structures for our group and others demonstrate significant changes in both the tertiary and quaternary structure of the AChBPs dependent, to some degree, on the ligand bound. At the same time the increasing number of high quality structures bring into question some assertions made about the AChBPs in the past. In particular it is apparent that comparisons made between different species with different ligands must be considered with some skepticism due to the inherent differences in structure and specificity. Further, differences in the expression systems used and the expression/purification tags present result in subtle differences in quaternary organization of the AChBPs from the same species. These subtleties may have led to the over interpretation of structural differences in the past. Full consideration of both the benefits and limitations of the information presented by structures of the AChBPs provides a less biased interpretation of the data. A detailed comparison of these issues will be presented in an effort to provide the community with the tools needed to make an informed assessment of the AChBP structures available.

Abstract: The computer guided exploration of the yet unknown chemical space such as the Chemical Universe Database GDB-17 containing all possible small organic molecules up to 17 atoms,1 is one of the richest tools available today to identify new active molecules for a given target.2 Extending our previous drug discovery efforts at the nicotinic acetylcholine receptors,3 we have identified promising regions of the chemical space and refined our virtual screening

strategies, in particular focusing on optimizing pharmacological characteristics such as crossing the blood brain barrier. Functional testing using expression of the human α7 neuronal nicotinic acetylcholine receptors and counter screened at heteromeric nAChRs including the α4β2, α3β2, α3β4 or α1β1δε. Active molecules were further tested for their possible interaction with this serotoninergic receptors. Different molecules were retained through this screening strategy with the most promising HiQ0013 acting almost as full agonist the human α7 with an EC50 in the μM range. Further physiological characterization revealed that sustained exposure to HiQ0013 in the nanomolar range potentiates the acetylcholine-evoked currents through a mechanism referred as priming that was observed only for some α7 agonists. Priming of the α7 receptors is known to correlate with procognitive activity, which suggested that HiQ0013 might be a promising candidate to restore cognitive deficits. Experiments conducted in rodents (mice and rats) confirmed that exposure to low concentrations of HiQ0013 can restore pharmacologically induced cognitive deficits. Furthermore, HiQ0013 at 0.03 mg/Kg was shown to improve delay to match sample task in old monkeys. These data confirmed the procognitive nature of HiQ0013 opening promising avenues for novel therapeutic treatments. 1.Ruddigkeit, L.; van Deursen, R.; Blum, L. C.; Reymond, J. Title: Novel alpha 7 nicotinic acetylcholine receptor (nAChR) modulator, HiQ0013 exhibits pro-cognitive effects in young and aged animal models

Authors: *A. V. TERRY, JR[1], P. CALLAHAN[1], C. HERNANDEZ[1], M. PLAGENHOEF[1], J.-L. REYMOND[2], S. BERTRAND[3], J. BURGI[2], D. BERTRAND[3];
[1]Dept Pharmacol Toxicol, Georgia Regents Univ., Augusta, GA; [2]Chem. and Biochem., Univ. of Berne, Berne, Switzerland; [3]HiQScreen Sàrl, Geneva, Switzerland

Abstract: The alpha 7 nicotinic acetylcholine receptor (nAChR) has long been considered a therapeutic target for the cognitive deficits of disorders like Alzheimer's disease (AD) and schizophrenia. This premise is based on a number of observations including deficits in alpha 7-nAChRs in the post mortem brains of patients who suffered from AD or schizophrenia, the abundance of alpha 7-nAChRs in the hippocampus and prefrontal cortex (important structures for cognition) and the important role of alpha 7-nAChRs in modulating several calcium-dependent events in neurons including neurotransmitter release, postsynaptic signaling, and neuronal survival. In the experiments described here, the novel alpha 7-nAChR modulator, HiQ0013 was evaluated in several learning and memory-related behavioral tasks in animal models. These tasks included a spontaneous novel object recognition (NOR) procedure in young-adult (4-5 month old) rats (N=6), a delayed match to sample (DMTS) task in old monkeys (mean age = 22.8 years, N=8), and a contextual and cued fear conditioning procedure in old mice (mean age =27 months, N=8). In the NOR task, vehicle and three doses of HiQ0013 ranging from 0.3-3.0 mg/kg were administered i.p. 30 min before the A/A session and the A/B (recall) session was conducted 48 hr later. All 3 doses of HiQ0013 improved performance of the NOR task. In the DMTS task in old monkeys, five doses of HiQ0013 ranging from 0.01-1.0 mg/kg were administered i.m. 30 min before behavioral testing. In these studies three of the five doses administered were associated with improvement in matching accuracy most notably at the longest (i.e., presumably the most difficult) delays. In the contextual and cued fear conditioning task in old mice, one dose (3.0 mg/kg administered i.p 30 min before testing) has been evaluated to date and it was associated with improvements in both contextual and cued fear conditioning. Collectively, these studies in animals indicate that HiQ0013 has the potential to improve several domains of cognition that are often impaired in neuropsychiatric disorders such as AD and schizophrenia including recognition memory, working/short memory, and associative learning.

Title: Beta-amyloid and Lypd6 compete for binding to nicotinic acetylcholine receptors in human brain extracts

Authors: *M. ARVANITI[1], J. D. MIKKELSEN[2], M. S. THOMSEN[1];
[1]Univ. of Copenhagen, Copenhagen, Denmark; [2]Neurobio. Res. Unit, Copenhagen Univ. Hosp. Rigshospitalet, Copenhagen, Denmark

Abstract: Nicotinic acetylcholine receptors (nAChRs) are widely expressed in the nervous system, affecting major brain processes, including learning and memory, and are implicated in neurodegenerative disorders, such Alzheimer's disease (AD). The alpha7 (α7) nAChR has been established as a promising molecular target for the treatment of AD, and clinical trials have shown that nAChR agonists are able to mitigate symptoms of the disease, improving attention and memory. Moreover, beta-amyloid (Aβ1-42), the main component of amyloid plaques in brains of AD patients, binds to α7 nAChR with high affinity. Ly-6/neurotoxin (Lynx) proteins, a group of neuronal modulators structurally similar to neurotoxins, regulate nAChR function in brain by binding directly to the receptors, critically affecting nAChR-dependent cognitive function. Recently our group demonstrated that PSCA, a member of the Lynx family, is altered in brains of AD patients and in an animal model of AD, implicating for the first time Lynx proteins in AD pathology. Here we investigate the Lynx protein Ly6/Plaur domain containing 6 (Lypd6), which modulates calcium conductance of nAChRs and enhances nicotinic-related behaviours, such as pre-pulse inhibition and hypoalgesia. Interestingly, Lypd6 is also shown to act as a feedback enhancer of Wnt/β-catenin signaling by binding directly to the essential co-receptor LRP6. Since Lypd6 modulates both cholinergic and Wnt/β-catenin signaling, two systems which are critically impaired in AD, we hypothesize that Lypd6 is involved in AD pathophysiology. In this study, we use affinity purification of human temporal cortex to show that Lypd6 binds to several nAChR subunits in human brain extracts. Using the same method, we demonstrate that oligomeric Aβ1-42 and Lypd6 compete for binding to nAChRs. Moreover, competition studies with nAChR ligands are performed to determine the binding site of Lypd6 on nAChRs. Lastly, we demonstrate that soluble recombinant Lypd6 protein reduces nicotine-induced ERK phosphorylation in PC12 cells. In summary, our data illustrate for the first time that Lypd6 binds to nAChRs in the human brain and that binding of Lypd6 is sufficient to inhibit nAChR-mediated signalling. Our findings further suggest a possible role of Lypd6 in AD. This finding may be used as a basis for more rational drug development for cognitive dysfunction.

Abstract: Psychiatric and neurodegenerative diseases, such as Alzheimer's disease and schizophrenia, are characterized by disabling impairments of cognitive function, including memory lapses and lack of attention. The α7 (alpha 7) nicotinic acetylcholine receptor (nAChR) is one of the most promising molecular drug targets for cognitive disabilities. Previous research has largely considered the α7 nAChR to be a homomer in the brain. However, several lines of evidence suggest that α7 nAChR subunits interact directly other membrane proteins including other nAChR subunits. Here we provide evidence that the α7 nAChR forms complexes with several other proteins in human neocortical extracts: 1)We use affinity purification with α-bungarotoxin to demonstrate that α7 subunits can form complexes with β2 (beta2) nAChR subunits. Previous studies have shown that α7 and β2 subunits can form a heteromeric nAChR in

the rodent brain, and that this receptor is particularly vulnerable to blockage by Aβ, suggesting that effects on α7β2 nAChRs might underlie some of the cognitive dysfunction observed in AD. It has further been shown that existing α7 ligands vary in their efficacy on α7β2 receptors. Therefore the existence of the α7β2 nAChR may explain the differential clinical effects observed with "selective" α7 nAChR agonists. 2)We use affinity purification with α-bungarotoxin to demonstrate that α7 nAChRs can dimerize with the NMDA-receptor subunit NR1. This extends previous rat studies showing that α7 nAChRs can dimerize with NMDA-Rs by direct interaction with the NR2A subunit of the NMDA-receptor, and that disrupting this complex can alter nicotine addiction as well as memory function. 3)We use affinity purification with recombinant versions of the Ly-6/Neurotoxin (Lynx) proteins Lynx1 and Secreted Ly-6/uPAR-related protein 1 (SLURP-1) to show that Lynx proteins form complexes with α7 nAChRs in human brain extracts. Lynx1 has previously been shown to regulate the function of α7 nAChRs in heterologous expression systems and hamper associative memory and synaptic plasticity in mice by acting on nAChRs. Our results indicate that Lynx proteins may regulate α7 nAChR function in the human brain and affect not only cholinergic signalling, but also the effects of experimental drugs acting on the α7 nAChR.

Title: Direct actions of glycine on neurons of the mesencephalic trigeminal nucleus of the rat

Authors: V. SILVEIRA, F. R. MORALES, *I. POSE;
Facultad De Medicina, Montevideo, Uruguay

Abstract: Mesencephalic trigeminal (MesV) neurons are unique primary afferents because their cell bodies are located within the CNS and are contacted by numerous synapses containing different neurotransmitters. Thus, in addition to their sensory role, they may also function as

interneurons in networks that organize jaw movements. Recent available evidence indicates that MesV neurons of the rat are innervated by glycinergic fibers. The present study was conducted to examine the presence of glycinergic receptors on MesV neurons and the effects of glycine on their properties. Using specific antibodies we show that MesV neurons of the rat display immunoreactivity to the alpha 1, alpha 2 and beta subunits of the glycine receptor. The effects of glycine were studied in rat brainstem slices (P6-P20) in electrophysiological experiments with whole-cell recordings techniques. Glycine was bath or juxtacellularly applied. This neurotransmitter induced in all tested cells (35), a depolarization (2 to 8mV), a decrease in input resistance (20% to 25% reduction) and a decrease of the spike amplitude. These changes were accompanied, in some neurons, by an increase in excitability indicating that the depolarizing effect prevailed over the decrease in input resistance, whereas in others no obvious change in excitability was observed. Glycine exposure antagonized the excitatory effects of local glutamate application. The electrophysiological results suggest that glycine has complex actions on the excitability of MesV neurons, resulting excitatory in most cases but with the ability to reduce other excitatory actions. Our findings indicate that MesV neurons possess glycine receptors and are targets for glycine that may act on them as a neurotransmitter.

Title: Pathogenic mechanisms of glycine receptor antibodies in human disease

Authors: *S. J. CRISP[1], A. VINCENT[2], D. M. KULLMANN[1];
[1]Dept. of Clin. and Exptl. Epilepsy, Inst. of Neurology, Univ. Col. London, London, United Kingdom; [2]Nuffield Dept of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Antibodies against glycine receptors (GlyRAbs) have been found in some patients with progressive encephalomyelitis with rigidity and myoclonus (PERM) (Carvajal-Gonzalez A et al, Brain 2014). PERM is a life-threatening acquired neurological syndrome characterized by axial and limb muscle stiffness and spasms, brainstem dysfunction such as oculomotor disturbance, stimulus-sensitive exaggerated startle responses (hyperekplexia), and autonomic

crises. However, patients with GlyRAbs who receive immunotherapy often make a substantial recovery, suggesting an antibody-mediated pathogenic process. Nonetheless, as with other neuropil autoantibodies, the relationship between the identified antibody and neurological disease remains conjectural. We are using a functional assay to explore the effects of patient IgG on glycinergic currents. Using whole-cell patch-clamp we have recorded spontaneous miniature inhibitory postsynaptic currents (mIPSCs) from motoneurons in rat dissociated spinal cord cultures. GABA and glycine are co-released at interneuron-motoneuron synapses, both contributing to mIPSCs (Jonas P et al, Science 1998). However, pharmacologically isolated glycinergic currents have a shorter decay time than GABAergic currents. We use this difference in time course to separate the two components, in the absence of pharmacological blockade, to quantify the contribution of glycinergic neurotransmission to mIPSCs recorded from motoneurons. We have compared the contribution to mIPSCs recorded from neurons incubated in patient or control IgG for up to 24h prior to recording. Our preliminary results show a decrease in the contribution of glycinergic current to the mIPSCs for neurons incubated in patient IgG compared with control IgG from 41% to 12% ($p<0.005$). A reduction in glycinergic neurotransmission in patients would be consistent with many of the clinical features of PERM. The electrophysiological findings presented here therefore provide strong evidence that the antibodies in these cases are pathogenic. The likely cellular mechanism is antibody crosslinking and internalization of the receptors as occurs in HEK293 cells expressing glycine receptors and incubated with patient sera (Carvajal-Gonzalez A et al, Brain 2014). We plan to explore whether this functional assay can also be used to detect antibodies in sera from patients suspected to have antibody-mediated deficiency in glycinergic neurotransmission, without an identified antigenic target. We will also examine whether IgG from patients with GlyRAbs who have atypical clinical presentations, such as encephalopathy, produce similar electrophysiological phenotypes.

Title: Functional ion channel properties are altered by a single amino acid exchange in the human glycine receptor α1

Authors: G. LANGLHOFER, P. BAUMANN, *C. VILLMANN;
Univ. Wuerzburg, Wuerzburg, Germany

Abstract: Communication between neurons of the central and peripheral nervous systems essentially relies on the balance of activation and inhibition at synaptic sites. Glycinergic neurotransmission is a key mediator of fast synaptic inhibition in adult spinal chord and brain stem of humans and rodents. Mutations of the postsynaptic glycine receptor (GlyR), its associated anchoring proteins or affected presynaptic glycine transporter 2 have been shown to underlie the rare human neuromotor disorder hyperekplexia, characterized by exaggerated startle reflexes and loss of postural control. Here we give a detailed description of the influence of a novel human mutation P366L, located within a proline-rich stretch in the intracellular loop connecting transmembrane domains 3 and 4 (TM3-4 loop) of the GlyRα1, on channel functionality. Using transfected HEK293 cells stained for the human α1 subunit, we demonstrate that the hyperekplexia-like symptoms observed from a patient suffering from this mutation are not due to disturbances in receptor biogenesis. In contrast, patch-clamp recordings unveil a significant reduction in glycine-induced maximum inward currents. The proline-rich domain 365PPPAPSKSP373 including the pathological mutation harbors a SH3 consensus sequence probably involved in binding of so far unidentified intracellular proteins. Functional analysis of constructs generated to incrementally destroy a possible secondary structure demonstrates a remarkable influence of the motif on desensitization properties of the human GlyRα1. The role of proteins involved in binding to this structure is still under investigation. Together these results provide a molecular explanation for impaired GlyR function finally leading to hyperekplexia-like symptoms observed in the patient carrying the mutation P366L.

Title: Expression and subcellular localization of glycine receptor subunits and synaptic glycine transporter 2 in the nucleus accumbens of C57/BL6 mice

Authors: *B. FÖRSTERA[1], B. MUNOZ[1], K. STANIC[2], P. MURATH[1], L. G. AGUAYO[1]; [1]Dept. of Physiol., [2]Axon Guidance Lab., Univ. de Concepcion, Concepcion, Chile

Abstract: Introduction Alcohol abuse is a major health problem that affects millions of people worldwide, but the pharmacotherapeutic tools to assist behavioral intervention are limited and cause several undesirable side effects, which emphasizes the need for novel, mechanistically oriented therapies. Glycine gated chloride channels (GlyR) are potentiated by ethanol in mammalian neurons, resulting in a reversible increase in apparent affinity, and thus involved in the response of the CNS to alcohol. While the ethanol sensitive GlyR alpha1 subunit dominates in the spinal cord, GlyR in the brain are thought to be constituted mostly of alpha3 subunits, which are not affected by pharmacologically relevant concentrations of ethanol. Previous studies indicate the involvement of glycinergic currents in the nucleus accumbens (nAc) in alcohol consumption. After whole-cell patch-clamp recordings in dissociated neurons and acute slices of the nAc revealed strychnine sensitive glycine evoked currents and synaptic currents and showed that evoked currents where potentiated by low concentrations of ethanol, we investigated the expression and subcellular localization of GlyR subunits and the synaptic glycine transporter 2 (GlyT2) in the nAc. Results PCR indicates the predominant expression of the GlyR alpha1ins and alpha2A, as well as GlyT2, but also detects other GlyR subunit splice variants in the nAc. These findings are supported by western blot for GlyR alpha1 and GlyT2. Immunocyto- and -histochemistry in dissociated neurons and paraffin sections of the nAc using the same antibodies in combination with antibodies against GlyR pan-alpha, MAP2 and the vesicular inhibitory amino acid transporter (VIAAT) confirm the synaptic and extra-synaptic localization of these receptors in neurons of the nAc. Conclusion We identified GlyR alpha subunits and elucidated their expression and subcellular distribution, showing the synaptic and extra-synaptic presence of these receptors that enables them to support tonic and phasic currents in neurons of the nAc. These findings highlight GlyR as a target for innovative pharmacological approaches to treat alcoholism and other addiction-related behavior.

Title: Agonist and antagonist monoclonal antibodies with selectivity for ligand-gated glycine receptor isoforms

Authors: J. SIMARD[1], K. MICHELSEN[2], B. GRUBINSKA[1], Y. WANG[2], B. HALL[2], P. SHAFFER[2], *J. GINGRAS[1];
[1]Neurosciences, [2]Therapeut. Discovery, Amgen Inc., Cambridge, MA

Abstract: Ligand-gated ion channels, such as the glycine receptors (GlyRs) family, are targets of increasing interest for studies relevant to various neuronal diseases. Indeed, in the central nervous system, the most abundant GlyRs identified express either the alpha (α) 1 and/or the α3 subunits. Due to the high homology between the various GlyRα subunits, availability of selective tools necessary to better resolve their precise biological roles has been limiting. Here, we report the generation and characterization of multiple GlyRα3 antibodies. Selectivity against GlyRα1 was assessed by immunofluorescence, flowcytometry and surface plasmon resonance and their ability to modulate GlyRs activity investigated via an *in vitro* membrane potential dye assays on stable cell lines overexpressing human (hu) GlyRα1β or huGlyRα3β channels. We identified six functional dose-dependent mouse monoclonal antibodies with EC_{50} < 25nM and k_D values < 10nM. These include: three non-selective antagonist antibodies; one non-selective and two huGlyRα3β selective agonist antibodies. *In vitro*, the functional inhibition of these monoclonal antibodies can be blocked by pre-addition of a non-selective agonist/potentiator molecule, while their functional agonism can be prevented by pre-addition of strychnine, a known GlyRs antagonist. Together, this data demonstrates that ligand-gated ion channels functions can be modulated in a dose-dependent manner using high affinity antibodies and that, despite the high protein homology between the alpha subunits, selectivity is achievable within this receptor family.

Title: Molecular mechanisms for zinc-induced allosteric potentiation of GlyR α1 receptors

Authors: C.-H. WANG[1], N. ZHOU[2], *D. WU[2];
[1]Grad. Inst. of Clin. Med. Science, China Med. Univ., Taichung, Taiwan; [2]China Med. University, Grad. Inst. of Clin. Med. Science,, Taichung, Taiwan

Abstract: The inhibitory glycine receptor (GlyR)-mediated fast synaptic transmission is involved in motor control and other physiological processes. Deficits in channel functions of GlyR α1 subunit are linked to human hyperekplexia. Previous studies and our recent findings have revealed that, when agonist binding and channel activation remains normal, the lack of positive zinc modulation on GlyR α1 is sufficient to affect normal synaptic transmission and leads to human hyperekplexia. We have also identified that the amino acid residue W170 is a new site that is involved in zinc-mediated potentiation on GlyR α1 and that W170 is located close to the previously identified zinc-binding sites, D194 and H215. However, it remains unknown how these residues constitute a molecular pathway that mediates the micro-structural changes around these residues and thereby transduces conformational changes from zinc binding to allosteric potentiation of GlyR. In the present study, we used site-directed mutagenesis to substitute W170 with hydrophobic, positive charged, negative charged, polar or no-polar residues and found that both the benzo ring and the hydrophobic properties of the Trp residue are required for maintaining zinc-mediated potentiation of GlyR α1. We further explored adjacent residues around 170 site and found that L195 mutations reduced the sensitivity of zinc-mediated potentiation. Single mutations of W170 into Cys not only abolished zinc-mediated potentiation, also dramatically reduced glycine-induced current responses of GlyR α1. Interestingly, introduction of a disulfide bond between W170 and L195 by double Cys mutations not only restored glycine-induced currents comparable to the wild type receptor, but also partially rescued zinc-mediated potentiation of GlyR α1. Furthermore, either W170C or I210C single mutations impaired the glycine-induced current response, which was, however, totally rescued by double mutations of W170C and I210C. Unlike the Cys cross-link of W170C/L195C, the cross-link of W170C/I210C did not rescue zinc-mediated potentiation on GlyR α1. Our results indicate that W170 can act as a hub between the zinc modulation pathway and the receptor activation

pathway. These findings also suggested that the connection between β8 and β10 strands is required for agonist-induced channel opening, whereas the connection between β8 and β9 strands is crucial for signal transduction from the allosteric modulation to the channel activation pathway.

Title: Functional reconstitution of glycinergic synapses incorporating defined glycine receptor subunit combinations

Authors: ***Y. ZHANG**, C. L. DIXON, A. KERAMIDAS, J. W. LYNCH;
Queensland Brain Inst., Brisbane, Australia

Abstract: Glycine receptor (GlyR) chloride channels mediate fast inhibitory neurotransmission in the spinal cord and brainstem. Four GlyR subunits (α1-3, β) have been identified in humans, and their differential anatomical distributions result in a diversity of synaptic isoforms with unique physiological and pharmacological properties. To improve our understanding of these properties, we induced the formation of recombinant synapses between cultured spinal neurons and HEK293 cells expressing GlyR subunits of interest plus the synapse-promoting molecule, neuroligin-2A. In the heterosynapses thus formed, recombinant α1β and α3β GlyRs mediated fast decaying inhibitory postsynaptic currents (IPSCs) whereas α2β GlyRs mediated slow decaying IPSCs. These results are consistent with the fragmentary information available from native synapses and single channel kinetic studies. As β subunit incorporation is considered essential for localizing GlyRs at the synapse, we were surprized that α1-3 homomers supported robust IPSCs with β subunit incorporation accelerating IPSC rise and decay times in α2β and α3β heteromers only. Finally, heterosynapses incorporating α1D80Aβ and α1A52Sβ GlyRs exhibited accelerated IPSC decay rates closely resembling those recorded in native synapses from mutant mice homozygous for these mutations, providing an additional validation of our technique.

Glycinergic heterosynapses should prove useful for evaluating the effects of drugs, hereditary disease mutations or other interventions on defined GlyR subunit combinations under realistic synaptic activation conditions.

Title: New excitatory and inhibitory pharmacogenetic receptors based on the ivermectin-activated glycine receptor

Authors: ***J. W. LYNCH**[1], R. ISLAM[2];
[2]Queensland Brain Inst., [1]Univ. of Queensland, Brisbane, Australia

Abstract: The ability to control the electrical activity of defined neuronal populations *in vivo* is dramatically advancing our understanding of brain function. Optogenetic approaches, whereby light is used to activate anion or cation-selective channels, has proved a successful means of achieving both excitation and inhibition. However, as it requires surgically implanted light delivery probes, it may not be suited for activating populations of neurons distributed over a large parts of the brain. Pharmacogenetic approaches provide an alternate means of controlling the activity of widely distributed neuron populations. For example, neuronal silencing has been achieved with the invertebrate allatostatin-activated G protein-coupled receptor and excitation has been achieved with a synthetic M3 muscarinic receptor that is insensitive to acetylcholine but activated by the non-endogenous ligand, the clozapine-N-oxide. Alternate pharmacogenetic silencing methods based on ivermectin-activated glutamate or glycine receptor (GlyR) chloride channels have also been developed. We previously described a modified α1 GlyR incorporating the F207A mutation to eliminate glycine sensitivity and the A288G mutation to enhance ivermectin sensitivity to around 30 nM. Here we describe a new modified GlyR with significantly enhanced ivermectin sensitivity. This receptor, which incorporates the Y279F and A288G mutations, is reliably and potently activated by 3 nM ivermectin. We also developed an

excitatory GlyR, permeable to both sodium and calcium, that incorporates the A-1'E and A288G mutations. This produces potent neuronal depolarisation at 1 μM ivermectin. These tools may be useful for controlling neuronal activity *in vivo* and *in vitro*.

Title: Interaction of quinazolines with the E binding loop of the serotonin-type 3A (5-HT3A) receptor determined using double mutant cycling

Authors: *S. N. KHATRI[1,2], O. ALWASSIL[3], D. PHILIP[3], M. DUKAT[3], M. SCHULTE[2]; [1]Pharmacol. and toxicology, Univ. of Sci., Philadelphia, PA; [2]Dept. of Pharmaceut. Sci., Philadelphia Col. of Pharmacy, Univ. of Sci., Philadelphia, PA; [3]Dept. of Medicinal Chem., Sch. of Pharmacy, Virginia Commonwealth Univ., Richmond, VA

Abstract: The serotonin type 3A (5HT3A) receptors is a homomeric ligand gated ion channel receptor that has been targeted clinically for the treatment of chemotherapy induced emesis. More recently, 5-HT3 receptors have been shown to play a role in pain and cognition. They may also contribute to multiple neurological disorders including depression, epilepsy, anxiety, learning, and attention deficit disorders. In a recent study, analog of the 5-HT3R agonist mCPBG (3-CPG) enhanced the antinociceptive actions induced by clonidine in the mouse tail-flick assay without potentiating the side effects of clonidine. Based on molecular modeling, we identified two distinct interactions of 3-CPG with the 5-HT3AR. Our models suggest that the guanidine moiety of 3-CPG interacts with W183 and the aryl group interacts with Y143 of the 5HT3AR. Constrained quinazoline analogs of 3-CPG act as antagonists on the 5-HT3AR. During site directed mutagenesis analysis of the interaction of these compounds with W183 and Y153, we discovered that Y153A and W183F mutations converted these antagonists to partial agonists. To better understand the binding interactions of quinazoline analogs and possibly gain improved understanding of partial agonism on the 5-HT3R, we conducted a double mutant cycling study to determine if interactions were present at W183 and Y153 or whether observed changes in potency in these mutants were due to a functional effect of mutating these two residues. Our studies show that Y153 does not directly interact with the quinazoline analogs suggesting the observed changes in potency are due to an indirect or functional interaction.

Title: Effects of chronic caffeine exposure on rat brain serotonergic systems

Authors: *P. WILLIAMS;
Univ. of Colorado Boulder, Boulder, CO

Abstract: Chronic caffeine exposure during adolescence has been shown to induce persistent maladaptive anxiety-like behavioral responses in the adult rat. It is possible that these maladaptive responses are mediated by the serotonergic system. In this study, we investigated the effects of chronic adolescent caffeine exposure on the rat brain serotonin (5-hydroxytryptamine; 5-HT) system. Specifically, we analyzed serotonergic neuron activation in subregions of the dorsal raphe nucleus (DRN), a brainstem region with abundant serotonergic neurons. After a week of acclimatization, rats were randomly divided into four groups in a two-by-two experimental design. Two groups received chronic caffeine (CC) administration in drinking water (0.3 g/L) from postnatal day 28 to postnatal day 56 while the other two groups received drinking water (NC) alone during the same developmental time period. After 28 days of caffeine or control treatment and a 24-hour washout period, rats received an i.p. injection of either 30 mg/kg caffeine (C) or 0.9% sterile saline (S) vehicle, were then replaced in their home cages, and were euthanized 90 minutes following treatment. This was a 2 x 2 design with four treatment groups, NCS, NCC, CCS, and CCC. Using a double immunostaining technique we quantified the immunoreactivity for the acute activation marker c-Fos and tryptophan hydroxylase 2 (Tph2) as a marker of serotonergic neurons. NCC rats, relative to NCS and CCC groups, had higher activation of 5-HT neurons in the rostral DRD and caudal DRD, ventral part of the dorsal raphe nucleus (DRV), DRC, and DRI. These data are consistent with the hypothesis that the DRN is a key structure in promoting the adult pro-anxiety behavioral phenotype following adolescent caffeine exposure.

Title: Oxytocin receptor activation depolarizes spiny hilar interneurons and induces GABA release in the dentate gyrus of the rat hippocampus

Authors: *S. W. HARDEN[1,2,3], C. J. FRAZIER[1,2];
[1]Pharmacodynamics, [2]Neurosci., [3]Col. of Dent., Univ. of Florida, Gainesville, FL

Abstract: Aberrant central oxytocin (OXT) signaling is implicated in a variety of neurodevelopmental disorders, including autism spectrum disorder (ASD). However, relatively little is known about the physiology of central OXT signaling outside the hypothalamus, where OXT-synthesizing neurons reside. The dentate gyrus (DG) serves as the entry point of perforant path information flow into the hippocampus, and hilar interneurons (HINs) express OXT receptors (OXTRs) as demonstrated by in-situ hybridization and autoradiography studies. However, no reports exist which characterize the electrophysiological nature of OXTR activation in the DG, or its direct effect on HINs. In this study, we identify OXT-responsive HINs using cell-attached recordings and the selective OXTR agonist TGOT, and subsequently characterize these HINs electrophysiologically and morphologically utilizing whole cell patch-clamp recordings. Our results indicate that OXTR activation produces a strong but transient suprathreshold depolarization in a subset of HINs. Although the hilus has a heterogeneity of interneuron phenotypes, preliminary data indicate OXT-responsive neurons are GABAergic spiny interneurons. Interestingly, OXTR responsive HINs also often display intrinsic peri-threshold oscillations, as well as an unreported form of choline-independent, persistent firing behavior that can be terminated with strong transient depolarization. Further, both of these phenomena appear to be modulated by OXTR activation. Continued investigation of OXT-responsive HINs and their effect on the excitatory pathways they modulate will provide insight into the role of OXT as a neuromodulator of hippocampal neurotransmission, and may aid in the development of pharmacological therapeutics for ASD and other neurodevelopmental disorders.

Title: Anatomical and functional expression of channelrhodopsin-2 (ChR2) in the basal forebrain and thalamus of the Vglut2-ChR2-eYFP BAC optogenetic mouse

Authors: *D. W. DUBOIS, D. A. MURCHISON, K. S. MONTGOMERY, A. S. FINCHER, A. H. MAHNKE, W. H. GRIFFITH;
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Disruption of synaptic function is a major contributor to cognitive decline during aging. Our lab has focused on understanding the relationship between altered synaptic physiology and age-related cognitive impairment in the rodent basal forebrain (BF). Our long term goal is to reverse cognitive decline by maintaining youthful synapses across aging. The BF has a complex synaptic circuitry featuring multimodal inputs onto cholinergic, GABAergic, glutamatergic and peptidergic neurons, as well as cortically projecting neurons originating in the BF. Previous data from our lab suggests that the postsynaptic current densities of AMPA glutamate receptors in the rat BF increased with age (Jasek and Griffith, Neuroscience, 82:1179-94, 1998). Because some glutamatergic BF neurons are thought to express vesicular glutamate transporter 2 (Vglut2) (Colom et al., Synapse, 58:151-164, 2005), we tested the idea that synaptic glutamate release from Vglut2 neuron terminals may contribute to synaptic plasticity during aging. To examine the network connectivity of glutamatergic synaptic transmission within the BF, we used light-evoked synaptic currents from Vglut2-ChR2 (H134R)-eYFP BAC optogenetic mice (1-4 mo). We combined whole-cell patch clamp electrophysiology and LED-evoked light stimulation (470 nm) in brain slices and in a reduced synaptic preparation in these optogenetic mice. Postsynaptic neurons were identified by biocytin filling and immunohistochemistry, or by single cell RT-PCR. Despite previous research showing widespread Vglut2 immunoreactivity in the BF, confocal microscopy of BF slices revealed that the vast majority of eYFP fluorescence was localized in the medial septum with limited fluorescence in the vertical limb of the diagonal band and essentially no eYFP positive neurons found in the horizontal limb. Using prolonged (5-10s) light stimulation, no glutamatergic synaptic transmission was detected in neurons from BF slices (0/46 cells). In contrast, confocal images from the thalamus displayed a robust number of eYFP positive cells, and when patch-clamped, these neurons (21/27) displayed inward ChR2 currents in response to brief (5 ms) light

stimulation. scRT-PCR confirmed that 100% of eYFP fluorescent thalamic neurons were negative for both ChAT and GAD (n=11) and were presumably glutamatergic. The Vglut2-ChR2 (H134R)-eYFP BAC optogenetic mouse works well in some brain areas, but it may not be ideal for studying BF glutamatergic transmission. Future experiments will seek to confirm this finding in the BF reduced synaptic preparation and to identify age-related functional and expressional changes in the Vglut2-eYFP-ChR2 construct.

Title: Brain-derived estradiol controls hunger state-dependent plasticity of GABA synapses

Authors: *J. GARDNER GREGORY, E. R. HAWKEN, S. ANGELIS, E. C. DUMONT; Ctr. for Neurosci., Queens Univ., Kingston, ON, Canada

Abstract: The oval bed nucleus of the stria-terminalis (ovBNST) is one of the most sexually dimorphic regions of the brain, containing androgen, estrogen and progestin receptors. It is a region critical in controlling both feeding and anxiety-related behaviours. We showed that GABA inhibitory post-synaptic current (IPSC) in the ovBNST is a neurophysiological mechanism regulating these behavioural phenomena. Interestingly, estradiol (E2) has both anxiogenic and anorectic effects, but whether and how estradiol in the ovBNST regulate these behavioural phenomena is unknown. Therefore, we examined the neurophysiological and behavioural effects of E2 in the ovBNST. We used both naïve male and female Long-Evans rats and conducted whole cell patch clamp electrophysiology in the ovBNST measuring GABA IPSC's. Bath application of E2 potentiated GABA IPSC's both in male and female rats, although the effect varied with the estrous cycle in females. E2 potentiated GABA through estrogen receptor alpha (ERα). Furthermore, we observe that a low frequency stimulation (LFS) protocol caused a long-term potentiation (LTP) of GABA synapses that was dependent on both the production of E2 and the activation of ERα. E2 acted post-synaptically and ultimately interfered with a pre-synaptic tonic inhibition of GABA IPSCs by endocannabinoids. Finally, 24 hour food

restriction had the ability to reduce LFS induced GABA LTP and unmasked a long-term depression of GABA synapses. The neurophysiological effects of acute food restriction on GABA IPSC's are mostly reversed by either refeeding the rat or the activation of estrogen receptors. Therefore, estradiol is critical in GABA plasticity within the ovBNST and appears to be essential in the regions regulation of feeding behaviours.

Title: Impaired gaba plasticity at ovbnst synapses predicts compulsive drinking in cfr-induced schedule-induced polydipsia

Authors: *S. ANGELIS, J. GARDNER GREGORY, E. R. HAWKEN, M. H. NAUGHTON, C. P. NORMANDEAU, E. C. DUMONT;
Queens Univ., Kingston, ON, Canada

Abstract: Schedule-Induced Polydipsia (SIP) is an animal model of compulsivity resulting in an adjunctive drinking behavior in food restricted animals. The bed nucleus of the stria terminalis (BNST) is involved in anxiety, food intake, and goal directed behaviors and may thus be an important modulator of compulsive behavior. *In vivo* electrophysiology stimulation activity in the BNST indicate that rats who develop compulsive drinking had higher neuronal firing rates of BNST neurons compared to controls and rats. The aim of the current research was to investigate the excitatory and inhibitory neurophysiological properties in the ovBNST underlying SIP. Rats were food restricted during the 21 days of SIP training, only having a 1 hour access to food daily. During SIP training rats were individually placed in an operant conditioning. Food pellets were delivered every minute for a total of 120 minutes in the food magazine and water bottles were weighed before and after each session. To be considered a compulsive drinker, rats must consume ≥15 ml of water for a minimum of 3 consecutive days during the session. At the end of 21 days of training, the rats were divided into two groups: SIP (compulsive drinkers) and SIP-RES (non-compulsive drinkers). At the end of training, rats were either continued to be food

restricted overnight or given ad libitum food. The rats were euthanized and their brains harvested so that *in vitro* whole cell patch-clamp electrophysiology in the ovBNST can be conducted. Glutamatergic and GABAergic synaptic signalling were investigated through AMPA/NMDA ratios and low frequency stimulation respectively. There were no differences in AMPA/NMDA ratios across all groups. There were no differences observed in GABA plasticity between the non-refeed rats in the SIP and SIP-RES conditions, however there were significant differences in the refeed conditions such that SIP rat neurons exhibited a long-term depression in contrast to the long-term potentiation observed in the SIP-RES rats. These findings indicate that an impaired GABA plasticity in the ovBNST may be a biomarker for the development of schedule-induced polydipsia.

Title: Cell type differences in light-evoked GABAergic synaptic transmission in basal forebrain neurons from VGAT-ChR2-eYFP optogenetic mice

Authors: *K. S. MONTGOMERY[1], D. W. DUBOIS[2], D. A. MURCHISON[2], A. S. FINCHER[2], A. H. MAHNKE[2], U. H. WINZER-SERHAN[2], U. H. WINZER-SERHAN[2], W. H. GRIFFITH[2];
[1]Neurosci. & Exptl. Therapeut., [2]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: We have previously shown that GABAergic synaptic transmission in the rat basal forebrain (BF) is altered with age and cognitive status (Griffith et al., J.Neurophysiol., 111:273-286, 2014). Here we examine the network connectivity of GABAergic synaptic transmission within the BF using light-evoked synaptic currents in identified neurons from VGAT-ChR2 (H134R)-eYFP BAC optogenetic mice. Our long term goals are to examine the anatomical and functional expression of channelrhodopsin-2 (ChR2) over the lifespan and to determine the properties of inhibitory synaptic transmission across a backdrop of aging and cognitive decline.

Present experiments utilize mice of either sex (1-4 mo), while future experiments will utilize mice from our aging colonies. We are using whole-cell patch clamp electrophysiology and LED light-evoked excitation (470 nm) in brain slices and a "reduced synaptic preparation," consisting of acutely dissociated neurons where synaptic boutons remain attached, for direct measurements of synaptic release. Postsynaptic neurons were identified as GABAergic or cholinergic by biocytin filling and immunohistochemistry, or by single cell RT-PCR. Postsynaptic functional expression of ChR2 was determined in GABAergic neurons by generating input/output curves for light-evoked ChR2 inward currents (1-200 mA, with 100 mA=1.76 mW/mm^2). With synaptic currents blocked, cells displayed a sigmoidal curve with amplitude dependent on ChR2 expression. With intact synaptic transmission, brief light pulses (2-5 ms) evoked synchronous IPSCs in the majority of GABAergic neurons (8/10). Whereas in 12 of 17 non-GABAergic neurons (cholinergic or others), asynchronous synaptic release was observed. Paired-pulse (PP) stimulation resulted in PP depression (n=6). During prolonged light stimulation (5-10 s), GABAergic neurons displayed a small 10% increase in mean IPSC frequency (n=5). In contrast, non-GABAergic neurons showed a substantial increase in mean IPSC frequency during light stimulation (1400%, n=8). These results highlight the cell type specific differences in the local BF inhibitory network. In order to explore these differences further, experiments are underway using confocal microscopy to stimulate synaptic boutons. These parameters will be examined across aging. Ultimately, a better understanding of excitatory and inhibitory synaptic mechanisms in young and aged animals is a necessary first step in elucidating the cellular mechanisms susceptible to change as a function of age, cognitive status and/or drug treatment.

Title: Insulin modulates GABAA-mediated tonic currents in the prefrontal cortex

Authors: *S. L. HERNANDEZ[1], S. TRUJEQUE-RAMOS[2], S. MIHAILESCU[2];
[2]Fisiologia, [1]Facultad de Med., Mexico, Mexico

Abstract: Extrasynaptic GABA receptors are high-affinity GABAA receptors located away from the synaptic sites and activated by ambient GABA concentrations. They are responsible for the tonic GABAA-mediated inhibition that regulates the excitability of cells and neural networks. These tonic GABAA receptor-mediated currents are found in different brain areas showing cell type-specific differences in magnitude and pharmacology. It has been suggested that GABAA extrasynaptic receptors are probably the most important sites of action of diverse drugs like benzodiazepines and general anesthetics, since they are activated by very low GABA concentrations and their activation causes tonic inhibition. Recent studies, have shown that insulin regulates the expression of extrasynaptic GABAA receptors in the hippocampus, causing permanent changes in the neuronal circuits. This effect could explain the alterations of cognitive processes associated to changes in insulin signaling previously reported. Another structure that possess insulin receptors and is involved in cognitive functions is the prefrontal cortex. In this work, we used patch clamp recordings in brain slices to examine the effect of insulin on the tonic GABAA receptor-mediated currents in the prefrontal cortex (layers 5-6). We found that insulin (10-500 nM) increased the tonic current recorded from pyramidal cells. Our data suggests that insulin increases the trafficking of extrasynaptic GABAA receptors to the membrane and that these receptors contain alpha-5 and delta subunits. Also, our results demonstrate that this effect of insulin decreases the excitability of pyramidal neurons.

Title: Inhibitory co-transmission with glutamate in hippocampal primary neurons

Authors: *C. A. BURLESON, H.-J. SHU, S. MENNERICK;
Dept of Psychiatry, Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Chemical transmission is more complex than previously realized. Several examples of cells utilizing multiple classical neurotransmitters have now been discovered, including glutamate and γ-amino butyrate (GABA) co-transmission. In hippocampus, co-transmission of glutamate and GABA has been controversial. Here, we provide direct evidence of inhibitory co-transmission in glutamatergic hippocampal pyramidal neurons. Utilizing cultured single neuron microislands, we confirmed that in addition to relatively large AMPA receptor-mediated autaptic currents, a subset of glutamatergic neurons exhibit a much smaller $GABA_A$ receptor ($GABA_AR$) mediated current only detectable in the presence of AMPA and NMDA receptor antagonists. We show that this "occult" inhibitory postsynaptic current (IPSC) is abolished by tetrodotoxin (TTX), and is dependent on extracellular Ca^{2+}, suggesting the transmitter responsible is released from axon terminals and is packaged into vesicles. The occult IPSCs were potentiated by several $GABA_AR$ positive allosteric modulators, including the endogenous neurosteroid allopregnanolone (272 ± 67% of control), and were abolished by the $GABA_AR$ antagonist gabazine. While GABA is the most appealing candidate neurostransmitter, occult IPSCs had significantly faster decay kinetics compared to bona fide IPSCs in GABAergic interneurons. Loading GABA into presynaptic vesicles through endocytosis in neurons with an occult current produced IPSCs with decay kinetics slower than endogenous occult currents (272 ± 24% of control). However, incubation in 10-20 μM GABA for 1-2 hours potentiated occult IPSCs (250 ± 81% of control) without changing the decay kinetics. Bona fide IPSCs were not significantly altered by GABA incubation. These contradictory effects of different GABA loading protocols on occult IPSCs could be explained by the expression of different $GABA_ARs$ at occult synapses and glutamatergic synapses; GABA loading through endocytosis does not discriminate between terminals and may activate $GABA_ARs$ distinct from those present in occult IPSC synapses. Despite the ambiguity in responsible co-transmitter, we demonstrate that single glutamatergic hippocampal primary neurons can also transmit inhibitory signals through $GABA_ARs$ that are modifiable by endogenous neuromodulators.

Title: Nicotine reduces inhibitory synaptic currents in mouse layer 5 prefrontal cortex

Authors: *R. D. CUEVAS OLGUIN[1], E. ESQUIVEL-RENDÓN[2], O. IBAÑEZ-SANDOVAL[3], H. ARIAS[4], M. ATZORI[2];

Abstract: Nicotine use alters numerous brain functions including working memory. Synaptic transmission in the infragranular layers controls the output from the prefrontal cortex, a critical area for executive function and working memory. We investigated the effects of nicotine on synaptic transmission of the output layers of the medial prefrontal cortex (mPFC) of C57BL/6 mice in a brain slice preparation, using whole-cell patch-clamp recording. Synaptic currents were evoked onto visual identified neurons in layer 5 by electrical stimulation of local afferents in a brain slice preparation. We found that bath applications of nicotine (0.3 microM) induce a reversible decrease of mixed excitatory and inhibitory synaptic currents. In order to determine whether inhibitory (vs. excitatory) synaptic currents were affected by nicotine, we repeated a similar experiment in the presence of the blockers of the α-amino-3-hydroxyl-5-methyl-4-isoxazol-propionate receptors (AMPAR) 6,7-dinitroquinoxaline-2,3-dione (DNQX, 10 microM), and of the N-methyl-D aspartate receptors (NMDAR) kynurenic acid (2 mM). Similar to the previous experiment, bath-applied nicotine markedly reduced the amplitude of gamma amino butyric acid type A receptors (GABAAR) mediated currents, by approximately 50%.

Title: Changes in inhibitory synaptic transmission in glutaric acidemia type I

Authors: *M. E. CALCAGNOTTO[1], L. MEIER[1], M. VENDRAMIN PASQUETTI[1], B. JUNGES[1], M. GANZELLA[1], S. LOUREIRO[1], A. UMPIERREZ AMARAL[1], D. M. KOELLER[2], S. I. GOODMAN[3], M. WOONTNER[3], M. WAJNER[1], D. GOMES DE SOUZA[1]; [1]Biochem., UFRGS, Porto Alegre, Brazil; [2]Pediatrics, Oregon Hlth. and Sci. Univ., Portland, OR; [3]Pediatrics, Univ. of Colorado Denver, Aurora, CO

Abstract: Glutaric academia type I (GAI) is an inherited glutaryl-CoA dehydrogenase (GCDH) deficiency characterized by progressive dystonia, neurological deficit, macrocephaly and recurrent seizures. An increased level of organic acids in the cerebral cortex and striatum in GAI seems to inhibit glutamic acid decarboxylase (GAD) activity that may lead to decreased GABA levels in the brain parenchyma. This decreased inhibition could contribute to seizure activity. In this work, we used an animal model of GAI, the GCDH knockout mice under lysine overload diet ($Gcdh^{-/-}$-Lys), to evaluate the cortical GABAergic synaptic transmission using biochemical and electrophysiological approaches. All animal procedures were performed according the local Ethics Commission (CEUA/HCPA approval #140270-120472). *Neurochemical parameters:* Cortical synaptosomes were used to evaluate GABA release by HPLC and GAD immunocontent by Western blot. GAD activity was determined by HPLC with specific GAD inhibitor. Electrophysiology: Spontaneous and miniatures inhibitory postsynaptic currents (sIPSC and mIPSC) were recorded in layer V cortical pyramidal neurons from brain slices of $Gcdh^{-/-}$-Lys mice using visualized IR-DIC whole cell voltage patch-clamp technique (h.p = 0mV). To isolate GABA currents, slices were perfused with nACSF containing CNQX/APV, and TTX (for mIPSC). The same biochemical and electrophysiological experiments were performed in age-matched (P30-P45) $Gcdh^{-/-}$ mice under normal diet ($Gcdh^{-/-}$-nd), and $Gcdh^{+/+}$ mice under either normal or lysine overload diet (controls). Our results show that GABA release before and after depolarization was low in $Gcdh^{-/-}$-nd (n=8) but lower $Gcdh^{-/-}$-Lys mice (n=11) when compared with controls (n=11) ($p<0.05$). This significant reduction in GABA release was associated with a decreased in cortical GAD immunocontent and activity from $Gcdh^{-/-}$-Lys (n=7, 13) when compared with $Gcdh^{-/-}$-nd mice (n=8, 14) and controls (n=15, 18) ($p<0.05$). Moreover, cortical pyramidal cells from $Gcdh^{-/-}$-Lys mice exhibited decrease in sIPSC frequency (2.4 ± 0.4Hz, n=5) when compare to $Gcdh^{-/-}$-nd mice (5.4 ± 0.9Hz, n=5) and controls (5.5 ± 0.9HZ, n=5), ($p<0.05$). Frequency of mIPSC onto cortical pyramidal cells from $Gcdh^{-/-}$-Lys mice was also decreased (1.4 ± 0.1Hz, n=6) when compare to $Gcdh^{-/-}$-nd mice (4.6 ± 0.4Hz, n=6) and controls (4.1 ± 0.1HZ, n=6), ($p<0.05$). No difference was found in sIPSC and mIPSC amplitude, decay time constant or rise time. Our data suggest a reduction in cortical inhibition in $Gcdh^{-/-}$-Lys mice probable caused by GAD dysfunction with consequent decrease in GABA levels that may contribute to the epileptogenesis in GAI.

Title: 5-HT6 receptor ligands modulate seizure thresholds and inhibitory synaptic transmission in the dentate gyrus

Authors: *G. J. REMIGIO[1], G. W. SAUNDERS[2], P. J. WEST[3,2];
[2]Anticonvulsant Drug Develop. Program, [3]Dept. of Pharmacol. & Toxicology, [1]Univ. of Utah, Salt Lake City, UT

Abstract: 5-HT6 receptor antagonists exhibit procognitive, and possibly anticonvulsant, effects. However, their effects on memory in animal models of Alzheimer's disease (AD), and in multiple acute seizure tests, are lacking. Moreover, how 5-HT6 receptor antagonists produce their procognitive and anticonvulsant effects remains unclear. Thus, we hypothesized that 5-HT6 receptor activation enhances inhibitory neurotransmission in the DG, and that 5-HT6 receptor antagonists improve DG-dependent memory in a transgenic model of AD while having paradoxically anticonvulsant activity in naïve mice. To test the acute anticonvulsant effects of 5-HT6 antagonists, drug-induced changes in minimal clonic seizure thresholds were assessed in naïve mice. To test the effects of 5-HT6 receptor activation on neurotransmission, coronal brain slices containing dorsal hippocampus were prepared from naïve rats. Field potential recordings and patch-clamp electrophysiology were used to test the effects of a 5-HT6 receptor agonist WAY-208466 (1μM) on baseline field excitatory postsynaptic potentials (fEPSPs), as well as evoked and spontaneous inhibitory postsynaptic currents (eIPSCs, sIPSCs). To assess spatial memory in a transgenic model of AD, male J20 mice and their non-transgenic littermates were injected with the 5-HT6 receptor antagonist SB-399885 or methyl cellulose and tested in the

metric task, which relies on spatial memory. Drug effects were compared with the Fisher exact test, Student's t-test, or ANOVA. SB-399885 (10mg/kg, 30 min, i.p.) was proconvulsant in C57Bl6 mice but had no effect in CF1 mice. Another antagonist, SB-271046 (10mg/kg, 30 min, i.p.), had no effect on seizures in either species. Additionally, the 5-HT6 receptor agonist WAY-208466 significantly decreased the amplitude of fEPSPs in the DG in brain slices from naïve rats. WAY-208466 also increased the amplitude of eIPSC onto DG granule cells. Finally, preliminary data suggest that SB-399885 (10mg/kg, 30 min, i.p.) reverses spatial memory impairments in J20 mice; further testing is underway. In conclusion, the 5-HT6 receptor antagonist SB-399885 exhibited proconvulsant effects in the minimal clonic seizure test in C57BL6 mice. The 5-HT6 receptor agonist WAY-208466 attenuated the amplitude of fEPSPs and increased the amplitude of eIPSCs onto DG GCs. Additionally, preliminary data suggests that SB-399885 may reverse memory impairments in a transgenic model of AD. Together, these results suggest that 5-HT6 receptor antagonists, which are in clinical trials in AD, have complex effects on synaptic transmission in the DG and may affect seizure liability and cognition.

Title: Ultrastructure of basket cell-to-granule cell synapses in a rat model of temporal lobe epilepsy

Authors: *P. BUCKMASTER, K. THIND, R. YAMAWAKI;
Dept Comparative Med., Stanford Univ., Stanford, CA

Abstract: Reduced inhibition of hippocampal granule cells might contribute to the generation of seizures in temporal lobe epilepsy, so it is important to identify underlying mechanisms. Abnormally low frequencies of miniature inhibitory postsynaptic currents in granule cells are a common finding in different rat models of temporal lobe epilepsy. Previously, recordings of monosynaptically coupled neurons revealed impaired transmission at basket cell-to-granule cell synapses in epileptic rats, which was hypothesized to be attributable to fewer docked vesicles. To test this hypothesis, in the present study randomly selected axo-somatic symmetric synapses

were evaluated in the granule cell layer of control and epileptic rats 2-6 months after pilocarpine-induced status epilepticus (4 rats/group). Synaptic boutons (10/rat) were reconstructed 3-dimensionally from serial 35-nm-thick sections. Electron micrographs were shot at 36,000X and printed at a final magnification of 90,000X so that docked vesicles could be identified by their contact with the presynaptic membrane. Boutons were reconstructed from an average of 39 ultrathin sections (range 17-82 sections/bouton). Preliminary results suggest the following average control values: 0.4 μm^3 bouton volume, 21% bouton volume as mitochondria, 1.5 synapses/bouton, 0.12 μm^2 synapse area, 1000 vesicles/bouton, 12 docked vesicles/bouton, and 63 vesicles within 50 nm of a synapse. Values from epileptic rats that were significantly different from controls include twice as many vesicles/bouton (2042, p=0.007, t test), 2.4-times more docked vesicles/bouton (29, p=0.04), and 1.8-times more vesicles within 50 nm of a synapse (115, p=0.048). These findings reveal more, not fewer, docked vesicles in epileptic rats, suggesting that in epileptic animals basket cell-to-granule cell synaptic transmission might be dysfunctional at a step following vesicle docking, such as vesicle priming or vesicle fusion.

Title: Oxytocinergic modulation and plasticity in cortical and subcortical circuits

Authors: *J. SCHIAVO, R. FROEMKE;
New York Univ., New York, NY

Abstract: The neuropeptide oxytocin regulates a variety of social behaviors ranging from sociosexual to parental behavior (Insel and Young, 2001; Dulac et al., 2014; Nakajima et al., 2014). Recently, it was shown that oxytocin administration in the left auditory cortex enables

pup retrieval, a behavior characteristic of maternal females, in virgin female mice by modulating cortical responses to pup calls (Marlin et al., 2015). Oxytocin rapidly reduced inhibitory post-synaptic currents (IPSCs) *in vitro* and reduced call-evoked IPSCs *in vivo* in the left auditory cortex while gradually enhancing excitatory post-synaptic currents (EPSCs) and temporal precision of spiking. This provided evidence that oxytocin may disinhibit cortical circuits in a similar manner to acetylcholine to increase the salience of social stimuli. In the present study, we aim to further understand the role of oxytocin in cortical disinhibition and subsequent induction of long-term plasticity. Oxytocin binds to a single isoform of a G-protein coupled receptor (Gimpl & Fahrenholz, 2001), but it still remains unknown what type of neurons express this receptor and the response properties of these populations following oxytocin receptor activation. Using *in vitro* whole-cell recordings, we examined the disinhibitory effect of oxytocin in brain regions containing a high density of oxytocin receptor labeling, such as the piriform cortex and paraventricular nucleus, to determine if there are general principles by which oxytocin modulates diverse neural circuits. In addition, this study examined the ability of oxytocin to induce a form of long term potentiation in the auditory cortex by measuring the effects of oxytocin on evoked spike probability and the ratio of excitation to inhibition (E:I ratio). We confirmed the finding that oxytocin induces a rapid reduction in IPSC peak amplitude in layer 5 pyramidal neurons of the auditory cortex following bath application of oxytocin and endogenous activation of oxytocin release via optogenetic stimulation of PVN terminals. Subsequently, E:I ratio increases and is maintained for an extended period of time following cessation of endogenous and exogenous stimulation. Similar effects in the PVN and piriform cortex were observed. In addition, we found that oxytocin results in an increase in evoked spike probability and an increase in EPSP slope during oxytocin receptor activation (via both optogenetic stimulation and bath application) and is maintained for 6-10 minutes following cessation. Our study provides a potential mechanism by which oxytocin may induce long-term neural plasticity in the brain.

Title: Developmental change in the modulation by oxytocin of synaptic transmission in rat spinal substantia gelatinosa neurons

Authors: *C.-Y. JIANG, T. FUJITA, L. ZHU, C. WANG, T. YU, R. HIRAO, E. KUMAMOTO;
Fac. Med. Saga Univ., Saga, Japan

Abstract: Although there is much evidence indicating that a posterior pituitary hormone oxytocin is involved in antinociception in the spinal dorsal horn, this action has not yet been examined thoroughly. We previously reported that bath-applied oxytocin produces an inward current at a holding potential of -70 mV without a change in glutamatergic spontaneous excitatory transmission while enhancing GABAergic and glycinergic spontaneous inhibitory transmission in adult (6-8 weeks old) male rat spinal lamina II (substantia gelatinosa; SG) neurons. The SG neurons play a pivotal role in regulating nociceptive transmission from the periphery. These oxytocin responses were mimicked by an oxytocin-receptor agonist TGOT and inhibited by its antagonist. The inward current was resistant to a voltage-gated Na^+-channel blocker tetrodotoxin, Ca^{2+}-free and non-NMDA receptor antagonist; the inhibitory transmission enhancements were depressed by tetrodotoxin. In spinal superficial dorsal horn neurons of young (2-4 weeks old) male rats, on the other hand, it has been reported that TGOT increases the spontaneous release of L-glutamate on GABAergic interneurons, resulting in spontaneous GABA release enhancement. Glycinergic spontaneous inhibitory transmission was unaffected by TGOT. In order to reveal a detail of the developmental change in oxytocin actions in the spinal dorsal horn, the present study examined the effect of oxytocin (0.5 μM) on synaptic transmission in SG neurons of young (< 3 weeks old) rat spinal cord slices by using the conventional blind whole-cell patch-clamp technique. Moreover, we addressed whether there is a difference between male and female rats in synaptic modulation by oxytocin. Superfusing oxytocin increased the frequency of spontaneous excitatory postsynaptic current recorded from young male rat SG neurons, as reported previously. On the other hand, oxytocin enhanced not only GABAergic but also glycinergic spontaneous inhibitory transmission in young as well as adult rat SG neurons. With respect to a change in holding currents at -70 mV, oxytocin produced not only inward but also outward currents. Female adult and young SG neurons exhibited inward current and glutamatergic spontaneous excitatory transmission enhancement, respectively. These results indicate that synaptic modulation by oxytocin in SG neurons alters with development in a similar manner in both male and female rats and that not only inhibitory transmission enhancement but also membrane hyperpolarization produced by oxytocin may contribute to its antinociceptive effect in young rats.

Title: Regulation of Arc protein by SUMOylation during LTP in the adult dentate gyrus *in vivo*

Authors: *S. S. PATIL, R. R. NAIR, C. BRAMAHAM;
Neurosicence, Inst. of biomedicine, Bergen, Norway

Abstract: Arc protein is posited as a master regulator of long-term synaptic plasticity in the mammalian brain. The requirement for Arc synthesis in both long-term potentiation (LTP) and long-term depression (LTD) implies functional versatility of Arc protein. Biochemically, Arc is flexible modular protein with many binding partners. Post-translational conjugation by SUMO (small ubiquitin protein-like modifier) is important for regulation of protein-protein interactions in cells. Arc is SUMOylated *in vitro* but the role of endogenous Arc SUMOylation is largely unknown. Here, we examined Arc SUMOylation following LTP induction by brief bursts of high-frequency stimulation applied to medial perforant input to the dentate gyrus of adult anesthetized rats. Sustained Arc synthesis over a period of hours is required to stabilize this LTP. Using co-immunoprecipitation assays performed in dentate gyrus lysate, we obtained evidence for rapid SUMO1-ylation of newly synthesized Arc during the maintenance phase of LTP. SUMOylated Arc was highly enriched in the synaptoneurosomal fraction relative to whole lysate. The results demonstrate rapid SUMOylation of newly synthesized Arc during LTP *in vivo*.

Title: A potential role for postsynaptic synaptotagmins in LTP

Authors: *D. WU, T. BACAJ, W. MORISHITA, D. GOSWAMI, R. MALENKA, T. SÜDHOF; Stanford Univ., Stanford, CA

Abstract: Experience-dependent synaptic plasticity in the mammalian brain underlies fundamental neurological processes such as learning and memory. One prominent form of synaptic plasticity is NMDA receptor-dependent long-term potentiation (LTP), which occurs when Ca2+ influx into the postsynaptic spine following NMDA receptor activation triggers a series of downstream events, eventually leading to exocytosis of AMPA receptor-containing vesicles and insertion of AMPA receptors into the postsynaptic plasma membrane. The molecular mechanisms of vesicle fusion has been studied in detail at the presynaptic active zone. The core machinery of membrane fusion are the SNARE proteins: syntaxin, synaptobrevin/VAMP, and SNAP. Synaptic vesicle fusion, which is dependent on Ca2+ entry into the presynaptic terminal, additionally requires the action of Ca2+-sensing proteins, synaptotagmins, in conjunction with the cofactor complexin. Thus far, SNARE proteins and complexin have also been identified as obligatory molecular components of AMPA receptor exocytosis postsynaptically. However, a putative Ca2+ sensor for AMPAR exocytosis has yet to be found. Here we explore the potential role of synaptotagmins in Schaffer collateral-CA1 LTP in the hippocampus. Since identifying a synaptotagmin function for postsynaptic vesicular traffic would provide significant progress in our understanding of LTP but represents a difficult challenge, a multipronged approach will be necessary to achieve this. Given the requirement of complexins for LTP, we feel that it is likely that a synaptotagmin will be involved.

Title: LPS-induced neuroinflammation alters synaptic plasticity at the mossy fiber - CA3 synapse

Authors: ***A. M. AVILA**, G. HERRERA-LOPEZ, C. TECUATL-TOLAMA, E. GALVAN; Cinvestav, Cuidad de Mexico, Mexico

Abstract: Lipopolysaccharide (LPS) is a pathogen-associated molecular pattern derived from gram-negative bacteria and recognized by Toll-like receptor (TLR)-4, the principal stimulator of inflammation. In the hippocampal formation, activation of TLR4 is implicated in the process of neuro-inflammation that also causes an unbalance of the synaptic transmission. Here we sought to determine synaptic alterations at the mossy fibers - CA3 synapses following endotoxemia induced with systemic injection of LPS (1 mg/kg). Extracellular recordings were performed in the stratum lucidum of area CA3b of hippocampal slices 24 hours after the immunological challenge. Although baseline synaptic transmission was unaffected in the LPS-treated animals, paired pulse facilitation showed a decrease (control MF PPF = 2.4 ± 0.3; LPS-treated animal 1.3 ± 0.1; ISI = 60 ms.). When high frequency stimulation (100 Hz, repeated 3 times at 10 sec interval) was applied at the mossy fibers, induction of MF LTP was blunted in the LPS-treated animals (MF PTP = 450 ± 70%; MF fEPSP at 90 min post HFS 230 ± 10%; in the LPS-treated animals PTP = 230 ± 30%; MF fEPSP at 90 min post HFS 111% ± 20%). The MF-origin of the evoked responses was systematically verified in all the experiments by applying DCG-IV 1 μM (MF fEPSP depression >95%). Immunohistochemistry experiments revealed a reduction in the expression of GAD67 on the LPS-treated slices. Lastly, western blots obtained from microdissected regions of stratum lucidum showed a stronger phosphorylation of Akt, TrkB and CamKII in LPS-treated mice. Our results suggest that the acute and systemic LPS exposure alters different signaling pathways involved in the induction of MF LTP.

Title: Roles of 5-HT3a receptors in hippocampal long-term synaptic plasticity and learning

Authors: *Y. HUANG, Y. YU, D. CAO, R. HAO, Y. QI, H. XU, X. LIU, N. LU;
Fudan Univ., Shanghai, China

Abstract: The 5-hydroxytryptamine type-3a receptor (5-HT3aR) as the only ligand-gated ion channel in serotonin receptor family is known to involve in schizophrenia and anxiety. However, the physiological role and mechanisms of 5-HT3aRs in synaptic plasticity and memory remains unclear. Here we show that in the CA1 region of mouse hippocampus, pharmacological blockade (ondansetron, 25nM) or genetic deletion of 5-HT3aR specifically impaired theta burst or 200Hz high frequency stimulation induced long-term potentiation (LTP) and LFS induced long-term depression (LTD), while basal glutamatergic neurotransmission and the metabotropic glutamate receptor dependent LTD were not affected by 5-HT3aR perturbations. In addition, 5-HT3aRs disruption inhibited AMPA receptors (AMPARs) internalization, without altering basal surface levels of AMPARs. However, the deletion of 5-HT3aRs did not lead to loss of synapses and structural alteration of dendritic spines. The concentrations of 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) in the hippocampus were not affected by the deletion of 5-HT3aRs either. Moreover, behavioral studies showed that 5-HT3aR knock-out mice exhibited impaired hippocampus-dependent learning and memory in morris water maze, but had no change in motor coordination and balance. These results reveal a direct role of 5-HT3aR in hippocampal synaptic plasticity and spatial memory, which may have implications for understanding the cognitive impairments in psychiatric disorders.

Title: Chronic nicotine reverses memory impairments and attenuates hippocampal-medial prefrontal cortex synaptic plasticity dysfunctions in the streptozotocin model of sporadic Alzheimer's disease

Authors: *I. M. ESTEVES[1], C. LOPES-AGUIAR[2], R. N. RUGGIERO[2], M. T. ROSSIGNOLI[2], L. KANDRATAVICIUS[2], R. N. ROMCY-PEREIRA[3], J. P. LEITE[2];

[1]FMRP/USP Ribeirão Preto, Ribeirão Preto, Brazil; [2]Dept. of Neurosciences and Behavior, FMRP/USP-University of São Paulo, Ribeirão Preto, Brazil; [3]Brain Inst., Federal Univ. of Rio Grande do Norte (UFRN), Natal, Brazil

Abstract: Severe abnormalities in brain glucose/energy metabolism and insulin signaling have been documented to play an important role in early stage of AD (esAD) pathology. An intracerebroventricular administration (icv) of subdiabetogenic doses of streptozotocin (STZ) in rats can induce an insulin-resistant brain state associated to cholinergic dysfunctions, memory impairments and formation of beta amyloid plaques, which make it a suitable experimental model of esAD. Usually, studies with this model have focused upon measure cognitive impairment and molecular dysfunction. there are no studies that have addressed the effect that chronic treatment of nicotine has on CA1-mPFC synaptic plasticity in STZ rat model. Here, Wistar rats received bilateral microinjection of STZ and were submitted to 20 days of nicotine treatment. After 2 days of withdraw, the subjects were submitted to open field and object recognition tests to access locomotion and evaluate recognition memory, respectively. On day 28, rodents were anesthetized with urethane for electrophysiological tests. Twisted bipolar electrode was used to stimulate CA1 with paired-pulse protocol (two monophasic square-pulses; duration=0.2ms; inter-stimulus interval=80ms; rate=0.05Hz) and basal field post-synaptic potentials (fPSP1) and facilitated responses (fPSP2) were recorded by a monopolar electrode in the mPFC. After 30min of baseline, high frequency stimulation (HFS) was applied to induce long-term potentiation (LTP) and additional four hours of electrophysiological recordings was performed. HFS consisted of two series of 10 trains (50 pulses at 250Hz every 10s), 10min apart. Our results indicate that STZ produced a significant decrease in the induction and maintenance of LTP. The nicotine treatment attenuates the STZ-induced LTP dysfunction in the CA1-mPFC pathway. Besides, PPF shows that the shortterm synaptic plasticity, impaired by STZ injection, was reversed by nicotine treatment. These results are associated to behavioral data, since animals just injected with STZ also displayed significant deficits in novel object recognition task and general decrease exploratory behavior in the open field test. Nicotine treatment reversed the deficits in recognition memory but maintained the reduced exploratory behavior. We suggest that the brain cholinergic system, which plays an important role in cognition function and LTP, is affected inSTZ injected animals and a chronic treatment with nicotine can attenuate the STZ-induced synaptic plasticity and behavioral dysfunctions.

Title: The developmental onset age of hippocampal LTP in mice

Authors: G. CAO, *K. M. HARRIS;
Ctr. for Learning and Memory, Univ. of Texas, Austin, TX

Abstract: Long-term potentiation (LTP), a persistent strengthening of synapses after patterned stimulation, has been widely accepted as a cellular substrate of learning and memory. In order to test whether dendritic spines are required for enduring LTP that lasts more than 3 hours, we investigated the developmental onset age for enduring LTP in rats and mice. Previously, we found that the onset age for enduring LTP induced by theta-burst stimulation (TBS) is postnatal day (P)12 in hippocampal area CA1 of Long Evans rats (Cao and Harris, 2012). In addition, we found that prior to P20, test pulses delivered even as slowly as 1 pulse/5 minutes produced synaptic depression. The test pulse-induced depression is frequency-dependent, as higher frequency test pulses induced more depression than lower frequencies. Before the LTP onset age, TBS reversed the test pulse-induced depression in P8-11, but no potentiation was produced above the original naïve response. An additional episode of TBS delivered 30-120 minutes after the first TBS produced enduring LTP at P10-11, but not at younger ages in rats (P8-9). We further examined the developmental profiles of test pulse-induced depression and onset age for enduring LTP in C57BL/6 mice. Similar to rats, test pulses induced synaptic depression in P9-12 mice. However, the test pulse-induced depression in mice was dependent on the number instead of the frequency of test pulses. After ~ 120 pulses at 0.2Hz or 0.5Hz, the test pulse-induced depression reached a plateau. Similar to rats, test pulse-induced depression attenuated as the animals became older, and disappeared in young adult mice (P60). Unlike in rats, the developmental onset for enduring LTP in mice was much later, as enduring LTP could not be reliably induced with TBS until ~P35. Furthermore, unlike in rats, an additional episode of TBS did not produce enduring LTP in mice right before the onset age (P28-33). Preliminary results from our lab showed P12 to be the onset age of mature dendritic spines in rat hippocampal area CA1, suggesting they are necessary for enduring LTP. Prior work shows dendritic spines occur

by P15 (Nikonenko et al., 2013) in C57BL/6 mouse hippocampal area CA1, suggesting dendritic spines may be necessary, but not sufficient for enduring LTP in the mouse.

Title: Metaplastic regulation of CA1 Schaffer collateral pathway plasticity by Hebbian mGluR1a-mediated plasticity at excitatory synapses onto somatostatin-expressing interneurons

Authors: *O. C. VASUTA[1], J. ARTINIAN[2], I. LAPLANTE[2], S. HEBERT-SEROPIAN[2], K. ELAYOUBI[2], J.-C. LACAILLE[2];
[1]Groupe de Recherche sur le Système Nerveux Central and Dept. of Neuroscienc, Univ. De Montréal,, Montreal, QC, Canada; [2]Groupe de Recherche sur le Système Nerveux Central and Dept. of Neurosciences, Fac. of Medic, Univ. de Montréal, Montreal, QC, Canada

Abstract: Cortical GABAergic interneurons represent a highly diverse neuronal type that regulates and synchronizes neural network activity. In particular, interneurons in the hippocampal CA1 oriens/alveus (O/A-INs) area provide feedback dendritic inhibition to local pyramidal cells and express somatostatin (SOM). Under relevant afferent stimulation patterns, they undergo long-term potentiation (LTP) of their excitatory synaptic inputs through multiple induction and expression mechanisms. However, the cell type specificity of these different forms of LTP and their specific contribution to the dynamic regulation of the CA1 network remain unclear. Here we addressed these questions using cell-specific transgenic mice lines expressing enhanced yellow fluorescent protein (EYFP) under the control of SOM (SOM-Cre-EYFP) or parvalbumin (PV-Cre-EYFP). Immunofluorescence detection in hippocampal CA1 revealed that SOM-expressing interneuron (SOM-INs) somas were located mostly in stratum oriens and

alveus whereas PV-expressing interneuron (PV-INs) somas were mainly found in and around the pyramidal cell layer, indicating a specific labeling of mostly non-overlapping interneuron populations. We then used whole cell recordings from SOM- and PV-INs and found that pairing theta burst stimulation (TBS) delivered at the O/A border with postsynaptic depolarization induced a Hebbian LTP in SOM-INs. Bath application of 40 μM LY367385 prevented the induction of LTP, revealing a metabotropic glutamate receptor type 1a (mGluR1a) dependence. However, TBS failed to induce LTP in PV-INs, showing that mGluR1a-mediated Hebbian LTP occurs in a cell type-specific fashion in CA1 interneurons. We then used field recordings from transgenic mice expressing archaerhodopsin Arch3 selectively in SOM-INs to assess the role of LTP in SOM-INs in the regulation of synaptic plasticity in the Schaffer collateral pathway of pyramidal cells. We found that high frequency stimulation (HFS) applied in the stratum radiatum elicited LTP in pyramidal cells, and this LTP was up-regulated by a prior conditioning TBS in O/A. LTP facilitation was prevented by light-induced hyperpolarization of SOM-INs during TBS, or by application of the mGluR1a antagonist LY36785, indicating a necessity for mGluR1a and SOM-INs activation. These results uncover that mGluR1a-dependent LTP in SOM-INs performs an activity-dependent metaplastic control on hippocampal CA1 microcircuits in a cell-specific fashion. Our findings provide new insights on the contribution of interneuron synaptic plasticity in the regulation of the hippocampal network activity and mnemonic processes.

Title: Contribution of M-currents to the effects of neurotrophins on long-term potentiation in sympathetic ganglion

Authors: *F. R. CIFUENTES[1], E. R. ARIAS[2], M. A. MORALES[2];
[2]Cell Biol. & Physiol., [1]Inst. de Investigaciones Biomedicas, UNAM, Mexico DF, Mexico

Abstract: We have previously shown that brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) acting on TrkB or p75NTR, and TrkA receptors, differentially regulate

long-term potentiation (gLTP) in rat sympathetic ganglion. Additionally, we have characterized the presence of neurotrophin receptors TrkA, TrkB and p75NTR in intact superior cervical ganglia of adult Wistar rats. Taking into account that BDNF and NGF acting on Trk receptors produce opposite effects on neuronal excitability, depending on the activation or inhibition of KCNQ/M-currents, either in sympathetic or in central neurons. Herein, we asked if this current could play a role as a possible effector in the previously reported effects of BDNF and NGF on gLTP. To characterize the possible involvement of KCNQ channels in the phenomenon of gLTP, we applied a train of stimulus (40 Hz, 3 sec.) in the cervical sympathetic trunk, and recorded the post-synaptic responses (compound action potentials) in presence of XE991 (a Kv7/KCNQ channel antagonist). We found that blockade of KCNQ channels with XE991 [1 μM] mimicked the effect of NGF on gLTP, producing a significant reduction in gLTP, LTP decay time and LTP extent decreased ~55% of control values ($p< 0.04$). Furthermore, we found that the stimulatory effect of BDNF on gLTP was abolished by co-application of XE991, thus in this experimental condition both LTP decay time and LTP extent were similar to control gLTP values ($p >0.1$). Our data suggest that the M-currents are involved in the modulation of the gLTP by neurotrophins in sympathetic ganglion, however, the contribution of other effectors to this modulation can not be excluded. Therefore, we propose that BDNF acting on TrkB or p75NTR receptors would activate Kv7 channels, whereas NGF through TrkA activation would inhibit these channels, resulting in a differential regulation of synaptic plasticity in sympathetic ganglionic synapses.

Title: Functional requirement of hippocampal CaMKII in long-term potentiation

Authors: ***M. J. KOOL**, N. Z. BORGESIUS, M. R. HOJJATI, G. M. VAN WOERDEN, Y. ELGERSMA;
Dept. of Neurosci., Erasmus MC, Rotterdam, Netherlands

Abstract: With a highly unique network architecture the CA3 region of the hippocampus functions critically in higher-order spatial processing. Specifically, long-term potentiation (LTP) of both Schaffer-collateral (CA3-CA1) and associational/commissural (CA3-CA3) pathways has been widely proposed as candidate mechanisms for hippocampus-dependent spatial processing. At the molecular level, the calcium/calmodulin-dependent protein kinase II (CaMKII) is among the most abundant proteins in the hippocampus, and widely demonstrated to function critically in regulating the postsynaptic induction of LTP at the hippocampal Schaffer-collateral CA3-CA1 synapse. However, little is known about the independent presynaptic and postsynaptic requirements for CaMKII during LTP at the CA3 synapses. Therefore, we investigated the requirement of α- and βCaMKII for Schaffer collateral (CA3-CA1) and associational/commissural (CA3-CA3) LTP using a selective genetic ablation of *Camk2a* and *Camk2b* in the CA3 neurons of the hippocampus. In contrast to the conventional *Camk2a* and *Camk2b* global knockout mice, CA3-*Camk2a* and CA3-*Camk2b* KO mice showed robust and stable CA3-CA1 LTP. In addition, LTP of the associational/commissural pathway between CA3 neurons was intact in both CA3-*Camk2a* and CA3-*Camk2b* KO mice. However, when both α- and βCaMKII were deleted simultaneously in CA3 neurons, LTP at the associational/commissural pathway between CA3 neurons was impaired while LTP at the Schaffer-collateral pathway was unaffected. Taken together, αCaMKII and βCaMKII appear to function in a highly specific manner for regulating LTP within hippocampal circuits and the highly homologous α and β isoforms of CaMKII are redundant as shown by impaired LTP at the CA3-CA3 synapse only upon deletion of both isoforms simultaneously.

Abstract: Cyclin Y (CCNY) is a member of the cyclin protein family, known to regulate cell division in proliferating cells. Interestingly, CCNY is expressed in neurons that do not undergo cell division. Here, we report that CCNY negatively regulates long-term potentiation (LTP) of synaptic strength through inhibition of AMPA receptor trafficking. CCNY is enriched in postsynaptic fractions from rat forebrain and is localized adjacent to postsynaptic sites in dendritic spines. We found that during LTP-inducing stimulation, CCNY inhibits AMPA receptor exocytosis in dendritic spines. Furthermore, knockdown of CCNY enhances LTP in hippocampal slices. Taken together, our findings demonstrate that CCNY inhibits plasticity-induced AMPA receptor delivery to synapses and thereby blocks LTP, identifying a novel function for CCNY in post-mitotic cells.

Title: Optical Imaging of miniature synaptic Ca^{2+}-transients to monitor synaptic potentiation

Authors: *G. NADEAU, T. WIESNER, M. LEMIEUX, P. DE KONINCK;
Inst. Universitaire En Santé Mentale Du Québec, Québec, QC, Canada

Abstract: Classical measurements of synaptic plasticity have involved electrophysiological methods which provide high sensitivity for detecting small changes in synaptic strength. However, this approach does not provide much information about the location of the synapses that undergo plastic changes. Because synaptic plasticity can be synapse-specific, having the ability to monitor changes in synaptic strength at individual synapses is important in order to enable simultaneously monitoring of local molecular mechanisms associated with the plasticity. New fluorescent tools developed in the last decades allow to directly visualize synaptic activity, signaling, and remodeling at individual synapses. In this study, we are using optical imaging of a genetically-encoded Ca2+ sensor, GCaMP6f, to record miniature synaptic Ca2+-transients (MSCTs) in cultured rat hippocampal neurons. For these experiments, we perform video-microscopy on neurons perfused with external solution lacking Mg2+ and containing Tetrodotoxin (TTX). We have observed highly localized and transient increases of intracellular Ca2+ in dendritic compartments and spines. To test whether these MSCTs can be potentiated, we have measured them before and after a 5 min stimulation known to induce plasticity in cultured neurons (0Mg2+/Glycine, cLTP). A lasting increase in the frequency and amplitude of MSCTs, for at least an hour, arose from this stimulation protocol. We are thus investigating the molecular mechanisms of this plasticity. The MSCTs are mostly mediated by NMDA receptors, since they are almost totally blocked by the selective antagonist to the receptor, AP5. Moreover, addition of AP5 only during the cLTP stimulation blocks the MSCT plasticity. It thus appears that both the MSCTs and their plasticity are NMDA receptor-dependent. Interestingly, the MSCTs and their plasticity are not blocked by the AMPA receptor antagonists NBQX, pointing to possible changes in NMDA receptor content, post-synaptic Ca2+ signaling, or neurotransmitter release. To test theses hypotheses, we are combining Ca2+ imaging with electrophysiological measurements of NMDA receptor currents, imaging of other pre and postsynaptic components, and various pharmacological treatments to identify the molecular mechanisms responsible for the MSCT plasticity. Our approach might provide new knowledge on the diversity of molecular processes that support synaptic potentiation.

Title: TARP γ8 and GSG1L function in GluA1 and GluA4 subunit-specific synaptic delivery of AMPARs in classical conditioning

Authors: *J. KEIFER, N. K. TIWARI, Z. ZHENG;
Neurosci Grp, Univ. South Dakota Sch. Med., Vermillion, SD

Abstract: Appropriately timed interactions of AMPARs with specific scaffolding proteins and kinases determines their subcellular localization and function. Previously, we developed a two-stage model of AMPAR trafficking for classical conditioning in an *in vitro* model of eyeblink classical conditioning in which GluA1-containing AMPAR synaptic delivery occurs early in conditioning followed later by synthesis and delivery of GluA4 subunits that replace GluA1 and supports conditioning (Zheng et al., J Neurophysiol. 108: 101, 2012). We also showed that GluA1 and GluA4 subunits with associated kinases are sequentially delivered to synapses by the common scaffolding protein SAP97 (Zheng & Keifer, JBC 289: 10540, 2014). Since there is a common interacting protein, how subunit-specific synaptic delivery of native AMPARs is achieved during this form of learning was the goal of this study. Using an isolated preparation of the pons from turtles, an auditory nerve conditioned stimulus (CS) paired with a trigeminal nerve unconditioned stimulus (US) generates a neural discharge characteristic of a fictive "blink" learned response in the abducens nerve. High-resolution proteomics analysis has revealed a diversity of AMPAR-associated proteins but the function of these auxiliary proteins in AMPAR trafficking is just beginning to be revealed. Using Western blots, we found that protein levels for TARP γ8 and GSG1L are regulated in conditioning with GSG1L being significantly increased during conditioning. Co-immunoprecipitation (co-IP) studies show that TARP γ8 interacts with GluA1 early in conditioning after 15 min and one pairing session (C1 or 25 min) but this is undetectable after two pairing sessions (C2 or 80 min). In contrast, GluA4 interacts with GSG1L later in conditioning reaching its peak at C2. Unexpectedly, GluA4 also interacts with TARP γ8 at C2. Therefore, TARP γ8 appears to chaperone GluA1-containing AMPARs during early stages of conditioning while GSG1L chaperones later arriving GluA4 subunits. Based on these findings, we hypothesize that subunit-specific trafficking of AMPARs during conditioning is achieved through not only the timing of their interactions with auxiliary proteins but also by selected protein assemblies marking each subunit.

Abstract: Long-term potentiation (LTP) and depression (LTD) are the mechanisms by which neurons modulate their inherent synaptic plasticity and support the storage and recovery of memories in the mammalian brain. The ability to potentiate a synapse declines significantly in neurodegenerative disorders and is related to deficiencies in LTP. In addition to deficiencies in synaptic plasticity, degenerating neurons display acute and chronic mitochondrial dysfunction, suggesting that dysregulated mitochondria play a hand in synaptic dysfunction in addition to their known role in apoptotic death. Our previous work shows that the anti-apoptotic protein Bcl-xL not only prevents somatic cell death, but it also potentiates long-term synaptic responses. Here, we show that Bcl-xL is responsible for dramatic changes of ATP levels at synapse-specific sites in hippocampal neurons. Using fluorescent imaging of an ATP-FRET construct in living cells, we find that LTP induction in control neurons causes a short decrease in ATP levels followed by a persistent long term increase in ATP production. This suggests that after high frequency or intense synaptic stimulation, neurons may become metabolically more efficient; oxygen consumption rates during LTP are now being performed to confirm or refute the proposed change in efficiency. The long-term increase in ATP levels of LTP-stimulated synapses is blocked when we inhibit Bcl-xL. Bcl-xL inhibition also prevents a long-term increase in surface glutamate receptor insertion. In hippocampal slice recordings, inhibition of Bcl-xL greatly impairs early stage LTP and prevents late stage LTP. We suggest that long term changes

in mitochondrial efficiency brought on by activity-dependent translocation of Bcl-xL to mitochondria are required for LTP. Our studies shed light on the role of changes in mitochondrial metabolic efficiency in the acute induction and long term maintenance of learning and memory storage. If such mitochondrial changes fail to occur, synaptic dysfunction associated with neurodegeneration may ensue. Our study places mitochondria and Bcl-xL at the center of synaptic metabolism and synaptic plasticity.

Title: The epigenetic modulation of aberrant synaptic plasticity in Tuberous Sclerosis Complex

Authors: *T. BASU, K. J. O'RIORDAN, W. POTTER, N. KHAN, A. ROOPRA;
Dept. of Neurosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Tuberous Sclerosis Complex (TSC) is an autosomal dominant, multi-system spectrum disorder that affects approximately 1 in 6,000 people. The disorder is characterized by the formation of benign growths that most commonly develop in the brain, kidney, heart, lungs, eyes and skin (Curatolo, P., 2002; Crino, P.B. 2006 & 2013). Patients with TSC display developmental delays, cognitive defects, autism and epilepsy. This disease is caused by a loss of function mutation in either the TSC1 or TSC2 genes, resulting in the disinhibition of mammalian Target of Rapamycin (mTOR), a key regulator of cell survival and proliferation, protein synthesis and metabolism (van Slegtenhorst, 1997; Tang, S.J., 2002; Hou, L., 2004). Current treatment involves the modulation of hyperactive mTOR activity, but chronic mTOR inhibition may have adverse effects on patient health (Schindler, C.E., 2014; Carracedo, A., 2008; Kusne, Y., 2014). There is a need to find a TSC specific treatment that does not present with harmful side effects. Acute hippocampal slices from adult male heterozygous TSC2 mutant mice

(TSC2+/-) display abnormal long term potentiation (LTP) and long term depression (LTD). A 1X theta burst stimulation elicits short term potentiation in adult male wild type (WT) hippocampi, but this paradigm induces LTP in hippocampi obtained from gender and age matched TSC2+/- mice. In contrast to adult male WT mice, the TSC2+/- mice display a rapamycin insensitive form of metabotropic glutamate receptor (mGluR) mediated LTD. We have shown that adult TSC2+/- mice have increased Erk1/2 signaling that bypasses the canonical mTOR signaling cascade to drive atypical synaptic plasticity (Potter, W., 2013). A whole genome expression analysis of cortical samples resected from human TSC and non-TSC patients suggests that chromatin alterations around key genes encoding components of the Mek/Erk signaling pathway appear to drive the plasticity alteration upon loss of a TSC allele. We find that the modification of chromatin structure through the pharmacological inhibition of histone deacetylation and demethylation attenuates Erk1/2 signaling and restores normal LTP and LTD in adult male TSC2+/- mice. This study is the first to describe epigenetic mechanisms influencing synaptic plasticity alterations in TSC and can unearth a novel therapeutic option for TSC patients.

Title: Modulation of synaptic plasticity and associativity in hippocampal CA2 pyramidal neurons by substance P

Authors: ***A. DASGUPTA**[1], M. HAKIM[2], S. SREEDHARAN[3];
[1]PHYSIOLOGY, NATIONAL UNIVERSITY OF SINGAPORE, Singapore; [3]Physiol., [2]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Mammalian brain is well known for its ‘plasticity’ i.e. the ability of an experience-generated neural activity to alter the strength and efficacy of its neural circuits and has been

widely studied in hippocampal CA1 area. Recently area CA2 is in the limelight as this small region which is largely ignored over many years, is now found to play a pivotal role in the formation of social and emotional memory. This area is innervated by supramammilary (SuM) axonal fibres that are abundant in Substance P (SP), a tachykinin neuropeptide which acts both as a neurotransmitter and neuromodulator of pain in nervous system. These innervations could possibly modulate the excitability of hippocampal neurons and its theta rhythm. Although, SP is released from the presynaptic vesicles of the SuM axons which terminate into the hippocampal CA2 subfield, not much information is available regarding the role of it in CA2 and is yet to be investigated. In this study, we found that, bath application of substance P leads to protein synthesis and N-methyl-D-aspartate (NMDA) receptor dependent plasticity and late associativity such as synaptic tagging and capture only in CA2 but not in CA1 where SP is mostly known to have a memory enhancing effect. Overall, our study indicates that SP can be a critical regulator of plasticity and associativity in CA2 pyramidal neurons and could be a potential mediator for emotional and social memory formation. Furthermore, substance P which coexists with most of the cholinergic neurons, could facilitate the cholinergic transmission in area CA2, rich in both nicotinic and muscarinic cholinergic innervations and play an important role in memory formation. Thus, it can not be ruled out that SP could be a major player in the formation and enhancement of social memory in CA2 and can be an important target for Alzheimer's and other forms of dementia that lead to cognitive decline due to defects in cholinergic transmission.

Title: Long-term potentiation of excitatory synaptic transmission from ipsilateral pericentral canal to motoneurons of neonatal rat spinal cord slices

Authors: H. SONG[1], L. ZHANG[1], W. QIN[1], Y.-H. SHI[1], *M.-Y. WANG[2];
[1]Cell Electrophysiol Lab., [2]Wannan Med. Col., Wuhu, Anhui 241002, China

Abstract: Our previous study has shown that the excitatory postsynaptic potentials (EPSPs) evoked by ipsilateral pericentral canal (iPCC) stimulation, iPCC-EPSPs, recorded in

motoneurons (MNs) may be mediated by heterogeneous transmitter-receptor mechanisms in addition to glutamate-NMDA and AMPA receptors. To explore the possible synaptic plasticity of excitatory synaptic transmission from ipsilateral pericentral canal, a presumed site of "central pattern generator" of motor control, to MNs in spinal cord, the intracellular recordings were performed in MNs of spinal cord slices isolated from neonatal rats (8-14 days old) and iPCC-EPSPs were mainly induced by electrical stimulation of iPCC. After the tetanic electrical stimulation (100 Hz, 50 pulses/train, duration 0.3~1.0 ms, 6 trains, main interval 10 seconds, 20~100 V) on iPCC in 24 MNs with iPCC-EPSPs, the amplitude of iPCC-EPSPs was enhanced to more than 120% of the baseline and the enlargement lasted longer than 30 min in 8 MNs, which could be referred to as long-term potentiation (LTP, iPCC-LTP). During iPCC-LTP, the area under curve and maximum left slope of iPCC-EPSPs were increased comparable to amplitude change of iPCC-EPSPs, while with the varied duration and latency changes compared to control. The analyses of apparent receptor kinetics (Acta Physiol Sin 2014, 66: 129) of iPCC-EPSPs during iPCC-LTP showed that apparent association rate constant (K1) increased, apparent dissociation rate constant (K2) and apparent equilibrium dissociation constant (KT) decreased only in 4 MNs. It was also observed that the induction of iPCC-LTP was facilitated by pretreatment of bicuculline (30 μM) and strychnine (1 μM), but the maintenance of iPCC-LTP was nullified by APV (30 μM) and DNQX (1 μM). However, the estimated parameters of cell electrophysiological properties of recorded MNs were not significantly altered. These preliminary data show that the MN's activities are modulated by the iPCC intraspinal activation, and the possible long-term synaptic plasticity is induced in those pathways, which may be considered as a candidate of neural basis underlying the "central pattern generator" of motor control.

Title: Septal facilitation of normal and LTP electrophysiological responses in the rat perforant path

Authors: S. E. HAMILTON, N. A. UPRIGHT, M. K. MOSES-HAMPTON, *J. J. RAMIREZ; Psychology Dept and Neurosci. Program, Davidson Col., Davidson, NC

Abstract: Long-term potentiation (LTP) has been investigated as a potential neurobiological mechanism of learning and memory. The hippocampal formation, particularly the dentate gyrus (DG), has been frequently utilized as a model structure for the exploration of memory. The perforant path (PP) arises in the entorhinal cortex and terminates in the ipsilateral dentate gyrus (DG). The septal input to the DG, termed the septodentate pathway (SD), projects from the medial septum/nucleus of the diagonal band of Broca and has important implications in hippocampal theta rhythm. The extent of the septum's role in hippocampal function has not been fully determined, particularly in regards to LTP in the PP response. Using an extracellular electrophysiological approach, we explored whether preliminary stimulation of the SD alters normal and LTP responses in the DG induced by PP stimulation. In male, Sprague-Dawley rats, stimulating electrodes were placed in the medial septum and medial EC unilaterally. Population spikes (popspikes) were recorded in the ipsilateral DG. An input-output curve of the PP response was determined prior to tetany, and recordings were made at the following intensities: 25%, 50%, 90%, and 100%. A heterosynaptic paired-pulse electrophysiological paradigm was performed to determine whether stimulation of the SD prior to PP stimulation could influence the PP response before and after tetany. The paired-pulse paradigm involved stimulation of the SD pathway (conditioning pulse) 60 ms prior to stimulation of the PP (test pulse). Paired-pulse recordings were made pre- and post-application of tetany (i.e. high frequency stimulation). Recordings continued for up to 120 minutes post-tetany. LTP was defined as an increase in popspike amplitude of at least 30% over the pre-tetany response. There was a significant interaction between the effects of stimulation intensity, tetany, and pairing on popspike amplitude in both the successful LTP and unsuccessful LTP groups. At 50% intensity in the successful LTP group there was a significant increase in popspike amplitude following tetany; however, in the unsuccessful LTP group at 50% there was a significant decrease following tetany. The cause of the depression in the unsuccessful LTP group is unclear. In both the successful and unsuccessful LTP groups examined at the 50% intensity, there were statistically significant increases in popspike amplitude due to heterosynaptic paired-pulse stimulation of the SD and PP both pre- and post-tetany. Therefore, the SD has the ability to facilitate the response of the normal and potentiated PP.

Title: Running exercise mitigates the negative consequences of stress on hippocampal LTP

Authors: *R. M. MILLER, D. MARRIOT, J. TROTTER, R. DE ROQUE, D. LYMAN, T. HAMMOND, J. WELCH, A. FIELD, B. WALKER, N. CHRISTENSEN, D. HAYNIE, M. LEWIS, Z. BADURA, J. G. EDWARDS;
Physiol. and Developmental Biol., Brigham Young Univ., Provo, UT

Abstract: Cognition and memory in the mammalian brain can be impacted by behavior. For example, exercise and stress have positive and negative impacts respectively. While stress is anxiogenic and detrimental to neural function such as memory, exercise in contrast is anxiolytic and improves neural function. In the hippocampus, learning and memory are mediated at the cellular level by synaptic plasticity, known as long-term potentiation (LTP). It is now well established that stress decreases LTP and performance on behavioral memory assays while exercise enhances LTP and memory performance. What is not known however is whether exercise in association with stress can mitigate the negative impact stress has on memory. Therefore, we examined the effect exercise had on stress in the hippocampus using physiological, molecular, and behavioral techniques on C57BL/6 male mice. We conducted experiments on four groups: exercise without stress, sedentary without stress (control), exercise with stress, and sedentary with stress. Field electrophysiology confirmed that stress alone significantly ($P < 0.05$) reduced CA1 hippocampal LTP compared to sedentary controls and that exercise alone significantly increased LTP compared to controls. Importantly, we noted that mice that were exercised prior to stress exhibited LTP that was significantly greater than LTP for mice undergoing stress alone, but were not significantly different from control sedentary mice. Next, we used quantitative PCR to determine the differences in hippocampal mRNA expression of certain proteins that are part of the exercise and stress neural pathways. Specific proteins that were analyzed between the four groups were those in the brain-derived neurotrophic factor (BDNF) pathway, which others have demonstrated are upregulated in exercised mice, and glucocorticoid and mineralocorticoid receptors, which are upregulated in stressed mice. The CA1 region of the hippocampus is associated with spatial memory, so we used the radial arm maze to detect differences in spatial memory between the groups. Differences in time to complete a trial,

total distance traveled, and reference and working memory errors between the groups of mice were examined. Collectively, these results are significant as they suggest exercise as a suitable treatment to counteract the negative effects stress has on the hippocampus, specifically memory. By better understanding the neural pathways that are involved during exercise and stress, we can better understand how to use exercise to prevent everyday stresses from having a detrimental effect on cognition.

Title: Exercise training prevents hypobaric hypoxia induced neurodegeneration and synaptic strength

Authors: ***V. JAIN**[1,3], S. B. SINGH[2], K. RAVI[3];
[1]Defence Inst. of Physiol. and Allied Sci., Ghaziabad, India; [2]Defence Inst. of Physiol. and Allied Sci., delhi, India; [3]Physiol., Vallabhbhai Patel Chest Inst., Delhi, India

Abstract: Hypobaric hypoxia (HH) is an psychophysiological stress transpires at high altitude condition. Animal studies showed that chronic exposure to HH leads to neurodegeneration in hippocampus and other brain regions. Exercise training on other hand is known to enhance hippocampus associated neuronal function. In present study, we investigated the effects of treadmill running (exercise) on the memory task, neuronal morphology and level of synaptic proteins. 3 months old Sprague dawley rats were exposed to simulated HH condition in an Animal Decompression Chamber at an altitude of 25000 feet for 7 days. Four weeks of treadmill exercise training was given to rats before HH exposure as an intervention. Results showed that 4 weeks of treadmill running significantly increased the hippocampus learning memory and dendritic arbor of the CA1 neurons. Exercise Training also restored the level of synaptic proteins in hippocampus. Furthermore, exercise training reduced the neurodegeneration and prevents morphological alteration of neurons in CA1 region of hippocampus. In addition to above parameters neurogenesis was also studied in different groups and it was found that chronic HH

exposure significantly reduced hippocampal neurogenesis which further ameliorated in groups provided with exercise training before exposure. Taken together above findings, it can be concluded that providing exercise training can be proved beneficial against HH like stress conditions. Physical exercise may serve as a means to prevent deteriorating effect of stress which involves oxidative stress in their pathophysiology.

Title: Exercise reverses deficits in hippocampal long term potentiation in mice selected for high voluntary wheel running

Authors: *K. D. PARFITT[1], A. R. K. AYABE[2], K. GUAN[2], Z. THOMPSON[3], T. GARLAND, Jr.[3];
[1]Dept of Neurosci., Claremont, CA; [2]Neurosci., Pomona Col., Claremont, CA; [3]Biol., UC Riverside, Riverside, CA

Abstract: Motivation and exercise can influence synaptic plasticity, neurogenesis, BDNF release, and learning and memory, though the mechanisms have yet to be elucidated. In these studies, mice selected for high voluntary running (High Runner or HR mice) were used to examine effects of genotype and running on hippocampal long term potentiation (LTP), a cellular model for learning and memory. House mice (Mus domesticus) were bred for voluntary wheel-running for 73 generations; these mice now typically run 18 km/day, or twice as far as standard house mice and up to 2.7 times farther than control (C) mice. Slices prepared from HR mice that did not have access to running wheels showed significantly reduced LTP in area CA1 in response to a single theta burst stimulus, as compared to C mice, who showed robust potentiation in response to this mild stimulus (137.6 ± 7.6% vs 166.3 ± 7.2% of baseline, respectively). These LTP deficits in the HR mice were rescued, however, when the mice had access to exercise wheels (the magnitude of LTP was 221.3 ± 13.2% of baseline). The magnitude of LTP in slices from C mice with running wheels (single theta burst), and non-exercising HR and C mice in response to a stronger theta burst protocol (three theta bursts) was not significantly

different. Thus, it appears that the threshold for inducing LTP in the HR mice is altered, but the same levels of LTP can be achieved with sufficient stimulation. Input-output curves for HR and C mice, with or without access to running wheels, were not significantly different, indicating that neither the selection for voluntary wheel running nor running itself influences basal synaptic transmission. Similarly, there were no significant differences in paired-pulse facilitation between HR and C mice, suggesting that presynaptic differences between the mouse strains are unlikely. The LTP deficits observed in the HR mice, together with their hyperactive behavior, suggest that these mice may serve as a suitable animal model of attention deficit hyperactivity disorder (ADHD). Our observation that the LTP deficits could be reversed with exercise, and previous work showing that the intensity of running in HR mice can be reduced with ADHD medications such as methylphenidate, are consistent with this idea.

Title: Neuroepigenetic blockade of HDAC3i reverses Alzheimer's pathology in murine hippocampus

Authors: *K. MUTHUKUMARAPPAN[1], T. BEHNISH[3], S. SAJIKUMAR[2];
[2]Physiol., [1]Natl. Univ. of Singapore, Singapore, Singapore; [3]Inst. of Brain Sci., Shanghai, China

Abstract: Histone deacetylase 3 (HDAC3) is known to play a critical negative role in learning and memory including in various pathological conditions. Considerable evidences support that sporadic AD and its progression are associated with epigenetic components leading to memory loss, cognitive decline, dementia and death. In this study, the attenuation of LTP by amyloid-β oligomer has been observed in the acute rat hippocampal slices which underlie the early synaptic dysfunction in AD. Modulation of chromatin structure through histone acetylation by HDAC inhibitors is reported for enhancing memory and synaptic plasticity, including its cellular correlate LTP. Thus, in this study, we retrieved amyloid-β oligomer induced LTP deficit by a

selective HDAC3i called RGFP 966, indicating a potential selective therapeutic candidate to treat cognitive decline in AD.

Title: Heterosynaptic LTP of NMDA receptor-mediated transmission in the dentate gyrus

Authors: *A. RODENAS-RUANO, P. E. CASTILLO;
Neurosci., Albert Einstein Col. Med., Bronx, NY

Abstract: In the hippocampus, the dentate gyrus is a key relay station that controls the transfer of information from the entorhinal cortex to the hippocampus proper (CA1-CA4). This process requires that dentate granule cells (DGC) receive and integrate synaptic inputs from entorhinal cortex via perforant path, and proximal associational inputs from hilar mossy cells (MCs). Therefore, dentate gyrus function relies heavily on the integrative properties of DGC dendrites. N-methyl-D-aspartate receptors (NMDARs) can contribute to the integrative properties of neurons, and growing evidence indicates that NMDARs are dynamically regulated and subject to activity dependent long term plasticity. While early studies have shown that excitatory inputs onto DGCs can undergo LTP and LTD of NMDAR-mediated transmission, no study has addressed the input-specificity of this plasticity along dendritic axis. Here, we used an electrophysiological approach via whole-cell and field recordings in acute rat hippocampal slices, to investigate NMDAR plasticity rules at the three main excitatory inputs along the dendritic axis of DGCs [Lateral Perforant path (LPP)-DGC, Medial Perforant path (MPP)-DGC, and MC-DGC]. Using both high frequency stimulation and burst-timing dependent induction protocols, we found that only MPP-DGC, but not LPP-DGC nor MC-DGC, express NMDAR-LTP. We tested the possibility that NMDAR plasticity at MPP synapses could influence synaptic strength distally (LPP) and proximally (MC) along the dendrite, and found that induction of

NMDAR-LTP at MPP-DGC synapses heterosynaptically potentiates distal LPP-DGC NMDAR plasticity, but not MC-DGC synapses. We are currently investigating the molecular basis underlying input-specificity and heterosynaptic plasticity at DGC synapses. Our findings highlight a potentially key mechanism by which the dentate gyrus processes information that may contribute to hippocampal-dependent memory formation.

Title: Characterization of *Aplysia* KIBRA, a conserved PKM stabilizing protein

Authors: *L. FERGUSON[1], S. CHEN[2], J. PARK[2], D. GLANZMAN[2], W. SOSSIN[1];
[1]Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada; [2]Dept. of Integrative Biol. and Physiol., Univ. of California, Los Angeles, CA

Abstract: The persistent activity of PKMs has been proposed to be critical to the maintenance of transcription-dependent memory, despite the fact that no links have been established between transcription and PKM maintenance. We have been studying the role of PKM in maintaining memories in the sensory-motor reflex of the marine mollusk, *Aplysia* californica. In this system, PKM formation is mediated through transcription-independent calpain-mediated cleavage of PKC into PKM. Indeed, PKMs are important in the maintenance of several forms of transcription-independent forms of intermediate facilitation (Sutton et al, 2004; Bougie et al, 2012). Nevertheless, similar to vertebrates, inhibitors of PKM can erase transcription-dependent forms of memory and synaptic facilitation, suggesting that transcriptional events can prolong the lifetime of PKM activity (Cai et al, 2011). We are examining the kidney-brain adaptor protein, KIBRA, as the link between transcription and PKM. KIBRA has been implicated in human episodic memory and has recently been shown to stabilize PKMs in rodent hippocampus and to be required for long-term memory formation (Vogt-Eisele et al., 2014). We have cloned the *Aplysia* orthologue of KIBRA and found that the PKM-binding domain (as well as the WW and C2 domains) is highly conserved between mammalian and *Aplysia* KIBRA. Quantitative PCR experiments demonstrate that KIBRA mRNA is upregulated during learning. Using an antibody

specific to *Aplysia* KIBRA, we will assess the upregulation of the KIBRA protein following 5HT-induced facilitation of *Aplysia* sensory/motor neurons. Finally, we will present results on whether KIBRA can stabilize PKMs formed during intermediate facilitation and if this depends on the PKM binding domain of KIBRA. Confirming KIBRA's role as the stabilizer of PKM responsible for prolonging the kinase's half-life in the potentiated synapse will broaden our understanding of the relationship between transcription-independent PKM formation and the corresponding transcription-dependent synaptic facilitation the kinase is responsible for maintaining.

Title: Hippocampal stratum oriens interneurons express endocannabinoid biosynthetic enzymes and undergo anandamide-dependent potentiation

Authors: *L. N. FRIEND[1], R. WILLIAMSON[2], C. MERRILL[3], S. NEWTON[2], M. CHRISTENSEN[2], J. EDWARDS[2];
[1]Brigham Young Univ., Provo, UT; [2]BYU, Provo, UT; [3]UC Irvine, Irvine, CA

Abstract: The hippocampus is thought to mediate learning and memory by altering synaptic strength within its circuitry. In many cases, synaptic plasticity can be induced by signaling molecules such as lipid-based endocannabinoids like anandamide. Endocannabinoids modulate synaptic plasticity among hippocampal pyramidal cells and stratum radiatum interneurons; however, the role of endocannabinoids in mediating synaptic plasticity among interneurons in the stratum oriens is still unclear. These interneurons are feedforward inhibitory cells that have unique synaptic plasticity compared to those in the radiatum as they exhibit presynaptic LTP, rather than LTD. This plasticity is TRPV1 and nNOS independent. We therefore examined

whether oriens interneurons can produce endocannabinoids and whether these might be involved in presynaptic LTP. Using patch-clamp electrodes to extract single cells, we analyzed the expression of endocannabinoid biosynthetic enzyme mRNA using real-time, reverse transcription PCR. The cellular expression of several calcium-binding proteins and neuropeptides were used to determine interneuron subtype. We also analyzed cellular expression of several endocannabinoid biosynthetic enzymes, including N-acyl phosphatidylethanolamine phospholipase D (NAPE-PLD), diacylglycerol lipase alpha (DAGLα), and 12-lipoxygenase, as well as type 1 metabotropic glutamate receptors (mGluRs). Preliminary data suggests that stratum oriens interneurons express mRNA for both biosynthetic enzymes and the type I mGluRs necessary for their production. We identified interneurons that coexpress mRNA for somatostatin and DAGLα as well as parvalbumin positive basket cells coexpressing NAPE-PLD, suggesting that both basket cells and O-LM cells, or another somatostatin-positive interneuron subtype, possess the enzymes necessary to produce various endocannabinoids. To test the role of endocannabinoids in synaptic plasticity, we performed whole-cell experiments and measured glutamate currents in the presence of a fatty acid amide hydrolase inhibitor (URB597; 1μM), which increases endogenous anandamide. Interestingly, URB597 potentiated stratum oriens interneurons in a CB1-dependent manner as it was blocked by AM-251 (2 μM). Collectively, this suggests oriens interneurons express the cellular machinery needed for endocannabinoid production, and can alter their plasticity in response to anandamide signal.

Title: Excitatory and inhibitory plasticity at an associative hippocampal circuit

Authors: ***K. R. JENSEN**, P. E. CASTILLO;
Albert Einstein Col. of Med., Bronx, NY

Abstract: The hippocampus contains two associative excitatory circuits; an auto-associative circuit formed by interconnected CA3 pyramidal neurons, and a hetero-associative circuit where

dentate granule cells (DGCs) synapse with glutamatergic hilar mossy cells (MCs) that project back to DGCs. While activity-dependent plasticity at CA3-CA3 synapses is well characterized, much less is known about synaptic plasticity in the hetero-associative circuit, in particular at the MC-DGC synapse. Given that a single MC contacts over 30,000 DGCs, plasticity at MC-DGC synapses is expected to have a profound effect on dentate gyrus output. MCs project their axons to a restricted region in the inner third of the molecular layer (IML). Interestingly, type 1 cannabinoid receptors (CB1Rs) are highly expressed on the presynaptic terminals of both MCs and hilar interneurons (INs) projecting to the IML, suggesting that endogenous cannabinoids (eCB) fine-tune proximal excitatory and inhibitory synapses. To test this possibility, and to examine activity-dependent MC-DGC plasticity, we used electrophysiology and optogenetics in acute rat hippocampal slices. While early *in-vivo* studies reported Hebbian, NMDA receptor-dependent LTP at MC-DGC synapses, we found that a pairing protocol (200 stimuli in IML, 2 Hz, Vh = 0 mV) elicited robust long term potentiation (LTP) in the presence of the NMDAR antagonist D-APV (50 μM). LTP was also elicited by selective activation of MC axons using optogenetics, making it unlikely that neuromodulatory fibers or CA3 back-projections contribute significantly to plasticity. MC-DGC LTP was associated with a significant decrease in paired-pulse ratio (PPR) and coefficient of variation (CV), strongly suggesting a presynaptic mechanism of expression. Previous work from our laboratory showed that MC-DGC synapses express endocannabinoid (eCB)-mediated short-term but not long-term depression (LTD) (Chiu & Castillo, 2008). To determine whether neighboring inhibitory inputs onto proximal DGC dendrites undergo eCB-mediated LTD (eCB-iLTD), we performed the following three manipulations: (a) theta-burst firing of DGCs; (b) transient application of the mGluR1/5 agonist DHPG (50 μM for 10 min); and (c) transient application of the CB1R agonist WIN55,212-2 (5 μM for 10 min). All three manipulations induced robust iLTD. Thus, by inducing LTD at inhibitory but not excitatory inputs, eCBs can shift the excitatory/inhibitory balance and regulate the DGC output. Activity-dependent plasticity at MC-DGC and neighboring IN-DGC synapses may play an important role in dentate gyrus-dependent memory formation.

Title: Kainate receptor activation regulates KCC2 function

Authors: *D. GARAND, M. WOODIN;
Cell and Systems Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: The potassium-chloride cotransporter 2 (KCC2) plays a critical role in inhibitory neurotransmission through its ability to maintain a low intracellular chloride level in the neuron. Surprisingly, KCC2 has also recently been found to interact with proteins involved in excitatory neurotransmission, including the kainate receptor (KAR) subunit GluK2. It is known that independent of kainate receptor activity, the physical interaction between KCC2 and GluK2 is important for KCC2 surface expression and oligomerization. However, it is unknown whether the activity of kainate receptors can directly influence KCC2 function. In this study we hypothesized that the activation of GluK2-containing kainate receptors would increase KCC2's ability to extrude chloride from the cell. We tested this hypothesis by performing slice electrophysiology experiments in the CA3 region of the hippocampus, recording E_{GABA} as a measure of KCC2 function. Activation of KARs with 1uM kainate, which activates both the canonical (ionotropic) and noncanonical (metabotropic) signalling pathways, produced a depolarization of the resting membrane potential, however this was accompanied by a significant hyperpolarization in E_{GABA}. This depolarization of resting membrane potential and hyperpolarization of E_{GABA} together produce a dramatic increase in the driving force for Cl- through the GABAA receptor, and thus an increase in GABAergic current amplitudes. Activation of KARs with 0.1uM kainate, which has been previously shown to selectively activate metabotropic signalling of KARs, produced an even larger hyperpolarization of E_{GABA}. This suggests that the two KAR signalling pathways exert different effects on KCC2. Metabotropic KAR signalling has been previously shown to decrease GABA release from interneurons, and consistent with this we found a decrease in conductance despite the hyperpolarization of E_{GABA}. Our findings demonstrate that activation of the kainate receptor is able to regulate KCC2 function, revealing a novel mechanism for excitatory: inhibitory balance.

Title: Ectopic activity of nociceptive sensory neurons in an animal model of cancer-induced pain

Authors: ***Y. ZHU**[1], E. SEIDLITZ[2], R. UNGARD[2], N. ZACAL[2], G. SINGH[2];
[2]Pathology & Mol. Med., [1]McMaster Univ., Hamilton, ON, Canada

Abstract: Background: Primary and metastatic cancers that affect bone are frequently associated with severe and intractable pain. The mechanisms underlying the development of cancer-induced pain remain unclear. The aim of this study was to determine whether ectopic activity of primary nociceptive sensory neurons contributed to peripheral sensitization and tumor-induced tactile hypersensitivity in cancer-induced pain. Methods: *In vivo* intracellular recording, immunofluorescent staining, and behavioral testing were used to investigate whether the intrinsic membrane properties and excitability of functionally-defined nociceptive dorsal root ganglion (DRG) neurons were altered in a rat model of bone cancer pain. Copenhagen rats were injected with 106 MATLyLu rat prostate cancer cells into the hind leg distal femur epiphysis to generate a bone cancer pain model. Once behavioural changes were detected using a von Frey tactile assessment, the animals were prepared for acute electrophysiological recordings of mechanically sensitive neurons in the DRG. Results: Our study showed that tumors growing in the femur produced significant tactile hypersensitivity in the ipsilateral hind paw. Furthermore, enhanced excitability of nociceptive (substance P expressing) DRG neurons was observed as a decreased threshold to activation of the peripheral receptive field, an excitatory discharge response to intracellular injection of depolarizing current into the soma, and an excitatory discharge response to electrical stimulation of the dorsal roots. Several alterations in intrinsic membrane properties were also observed in nociceptive DRG neurons, including: 1) depolarized resting membrane potential; 2) a dramatic decrease in amplitude and duration of evoked action potential; and 3) a dramatic decrease in amplitude and duration of the afterhyperpolarization. Conclusions: Our data suggest that injection of tumor cells into the distal epiphysis in rats induces an enhanced excitability of substance P-expressing DRG neurons. This enhanced excitability may be the result of alterations in intrinsic electrogenic properties of these neurons. Therefore, alterations in intrinsic membrane properties associated with the hyperexcitability of nociceptive sensory neurons appears to contribute to the peripheral sensitization and tumor-induced tactile hypersensitivity in cancer-induced pain.

Title: Alterations in neuronal function of central nucleus of amygdala in BK beta-1 or 4 knockout mice following chronic intermittent ethanol exposure

Authors: *Q. LI[1,2], C. CONTET[3], S. TREISTMAN[4], S. D. MOORE[1,2];
[1]Psychiatry, Duke Univ. Med. Ctr., Durham, NC; [2]Durham VA Med. Ctr., Durham, NC; [3]The Scripps Res. Inst., Committee on the Neurobiology of Addictive Disorde, CA; [4]Inst. of Neurobio., San Juan, Puerto Rico

Abstract: Large conductance Ca++ activated potassium (BK) channels associate with specific auxiliary subunits(encoded by four genes,β1-4) and BK channels associated with β1 and β1 subunits are expressed in central neurons. These BK channels regulate neuronal excitability and synaptic transmission. Neurons in the central nucleus of the amygdala (CeA) are involved in alcohol seeking and addiction, and BK channels are thought to be potential targets for ethanol action as presynaptic BK channels in the CeA mediate alcohol-induced GABA release. The accessory β1 and β4 subunits of BK channels are essential for modulating BK channel function and sensitivity to actions of ethanol; thus alterations in these subunits may influence the function of CeA neurons after both acute and chronic intermittent ethanol (CIE) exposure. Using genetic tools and whole-cell recordings in CeA neurons in an acute slice preparation, we have examined the membrane properties and inhibitory synaptic neurotransmission in CeA neurons from BK β1 or β4 KO and WT male mice following CIE exposure via a vapor inhalation chamber. Under whole-cell current clamp conditions, three distinct types of firing patterns (regular spiking, late spiking and low threshold firing) were recorded in neurons from these mice. No statistical differences in the resting membrane potentials and time constants between CeA neurons from WT and KO mice after CIE were observed. In CIE-mice, the mean input resistance of neurons from β4 KO mice was significantly higher than in neurons from WT mice. The threshold of action potentials determined by ramp current injection was not altered in CeA neurons lacking either β1or β4 in CIE-mice. In response to depolarizing current injections, β1 KO CeA neurons fire more spikes than WT neurons in CIE-mice but β4 KO CeA neurons appear to fire fewer spikes than WT neurons after CIE. Upon a strong depolarization, a depolarization block was also observed in some β4 KO CeA neurons from CIE-mice. Under whole-cell voltage clamp recording, both eIPSCs and sIPSCs were recorded in CeA neurons from β1 KO and WT CIE-mice. There was a significant increase in input/output curves of eIPSCs evoked by electrical stimulation in β1 KO CeA neurons of CIE-mice compared to WT CIE-mice. However, no significant differences in paired pulse ratio of eIPSCs (50 msec interval) or the mean frequency of sIPSCs of CeA neurons between β1 KO or WT CIE-mice were detected. Our current results

suggest that different BK channel accessory subunits in CeA neurons could regulate neuronal function following long-term intermittent exposure to ethanol, thus providing novel targets for pharmacotherapies aimed at reducing excessive ethanol consumption.

Title: Characterization of spines undergoing ryanodine receptor induced enhancement of activity related calcium transients

Authors: *A.-K. THEIS[1], D. SCHMITZ[1,2,3,4], F. W. JOHENNING[1];
[1]Neurowissenschaftliches Forschungszentrum, Charité - Universitätsmedizin Berlin, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci. Berlin, Berlin, Germany; [3]Cluster of Excellence ‘‘NeuroCure’’, Berlin, Germany; [4]DZNE-German Ctr. for Neurodegenerative Dis., Berlin, Germany

Abstract: Spines are dendritic protrusions that receive excitatory synaptic input from other neurons. Spines can also be depolarized by action potentials travelling back through the dendritic tree. The backpropagating action potential elicits calcium transients in dendrites and spines that are mostly mediated by voltage-sensitve calcium channels. Previously, we demonstrated that action potential firing enhances these backpropagating action potential evoked spine calcium transients, serving as a calcium memory of neuronal activity. The enhancement appeared compartmentalized to individual spines and was independent from enhancement of neighboring spines. We were able to define a calcium nanodomain created by intraspine ryanodine receptor activation mediated release of calcium from the intracellular stores. We aimed to further specify the spines that undergo the activity dependent enhancement with respect to development and dendritic localization. We performed two-photon calcium imaging on spines on proximal and distal dendritic segments of medial entorhinal cortex layer II cells. Spines located proximal as well as distally located spines did show an enhancement of the backpropagating action potential mediated calcium transient. Enhancement of spine calcium seems to be a spine specific process that is not dependent on the spines location in the dendritic tree. Rather intrinsic spine properties

determine the spine's potential for enhanced calcium signaling evoked by neuronal firing. All the results obtained so far were derived from measurements of animals in an age window were spine maturation is still ongoing and the number of spines is increasing. We therefore extended our measurements to older, more mature animals, where spines are generally considered less plastic. Significant enhancement was also observed in a more mature spine population.

Title: HCN channels dysregulation leads to increased excitability of hippocampal neurons from PrP−/− mice

Authors: ***J. FAN**, P. STEMKOWSKI, S. A. G. BLACK, I. A. SOUZA, G. W. ZAMPONI; Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: It is well established that the loss of cellular prion protein (PrP) function is involved in a variety of electrophysiological abnormalities that contribute to epileptogenesis. We have previously shown that synaptic activity in hippocampi of PrP-null mice is increased due to enhanced N-methyl-D-aspartate (NMDA) receptor function. We now examined the intrinsic firing pattern of cultured hippocampal neurons. Using whole-cell voltage-clamp and current-clamp recordings from mature primary hippocampal cultures, the effect of PrP deletion on intrinsic neuronal excitability and ion channel activity was examined. We observed that the absence of PrP profoundly affected the firing properties of hippocampal neurons in the presence of synaptic blockers, increasing the number of action potentials (APs) ($p < 0.05$), decreasing the spike threshold ($p < 0.001$) and reducing cumulative AP latencies ($p < 0.05$). Interestingly, only membrane impedance, among tested active and passive parameters, was observed to be different, which was greater in PrP-null neurons ($p < 0.05$). To determine whether Ih may serve as an underlying ionic mechanism, HCN channel activity was examined. In current clamp recordings, the amplitude of voltage sag in PrP-null neurons decreased in response to hyperpolarizing

current injection ($p < 0.05$). In voltage clamp, a series of hyperpolarizing test potentials revealed that PrP-null neurons exhibited a decrease in Ih peak current ($p < 0.05$), along with a hyperpolarizing shift in half activation voltage. In addition, we observed that the time course of Ih activation became significantly slower in PrP-null neurons over a command voltage range ($p < 0.05$). To determine whether the difference in membrane impedance resulted from a decrease in Ih activity, we assessed changes in membrane impedance following bath application of ZD7288. The membrane impedance in WT and PrP-null neurons became indistinguishable in the presence of ZD7288. Despite the upregulation of Ih, HCN1 and HCN2 protein levels remained similar and neither HCN1 nor HCN2 was found to form a complex with PrP. These data suggest that the absence of PrP causes a downregulation in the activity of HCN channels, which in turn increases membrane impedance to potentiate intrinsic excitability of hippocampal pyramidal cells.

Title: Chronic toluene exposure alters the neural activity in medial prefrontal cortex of adolescents rats

Authors: *M. ARMENTA-RESÉNDIZ, S. L. CRUZ, E. J. GALVAN;
CINVESTAV Sede Sur, México, Mexico

Abstract: Toluene is an abused solvent used mainly among adolescents for its psychoactive effects. It has been documented that chronic exposure to toluene-based products can produce severe cognitive deficit. Although there are a few studies regarding the electrophysiological effects of acute toluene exposure, little is known on the possible adaptations that result from chronic exposure in specific brain areas. This study examined the effects of intermittent chronic toluene exposure on intrinsic excitability and spontaneous synaptic activity of pyramidal neurons in medial prefrontal cortex (mPFC) of adolescent rats. Individual male Wistar rats were exposed for 30 min in a static exposure chamber to air or 8000 ppm toluene twice a day for 10 days from postnatal day 22 to 35. After completing the exposure period, rats were decapitated and layer V

pyramidal neurons were recorded from medial prefrontal cortex slices using whole-cell patch-clamp recordings. Toluene did not change the resting membrane potential, but altered other measures of intrinsic excitability; in particular, it reduced neuronal input resistance, increased the I-V curve rectification phase and decreased the rheobase current to induce action potentials. Toluene also augmented neuronal firing frequency without altering the kinetic of action potential and increased the frequency, but not the amplitude, of spontaneous excitatory postsynaptic currents (EPSCs). Taken together, our results show that repeated exposure to a behaviorally relevant concentration of toluene increases the excitability of layer V pyramidal neurons in mPFC in adolescent rats.

Title: Clarithromycin increases neuronal excitability by reducing gaba-ergic signaling

Authors: ***E. K. BICHLER**[1,2], C. C. CRON[2], P. S. GARCÍA[1,2];
[1]Res. Div., Atlanta VA Med. Ctr., Decatur, GA; [2]Dept. Anesthesiol., Emory Univ., Atlanta, GA

Abstract: Antibiotics are used in the treatment and prevention of bacterial infections but side effects such as convulsions can limit their use. The adverse effects of cephalosporin on neuron excitability has been recognized for decades, however recently we demonstrated that administration of clarithromycin improves daytime sleepiness in hypersomnic patients known to have enhanced $GABA_A$ signaling (Trotti et al., 2014). Similarly, our laboratory has previously shown that clarithromycin decreased inhibitory chloride currents in HEK 293 cells expressing recombinant human $GABA_A$ receptors (Garcia and Jenkins, 2009). In order to explore the potential application of clarithromycin as a stimulant, we performed whole-cell patch-clamp recordings in rat pyramidal cells from the CA3 region in acute hippocampal slices. We hypothesized that by reducing $GABA_A$ receptor activation clarithromycin would increase neuron excitability. In the presence of 300uM clarithromycin, rheobase current was reduced to 50 % of controls (measured as the smallest required step current injected at the soma that results in an action potential), F-I relationship (number of action potentials as a function of injected current)

was shifted to the left and the resting membrane potential was significantly more depolarized compare to controls (-55 mV vs. -65mV; $p<0.001$). Additionally, we tested the effect of clarithromycin in an *ex vivo* seizure model (high K^+ and low Mg^+ solution) by evaluating its effect on spontaneous local field potentials in stratum pyramidale of the CA3 hippocampal region. Bath application of clarithromycin enhanced burst frequency 2-fold compared to controls ($p<0.05$). Taken together, these results suggest that blocking GABA-ergic signaling by clarithromycin increases cellular excitability and cause higher susceptibility to seizure. The stimulatory properties of clarithromycin may have a positive impact on clinical applications such as emerging from anesthesia and promoting vigilance in hypersomnic patients. However, the administration of clarithromycin should be carefully considered in patients with seizure disorders.

Title: ATP depletion supresses action potential firing independently of synaptic transmission

Authors: ***S. J. LUCAS**[1], C. B. MICHEL[2], Y. SWEENEY[3], M. H. HENNIG[3], B. P. GRAHAM[2], I. D. FORSYTHE[1];
[1]Univ. of Leicester, Leicester, United Kingdom; [2]Univ. of Stirling, Stirling, United Kingdom; [3]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Information transmission requires high levels of energy to maintain ionic gradients, Ca^{2+} extrusion and vesicular recycling. There is a large metabolic cost for restoring Na^+ and K^+ gradients following action potential generation and conduction. Hence at times of high activity and in brain regions, such as the auditory pathway, with high metabolic rates, the balance between energy consumption and maintenance of neuronal function may compromise information transmission. Many studies of metabolism in brain slices have used established pharmacological protocols to inhibit ATP production, but do not differentiate between suppression of neuronal excitability and synaptic transmission. The calyx of Held/MNTB synapse in the auditory brainstem, which transmits information at high frequencies and would be

expected to require high levels of ATP, provides a model at which to study the effects of ATP depletion on neuronal excitability and transmitter release, independently and at the level of a single synaptic connection. Using whole-cell recordings from MNTB neurons, in auditory brainstem slices from P14-18 mice, we have studied the effects of ATP depletion protocols on neuronal function at the calyx of Held/MNTB synapse. Sodium azide, an inhibitor of mitochondrial function, together with 2-deoxy-D-glucose (2-DG), an inhibitor of glycolysis, are commonly used to induce a chemical hypoxia. As expected we found that depletion of ATP with perfusion of 5 mM sodium azide and 5 mM 2-DG for 8 min depolarises neurons and inhibits low frequency (0.1 Hz) synaptic transmission. This ATP depletion, however, also results in a loss of action potential firing; hence the loss of postsynaptic responses can be due to to a failure in presynaptic action potential conduction rather than a true synaptic failure of transmitter release. Removal of energy substrates from the perfusing aCSF similarly impairs firing, with some neurons appearing more vulnerable to metabolic impairment. Preceding the loss of firing, neurons show early changes in action potential threshold, which is followed by a decrease in action potential amplitude while the half-width increases. Using a mathematical model of the calyx of Held synapse coupled with metabolic pathways, the contributions of ATP depletion to impairments of neuronal function were predicted. The impairment in action potential firing following ATP depletion has important implications when attempting to study energy depletion on synaptic function: it confounds the interpretation of studies that investigate hypoxia or energy depletion using indirect measures of synaptic function, such as the network activity and field potential measurements.

Title: Neuropeptide Y modulates the spike discharge characteristics in mesencephalic trigeminal neurons

Authors: S. SEKI, *S. TANAKA, Y. ONO, T. TSUJI, M. KOGO;
1st Dept. of Oral and Maxillofacial Surgery, Osaka University, Grad. Sch. of Dent., Osaka, Japan

Abstract: Background and purpose: Neuropeptide Y (NPY) is one of neuropeptides with powerful orexigenic effect. Our recent study has demonstrated that intracerebroventricular administration of NPY induced increase of food intake in a dose-dependent manner, while feeding rate was decreased in a higher concentration (Ushimura et al., 2015). In addition to a role on the feeding behavior, NPY also has integral effects on neuronal systems related to other spontaneous behaviors such as hyperactivity, rearing, grooming. Previous studies have revealed that 1) the rat trigeminal complex, including the trigeminal motoneurons and mesencephalic trigeminal neurons (MTN), display rich immunoreactive staining for both the NPY-Y1 and -Y5 receptors (Wolak et al., 2003), 2) The intrinsic membrane properties of MTN are critical for producing rhythmical oral motor activities (Tanaka and Chandler, 2006; Tanaka et al., 2003). Therefore, in the present study, we examined the potential for NPY-induced modulation of membrane excitability in MTN underlying rhythmical jaw movements. Methods: Coronal brain-slices were prepared from Sprague-Dawley rats (P3-19) and immersed in oxygenated normal ACSF, then whole-cell configuration was obtained from MTN using patch-clamp technique. Patch-electrodes with 3-4㏁ resistance were filled with K-gluconic acid-containing normal solution. Voltage and current signals were digitized and recorded using pCLAMP acquisition software (v9.0, Molecular Devices). Liquid junction potential between bath and pipette solutions was not corrected off-line. Results and Conclusions: Bath application of NPY (0.1 μM) depolarized the membrane potential and induced inward current in MTN, which was persisted in the presence of TTX and dependent on external Na+ and Ca2+. The duration of AHP following an action potential was significantly shortened and the mean spike frequency in the repetitive firing activity was consistently increased by NPY. In addition, intrinsic bursting activities induced by maintained current injection showed decrease of burst duration and significant increase of bursting frequency after application of NPY, indicating the excitatory effects of NPY on spike discharge characteristics in MTN. Further experiments revealed an involvement of both Y1 and Y5 receptor activations in the modulatory effects of NPY.

Title: Spike amplification by the afterhyperpolarization; a possible mechanism of short term synaptic plasticity?

Authors: *N. KUCZEWSKI, N. FOURCAUD-TROCMÉ, S. GARCIA, P. DUCHAMP-VIRET;
Ctr. de Récherche en Neurosci. de Lyon, Lyon, France

Abstract: The modification of the action potential (AP) waveform is well known as affecting the quantity of neurotransmitter released at the synaptic level. Since the beginning of the 21th century, accumulating evidences showed that AP waveform and the following synaptic transmission can be affected by modifications of the neuronal resting potential (Vrest). Experimentally these modifications are obtained either, by somatic current injection or, by some peculiar form of physiological activity, such as the cortical up and down states. However, in these studies, the AP waveform changes were induced by important (several dozen of mV) and relatively long lasting modification of somatic Vrest. Moreover, as a consequence of the spatial attenuation, the synaptic effect of the somatic Vrest modifications were limited to proximal synapses. Here, in rat olfactory bulb slices, we reported that, in Mitral Cells (MCs), the small hyperpolarization generated by the post spike afterhyperpolarization (AHP) increases both the AP amplitude and duration during spontaneous firing activity. Preliminary results suggest that this amplification results from the hyperpolarization-induced recovery from inactivation of sodium and T-type Ca2+ channels and, that such an effect is partially counterbalanced by the contemporary recovery from inactivation of potassium channels. As a consequence of the AHP short duration, the spike amplification is only observed when two successive APs are generated at short time intervals (<100 ms); thus, the occurrence of the amplification phenomenon increases with the MC instantaneous firing frequency. Preliminary data suggest that the AHP-induced AP amplification is capable to increase the release of glutamate from MC dendrites, suggesting that the small variations of somatic Vrest produced by the AHP are capable to affect AP waveform in the dendritic three. This could be the achieved without spatial attenuation thanks to the AP regenerative properties that it supposed to allow the AHP propagation throughout the neuronal processes. Ongoing experiments are testing this hypothesis. Our results open the possibility that the frequency-dependent modifications of AP waveform produced by the AHP could participate in the changes of the synaptic transmission responsible of short term synaptic plasticity.

Title: Strongly enhanced activin signaling after electroconvulsive seizures impacts on granule cell excitability

Authors: F. ZHENG[1], A. S. LINK[1], *C. ALZHEIMER[2];
[1]Physiol. and Pathophysiology, [2]Univ. Erlangen-Nuremberg, Erlangen, Germany

Abstract: Activin A is a member of the transforming growth factor-beta family. In the nervous system, it was originally identified as a neurotrophic and neuroprotective factor, but recent evidence from our and other laboratories showed that activin also tunes excitatory and inhibitory neurotransmission in the brain in a fashion that impacts on cognitive functions and affective behavior. In addition to the canonical pathway, which involves activin binding to heteromeric receptor complexes and subsequent phosphorylation of the intracellular effector proteins SMAD-2/3, activin receptors might also act on other signaling systems, in particular mitogen-activated protein kinase (MAPK) signaling. In neuropsychiatry, activin A has been implicated in the regulation of mood disorders and has been suggested to serve as an endogenous antidepressant. In fact, activin signaling is targeted by the two prevailing treatment strategies in major depression, antidepressant drugs and electroconvulsive therapy (ECT), but it is still unknown how activin might produce its putative therapeutic benefits. Here we report that electroconvulsive seizures (ECS, 25 mA for 0.5 s at 50 Hz), the mouse analog of ECT in humans, strongly induced activin signaling in the granule cell layer of the dentate gyrus of mouse hippocampus. Whole-cell and field potential recordings from brain slices, prepared 12 h post ECS, showed that granule cell excitability was greatly enhanced. Linking the electrophysiological effects of ECS on granule cell excitability to the accompanying rise in activin in the same hippocampal region, we found that incubation of control slices with activin (50-100 ng/ml) for 3-6 h closely mimicked the features of the ECS-mediated increase in granule cell excitability. The activin-induced enhancement of granule cell firing was abolished by the activin-binding protein follistatin 288, but not by SB 421532, which interferes with the canonical activin signaling by inhibiting SMAD phosphorylation. Furthermore, the effect of activin on granule cell firing was greatly truncated in the presence of the ERK-MAPK inhibitor PD 98058, indicating the involvement of the non-canonical pathway. Our results suggest that enhanced activin signaling might be responsible for a functionally significant effect of ECS in dentate granule cells and that the underlying mechanism might involve a SMAD-independent pathway.

Title: Measurement and simulation of temperature effects on axonal conduction, synaptic transmission and network activity - Implications for the evolution of hibernation

Authors: *T. BULLMANN[1], K. DELIGKARIS[1], A. HIERLEMANN[2], U. FREY[1];
[1]RIKEN QBiC, Kobe-Shi / Hyogo, Japan; [2]Dept. of Biosystems Sci. and Engin., ETH Zurich, Basel, Switzerland

Abstract: Temperature plays a fundamental role in physiology, determining the rate of biochemical processes. This dependence is usually expressed by using the Q10 temperature coefficient. In the nervous system, temperature affects the ion channel kinetics, axonal conduction, calcium signaling, synaptic release, binding of transmitters to receptors, for which the Q10 values diverge and range between 2~3. This divergence poses a problem if the function of the nervous system as a whole must be maintained over a large temperature range, e.g., in cold-blooded animals. In the stomatogastric nervous system of crabs, the rhythmic motor pattern is well preserved within the physiological temperature range (7~23°C, ΔT=16°K; Tang et al., 2012). This robustness can be explained by 'sloppy' parameter sensitivity and similar Q10 values (Caplan et al., 2014). In most warm-blooded animals, with the exception of animals that hibernate, the physiological temperature range is small (typically 35~38°C, ΔT=3°K), and so should be the 'permissible' temperature range. We cultured primary neurons from rat on high-density microelectrode arrays (HD-MEA; 11016 electrodes). Surprisingly, network recordings revealed stereotypical bursts over a wide temperature range (15~40°, ΔT=25°K). Bursts retained their temporal structure despite diverging temperature dependence of inter spike intervals, number of spikes/bursts, burst periods and burst lengths. During cooling, bursts were observed to be increasingly stretched in time, disappeared below 15°C, but reappeared upon warming, and then showed again the same patterns, even after prolonged cooling down to 10°C. We simulated the temperature dependence of network bursting by introducing a Q10=3 into the activation of the slow component of a simple neuron model. In a next step, we want to include axonal conduction delays and spike-time-dependent plasticity, which leads to repeated spike patterns (polychronization; Izhikevich, 2006). Therefore, we recorded action potentials along full axonal arbors at subcellular resolution (3,150 electrodes/mm2) over a similarly temperature range (20~40°C). Together with imaging of cooling-induced synapse regression this will allow us to

build a richer model of the temperature dependence by incorporating Q10 values for several crucial parameters. From an evolutionary standpoint, the wide 'permissible' temperature range and the stability after prolonged cooling is surprising for warm-blooded animals. This low-temperature tolerance might represent a plesiomorphic trait, which has been previously hypothesized from the patchwork distribution pattern of hibernators in the phylogeny of mammals.

Title: Uncovering cellular properties from network dynamics

Authors: ***J. GJORGJIEVA**, G. DRION, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: Functionally equivalent circuits can generate similar activity patterns despite disparate intrinsic neuronal and synaptic properties. One way to alter these properties is through neuromodulatory substances, which can reconfigure circuits and produce multiple behavioral outputs. Here we use computational models to investigate the role of descending neuromodulatory inputs in regulating the output of a simple circuit: a half-center oscillator. We interpret our results in the context of the crustacean stomatogastric nervous system using conductance-based model neurons for spike generation with intrinsic and synaptic conductances chosen to reproduce the properties of gastric mill neurons. We focus on the action of modulatory commissural neuron 1, MCN1, which provides excitatory input to a pair of gastric mill neurons, LG and Int1. First we examine how the spatiotemporal input structure influences the rhythm generated by the half-oscillator. Because descending inputs from modulatory neurons on the two sides of the animal may not be identical, we examine the transfer of input correlations of varying strength for networks with a different composition of intrinsic and synaptic

conductances. In the case when similar network activity arises from disparate cellular intrinsic properties, we use these results to determine conditions to read out the different cellular properties from network output. For this purpose we compare model neurons whose biophysical composition endows them with very different firing patterns, for instance spiking versus intrinsically bursting. When coupled in half-center oscillator networks, cellular identity becomes hidden and the two networks generate similar patterns. Different network patterns emerge only when driving the networks with neuromodulatory inputs with an appropriate structure. This approach enables us to uncover single cell identity from network activity in a manner that can be applied to other circuits. It also allows the use of correlated descending input to interpret trade-offs between synaptic and intrinsic properties in governing circuit output.

Title: Contribution of different neuromodulators on persistent firing in hippocampal CA1 pyramidal cells

Authors: *M. J. VALERO-ARACAMA, M. M. SAUVAGE, M. YOSHIDA;
Ruhr Univ. Bochum, Bochum, Germany

Abstract: Persistent firing, a neuronal firing activity that outlasts triggering stimulation, has been observed in neurons from multiple brain regions *in vivo*. The function of persistent firing in the hippocampus is believed to be information maintenance, which is required for hippocampal dependent temporal association tasks. We have recently shown that principal neurons of the rat hippocampal CA1 area maintain persistent firing *in vitro*, supported by the calcium activated non-specific cationic (CAN) current, in the presence of the cholinergic receptor agonist carbachol. While cholinergic receptor dependency of persistent firing is in line with the importance of acetylcholine in temporal association tasks, other neuromodulators that also play a

crucial role in memory, such as noradrenaline and serotonin may contribute to persistent firing as well. In fact, an *in vitro* work has recently shown that noradrenaline facilitates persistent firing in the prefrontal cortex. However, the effects of these neuromodulators on persistent firing in CA1 pyramidal cells remain largely unknown. In this study, we report the effects of noradrenaline and serotonin on persistent firing either by applying them alone or in combination with carbachol using *in vitro* whole cell patch clamp recordings from mouse CA1 pyramidal cells.

Abstract: Inhibitory interneurons are an important source of synaptic inputs (i.e., LII/III Stellate Cells and Pyramidal Cells) that may contribute to network mechanisms for coding of spatial location by grid cells. The intrinsic properties of inhibitory interneurons in the entorhinal cortex (EC) are mostly undescribed. We recorded a range of intrinsic properties (i.e., resting membrane potential, input resistance, and time constants; AP threshold, half-height-width, amplitude, latency, and frequency adaptation; F-I and V-I curves; voltage phase plots, SAG, and dv/dt ratios) from 5 classes of EC interneurons identified by molecular biomarkers (i.e., RCan2, SOM, 5HTR3a, VIP, and NPY) and from 2 classes of EC principal cells (i.e., stellate cells and pyramidal cells). We report a broad physiological diversity between and within different cell classes in the EC. To better understand the source of this intrinsic variability we applied supervised and unsupervised methods of hierarchical cluster analysis to functionally classify neurons. The analysis revealed 7 physiologically-derived cell types in the superficial layers of

the EC that mostly corresponded to the mouse lines identified by biomarkers. For instance, most of the stellate cells, pyramidal cells, and RCan2 cells formed distinct functional clusters that did not include other cells but themselves. Despite these similarities, the functional analysis revealed a few unexpected and important differences. For instance, SOM+ cells were divided in two functional groups, one of these sub-groups (that included 26 of the 34 SOM+ cells) was intrinsically more similar to NPY+-Non-NGF cells than to the other SOM+ sub-group. Similarly, while most of the 5HTR3a+ (27 out of 39) were functionally related to most VIP+ cells (16 out of 19), about 13% of 5HTR3a+ cells functioned like NPY+-NGF interneurons. Finally, we reduced the complex multi-dimensional space of intrinsic properties to the most salient five (i.e., spike frequency adaptation, SAG, dV/dt, membrane time constant, and AP threshold) that predicted with high accuracy (>90%) the cellular biomolecular identity based on their intrinsic properties. We also report immunohistochemical cell counts and neuronal morphological reconstructions. Our results provide a framework for classification of functional subtypes of cortical neurons by their intrinsic membrane properties.

Title: Input/output properties of interneurons in the medial entorhinal cortex

Authors: ***J. J. MARTINEZ**[1,2], J. A. WHITE[2];
[1]Bioengineering, Univ. of Utah, Salt Lake City, UT; [2]Boston Univ., Boston, MA

Abstract: Local GABAergic interneurons regulate the activity of spatially-modulated principal cells in the medial entorhinal cortex (MEC), mediating stellate-to-stellate connectivity and enabling grid formation via recurrent inhibitory circuitry. Despite the important role interneurons seem to play in the MEC cortical circuit, the combination of low cell counts and functional diversity has made systematic electrophysiological studies of these neurons difficult. There thus

remains a paucity of knowledge on the electrophysiological profiles of superficial MEC interneuron populations. Using GAD2-Cre and PV-Cre genetic markers to label GABAergic cells throughout the cortex, we targeted GABAergic interneurons for whole cell patch clamp recordings and characterized their passive membrane features, basic input/output properties and action potential shape. These electrophysiologically characterized cells were then anatomically reconstructed, with emphasis on axonal projections, soma morphology, and localization within the MEC DV axis. The pial depth of each neuron and the spatial extent of axonal projections were used to cluster interneuron populations. This method was used determine the electrophysiological profile of anatomically distinct interneuron groups in the MEC, including but not limited to basket/chandelier cells, multipolar, horizontal and bipolar cells. Basket cells in the MEC were shown to fire at the fastest rate relative to other interneurons, and did not show any significant difference along the dorsal ventral axis in any electrophysiological measurements. Superficial horizontal layers, in turn, fired at slower rates than most other interneuron populations. These results, among others, will provide greater understanding of the electrophysiological characteristics of MEC interneurons, help guide future *in vivo* studies, and aid in uncovering the mechanism of grid field formation.

Title: BK channel alternative splicing contributes to homeostatic adaptation of neuronal excitability

Authors: *B. LI, B. SUUTARI, R. W. TSIEN;
Neurosci. Institute, Tsien Lab., New York Univ. Med. Ctr., New York, NY

Abstract: Homeostasis of intrinsic excitability is an important capability of CNS neurons to keep neuronal firing away from extremes of frequency and thus protect the information transfer capacity of brain circuits. Our previous study showed that chronic inactivity increased action potential width, but the underlying mechanism has not been elucidated. Here, we found that BK channel, an important regulator of action potential shape and neuronal excitability, undergoes alternative splicing (AS) of exon 29 (E29) in response to 48 hr TTX treatment of cultured cortical neurons: E29 levels dropped to ~50% of control without a significant change in total BK channel mRNA. In turn, neurons overexpressing BK channels lacking E29 showed wider action potentials than those expressing BK channels including E29, suggesting that TTX-induced E29 skipping might contribute to regulation of excitability. The AS of E29 was regulated by Nova-2, which directly binds to the intron downstream of E29. Indeed, overexpression of Nova-2 induced E29 inclusion in E29 minigene-transfected N2A cells. Moreover, knockdown of Nova-2 strongly reduced E29 inclusion in cortical neurons. These data suggest that Nova-2 is both sufficient and necessary for E29 inclusion. Chronic inactivity triggered Nova-2 nuclear export, apparently suppressing E29 inclusion. Mechanistically, we found that blockade of Ca_V1 channel by nimodipine, inhibition of CaMKs by KN-93, inhibition of CaMKK by STO-609 and buffering of nuclear CaM by CaMBP4(nu) blocked TTX-induced Nova-2 translocation and regulation of E29 splicing, indicating that long term inactivity-induced activation of a Ca_V1-CaMKIV pathway mediates this process. Indeed, 48 hr TTX treatment induced activation of CaMKII and CaMKIV, and overexpression of constitutively active CaMKIV recapitulated TTX-induced Nova-2 translocation. Furthermore, we found that CaMKIV directly binds to and phosphorylates Nova-2. Constructs mimicking the phosphorylation by CaMKIV induced Nova-2 translocation. It has been suggested that abnormal homeostatic adaptation contributes to autism. To this end, we demonstrate that neurons from Timothy Syndrome mice, a widely studied autism model induced by Cav1 channel point mutation, express a significant lower level of E29 (<50% of control) after chronic TTX treatment. This effect was reversed by nimodipine, KN-93 and STO-609, indicating that the atypical E29 splicing in TS neurons reflects hyperactivity of the Ca_V1-CaMKIV pathway in response to inactivity. These results suggest that abnormal homeostatic adaptation of E29 AS contributes to this highly penetrant form of autism.

Title: Pyramidal neuron heterogeneity in the monkey posterior parietal and dorsolateral prefrontal cortices

Authors: ***G. GONZALEZ-BURGOS**, T. MIYAMAE, D. ARION, D. A. LEWIS; Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The functional specialization of primate neocortical areas may depend on area-specific neurophysiological and morphological properties, partly determined at the transcriptional level. Layer 3 pyramidal neurons (L3PNs) play a crucial role in neocortical circuit function, by integrating inputs from multiple sources and generating output signals conveyed onto other cortical regions via their long-distance axonal projections. In sensory versus association areas of the primate neocortex, L3PNs have significantly different properties that could contribute to area-specific function. However, it is not known if L3PNs show different features between the dorsolateral prefrontal (DLPFC) and posterior parietal (PPC) areas of the primate neocortex, which are distinctively involved in cognition, but co-activate in various cognitive tasks and communicate via reciprocal connections. We therefore began comparing the electrophysiological, morphological and transcriptional properties of L3PNs from the macaque monkey DLPFC and PPC. In whole-cell recordings from L3PNs in acute slices from DLPFC or PPC, we assessed the intrinsic membrane properties via the response to injection of current steps. Recordings from L3PNs (n=20 DLPFC and n=19 PPC) showed that, in both areas, L3PNs were divided into regular spiking (rsL3PNs) or burst spiking (bsL3PNs) subtypes (most bsL3PNs had weak bursting properties). Two Way ANOVA (rsL3PNs/bsL3PNs x DLPFC/PPC) for 9 intrinsic electrophysiology parameters showed that rsL3PNs and bsL3PNs had similar properties, but differed in the amplitude of the single-spike afterhyperpolarization and the hyperpolarizing response sag. No significant effects of cortical area on intrinsic properties were found thus far, but, interestingly, the proportions of L3PN subtypes differed between DLPFC (rsL3PNs:bsL3PNs, 12:8) and PPC (rsL3PNs:bsL3PNs, 17:2; p=0.035, Chi-Square test), suggesting greater heterogeneity of input/output transformation properties in DLPFC. Ongoing

work is assessing the morphological properties of the L3PNs filled with biocytin during recording and the transcriptional profile using DNA microarray amplification in RNA samples collected from L3PNs using laser capture microdissection. Moreover, to specifically study the L3PNs interconnecting DLPFC and PPC, we started using *in vivo* injections of fluorescent latex microspheres (retrobeads) to retrogradely label the PPC-projecting and DLPFC-projecting L3PNs in DLPFC and PPC. Our preliminary data show effective retrobead transport which allows us to identify the labeled L3PNs for electrophysiological, morphological and transcriptional analysis.

Title: β-arrestin signaling increases excitability of fast-spiking interneurons in the prefrontal cortex

Authors: *S. GEE, P. O'DONNELL;
Pfizer, Cambridge, MA

Abstract: Activation of dopamine 2 receptors (D2R) not only activates downstream signaling pathways through canonical G-protein signaling, but also through non-canonical, β-arrestins. Indeed, all clinically effective antipsychotics interact with D2Rs and signal through both canonical and non-canonical pathways (Masri et al., 2008). Parsing apart the effects of these signaling pathways in prefrontal and striatal circuits may shine light on the mechanisms of current antipsychotics and lead to the development of more effective ones. Here, we examined the effects of second-generation antipsychotic, aripiprazole, and β-arrestin biased D2R ligand

UNC9994, on fast spiking interneurons (FSIs) in the prefrontal cortex. We performed whole-cell recordings from GFP-labeled FSIs in acute slices from GAD1-eGFP mice. We injected depolarizing current steps in current-clamp mode and recorded the number of action potentials generated. Aripiprazole elicited an increase in excitability in prefrontal FSIs, consistent with agonist-like activity previously reported with the D2R agonist, quinpirole (Tseng and O'Donnell, 2004). Interestingly, we found that UNC994 elicited a more robust increase in FSI excitability than the increase observed in aripiprazole. This effect was absent in FSIs recorded from β-arrestin2 KO mice, suggesting signaling through β-arrestin. Parvalbumin-positive FSIs in the prefrontal cortex are thought to be dysfunctional in schizophrenia and enhancing their activity may reverse the cognitive deficits observed in schizophrenia (Cho et al,. 2015). Thus, enhancing the activity of prefrontal FSIs by β-arrestin signaling may be an important mechanism of current antipsychotics and potentially relevant for the development of future ones.

Title: Intrinsic plasticity during state-dependent calcium homeostasis in hippocampal model neurons

Authors: ***S. SRIKANTH**, R. NARAYANAN;
Indian Inst. of Science, Bangalore, Bangalore, India

Abstract: How do neurons reconcile the maintenance of calcium homeostasis with perpetual switches in afferent activity? Here, we assessed state-dependent evolution of calcium homeostasis in a population of hippocampal pyramidal neuron models, through an adaptation of a recent study on stomatogastric ganglion neurons (O'Leary, T. *et al*., Neuron, 2014). Calcium homeostasis was set to emerge through cell-autonomous updates to 12 ionic conductances, responding to different types of synaptically driven afferent activity. We first assessed the impact of theta-frequency inputs on the evolution of these conductances towards maintenance of calcium homeostasis. Although calcium homeostasis emerged efficaciously across all models in the population, disparate changes in ionic conductances that mediated this emergence resulted in variable plasticity to several intrinsic properties, also manifesting as significant differences in firing responses across models. Further, intrinsic neuronal properties and the firing response

were sensitive to the target calcium concentration and to the strength and frequency of afferent activity. Next, we studied the evolution of calcium homeostasis when afferent activity was switched between two behaviorally distinct types of activity: theta-frequency inputs and sharp-wave ripples. We found that the conductance values, intrinsic properties and firing response of neurons exhibited differential robustness to an intervening switch in the type of afferent activity. Finally, we asked how neurons that implement cell-autonomous calcium homeostasis react to knockout of specific ion channel conductances. To answer this, for each neuron, we removed specific conductances, one at a time, after steady state in calcium levels was attained while receiving theta frequency inputs. We assessed neuronal intrinsic properties at two time points: immediately following the knockout of the conductance (acute measurements) and at steady state in the post-knockout emergence of calcium homeostasis (through update of conductances other than the one that was knocked out) with theta-frequency inputs. We found that the robustness of models to acute knockouts and compensation-induced restoration of function were critically tied to specific neuronal measurements, with significant variability across measurements and across specific channels that were knocked out. These results unveil critical dissociations between different forms of homeostasis, and call for a systematic evaluation of the impact of state-dependent switches in afferent activity and genetic knockouts on neuronal intrinsic properties during neural coding and homeostasis.

Title: The biphasic effect of L-lactate on hippocampal cells spike frequency

Authors: *G. HERRERA-LOPEZ, E. J. GALVAN;
CINVESTAV SUR, Mexico City, Mexico

Abstract: Lactate has an important role as a supplemental energy substrate for the brain, but also work as a signaling molecule through the activation of the Gi protein-coupled receptor, HCA1 (HCAR1). Here, we sought to determine whether physiological concentrations of L-lactate modify the intrinsic excitability of hippocampal neurons. Whole cell recordings were performed

to assess the effects of L-lactate on the intrinsic properties and firing frequency of CA1 neurons. Perfusion of L-lactate (5 mM) reduced the input resistance and increased the rectification phase of the I-V curve as well the rheobase current to induce action potentials (n=8), indicating that L-lactate decreases the cellular excitability. Similar results were found with pyruvate (10 mM; n=9), but these effects were prevented when slices were preincubated with the lactate dehydrogenase inhibitor oxamate (20 mM; n=8). None of these parameters were modulated by the enantiomer D-lactate (5 mM; n=7). To explore whether lactate may act as a signaling molecule, the monocarboxilates transport was blocked with 4-CIN (0.5 mM; n=8). Under these conditions, L-lactate still reduced the intrinsic excitability of pyramidal cells, suggesting that the active transport of L-lactate is not responsible of the effects previously described. Next, we sought to determine whether the activation of the endogenous L-lactate receptor HCAR1 mimics the effects induced by L-lactate. The HCA1 receptor was activated with 3,5-dihydrobenzoic acid (3,5-DHBA, 0.56 mM, n=7), both passive properties and firing frequency exhibited similar changes as those induced by L-lactate, suggesting that lactate decreases the neuronal excitability of CA1 pyramidal cells through the activation of the HCA1 receptor. Interestingly, at lower concentrations of 3,5-DHBA (0.001 to 0.56 mM) or L-lactate (0.01 to 10 mM) pyramidal cells showed a reduction of the fire frequency. Conversely, higher concentrations of both molecules (1 mM to 10 mM for 3,5-DHBA and 20 to 30 mM for L-lactate) caused an increase in spike frequency. Lastly we examined the effects of L-lactate and 3,5-DHBA on the afterhyperpolarization current (IAHP). Lower concentrations of L-lactate increased the IAHP amplitude, but higher doses of 3,5-DHBA were required to increase the IAHP. The results suggest that activation of the HCA1R with L-lactate decreases neuronal excitability through a mechanism that involves upregulation of the IAHP.

Title: Unitary synaptic connections among substantia nigra pars reticulata neurons

Authors: ***M. H. HIGGS**, C. J. WILSON;
Biol., The Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Substantia nigra pars reticulata (SNr) is a major basal ganglia output nucleus that integrates synaptic input from the direct and indirect pathways, combining this input with local inhibition via axon collateral synapses. Because SNr neurons fire rhythmically, these synapses are constantly active. To investigate their function, we recorded spontaneous IPSCs from SNr neurons in coronal brain slices, where afferents from upstream nuclei are severed. Most sIPSCs occurred at regular intervals and were tetrodotoxin-sensitive. Fourier analysis of sIPSC trains showed that each cell received 0-6 unitary inputs. Many cells had only one unitary input, providing an ideal preparation for synaptic studies. Presynaptic firing rates and inter-spike interval (ISI) variability inferred from sIPSC trains were similar to direct observations of SNr neuron firing. A running estimate of the phase of presynaptic firing was obtained by bandpass filtering the sIPSC trains, providing a statistical discrimination between unitary IPSCs (uIPSCs) clustered near the predicted spike times and miniature IPSCs that occurred randomly. We found that uIPSCs had large, variable amplitudes, fast kinetics, and synaptic failures. Based on failure rates, the mean quantal content ranged from 0.2-3 quanta. To estimate the synaptic release probability (p), variance-mean analysis of uIPSC amplitudes was performed using high-Ca^{2+} ACSF (4 mM Ca^{2+}, 0 Mg^{2+}) to increase p. In most cells, downward-curving variance-mean plots were obtained. On average, the data indicated that $p \sim 0.2$ in control ACSF (2 mM Ca^{2+}, 2 mM Mg^{2+}), suggesting that each unitary input makes 1-15 synapses. In combination with previous studies counting SNr axon collateral boutons, these data suggest that each cell forms and receives ~10-20 unitary inputs in the intact SNr. To investigate whether sIPSCs were depressed by autonomous activity, viral expression of halorhodopsin was used to silence presynaptic firing reversibly. The sIPSC amplitudes were not increased after silencing, suggesting that most synapses were not depressed. The synaptic reversal potential (E_{rev}) was estimated by perforated-patch current-clamp recording. Based on sIPSP detection rates and amplitudes across the ISIs, the mean E_{rev} was ~ -61 mV, which is slightly below the trough of the spike afterhyperpolarization. In part because of the change in driving force across the ISI, sIPSPs late in the ISI had the largest effect on spike timing. Our data show that local axon collateral synapses provide strong, fast inhibition that perturbs SNr neuron spike timing, consistent with the hypothesis that these connections act to desynchronize the basal ganglia output.

Title: The mechanism for beta frequency membrane resonance and its effect on spiking in striatal LTS interneurons

Authors: *S. C. SONG[1], J. A. BEATTY[2], C. J. WILSON[1];
[1]Biol., Univ. of Texas At San Antonio, San Antonio, TX; [2]Physiol., Michigan State Univ., East Lancing, MI

Abstract: Striatal interneurons exhibit membrane resonances, each in a cell-type specific frequency band. Somatostatin- and NPY-positive low threshold spike (LTS) interneurons have their membrane resonance in the beta frequency range. The membrane resonance is tetrodotoxin insensitive but cadmium sensitive. We sought to determine the specific ion channels that produce the beta frequency membrane resonance in LTS interneurons. We also investigated the influence of membrane resonance on the neurons proclivity to phase-lock their action potentials to beta-frequency components of complex input waveforms (spiking resonance). To investigate both the mechanism for membrane resonance and its effect on spiking resonance, perforated-patch recordings were made in mouse striatal slices. The mice expressed GFP under the control of the NPY promoter to visually identify LTS cells in slice. To determine the ion channels responsible for the membrane resonance, voltage clamp frequency sweeps were applied to the LTS interneurons to measure its impedance at a range of input frequencies. The frequency sweeps were applied in control, ACSF conditions as well as in the presence of specific ion channel blockers. We found that blockade of N-type (CaV2.2) calcium channels (but not L or P/Q channels) specifically blocked membrane resonance. Blockade of calcium-activated chloride channels (CaCC) with niflumic acid was equally capable at preventing membrane resonance. We suggest a resonance mechanism for LTS cells in which depolarization activates CaV2.2 calcium current, which specifically activates CaCCs. To measure the contribution of membrane resonance to spiking resonance, shot-noise simulated EPSPs, designed to equally represent synaptic inputs at a range of frequencies, were applied to the neuron. The phase with which spikes occurred in regards to the Fourier filtered input was measured to determine the spiking resonance frequency. This was performed in control, ACSF conditions as well as with ω-conotoxin GVIA or niflumic acid present. The spiking resonance profile changed in the presence of the membrane resonance blockers, suggesting influence of membrane resonance on frequency specific phase-locking of striatal LTS interneurons to beta frequency components in their input.

Title: Prolonged spinal networks activation induces adaptive alterations in spinal motoneuron intrinsic excitability

Authors: *J. LOMBARDO, M. HARRINGTON;
Delaware State Univ., Dover, DE

Abstract: The persistent modification of neuronal properties resulting from past experiences and affecting future behavior has been presumed to exclusively involve the brain. However, recent work indicates that activity-dependent plasticity occurs in spinal motor neurons during development, as well as later in life with skills acquisition and maintenance, and in response to trauma and disease. Understanding how spinal motoneuron output can be modified by both increased and decreased activity is thus a fundamental challenge with implications for athletic training, rehabilitation and advanced prosthetics. To characterize the activity-dependent modulation of spinal motoneuron intrinsic properties, we have treated spinal cord slices for about 30 minutes with different stimulants that have been shown to trigger patterns of locomotion-like activity in spinal cord preparations. The intrinsic excitability of spinal motoneurons in treated slices was significantly altered; in particular, the resting membrane potential was hyperpolarized, input resistance was reduced and current threshold was increased. While other interventions can alter spinal motoneuron intrinsic properties, the changes triggered by sustained ~30 min-long locomotion-like-triggered spinal network activation have a unique time course - different from both central fatigue which is observed over seconds to minutes, and training-induced plasticity which emerges over days to weeks. Realistic conductance-based computational models of spinal motoneurons allowed us to identify potential mechanisms underlying the changes in intrinsic properties. Pharmacological tools were then used to test whether the mechanisms identified in silico were indeed occurring *in vivo*, and to identify intracellular signaling pathways that alter spinal motoneuron intrinsic excitability after prolonged spinal network activation.

Title: Chemogenetic control of the activity of cholinergic interneurons in the striatum

Authors: *S. CHOI[1,2], Y. DING[2], E. V. MOSHAROV[2], U. KANG[2];
[1]Dept. of Psychiatry, [2]Dept. of Neurol., Columbia Univ., New York, NY

Abstract: Striatal cholinergic interneurons (ChI) are implicated in motor control, associative plasticity, and reward-dependent learning. ChIs exhibit tonic action potential firing which consist of a brief (200-300 ms) cessation of firing, termed the pause response, and, depending on the nature of the stimulus and its behavioral context, suggesting a prominent role in plasticity. The critical question is how gain or loss of cholinergic activity regulate the functioning of striatum. Recent studies have shown that brief train stimulation by optical light on the ChI generates inhibitory responses in the medium spiny neurons (MSN), principal cells of striatum through increasing GABAergic conductance. We investigated pharmacological control of ChI by using chemogenetics and patch clamp recording in brain slices. Virally introduced Designer Receptors Exclusively Activated by Designer Drugs (DREADD) under choline acetyltransferase (ChAT) promotor is activated by CNO which either increase or suppress ChI activity through hM3Dq (Gq or Gs-coupled) and hM4Di (Gi/o-coupled) respectively. We found that electrophysiological membrane properties (i.e. resting membrane potential, I/V relationship, and input resistance) which were measured from hM3Dq, hM4Di, and control animal showed no difference between groups. 1 μM CNO application for 5 minutes on hM3Dq expressed ChI successfully increased tonic activity of neurons but it was not recovered after CNO washout. However, 10 μM CNO reversely suppressed tonic firing of hM4Di expressed ChI. These results suggest that chemogenetics is a feasible approach to control tonic cholinergic activity and this will help to explore unknown circuit mechanism between ChI and other principal neurons in the striatum.

Title: Inverse stochastic resonance in cerebellar Purkinje cells

Authors: *A. BUCHIN[1,2], S. RIEUBLAND[3], M. HAUSSER[3], A. ROTH[3], B. GUTKIN[1,4]; [1]Ecole Normale Superieure, Paris, France; [2]Inst. of Physics, Nanotechnology and Telecommunications, Peter the Great Saint-Petersburg Polytechnic Univ., Saint Petersburg, Russian Federation; [3]Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom; [4]Dept. of Psychology, Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Purkinje cells play an important role in cerebellar computation since their axons are the only projection from the cerebellar cortex to deeper cerebellar structures. They have complex internal dynamics, which allow them to fire spontaneously, display bistability and participate in network phenomena such as high frequency oscillations and travelling waves. Purkinje cells have type II excitability, which can be revealed as a discontinuity in their f-I curves. We show that this excitability mechanism allows Purkinje cell simple spiking to be efficiently inhibited by noisy current input of a particular variance, a phenomenon known as Inverse Stochastic Resonance (ISR). While this effect has been observed previously in theoretical models of single neurons, here we provide the first experimental demonstration of ISR. We find that an adaptive exponential integrate-and-fire model (aEIF), fitted using a modified dynamic IV method to reproduce the basic intrinsic properties of Purkinje cells, displays ISR and bistability between the rest state and a limit cycle representing repetitive activity. We then use the aEIF model to explain the link between the ISR and bistability in Purkinje cells. We show that ISR allows Pukinje cells to operate in different functional regimes, from the all-or-none toggle to the linear filter mode, depending on the variance of the background synaptic input. We propose that changes in synaptic noise provided by parallel fiber input allow Purkinje cells to quickly switch between these functional regimes. Using mutual information analysis, we demonstrate that ISR leads to an optimum in information transfer between the input and output spike train of the Purkinje cell. These results provide the first experimental evidence for ISR and suggest possible functional roles for ISR in cerebellar information processing.

Title: Memory, activity, olfaction, and sleep in a transgenic rat model of Alzheimer’s disease

Authors: L. KRYCH[1], R. REITH[1], A. K. SMITH[2], R. M. COHEN[2], *C. B. SMITH[1];
[1]Section on Neuroadapatation and Protein Metabolism, NIH, NIMH-SNPM, Bethesda, MD;
[2]Psychiatry and Behavioral Sci., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Alzheimer’s disease (AD) is a chronic neurodegenerative disease characterized by debilitating cognitive decline. The hallmark pathological changes in AD are extracellular deposition of the amyloid-beta peptide, intracellular inclusions of hyperphosphorylated microtubule-associated protein tau, aggravated neuroinflammation, and neuronal loss. The rat transgenic model of AD (TgF344-AD) recapitulates these four age-dependent characteristics of the disease and is accompanied by indications of declining memory function (Cohen et al. (2013) J Neurosci 33:6245). In the present study, we further investigated behavioral changes in TgF344-AD rats. We measured the following behaviors in both male and female WT and TgF344-AD

rats: olfaction (buried food task), activity in a novel environment (open field test), and hippocampal-dependent learning and memory (rewarded alternation in the T-maze). We report preliminary results in TgF344-AD and WT rats studied at 6 months (22 TgF344-AD, 22 WT) and 12 months (11 TgF344-AD, 9 WT) of age. Results of the buried food task indicate no olfactory impairment at either age (two sample t-tests). In the open field, TgF344-AD rats at 6 months of age were less active than WT (RM ANOVA, main effect of genotype, $p < 0.001$), whereas at 12 months of age differences did not reach statistical significance. Performance in the T-maze was similar in the two genotypes at 6 months of age, but at 12 months of age performance of TgF344-AD rats suggests a learning and memory deficit (2-sample test for equality of proportions, $p < 0.001$). In a subset of animals 6 months of age, we studied sleep patterns by means of an infrared home-cage monitoring system. Male rats demonstrate a genotype-dependent difference in total sleep time (6 TgF344-AD, 9 WT) (two sample t-tests, $p < 0.05$), but genotype-dependent differences in total sleep time were not observed in females (9 TgF344-AD, 6 WT). These observations of changes in sleep patterns call for further investigation. Taken together our preliminary results confirm the learning and memory deficit manifesting around 12 months of age in the TgF344-AD rat model.

Title: Alzheimer's disease early pathology and behavioral characterization in male and female 5xFAD mouse model of Alzheimer's disease

Authors: ***T. HALL**[1,2], C. LEARMAN[1,2], E. BATES[1,2], L. PALADUGU[1,2], M.-S. SONG[1,5], J. ROSSIGNOL[1,2,3], G. DUNBAR[1,2,4,5];

Abstract: Alzheimer's disease (AD) is an intricate protein misfolding neurodegenerative disorder characterized by profound memory loss and a neuropathological profile that includes: inflammation, oxidative stress, neurofibrillary tangles, and amyloid-β (Aβ) deposits; all of which contribute to neuronal dysfunction and atrophy. There are myriad of risk factors associated with developing AD, with aging being the number one factor. However, gender is also a risk factor of concern, with the proportion of women diagnosed with AD outnumbering men. Aβ plays a crucial role in AD pathology, much of the current research has focused on the extracellular Aβ plaque deposits. However, within the past decade it has been shown that the more toxic species is the oligomeric Aβ fragments (oAβ), largely due to its abilities to be transmitted from cell-to-cell and misfold other like proteins. With advances in AD early detection methods via various biomarkers within the cerebral spinal fluid (CSF), and the current emergence of oAβ positron emission tomography (PET) scans, the possibility of new treatment therapies centered on early interventions is plausible. Current research focuses on understanding the underlying mechanisms behind this "seeding" phenomenon to possibly provide a pathological timeline with key target locations for early treatment and intervention. The aim of the present study was to asses when and where certain AD-like pathologies emerge in both male and female 5xFAD transgenic mice at the ages of 1,2, and 4 month of age. Levels of various Aβ species and associated signaling molecules were assessed in brain in brain samples and blood serum via western blot and immunohistological assays. An array of behavioral batteries were utilized to assess anxiety, motoric and cognitive abilities, including: open field, novel object recognition, passive avoidance, and clasping. This study is the first to specifically compare early pathology with behavior between males and females in 5xFAD mice.

Title: High-throughput phenotyping of transgenic AD models

Authors: *D. BRUNNER, T. HANANIA, M. MAZZELLA, H. HAIN, E. SABATH, V. ALEXANDROV, J. BERGER, P. KABITZKE, K. COX, M. WINDISCH;
Psychogenics Inc, Tarrytown, NY

Abstract: Three popular models for Alzheimer's disease were investigated using behavioral high-throughput phenotyping technologies: : the single transgenic Tg 2576 (mutant APP) mouse model, the double transgenic model from the cross between the Tg 2576 and a mutant presenilin (PS1) line both expressing increased amyloid- beta 40 and 42 levels and amyloid pathology, and the rTg4510 mice, overexpressing human tau with the P301L mutation under control of a tetracycline responsive transacting element, showing cognitive impairment, motor deficits, tau hyperphosphorylation, neurofibrillary tangles, and neuronal loss in the forebrain. We exploited the option to switch off tau expression by doxycycline in the Tg4510 model, as a calibration for maximal effect of a putative treatment. PhenoCube® NeuroCube® and SmartCube® are high-throughput platforms that assess circadian, cognitive, motor behavior, anxiety, gait, and other domains using PGI's proprietary Computer Vision automated scoring system and machine learning algorithms to define phenotypic signatures. APP/PS1 mice were hyperactive as early as 12 weeks of age as assessed in our high-throughput phenotypic platforms. Tg2576 mice showed a milder yet similar signature. The deficits in the Tg4510 were age-dependent unlike those of the tTa control, which showed a significant phenotype at the earlier ages. Doxycycline partially reversed the Tau behavioral signature. The possibility to evaluate behavioral deficits with the novel high-throughput technology early in life forms a basis to test therapeutic interventions at early stages of developing brain pathology.

Title: Assessing outcomes of a middle cerebral artery occlusion injury in an APP transgenic rat

Authors: *A. M. REGIS[1], V. HACHINSKI[1,2], S. N. WHITEHEAD[1,2];
[1]Anat. & Cell Biol., [2]Clin. & Neurolog. Sci., Western Univ., London, ON, Canada

Abstract: It is estimated that by age 60, one in three individuals will develop Alzheimer's disease (AD), suffer a stroke, or experience both. While traditionally regarded and treated as distinct conditions, clinical and experimental findings begin to suggest an interaction may occur. However, conclusive pathophysiological links have yet to be determined. Based upon past studies, it may be hypothesized that following ischemic stroke, a transgenic rat model carrying human APP mutations will display enhanced Aβ deposition, suffer more severe cognitive decline and display increased stroke-related pathology. To model AD pathology, our study uses a genetically engineered rat model exhibiting mutations in the amyloid precursor protein (APP); this model overproduces the human pathogenic protein attributable in AD called amyloid-β. To model stroke injury, a macrosphere-induced permanent Middle Cerebral Artery occlusion (pMCAo) strategy will be utilized. pMCAO provides a clinically relevant model of human embolic ischemic stroke of the middle cerebral artery, a common type of human ischemic stroke. The proposed models will be studied both in combination as well as singularly over a period of two months post-stroke. A variety of behavioural tests will be used to determine any apparent cognitive and motor deficits, while biochemical analytical methods will be used to determine the mechanistic changes associated. These strategies will help us better understand how stroke and AD manifest themselves in combination throughout the disease processes. Preliminary results from our laboratory using rat models suggest that in the presence of amyloid deposition, facets of stroke including infarct size and the degree of neuroinflammation are heightened. These pathological effects are shown to be translated into behavioural deterioration in rodent models of AD and stroke. However, further studies are required to truly understand the interactions between amyloid toxicity, ischemic stroke damage, and neuroinflammation. Upon defining the specific pathological mechanisms, use of therapeutic intervention may be employed. Overall,

with a better understanding of the mechanistic roles of stoke and AD pathology on resultant cognitive impairment, it may be possible to employ strategies in rodents to minimize post-stroke cognitive burden; interventions that may become a translational strategy in humans who are susceptible to stroke and Alzheimer's disease related cognitive impairment.

Title: Increased cellular senescence in mouse models of Alzheimer's disease (or amyloidosis)

Authors: *G. F. PASSOS[1,2], R. DA COSTA[1], R. MEDEIROS[2], D. H. CRIBBS[2]; [1]Pharmaceut. Biotech., UFRJ, Rio de Janeiro, Brazil; [2]Inst. for Memory Impairments and Neurolog. Disorders, Univ. of California, Irvine, Irvine, CA

Abstract: Advanced age is considered the major risk factor for Alzheimer's disease (AD), however, the mechanisms underlying the contribution of aging to the development of AD are largely unknown. There is increasing evidence for a role of cellular senescence in physiological aging but also in injury and disease. Nevertheless, the mechanisms driving cellular senescence in the brain as well as how senescent cells affect brain pathology remain unclear. In this study, we investigated the molecular mechanisms associated with cellular senescence in AD. In order to determine whether amyloid-beta (Aß) accumulation, a pathological hallmark of AD, is associated with senescence *in vivo*, brain tissue from two different transgenic models of the disease were examined for the presence of increased senescence-associated beta-galactosidase (SA ß-gal) activity, a marker of senescence. Compared with age-matched nontransgenic (nTg) mice, a significant increase in SA ß-gal activity was observed in cortex and hippocampus of 24-month-old Tg2576 mice. Likewise, SA ß-gal activity was found to be significantly increased in the thalamus of TgSwDI mice, compared to nTg mice, when evaluated at 9 months of age. Taken together, our results suggest that the presence of senescent cells may contribute to the

pathogenesis of AD and may represent a link between the aging process and progression of the disease.

Abstract: Alzheimer's Disease (AD) is devastating and costly. AD is characterized by progressive loss of memory and other cognitive impairments. Although often overlooked, motor impairments with gait and postural stability are a common feature of AD. These deficits are generally considered secondary impairments, attributed to cerebral degeneration and dementia, but detailed studies of spinal cord function in AD are lacking. To study the potential role of spinal cord involvement in AD, we used an AD mouse model (PDGF-APPswe/Ind mice (J20)) and characterized changes in stepping assays as well as spinal Amyloid-precursor Protein (APP)/ Amyloid-beta (Aβ) expression in intact and spinally transected animals. We used the treadmill stepping paradigm to evaluate locomotion kinematics in J20 mice and compared them to wild-type (WT) littermates. Both J20 and WT mice were also divided into 4-month and 13-month groups to investigate the influence of AD-like pathological progression on stepping pattern (13-month J20, n=13; 13-month WT, n=10; 4-month J20, n=7; 4-month WT, n=7). The treadmill stepping was analyzed by the SIMI motion capture system for all groups. We found that J20 mice in both age groups exhibited locomotion difficulties when compared to their WT littermates. Our ELISA results showed an Aβ increase in all spinal cord segments of both 4-

month and 13-month J20 mice. To further investigate how spinal circuitry might contribute to motor alternations in J20 mice, complete spinal cord transections at the mid-thoracic level (Thoracic 7-9) was performed to isolate lumbo-sacral spinal circuitry (J20, n=7; WT, n=7). After a 2-week post-surgery recovery period, hindlimb locomotion of the spinalized mice was tested with the bipedal treadmill stepping paradigm before and after quipazine delivery for 6 weeks. We found J20 spinal mice recovered slower than WT controls but quipazine induced more bipedal treadmill steps in J20 spinal mice relative to WT controls. These results suggest differences in the functional output of J20 and WT lumbosacral spinal cord. The treadmill stepping together with the molecular results suggest that early and potentially independent changes in spinal cord circuitry are present in J20 mice. Changes in recovery time and in the response to serotonin agonist observed after spinal transection further support the hypothesis that motor behavior in J20 mouse after spinal transection can be attributed at least in part to dysfunctions caused by Aβ within the sensory-motor networks of the lumbosacral spinal cord segments.

Title: Age-related changes in feeding behaviours, weight, hormones, and metabolism in 12-month old female 5xFAD mice

Authors: ***W. H. GENDRON**[1], R. E. BROWN[1], S. PELLETIER[1], Y. ANINI[2];
[1]Psychology, [2]Physiol. and biophysics, Dalhousie, Halifax, NS, Canada

Abstract: The 5xFAD mouse is a double transgenic model of Alzheimer's disease (AD), which carries an amyloid precursor protein (APP) transgene with three mutations, and a presenilin-1 transgene with two mutations. These mutant transgenes act additively to produce increases in beta amyloid (AB)-peptides, and the presence of AB-plaques emerges at two months of age. Weight-loss is an issue in human AD patients, and age-related weight-loss is also seen in 5xFAD mice. We therefore investigated age-related changes in body weight, feeding behaviour, activity

levels, feeding-related hormones, and leptin and hormone sensitive lipase mRNA in female 5xFAD mice and their WT (C57BL/6JxSJL/J F1) controls from 3 to 12 months of age. The 5xFAD mice weighed more than WT controls at 9 and 12 months of age ($p<0.05$), but no differences were found in food intake between genotypes except at 9 and 12 months of age WT ate more than 5xFAD mice ($p<0.05$) . Levels of grooming and jumping did not differ between genotypes ($p>0.05$), however, 5xFAD mice showed less climbing and rearing ($p<0.05$), and spent more time remaining still than WT mice ($p<0.05$). At 12 months of age there were no genotype differences in plasma insulin or glucose concentrations ($p>0.05$). Perigonadal white adipose tissue (WAT) and interscapular brown adipose tissue (BAT) were collected and it was found that 5xFAD mice had less WAT than WT mice ($p<0.05$). No differences in BAT were seen. Expression of mRNA for leptin and hormone sensitive lipase was measured in WAT, and the 5xFAD mice expressed reduced levels of both mRNA's ($p<0.05$). Muscle tissue was collected to evaluate mice for sarcopenia (muscle loss), but the 5xFAD mice did not differ in muscle mass compared to WT mice ($p>0.05$). Our data suggest that weight-loss seen in 5xFAD may be partially explained by reduced food intake. We also conclude that the 5xFAD mice are hypoactive compared to WT behaviours that require a significant amount of energy. The 5xFAD mouse model does not suffer from sarcopenia, indicating that all motor deficits are likely due to neural defects. Finally the 5xFAD mice have less fat and express less leptin and hormone sensitive lipase mRNA compared to WT mice, indicating that they have less leptin and that fat loss is the main contributor to weight-loss in this mouse model.

Title: Peripheral nervous system is vulnerable before significant development of pathology in Alzheimer's disease mouse model

Authors: *J. KIM, A. A. B. RASHEED, S.-J. YOO, C. MOON;
DGIST, Dae gu, Korea, Republic of

Abstract: Abnormal processing of amyloid precursor protein (APP), through sequential cleavages first by β-secretase and then by γ-secretase complex, leads to excessive production of β-amyloid (Aβ) in the central nervous system (CNS), that is Alzheimer's disease. Specially, γ-secretase complex have presenilin1 and 2 as the catalytic core and that's gene mutations markedly trigger Aβ accumulation. Olfactory epithelium (OE), a kind of peripheral nervous system, could send the information from the brain to the external environment. Before AD symptoms such as memory loss or muscle retardation turn up, olfactory dysfunction usually occurs. It means that OE, odorant first detection site, have some problems. But it is unknown well the correlation of olfactory deficit and AD. Here, we found that 10month TG2576 mice meaning the early stage of AD have olfactory dysfunction. And APP processing and Presenilin2 expression pattern are differ in PNS and CNS. Specially, PS2 levels of TG2575 mice are increased significantly in mRNA and protein of PNS, compared with CNS. Through these results, there are differences between mechanisms of development of AD of PNS and CNS. It might help to detect the AD before the progression through the PNS, indirectly but easily.

Title: Aerobic glycolysis in the frontal cortex correlates with memory performance in wild-type but not APP/PS1 mice: implications for metabolic intervention in Alzheimer's disease

Authors: *R. A. HARRIS[1], R. CUMMING[2];
[1]Biol., [2]Univ. of Western Ontario, London, ON, Canada

Abstract: The majority of glucose consumed by the adult brain is fully oxidized in the mitochondria of neurons to supply the large amounts of ATP required for synaptic transmission. However, a certain percentage of glucose in the brain is exclusively metabolized by glycolysis to generate lactate, even when oxygen is not rate limiting. This form of metabolism is known as aerobic glycolysis. Emerging evidence now suggests that aerobic glycolysis in the brain plays a critical role in generating biosynthetic metabolites during early CNS development and persists in certain regions of the adult brain to support synaptic plasticity, learning and memory. However,

aerobic glycolysis steadily declines with age and virtually disappears in the elderly. Our lab has recently demonstrated that a metabolic shift to aerobic glycolysis confers nerve cells with a survival advantage against the toxic effects of amyloid beta, a key pathogenic peptide in Alzheimer's disease (AD). However, the beneficial effect of aerobic glycolysis in the AD brain remains to be fully elucidated. In this study, we demonstrate that a progressive decline in aerobic glycolysis occurs in the mouse brain with age, which correlates with a loss of spatial learning and memory in APP/PS1 mice (AD mice). Proton magnetic resonance spectroscopy revealed an age-dependent decline of lactate levels in the frontal cortex of control mice but not in AD mice. Western blot analysis of extracts from the frontal cortex revealed an age-dependent decline in key regulatory proteins of aerobic glycolysis in both control and AD mice at 12 months old. In contrast, lactate transporter expression increased with age. The expression of aerobic glycolysis enzymes correlated with better memory performance in the Morris Water Maze for control mice, but not AD mice. Confocal microscopy revealed a high expression of aerobic glycolysis enzymes in astrocytes surrounding plaques in the cortex of AD mice. Aerobic glycolysis enzymes were also expressed in the cell bodies of Tuj1 neurons in both control and AD mice. These data indicate that aerobic glycolysis and the production of lactate in the brain naturally declines with age, yet is compensated by up-regulation of lactate transporters. However, this process appears to be interrupted by the presence of amyloid plaque in the AD brain and may play a role in memory decline. This study suggests that metabolic intervention may be a therapeutic strategy for the treatment of memory loss in AD.

Abstract: Understanding the relevance of changes in Alzheimer's disease biomarkers that occur before the pathology becomes evident, can contribute to the development of a treatment for

Alzheimer's disease. A longitudinal follow-up of an animal species with a similar amyloid pathology in the brains as in humans may contribute to this research.Amyloid plaque formation is one of the two main neuropathological hallmarks of Alzheimer's disease in humans. Dogs are similar to man with respect to amyloid precursor protein (APP)-processing and age-related amyloid plaque deposition. Dogs also are used as a natural model of age-dependent cognitive dysfunction. In our colony of beagle dogs Aβ-concentrations in cerebrospinal fluid (CSF), sampled in awake animals from the lateral ventricle, were regularly measured over a period of years. We identified dogs showing low or high Aβ42 levels and formed two groups of ten animals each. The age of the animals, which ranged from 2-8 years, was comparable between both groups. Since dogs normally start to develop amyloid plaques from an age of 9-10 years onwards, these dogs are assumed to have no or minimal amyloid plaque formation. The cognitive performance of these dogs was evaluated in standard cognition tests such as object discrimination learning, reversal learning and delayed non-match to position (DNMP). A difference in learning performance was observed between dogs with low and high CSF Aβ concentrations. Our data suggest that high levels of Aβ in young to middle-aged dogs might contribute to learning impairment prior to amyloid deposition. Further experiments are needed to investigate whether there is a causal link between high levels of CSF Aβ and cognitive performance in young to middle-aged dogs as well as the longitudinal sequalae of these differences with respect to disease progression.

Title: Breaking Down Alzheimer's disease in Trisomy 21

Authors: ***L. PULFORD**[1], M. RICKMAN[1], S. NOY[1], J. TOSH[1], D. ABUCEWICZ[2], V. L. J. TYBULEWICZ[2], E. M. C. FISHER[1], F. K. WISEMAN[1];
[1]Inst. of Neurol., London, United Kingdom; [2]The Francis Crick Inst., London, United Kingdom

Abstract: Down syndrome (DS) or Trisomy 21, caused by inheriting an extra copy of human chromosome 21 (Hsa21), leads to a greatly elevated risk of developing Alzheimer's disease. This is largely due to triplication of the amyloid precursor protein gene (APP), present on Hsa21. APP is processed to produce Aβ, a toxic species central to AD pathogenesis. Despite nearly universal presence of AD plaques and tangles by 40 years, not all individuals with DS go on to develop dementia, and the age of onset varies. Alongside more aggressive pathology, individuals with AD/DS also have an elevated incidence of seizures compared to sporadic AD. With over 230 protein-coding genes on Hsa21 it is likely that genes other than APP contribute to, or even protect against the development of dementia in DS. The transchromosomic (Tc1) mouse model of DS contains a freely segregating copy of Hsa21 and is functionally trisomic for around 75% of Hsa21 genes. Importantly, the Tc1 mouse is not functionally trisomic for APP. When crossed with the J20 (APPSwInd) model of APP/Aβ pathology, Tc1 trisomy resulted in an exacerbation of Aβ plaque load, a sensitisation to APP/Aβ-induced behavioural deficits and a reduction in survival. This suggests that Hsa21 genes other than APP lead to an exacerbation of AD pathogenesis in DS. Chromosomal engineering has allowed us to 'fragment' Hsa21 in order to map the genetic region responsible for this exacerbation. To look at the contribution of 40 genes on mouse chromosome 10 (Mmu10) that are syntenic with Hsa21, we have similarly crossed a partial trisomy model (the Ts2Yey mouse) to the J20 mouse. In contrast to the Tc1 x J20 cross, Ts2Yey trisomy rescues the sudden-death phenotype observed in J20 mice, which is thought to be caused by epileptiform activity. This is coupled with a reduction in astrogliosis at 6 months, however no change in soluble or insoluble Aβ levels, Aβ plaque load, full-length APP protein or its C-terminal fragments is observed. To investigate whether the rescue of the sudden-death phenotype in Ts2Yey;J20 mice is due to a normalisation of hypersynchronous network activity, an electroencephalogram (EEG) study is underway. Two novel mouse crosses used here demonstrate the complexity of AD pathogenesis in DS, and aid in explaining the heterogeneity of dementia onset in the DS population. The Ts2Yey region of Hsa21 may confer some level of protection against AD-related phenotypes and further work is required to uncover the mechanism behind this result. Analysis of additional partial trisomy models of DS will allow the dissection of the region, and the genes, contributing to the aggravation of AD pathology in DS and the wider population.

Title: A graph diffusion model predicts a primarily retrograde pattern of pathology propagation in mouse models of Alzheimer's disease

Authors: ***C. MEZIAS**, E. LOCASTRO, A. RAJ;
Neurosci., Cornell University, Weill Cornell Med. Col., New York, NY

Abstract: Much of the research into Alzheimer's Disease (AD) has focused on the proximal cause of cognitive decline, neuronal loss, and protein pathologies. However, AD is not a disorder that simply stays put or seeds in multiple areas. Rather, the protein pathology hallmarks of the disease and the neuronal damage progress throughout the brain and are mirrored by the progressive cognitive deficits associated with the disease and an area of intense current research is the directional preference of the spread of these pathologies. Here we posit a model that explains the spread of pathological proteins, tau and amyloid, and neuronal loss solely based on the directional connectivity network of both the hippocampus, and the entire brain. Comparing the predictions of the model to small datasets of both tau and amyloid burden and neuronal loss in different sub-regions of the hippocampus and regions of the brain, we see an early APP and amyloid spread, and later stage tau proliferation primarily occurring in the retrograde direction, as well as a slight preference for cell loss pathology to proceed in this direction. Taken together, our results show that pathology in AD has a preference to spread in a primarily retrograde manner.

Abstract: Down syndrome (DS) is a common, complex disorder caused by having an extra copy of human chromosome 21 (Trisomy 21). While clinical presentation varies extensively, Alzheimer disease (AD) pathology is found in brains of virtually all people with DS by 40 years. This increases their dementia risk such that one third of the DS population develops AD by 60 years. Therefore DS allows the investigation of pathogenetic mechanisms underlying its clear genetic form of early-onset AD. To model DS in mice, a 'transchromosomic' model, Tc1, was generated carrying a freely-segregating copy of human chromosome 21 (Hsa21), which is trisomic for ~75% of Hsa21 genes. However, Tc1 is not functionally trisomic for *APP*. By crossing Tc1 with the J20 model, a transgenic mouse overexpressing mutant human *APP* that models amyloid deposition, it is possible to compare contributions of trisomy 21 and *APP* overexpression to phenotypes in the genotypically different offspring. One of the most striking phenotypes in this cross is the exacerbation of amyloid plaque deposition in mice expressing both Trisomy 21 and *APP* overexpression (Tc1;J20 mice), compared to mice overexpressing *APP* without Trisomy 21 (J20 mice). This is accompanied by a reduction in survival and increased behavioural deficits in the Tc1;J20 mice. It is therefore of interest to develop methods that would facilitate the identification of gene candidates on Hsa21 that may contribute to the aggravation of amyloid pathology in Tc1;J20 mice. To develop an *in vitro* model, which is more accessible to observation and amenable to manipulation than *in vivo* systems, we established a primary cortical culture system from early postnatal Tc1xJ20 mice. To assess the validity and utility of these cultures, they were characterized for APP expression, human A production, ratio

of neuronal to non-neuronal cells, and the proportion of mosaicism for the Tc1 chromosome. These *in vitro* phenotypes obtained were juxtaposed with relevant *in vivo* observations in Tc1xJ20 mice, allowing for the comparison of these two systems in modelling phenotypes relevant to AD. To further pinpoint AD-related phenotypes and downstream genetic pathways that may be differentially modified by genotype, we annotated and verified data obtained from a pilot RNA sequencing study of Tc1xJ20 hippocampal tissue, and identified gene candidates of interest to follow up. The work detailed here therefore discusses some approaches we have taken to identify novel genetic contributions of Hsa21, apart from *APP*, to AD phenotypes.

Title: Alzheimer’s disease research in the 21st century: the shift towards a new paradigm

Authors: *F. PISTOLLATO, C. P. CHANDRASEKERA;
Physicians Committee For Responsible Med., Washington, DC

Abstract: Animal models of Alzheimer disease (AD) have been extensively utilized in the last few decades in an effort to elucidate the pathophysiological mechanisms of this disease and to test novel therapeutic approaches. However, research success has not effectively translated into therapeutic success for human patients. We investigated the reasons for this translational discrepancy, presenting challenges and opportunities in AD research. Our analysis revealed that translational failure is due - at least in part - to the overuse of animal models that cannot accurately recapitulate human AD etiopathogenesis or drug responses and the inadequate use of human-based investigational methods. We propose how we can mitigate this translational barrier by employing human-based methods to elucidate disease processes occurring at multiple levels of complexity (from gene expression to protein, cellular, tissue/organ to individual and population level). Novel human-based cellular and computational models are already being applied in toxicology and regulatory testing, and the adoption and the widespread implementation of such tools in AD research will undoubtedly facilitate human-relevant data acquisition. Additionally, clinical studies focused on nutritional and lifestyle intervention strategies to reduce and/or prevent early symptoms of AD represent another relevant and

important way to elucidate AD pathogenesis and treatment options in a human-based setting. Taken together, it is clear that a paradigm shift towards human-based research is the best way to tackle the ever-increasing prevalence of AD in the 21st century.

Title: Baseline neuropathological and behavioral phenotypes for transgenic mice expressing apoE3 and apoE4

Authors: *S. HALAVI, M. DULCICH, R. E. HARTMAN;
Dept. of Psychology, Loma Linda Univ., Loma Linda, CA

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder associated with a build-up of amyloid-beta (Aβ) plaques that accumulate over time, causing neuronal dysfunction in the brain and cognitive deficits. Apolipoprotein (apoE) also plays a factor in the pathogenesis of AD, in that individuals who express apoE4 have a higher likelihood of developing AD, but apoE3 does not appear to modify the risk of developing the disease. The current study assessed whether the targeted expression of human apoE alters neuropathology in a transgenic mouse model of AD by establishing baseline neuropathological and behavioral phenotypes. All mice underwent behavioral testing (water maze, open field, rotarod, and zero maze) at 20 months old, and then brain sections were stained with HJ3.4 and thio-S to quantify Aβ. Transgenic mice expressing apoE4 had more severe spatial learning deficits than those expressing apoE3. They also spent more time in the open quadrants of the zero maze, which may be due to motor deficits and/or abnormal exploratory/risk-taking behaviors. The brains of transgenic mice expressing apoE4 stained with HJ3.4 also had more Aβ plaques in the dorsal cortex and the hippocampus combined compared to those expressing apoE3. In summary, transgenic mice expressing apoE4 had greater behavioral deficits and worse Alzheimer’s neuropathology than transgenic mice expressing apoE3.

Title: The effect of acute BACE1 inhibition on early cognitive deficits in a mouse model of Aβ toxicity

Authors: *M. LOOS[1], E. REMMELINK[1], B. LUBBERS[1], R. E. VAN KESTEREN[2], M. VERHAGE[3], A. B. SMIT[2];
[1]Sylics, Amsterdam, Netherlands; [2]Mol. and Cell. Neurobiology, Ctr. for Neurogenomics and Cognitive Res., [3]Functional Genomics, Ctr. for Neurogenomics and Cognitive Res. (CNCR), VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Alzheimer's disease (AD) is characterized by progressive neuropathological changes and decline in cognitive function. The formation of Aβ oligomers is regarded as an early event in the development of AD symptomatology. Indeed, application of Aβ oligomers affects synaptic plasticity (i.e. LTP) *in vitro* and *in vivo*. To study the consequences of Aβ oligomer-induced synaptotoxicity of on cognitive function *in vivo*, it is key to develop robust cognitive readouts that represent the direct toxic effects of oligomers before plaque deposition. However, in mouse models of AD, behavioral impairments are typically only observed at a relatively late stage, when plaque formation and other secondary pathological processes downstream of Aβ oligomerization may contribute to cognitive dysfunction. Here we describe a novel 1-night discrimination learning task to measure cognitive function in mice in an automated home-cage. In this task, that runs without any human intervention, mice could obtain all their food by passing through one of three entrances in a wall placed in front of a reward dispenser. A systemic injection of a low dose of MK-801, a non-competitive antagonist of NMDA receptors that attenuates LTP, impaired discrimination learning in wild type mice, as demonstrated by a significantly increased number of entrances to reach the learning criterion (80% through the correct entrance), pharmacologically validating this novel cognitive task. Next, we observed that transgenic mice overproducing Aβ oligomers were significantly slower at reaching the learning criterion, not only around the age at which amyloid plaques start to be visible (26 - 30 weeks of age), but also before plaque formation at 16 weeks of age. These data indicate that the synaptotoxic effects of Aβ oligomers, as previously reported *in vitro* and *in vivo*, might have directly affected discrimination learning in this task. A single acute dose of the BACE1 inhibitor LY2886721, a rate-limiting enzyme in Aβ production, was used to test the hypothesis that acute

reduction of Aβ oligomers is sufficient to restore the early cognitive deficit in the APP/PS1 mouse model.

Title: APP-induced neurodegeneration is mediated by the unfolded protein response

Authors: *A. GUMASTE, S. JIAO, L. BELLUSCIO;
NINDS, NIH, Bethesda, MD

Abstract: The molecular mechanism underlying cell death associated with Alzheimer's disease (AD) remains largely unknown. Recent studies suggest that endoplasmic reticulum (ER) stress and the resulting Unfolded Protein Response (UPR) play an important role in neurodegeneration. The UPR is a mechanism that regulates protein translation and serves to alleviate ER stress. Protein kinase RNA-like endoplasmic Reticulum Kinase (PERK) and eukaryotic translation initiation factor 2A (eIF2a) are two key components of the UPR. We have previously shown that expression of a mutated humanized amyloid precursor protein (hAPP) in mature olfactory sensory neurons (OSN) causes extensive, visible cell death throughout the olfactory epithelium. Here, we used this AD mouse model to determine the basis of this cell loss and initially found that hAPP expression caused a significant increase in UPR-related protein levels in olfactory epithelial tissue. To test the role of PERK and eIF2a in mediating OSN loss we crossed our previously used hAPP-expressing mice into two distinct mutant lines that disrupt either PERK or eIF2a protein function. We show that suppression of either PERK or eIF2a function results in a significant reduction of UPR-protein levels, bringing them closer to wild-type levels. In addition, we found that disrupting PERK or eIF2a protein function significantly decreases caspase-3 expression, while increasing OSN survival. Overall our results suggest that intervening in UPR

activity, through suppression of PERK or eIF2a, may be a useful strategy to reduce neuronal loss associated with AD.

Title: Perk inhibitor prevents neural death in mouse model of Alzheimer’s disease

Authors: ***S. JIAO**, A. GUMASTE, L. BELLUSCIO;
Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Alzheimer’s disease (AD) is the most common form of dementia in the elderly, however, the precise molecular machinery that control the neuronal death remains unclear. Studies have shown that the unfolded protein response (UPR), a mechanism that controls initiation of protein translation, is overactive in patients with Alzheimer’s disease, which can lead to shutdown of protein synthesis and subsequent neural apoptosis. To determine whether suppressing the UPR can improve neuronal survival in an AD context we utilized an animal model, previously established in our lab that overexpress a humanized mutated amyloid precursor protein (hAPP) in olfactory sensory neurons (OSNs) and exhibits early visible apoptosis. Using these mice we applied a specific inhibitor of the Protein kinase RNA-like endoplasmic Reticulum Kinase (PERK), a critical effector of UPR pathway, via direct nasal administration and assessed changes in OSN survival. The activity of PERK and other key proteins in UPR pathway had been suppressed after just one week of nasal delivery. Interestingly, despite persistent expression of hAPP in the mutant mice, we found a significant reduction of Caspase-3 expressing OSNs and a significant increase of OMP or hAPP expressing OSNs after treatment. Examination of the olfactory bulbs further revealed that PERK inhibition enhanced OSN axonal projections and partially restored the glomerular layer structure as compared to mutant controls. Moreover, behavioral assessment using a buried food assay, clearly demonstrated that these mutant mice treated with PERK inhibitor had significantly restored their olfactory function. Together, these data suggest that PERK may be an effective therapeutic target for blocking neural loss associated with AD progression.

Title: TRB3 mediates neuronal cell death evoked by β-amyloid by a dual mechanism: apoptosis and autophagy

Authors: S. SALEEM, *S. C. BISWAS;
CSIR-Indian Inst. of Chem. Biol., Kolkata, India

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by accumulation of misfolded and aggregated proteins in combination with prolonged cellular stress. This results in an Endoplasmic Reticulum stress in an AD brain. Mounting evidence also implicates defective autophagy in the pathogenesis of AD. Autophagy is a catabolic process causing degradation of accumulated proteins. TRB3, a novel ER stress inducible gene has a probable role in neurodegeneration as implicated by recent research. In our study we find that TRB3 is upregulated in cultured cortical neurons in response to β-amyloid $(A\beta)_{1-42}$ treatment and in Aβ overexpressing transgenic mouse model. It is reported that TRB3 inhibits Akt during apoptosis. We find that TRB3 lies upstream of Akt pathway and also observe an interesting regulatory mechanism between transcription factor FoxO1, a direct target of Akt and TRB3 in Aβ-treated cells. These two proteins regulate the expression of one another in a feed forward mechanism. Our results revealed that level of FoxO1 in shTRB3 transfected cells, following Aβ treatment decreases, whereas this reduction is averted by blocking MDM2 with an inhibitor. This indicates that Akt is active in TRB3 knockdown cells, which results in MDM2 mediated degradation of FoxO1.We further observed decreased expression of Bim, a pro-apoptotic gene, upon downregulation of TRB3. Furthermore, we find that TRB3 upregulates autophagy in neurons via the Akt/mTOR pathway in Aβ-treated neurons. Downregulating TRB3 leads to increased mTOR activity. It is reported that mTOR inactivates ULK1 by phosphorylation at S-757. We find that upon TRB3 downregulation, there is sustenance of the inhibitory phosphorylation of ULK1 resulting in diminished levels of autophagy which is depicted by decreased conversion of LC3-I to LC3-II. To check the efficiency of autophagy thus induced, we monitored changes in levels of p62 upon Aβ treatment in neuronal cells. Build-up of p62 at later

time points indicates a decrease in autophagy flux in the treated cells. We therefore deduce that upregulated levels of TRB3, in neurons exposed to $(A\beta)_{1-42}$ leads to apoptotic death together with enhanced formation of autophagosomes and their accumulation in these neurons. Most importantly, we observed significant protection of primary cortical and hippocampal neurons against Aβ insult on silencing of TRB3 by shRNA. Thus, our study indicates that TRB3 may serve as a potential target for therapeutic intervention in AD.

Abstract: The neurobiological substrates of cortical atrophy are not well understood in neurodegenerative diseases that cause dementia. We quantified the regional specificity of

Alzheimer disease (AD) pathology (i.e., amyloid-ß plaques [APs] and neurofibrillary tangles [NFTs]) and cortical atrophy measures in two patients with primary progressive aphasia (PPA) and AD pathology (PPA-AD) that had structural magnetic resonance imaging (sMRI) within 18 months of death. PPA is a clinical dementia syndrome associated with autopsy-confirmed AD pathology in approximately 40% of cases, as well as a signature pattern of asymmetric atrophy concentrated in the left perisylvian language network. The neuroanatomical selectivity of PPA allows for unique within-subject comparisons between compromised and relatively spared regions (e.g., left versus right hemispheres; language versus memory regions). This study compared two control regions of interest (ROIs) (memory-related entorhinal cortex and primary visual cortex) to five language ROIs: 1) inferior frontal gyrus, 2) anterior superior temporal gyrus, 3) posterior superior temporal gyrus, 4) anterior inferior parietal lobule, and 5) posterior inferior parietal lobule. The cortical volume of each ROI was quantified from the PPA-AD subjects' sMRI using FreeSurfer software and compared to a group of 22 age-matched cognitively healthy adults in order to quantify volume loss. ROIs delineated by the neuroimaging analysis served as boundaries for unbiased stereology performed on whole-hemisphere sections to quantify NFT and AP densities. Both PPA-AD subjects displayed a leftward asymmetry of cortical atrophy, with the most prominent volume loss in the posterior language ROIs, especially the anterior and posterior inferior parietal lobules. Negligible volume loss was found bilaterally in control ROIs in comparison to the language ROIs. NFT densities exceeded AP densities in all ROIs except primary visual cortex for both PPA-AD subjects. The largest densities of NFTs were found within the language ROIs, while AP densities were evenly distributed across both language and control ROIs. These preliminary measures suggest that NFT deposits parallel cortical atrophy in their neuroanatomical distribution. The findings further highlight the regional selectivity of neurodegenerative markers within the perisylvian language network in PPA-AD.

Title: Lack of evidence for peroxynitrite formation in nitric oxide-induced death in retinal cell cultures

Authors: C. COUGHLIN[1], S. SAJJAD[1], K. NELSON[1], O. ANDERSON[1], M. RAJSOMBATH[1], *D. GRAY[2];
[1]Biol., [2]Simmons Col., Boston, MA

Abstract: Alzheimer's Disease (AD) and glaucoma are two prevalent and debilitating neurodegenerative diseases that involve the beta amyloid (Ab) peptide. However, soluble Ab peptides present in healthy tissue and in cultured embryonic retinal neurons have been shown to inhibit evoked release of acetylcholine (ACh) from cultured embryonic retinal neurons. The cellular pathway of the Ab peptide involves nitric oxide (NO), guanyl cyclase (cGMP) and phosphokinase G (PKG) without inducing cell pathology or death. In late stages of these diseases, however, Ab peptide aggregation is certainly associated with cell death. One hypothesis is that NO generated by Ab activity may lead to a toxic side effect over time by combining with mitochondrial superoxides. The likeliest candidate is the toxic superoxide-NO conjugate peroxynitrite. A model of cell death was created by exposing retinal cells to high levels of NO using an NO donor (3,3-bisaminoethyl-1-hydroxy-2-oxo-1-triazene [NOC-18]) in combination with a superoxide dismutase inhibitor (1- N,N' Diethyl-dithiocarbamate, DDC). Evidence of peroxynitrite effect in this model of cell death was measured by measuring cell survival with and without a specific inhibitor of peroxynitrite (5-aminosalicylate, 5AS). There was no significant reversal of cell death in these conditions thus not supporting an endogenous role for peroxynitrite in neurodegenerative cell death. Similar results were demonstrated when Ab was used to endogenously produce NO. Future work will involve examining the concentration of NOD and DDC, incubating the cultures for a longer period of time to determine if the compounds affect the cells gradually, and using immuno-labeling to identify the specific cells in the culture.

Title: Separation of neurodegeneration and memory loss in a *Drosophila* model of Alzheimer's disease

Authors: *Y. HU[1], B. LIANG[2], Y. ZHONG[1];
[1]Sch. of Life, Tsinghua Univ., Beijing, China; [2]HaiNan Normal Univ., HaiNan, China

Abstract: Alzheimer's disease is an age-related, non-reversible, progressive neurodegenerative disease. Memory loss and neurodegeneration are the two dramatic characteristics in Alzheimer's disease. However, lots of drug and genetic screens conducted in animal models established some candidates that can only rescue memory loss but not neurodegeneration. It indicates that there might be some factors separating memory loss and neurodegeneration. In a *Drosophila* model of Alzheimer's disease, we found that suppression of Abeta expression could rescue neuronal loss but not learning defect. Conditional low expression of Abeta is sufficient to cause learning defect. This imply that there might be some distinct mechanisms underlying Abeta-contributing memory loss and neurodegeneration in Alzheimer's disease.

Title: Progressive degeneration and functional impairment of gray matter oligodendrocytes in a mouse model of Alzheimer’s disease

Authors: *E. GONZALEZ FERNANDEZ[1], J. D. ROTHSTEIN[2,3], S. KANG[1,4,2];
[1]Shriners Pediatric Hosp. Ctr., Philadelphia, PA; [2]The Solomon H. Snyder Dept. of Neurosci., [3]Dept. of Neurol., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Dept. of Anat. and Cell Biol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Although cytotoxic mechanisms of senile amyloid plaque may directly cause widespread neuronal loss in Alzheimer's disease (AD), non-neuronal cells also play active roles in disease progression. By means of patient brain imaging and examination of rodent models of AD, recent studies have revealed white matter abnormalities and related myelin pathology in the AD brain, suggesting a pathogenic role of oligodendrocytes (OLs) in this degenerative disease. In addition to myelin sheath formation, OLs mediate metabolic support for neurons by expressing the monocarboxylate transporter 1 (MCT-1), a major form of lactate transporter in the brain. Therefore, cell loss or impaired regeneration of OLs, and/or MCT-1 downregulation, will facilitate neuronal dysfunction, and will negatively impact disease outcomes. In the present study, in order to determine the homeostatic maintenance of OLs in the AD brain, we tracked age-dependent changes in mature OLs, and performed genetic fate analyses of OL progenitors (OLPs) and mature OLs in a mouse model of AD (APPswe/PSEN1-dE9). In MOBP-EGFP; APPswe/PSEN1-dE9 mice, EGFP-labeled OLs significantly decreased in an age-dependent manner, particularly in several gray matter areas, such as motor cortex and hippocampus. This cellular loss was more prominent near AB plaques. Despite the apparent OL loss, neither the number of NG2+ OLPs nor the degree of OLP proliferation was altered in the AD brain. In tamoxifen-administered (P37) PLP-CreER;ROSA26-mEGFP mice, a marked reduction of EGFP-labeled, OL process densities preceded the decrease of OL cell bodies, and such myelin abnormalities were accompanied by dystrophy of nodes of Ranvier. More interestingly, a significantly larger fraction of surviving OLs lost MCT1 expression, as assessed by tdTomato signal in OLs in APPswe/PSEN1-dE9; MOBP-EGFP; MCT1-tdTomato mice. Finally, the fate analysis of OLPs (from P35) in PDGFaR-CreER;ROSA26-mEGFP mice did not show any sign of compensatory increases in new OL differentiation in AD. Rather, it appeared that the number of newly born OLs was decreased in parallel to the gradual OL loss. Taken together, these results suggest that OL impairments are relatively early events in the progression of AD, and that OL dysfunctions are multifaceted, involving demyelination, cell death, failure of metabolic support, as well as the failure of their own regeneration.

Title: Targeting the stress pathway in cognitive decline

Authors: *P. SPILMAN[1], J. CAMPAGNA[1], B. JAGODZINSKA[1], K. POKSAY[2], O. GOROSTIZA[2], A. MATALIS[2], D. E. BREDESEN[1,2], V. JOHN[1];
[1]Neurol., Easton Ctr. for Alzheimer's Dis. Research, Univ. of California, Los Angeles, CA;
[2]Bredesen Lab., Buck Inst. for Res. on Aging, Novato, CA

Abstract: Background. Stress is associated with cognitive decline [Tschanz *Int Rev Psychiatry* 2013], and increases risk for Alzheimer's disease (AD). Corticotropin-releasing factor receptor (CRF1) stimulation increases the phosphorylation of tau (p-tau) [Rissman *PNAS* 2012] leading to formation of neurofibrillary tangles [Carroll *J. Neurosci*. 2011], a hallmark of AD. We tested CRF1 receptor antagonists *in vitro* and *in vivo* to determine effects on p-tau levels. We posit that drug therapy alone will not be sufficient to treat cognitive decline, therefore an individualized multi-modal lifestyle intervention program - Metabolic Enhancement for Neurodegeneration (MEND) - was developed and utilized in the treatment of patients reporting cognitive decline. Stress is one of the key factors addressed in the MEND program [Bredesen, *Aging* 2014]. **Methods**. CRF-1 antagonists were tested in SH-SY5Y cells at 1 uM with/without 100 nM CRF; the small molecule "J03" was found to decrease p-tau as determined by AlphaLISA (Perkin-Elmer). It then underwent efficacy testing *in vivo* in an AD mouse model at 10 mkd by subcutaneous injection for 14-days in comparison to vehicle-only. To increase cortisol signaling, isolation stress was induced by single-housing during treatment. Cognition as reflected by working object memory was assessed pre- and end-study using Novel Object Recognition. Both tau and p-tau were determined in brain tissue using the Perkin-Elmer AlphaLISA. In the MEND pilot study, ten patients reporting memory loss confirmed by cognitive assessment were enrolled. Nine had Mild Cognitive Impairment (MCI) and one advanced AD. These patients were required to participate in stress-reducing activities such as exercise, meditation, yoga, and music with allowances for personal choice. Other factors contributing to stress such as sleep disturbances were also addressed. **Results.** The CRF-1 inhibitor J03 decreased p-tau both *in vitro* and *in vivo* in brain tissue and cognitive improvements were tightly correlated to p-tau levels. After participation in MEND for a minimum of 9 months, nine of ten patients were improved; most returned to work. Only the moderate to late stage AD patient did not improve significantly. **Conclusions.** The J03-induced improvement in cognition further supports a connection between stress, p-tau and cognition. Future studies include synthesis and testing of analogs and study of the biochemical pathways affected. The small pilot MEND study suggests a larger clinical trial is

warranted. Improved cognition in patients complaining of memory deficits by stress reduction indicates alleviating chronic stress may be an important element in effective treatment.

Alzheimer's association

Title: Presenilin 1-induced apoptosis is mainly mediated γ-secretase-independently by PSAP and also γ-secretase-dependently by FLIP

Authors: L. ZENG[1], F. ZHANG[1], C. HU[1], D. C. XU[2], M.-Z. CUI[1], M.-Z. CUI[1], *X. XU[3]; [1]Univ. of Tennessee, Knoxville, TN; [2]Princeton Univ., Princeton, NJ; [3]Pathobiology, Univ. Tennessee, Knoxville, TN

Abstract: Presenilin 1 (PS1) has been implicated in apoptosis; however, its mechanism remains elusive. We report that PS1-induced apoptosis was associated with c-FLIP turnover and that γ-secretase inhibitors blocked c-FLIP turnover and also partially blocked PS1-induced apoptosis. A complete inhibition of PS1-induced apoptosis was achieved by knockdown of PS1-associated protein (PSAP), a mitochondrial proapoptotic protein that forms a complex with Bax upon induction of apoptosis, in the presence of γ-secretase inhibitors. PS1-induced apoptosis was partially inhibited by knockdown of caspase-8, FADD, or Bid. However, knockdown of Bax or overexpression of Bcl-2 resulted in complete inhibition of PS1-induced apoptosis. These data suggest that PS1 induces apoptosis through two pathways: the γ-secretase-dependent pathway mediated by turnover of c-FLIP and the γ-secretase-independent pathway mediated by PSAP-Bax complex formation. These two pathways converge on Bax to activate mitochondria-dependent apoptosis. These findings provide new insight into the mechanisms by which PS1 is involved in apoptosis and the mechanism by which PS1 exerts its pathogenic effects. In addition, our results strongly suggest that c-FLIP is a new substrate of γ-secretase.

Title: Progressive degeneration of monoaminergic afferents in the J20 line of amyloid precursor protein mouse model

Authors: ***C. GALLARDO**[1], S. E. LESNE[2], M. K. LEE[2];
[1]Univ. of Minnesota - Twin Cities, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, University of Minnesota - Twin Cities, MN

Abstract: Alzheimer's disease (AD) is the most prevalent neurodegenerative disease and cause of dementia afflicting over 5 million individuals in the United States. Histopathologically, AD is characterized by the presence of extracellular senile plaques (SPs), intraneuronal neurofibrillary tangles(NFTs)/neuropil threads(NTs) and overt neurodegeneration. Previously, we showed that the progressive degeneration of subcortical monoaminergic (MAergic) neurons seen in human AD is recapitulated in the APPswe/PS1ΔE9 (APP/PS1) transgenic mouse model (Liu et al.,J Neurosci 28:13805, 2008). In this study, we set out to determine if the amyloid-dependent, progressive MAergic neurodegeneration is a general feature of animal models of cerebral amyloid pathology by examining the integrity of MAergic neurons in the J20 mouse model. We show that the MAergic afferents are significantly lost with the aging and amyloid accumulation in the transgenic J20 line. Consistent with the prominent hippocampal amyloid pathology, greater loss of hippocampal MAergic afferents were observed. Our results indicate that Aβ pathology is sufficient to induce progressive neurodegeneration in multiple, independent transgenic lines of amyloid deposition. Furthermore, assessing the integrity of brainstem populations in AD mouse models provides a feasible model to study AD-related neurodegeneration *in vivo*.

Title: Alzheimer's disease classification with novel microstructural metrics from diffusion-weighted MRI

Authors: *T. M. NIR[1], J. E. VILLALON-REINA[1], B. GUTMAN[1], N. JAHANSHAD[1], L. ZHAN[1], C. R. JACK, Jr[2], M. W. WEINER[3], P. M. THOMPSON[1];
[1]Inst. for Neuroimaging and Informatics, Neurol., USC Imaging Genet. Ctr., Marina Del Rey, CA; [2]Dept. of Radiology, Mayo Clin., Rochester, MN; [3]Dept. of Radiology, Medicine, and Psychiatry, Univ. of California San Francisco, San Francisco, CA

Abstract: Alzheimer's disease (AD) deficits may be due in part to declining white matter (WM) integrity and disrupted connectivity, detectable using diffusion weighted MRI (dMRI). New microstructural measures derived from various dMRI models may carry different information about WM microstructure including the level of diffusion anisotropy, diffusivity, complexity, number of fiber compartments, number of crossing fibers and neurite dispersion. Here we aimed to find the most helpful dMRI metrics and brain regions to classify people into diagnostic group (AD vs CN), from a set of 17 dMRI-derived feature maps. Structural T1-weighted MRI and dMRI images (5 b0/41 diffusion-weighted) were collected from 53 CN (72.3+/-6.2 y; 24M/27F), and 47 AD patients (73.7+/-8.0 y; 27M/20F) as part of the ADNI initiative. After correcting for eddy current and EPI distortions, we computed 17 DWI microstructural measures (Fig 1a) from 4 different reconstruction models: diffusion tensor (DTI), orientation distribution function (CSA-ODF), tensor distribution function (TDF), and neurite orientation dispersion (NODDI). All maps were elastically normalized to a minimal deformation template (MDT). The MDT was segmented into cortical, subcortical and WM ROIs (Fig 1c). For each voxel, 17 separate 10-fold cross-validated logistic regression classifiers were run per DWI measure. The DWI measure with lowest mean squared error was selected for each voxel (Fig 1b). Individual voxels are noisy and neighboring voxels are not independent, so the best measure for each voxel was changed to the measure most frequently found in its neighborhood, constrained by its ROI (Fig 1d). A second

logistic regression classifier with an elastic net regularizer (a mixture of L1 and L2 penalties) was run on the resulting feature map (cross validating for tuning parameters). Classification accuracy was 82%. Voxels contributing to the classification were found in the hippocampus and temporal lobe (Fig 1e). The best metrics in these voxels were TDF-FA and TDF-AD - suggesting non-tensor diffusion models may be useful for classification.

Title: Cognitive reserve is differentially associated with grey matter atrophy in frontotemporal lobar degeneration and Alzheimer’s disease

Authors: *K. PLACEK, L. MASSIMO, C. OLM, D. IRWIN, V. M. Y. LEE, J. Q. TROJANOWSKI, V. M. VAN DEERLIN, C. T. MCMILLAN, M. GROSSMAN;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Frontotemporal lobar degeneration (FTLD) and Alzheimer's disease (AD) are neurodegenerative conditions characterized by a progressive decline in neuroanatomical structure and cognitive function. However, there is increasing evidence for heterogeneous rates of decline across individuals, and the mechanisms of this heterogeneity are poorly understood. One theory suggests that cognitive reserve (CR) can provide a protective benefit on the clinical manifestation of neurodegenerative disease. According to this account, individuals with higher intellectual achievement are able to sustain cognitive function despite significant neuronal injury. Here, we investigated the relationship between CR and brain atrophy as assessed by grey matter (GM) in AD and FTLD. GM density was retrospectively calculated from T1-weighted MRI in AD (N=98) and FTLD (N=120) patients with pathology confirmed by autopsy, a known pathogenic mutation, or a cross-validated cerebrospinal fluid ratio of total-tau to amyloid-beta1-42. To assess CR, we created a composite cognitive reserve index (CRI) comprised of ordinal measures of lifetime educational and occupational attainment. In FTLD patients, higher CRI scores were associated with greater GM in frontal and temporal regions known to be affected by FTLD pathology. Conversely, in AD patients, higher CRI scores were associated with lesser GM in parietal, temporal, and occipital regions known to be affected by AD pathology. These effects held after accounting for age and disease duration. Our findings suggest that CR is differentially associated with GM atrophy in FTLD and AD. These findings are consistent with a previous report suggesting that CR is associated with longer survival in FTLD and reduced survival in AD. We suggest that the protective benefit on GM conferred by CR in FTLD likely reflects an earlier clinical presentation due to increased sensitivity to symptom detection, given the locus of disease in frontotemporal regions important to executive functioning. Given the primarily temporoparietal locus of AD, AD patients with higher CR likely require more brain atrophy in affected regions to exhibit cognitive decline and thus exhibit decreased GM compared with lower-CR patients due to delayed clinical presentation. Together, these findings suggest a differential mechanism of CR in AD and FTLD-related neurodegenerative disease.

Title: Quantitative EEG characterization of mAChR1: the use of qEEG as a potential biomarker for therapeutic targets of Alzheimer's disease

Authors: S. GARSON, A. GOTTER, J. STEVENS, S. FOX, P. L. TANNENBAUM, A. SAVITZ, L. S. LUBBERS, M. H. PAUSCH, D. C. BESHORE, J. M. USLANER, C. J. WINROW, *Z. WU;
Neurol., Merck & Co., West Point, PA

Abstract: Muscarinic acetylcholine receptor 1 (mAChR1) are localized in forebrain areas including cerebral cortex, hippocampus, and striatum and are involved in mediating higher cognitive processes, such as learning and memory, making it an attractive therapeutic target for Alzheimer's disease (AD). A selective mAChR1 positive allosteric modulator (PAM), PQCA, has been shown to improve cognitive performance in various rodents and non-human primate models relevant to AD. Electroencephalography (EEG) and quantitative electroencephalography (qEEG) are important tools in quantifying changes in brain activity. Neurological diseases such as AD often affect the relative power of qEEG signals resulting in a "slowing" of the qEEG signal which corresponds to an increase of low-frequency spectral power bands and a decrease of higher-frequency bands. qEEG studies were conducted in ambulatory animals via radio telemetry to characterize the effects of the acetylcholinesterase inhibitor donepezil, the nonselective mAChR antagonist scopolamine, the nonselective mAChR agonist Xanomeline, and the M1-selective PAM PQCA. Telemetric physiological monitors were implanted subcutaneously, and included electrodes for EEG and EMG recording. Effects of each compound were analyzed and compared to within-animal vehicle controls. A custom-developed qEEG analysis algorithm was coded and compiled in Matlab to perform artifact rejection and short-time Fourier transform on EEG signals. qEEG data were analyzed from 1 to 100 Hz in 1 Hz increments in 3-second intervals and banded in standard frequency ranges (Delta, Theta, Alpha, Sigma, Beta, Gamma) and subsequently averaged into 30-minute time bins across 24-hours. Scopolamine induced increases in low to mid frequency powers (Delta 0.5Hz -Beta 19.0-30Hz) and decreases in high frequency gamma power (35.0-100.0 Hz), a similar pattern to that observed in AD patients. On the other hand, activating muscarinic receptors through acetylcholinesterase inhibitor, muscarinic receptor agonist or M1 selective PAM produced an opposite pattern of effects by reducing the qEEG signal in low to mid frequency powers and increasing high frequency gamma power. Additionally, Xanomeline, Donepezil and PQCA all increased the time spent in wake with concurrent reductions in NREM and REM sleep. These results support that qEEG could be an effective biomarker for the evaluation of potential mAChR-based AD treatments.

Title: White matter microstructure in an empirically-derived fornix template is associated with neuropathological markers of Alzheimer’s disease

Authors: *C. BROWN[1], G. A. JICHA[2], F. A. SCHMITT[2], L. J. VAN ELDIK[3], C. D. SMITH[4], B. T. GOLD[5];
[1]Anat. and Neurobio., [2]Neurology, Sanders-Brown Ctr. on Aging, [3]Sanders-Brown Ctr. on Aging, [4]Neurol., [5]Anat. and Neurobiology, Sanders-Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY

Abstract: Alzheimer’s disease (AD) has a prolonged preclinical stage, during which pathological proteins accumulate and alterations to brain structure and function begin to appear. Recent evidence suggests that, along with amyloid deposition, decline in white matter microstructure in the fornix may be an early preclinical process. The fornix is the primary white matter tract responsible for hippocampal output, and declines in white matter microstructure in this tract appear to precede hippocampal atrophy. However, widely available atlases of the fornix include only subsections of the tract, typically in the form of multiple submasks, limiting the ability and simplicity of assessing white matter microstructure in the fornix as a continuous

structure. In the present study, a new fornix template was developed using probabilistic tractography in adults ranging from 25-77 years old and then applied to an independent cohort of cognitively normal older adults (ages 65-92) to investigate the relationship between white matter microstructure and cerebrospinal fluid (CSF) biomarkers of preclinical AD. Ninety-five adults ranging from 25-77 years old underwent diffusion tensor imaging, which was used to perform probabilistic tractography. Tractography used hippocampal seeds and waypoint masks based on the current JHU-ICBM White Matter Labels Atlas to develop a continuous fornix from the fimbria through the body. This fornix template was applied to a separate cohort of 34 cognitively normal older adults for whom CSF levels of β-amyloid ($A\beta_{42}$), total tau, and phosphorylated tau ($p\text{-}tau_{181}$) were available. Correlation analyses revealed that fractional anisotropy (FA) in the fornix template was positively correlated with CSF $A\beta_{42}$ ($r = 0.46$, $p = 0.008$), negatively correlated with CSF $p\text{-}tau_{181}/A\beta_{42}$ ratio ($r = -0.38$, $p = .03$), and marginally negatively correlated with CSF total tau ($r = -0.30$, $p = 0.09$) when controlling for age and sex. In contrast, FA in the current (JHU-ICBM) labels atlas had only marginal positive correlation with CSF $A\beta_{42}$ levels ($r = 0.32$, $p = 0.07$) and had no correlation with other CSF markers ($p > 0.22$) when controlling for age and sex. Importantly, a global FA measure had no relationship with any CSF marker ($p > 0.14$). These findings indicate that there is a relationship between lower white matter microstructure in the fornix and early markers of Alzheimer's disease, particularly increasing $A\beta_{42}$ burden. The new fornix template provides a valid and sensitive tool for measuring age-related alterations to white matter microstructure. The new fornix mask may also provide an additional neuroimaging biomarker of preclinical AD pathology for use in future research.

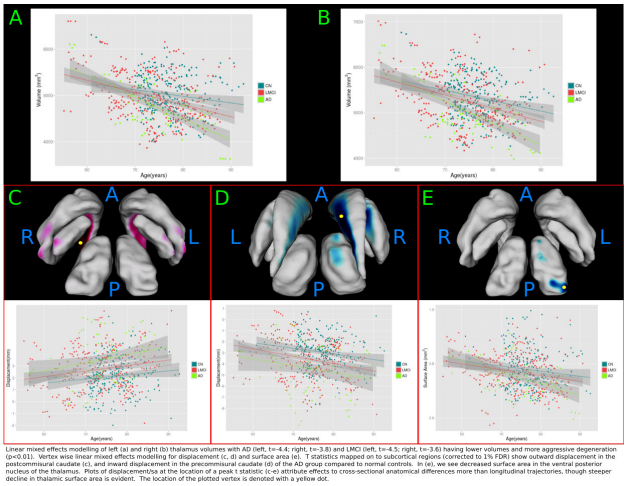
Title: Subcortical volume and morphology in Alzheimer's disease and mild cognitive impairment

Authors: *M. R. PATEL[1], G. DEVENYI[1], V. KONG[1,2], M. CHAKRAVARTY[1,3]; [1]Cerebral Imaging Ctr., Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Integrated Program in Neurosci., [3]Departments of Psychiatry and Biomed. Engin., McGill Univ., Montreal, QC, Canada

Abstract: Background The neurodegenerative processes in Alzheimer's disease have been well-characterized at the level of the neocortex and the hippocampus. Surprisingly, subcortical structures such as striatum, thalamus, and pallidum have received little attention. Here, we analyze these structures a longitudinal fashion. Methods 800 T1-weighted images from ADNI1 (291/509 1.5T/3T) were preprocessed with minc-bpipe-library then processed using MAGeT brain, which outputs volume, vertex displacement (DP), and vertex surface area (SA) on a per structure basis. 602 passed a manual quality control (79/291/232 AD/MCI/NC, 328/274 F/M). Effects of diagnosis were examined using a linear mixed effects model, accounting for age, and sex. Modelling of volume changes was done with and without covarying for ICV to explore correlations of diagnosis and volume. DP and SA were corrected for multiple comparisons with FDR. Results We observed decreased bilateral thalamic volume ($p<0.01$) in Alzheimer's patients (AD) (left, t=-4.4; right, t=-3.8) and late mild cognitive impairment patients (LMCI) (left, t=-4.5; right, t=-3.6) populations compared to normal controls (NC). AD and LMCI patients had increased inward DP in the anterior thalamus and decreased SA in the ventral posterior nucleus of the thalamus. Compared to NC, we found bilateral increased inward DP in the precommissural caudate, counterbalanced by increased outward DP in the postcommissural caudate in AD and LMCI patients (1% FDR). In the pallidum, we found bilateral inward DP at the anterior end and outward DP at the posterior end (1% FDR). No significant differences were found between AD and MCI groups. Conclusion We found that the thalamus shows pronounced degeneration in AD and LMCI patients at a steeper trajectory. We saw that AD and LMCI caudate show a posterior bulging out DP, suggesting an accompanying thinning of the nearby internal capsule. Finally, we found that subcortical structures do not appear to be major factors in distinguishing AD from MCI patients, but may be involved in the onset of the prodromal of Alzheimer's disease.



Linear mixed effects modelling of left (a) and right (b) thalamus volumes with AD (left, t=-4.4; right, t=-3.8) and LMCI (left, t=-4.5; right, t=-3.6) having lower volumes and more aggressive degeneration (p<0.01). Vertex wise linear mixed effects modelling for displacement (c, d) and surface area (e). T statistics mapped on to subcortical regions (corrected to 1% FDR) show outward displacement in the posterior commissural caudate (c), and inward displacement in the precommissural caudate (d) of the AD group compared to normal controls. In (e), we see decreased surface area in the ventral posterior nucleus of the thalamus. Plots of displacement/sa at the location of a peak t statistic (*) attribute effects to cross-sectional anatomical differences more than longitudinal trajectories, though steeper decline in thalamic surface area is evident. The location of the plotted vertex is denoted with a yellow dot.

Title: Heterogeneity in neuroanatomical differences in relation to amyloid burden in mild cognitive impairment

Authors: ***V. KONG**[1,2], G. DEVENYI[1], R. PATEL[1], M. CHAKRAVARTY[1,3];
[1]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Integrated Program of Neurosci., [3]Departments of Psychiatry and Biomed. Engin., McGill Univ., Montreal, QC, Canada

Abstract: Introduction Amyloid deposits have long been considered to be related to the initiation of Alzheimer’s disease (AD), but a high amyloid burden alone does not predict the diagnosis of AD. The goal of the project was to determine neuroanatomical differences between subjects with high and low amyloid burden and to investigate how those differ in the diagnostic groups of AD, mild cognitive impairment (MCI) and cognitively normal controls (NL). Methods

3458 3T T1-weighted magnetic resonance images (MRI) and analyzed florbetapir (FBP) positron emission tomography data were obtained from the Alzheimer's Disease Neuroimaging Initiative database for 860 subjects (141 AD, 456 MCI, 263 NL; baseline to 3 years). Subjects were divided into high and low amyloid groups, using average FBP standardized uptake rate with cerebellum as reference. MRI scans were processed using the CIVET pipeline for cortical thickness (CT), MAGeT Brain algorithm and BEaST for hippocampal volume (HV) and morphometry using surface displacement (HD). Linear mixed-effects model is used to examine the effect of amyloid burden on CT, HV and HD for all subjects (covaried for age, gender, baseline diagnosis and total brain volume) and within each diagnostic group (covaried for age, gender and total brain volume). Results There was significant reduction for high amyloid subjects in both left and right CT and HV and a further significant interaction between high amyloid burden and MCI. When stratified into diagnostic groups, NL and AD subjects showed no significant differences in all the measures, while MCI subjects have significant decrease in both left and right CT in the medial temporal and posterior association cortex regions. No hippocampal shape differences were observed. Discussion & Conclusion Here we show that high amyloid in MCI subjects is related to accelerated neurodegeneration in HV and CT, while differences are not pronounced in NL and AD subjects. NL subjects with high amyloid are able to maintain integrity, while AD subjects, regardless of amyloid burden, had considerable atrophy to show any difference in anatomy.

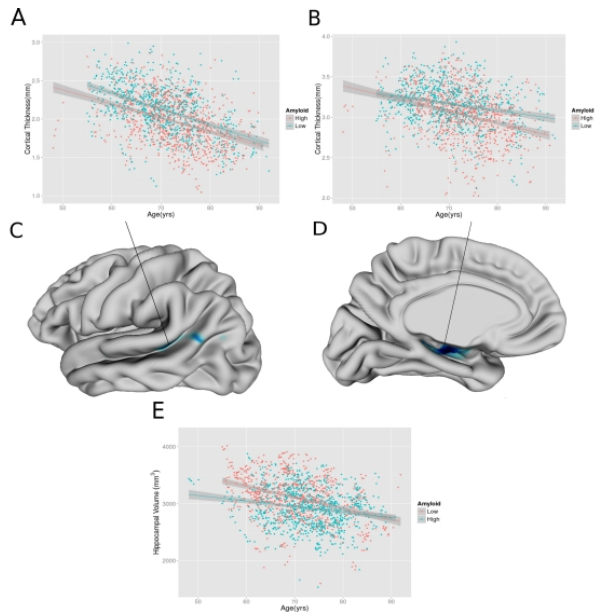

Figure. Differences of left hemisphere CT and HV in MCI subjects. C,D) CT difference between subjects high and low amyloid after FDR correction of 5%. A,B) CT differences over age at vertices selected from C and D. E) HV for subjects with high and low amyloid over age with linear regression lines

Title: 5-HT2c agonists-induced changes in cerebral blood oxygen-level dependent (BOLD) pharmacologic magnetic resonance imaging (phMRI) in awake rats and blockade with 5-HT2c antagonist: a potential pharmacodynamic biomarker

Authors: ***S. J. BAKER**[1], G. FOX[1], K. DRESCHER[2], J. BEAVER[1], A. M. BASSO[1]; [1]ZR13, AbbVie Labs, North Chicago, IL; [2]GmbH & Co.KG, AbbVie Labs, Ludwigshafen, Germany

Abstract: 5-HT_{2C} receptor activation plays a critical role modulating neurotransmission and brain circuits relevant to the pathophysiology of neuropsychiatric disorders, drug addiction and obesity. Preclinical studies and clinical trials with 5-HT_{2C} receptor agonists (Lorcaserin, Vabicaserin) indicate that 5-HT_{2C} biology translates from preclinical species to humans. The Vabicaserin clinical trials, however, provide no receptor occupancy or translational biomarker data. 5-HT_{2C} receptor occupancy and pharmacodynamic effects on brain function across rodents, NHPs and healthy humans could be used for dose selection in early clinical studies. At this time, however, no selective 5-HT_{2C} PET tracer is available to interrogate receptor occupancy and the plasma concentration relationship for 5-HT_{2C} receptor agonists. phMRI is an established imaging modality that can measure changes in BOLD activity following administration of pharmacological agents with regional specificity. The goal of the present study was to evaluate phMRI as a pharmacodynamic/*in vivo* biomarker for functional dose-response effects of 5-HT_{2C} agonists and the receptor specificity of this response. Previous phMRI studies by others demonstrated that mCPP, a 5-HT_{2C} receptor agonist, induces comparable effects on BOLD signal in anesthetized rats and healthy humans. Male Sprague-Dawley rats (350-450g) were used for phMRI studies. Following a mock MRI training regimen, animals were scanned using a restrainer specifically designed for small-animal awake MRI on a 70/30 Bruker Biospec: eight-shot spin-echo EPI sequence, TR/TE = 3200/50ms, in-plane resolution= 250 μm^2 in a 128 x 128 2D voxel matrix, slice thickness = 1.25 mm and inter-slice spacing = 1.5 mm. Total scan time for a single experiment was 42 min (10 minute baseline-2minute i.p. infusion-30 minute post-dose). BOLD signal percent-change was interpreted using VivoQuant (Invicro; Boston, MA) software. Average maps were created using analysis of functional neuro-images (AFNI) (Cox et al., 2005). The current study confirms the findings using mCPP in awake rats and expanded the dataset to include another 5-HT_{2C} agonist compound, Vabicaserin. Vabicaserin (1-30 mg/kg) induced dose-dependent increases in BOLD signal in brain regions consistent with the distribution of 5-HT_{2C} receptors and neuronal projections. SB-242084 (1 mg/kg) attenuated the increases in BOLD signal induced by mCPP, and Vabicaserin in conscious rats, suggesting that BOLD changes are

specifically mediated by 5-HT_{2C} receptors. Further studies are planned to investigate whether the BOLD signal changes observed in rodents will translate to a higher species, NHPs.

Title: Rapid, fully automated method for quantitative analysis of PET amyloid scans in Alzheimer’s disease

Authors: ***P. H. KUO**[1,2], P. K. BHARADWAJ[3], W. P. KRAFFT[1], M. C. FITZHUGH[3], G. E. ALEXANDER[3,4,5,6,7], G. ZUBAL[8];

Abstract: Amyloid imaging by positron emission tomography (PET) plays a critical role in patient selection for clinical trials for Alzheimer’s disease (AD) and is also poised for more routine clinical use. Unlike analyses of CSF for beta amyloid or tau, PET amyloid imaging provides information on the regional distribution of amyloid in brain. While visual read is the clinically approved method for interpretation of amyloid imaging, software quantification is vital for research and may also become an effective tool for computer-aided diagnosis. Important features of quantification software include diagnostic accuracy, reproducibility, speed, and resource requirements. The Alzheimer’s Disease Neuroimaging Initiative (ADNI) has collected a cohort of controls and AD patients’ clinical information, neuroimaging scans, and biomarkers. The ADNI database provides quantitative analyses of amyloid imaging with the application of a semi-automated method using Freesurfer (FS) software that can typically require hours to

analyze a scan. In contrast, the Alzheimer's Disease Evaluation of Radiotracers (ADER) software is a fully automated program that yields quantitative, reproducible regional results of amyloid deposition and can analyze a scan in less than a minute using a standard laptop computer. We report initial results using ADNI data to compare ADER and a semi-automated method with FS using discriminant analysis to determine classification accuracy between patients with AD and controls. In the ADNI database, a semi-automated processing stream involving registration of PET images with structural scans and cortical parcellation with FS is used to obtain a mean SUVr from four regions. The average value from a similar set of four regions for ADER (frontal, parietal, anterior cingulate, and precuneus) was then used for our evaluation. Only those ADER processed scans with a good quality control rating were used, including 93 controls and 64 AD patients. Discriminant analysis using the mean of 4 regions calculated by ADER produced an overall classification accuracy of 80%, controls' classification accuracy of 88% and AD classification of 67%. Discriminant analysis using the mean of 4 regions calculated by the semi-automated FS method resulted in an overall classification accuracy of 82%, controls' classification accuracy of 89% and AD classification of 72%. A linear regression analysis comparing the two methods showed good agreement (adjusted R2 = 0.71). These preliminary results show that the fully automated ADER achieves advantages of speed and lower resource requirements without sacrificing overall diagnostic accuracy compared to a semi-automated method with FS.

Abstract: Apolipoprotein E (APOE) has three isoforms: APOE2, APOE3, and APOE4. APOE4 is a major genetic risk factor for Alzheimer's disease (AD), a debilitating dementia characterized by early and progressive neurovascular dysfunction. APOE4 has direct effects on the cerebrovascular system, resulting in microvascular lesions and blood-brain barrier (BBB) damage. Using high-resolution dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) to simultaneously map BBB integrity regionally and quantitatively, our recent study in humans demonstrated BBB disruption restricted to the hippocampus in aging and in patients with mild cognitive impairment (MCI). In this new MRI study, we first analyzed disruptions in brain structure and function in humans with genetic risk of AD (APOE4 carriers vs. non-carriers) who were cognitively normal or MCI. We show accelerated BBB breakdown in APOE4 carriers, particularly in the hippocampal region. BBB breakdown is also highly correlated with loss in white matter integrity, measured using diffusion tensor imaging (DTI)-derived fractional anisotropy and mean diffusivity. Furthermore, we find reduced cerebral blood flow (CBF) using arterial spin labeling (ASL) method in the hippocampus and subcortical regions in MCI individuals, which worsens in APOE4 carriers. We conducted similar experiments in transgenic mice carrying 5 familial-AD mutations (5xFAD) that overexpress human amyloid-beta (Aβ), and express human APOE3 or APOE4 (E3/E4FAD). We show an age-dependent increased BBB permeability in the cortex and hippocampus of wildtype animals, consistent with our recent findings in humans. Notably, we provide the first *in vivo* preclinical evidence revealing that E4FAD mice have an increased cortical/hippocampal BBB permeability compared to age-matched E3FAD mice, which correlates with the magnitude of BBB breakdown using *in vivo* two-photon imaging. Correlation between DTI metrics and hippocampal BBB permeability measures are also found in AD mice. Finally, we show a decrease in CBF in the cortex and hippocampus of E4FAD mice compared to age-matched E3FAD mice using a dynamic susceptibility contrast (DSC) method. These new MRI findings corroborate our recent study in humans showing that individuals carrying the E4 allele may be predisposed to accelerated pericyte loss and greater BBB damage. In sum, we provide evidence in both humans and mice illustrating accelerated neurovascular alterations in APOE4 carriers, emphasizing that brain microcirculation and BBB integrity drive the initial pathological changes in the living brain leading to cognitive decline and neuronal loss.

Title: Electrophysiological alterations by 5-HT2C receptor agonist CP-809,101 in sleep EEG and power spectral activity

Authors: P. VESELCIC, Y. MORDASHOVA, *K. M. WICKE;
Abbvie Germany Gmbh & Co KG, Ludwigshafen, Germany

Abstract: The serotonergic 5-HT2C receptor is a key contributor to a variety of medical conditions including psychiatric and neurological diseases. Therapeutic approaches at this receptor, with both, agonists and antagonists continue to emerge1. To better understand 5-HT2C mediated function we have investigated electrophysiological changes in sleep structure and EEG power spectral distribution by the highly selective 5-HT2C receptor agonist CP-809,101. In two independent studies, male Fischer rats with chronically implanted supracortical EEG-electrodes were treated with 10 mg/kg of CP-809,101. In the 1st study, sleep structure changes in terms of total sleep time, percent of time spent in different sleep stages, the number of rapid eye movement (REM) episodes, and latency to first sleep and REM episode were analyzed. Treatment with CP-809,101 led to attenuation of time spent in mild, deep, and REM sleep. It increased time spent awake and latency to first sleep and REM episode. The 2nd study investigated power spectral distribution changes revealing an attenuation of delta and theta band by CP-809,101 in comparison to vehicle and baseline recordings while maintaining the delta/theta ratio. A refined statistical method for analysis of power spectral changes was applied. Our results clearly demonstrate that acute treatment with CP-809,101 changes sleep and power spectral parameters in a mutual way. 5-HT2C agonists have been suggested to exhibit antidepressant-like profile that fits to the sleep changes observed in our study. Further, 5-HT2C

agonists have been reported to inhibit theta oscillation, desynchronizing the EEG and leading to shifts to lower frequencies2,3. Yet, despite the inhibition of theta oscillation and desynchronization of the EEG by CP-809,101, the ratio between delta/theta revealed no changes underlying the wake-promoting effects of CP-809,101. 1 Rosenzweig-Lipson et al 2011 Neuropsychopharmacol. 36:363 2 Hajos et al 2003 JPET 306:605 3 Sörman et al 2011 Neuropharmacol 61:489 Disclosures: All authors are employees of AbbVie. Title: Synchrotron x-ray fluorescence indicates enhanced zinc load in plaques of CRND8 animals supplemented with dietary copper

Authors: *P. A. KAKALEC[1], K. N. BOGGS[2], S. N. HOWELL[2], C. M. GROEBER TRAVIS[3], J. M. FLINN[1];
[1]Psychology, [2]George Mason Univ., Fairfax, VA; [3]Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Amyloid beta (Aβ) plaques characteristic of Alzheimer’s disease contain varying levels of trace metals such as copper, iron, zinc, and aluminum, which may influence and accelerate their aggregation. Metals such as iron have been reported in tissue surrounding plaques, while copper and zinc have been shown to directly bind to Aβ. Furthermore, zinc being the second most abundant trace metal in the body, is required for many physiological processes such as protein folding and enzyme function. In fact, APP itself actually contains a zinc binding site in its promoter region, and its expression is tightly regulated by zinc-containing transcription factors (Vostrov & Quitschke, 1997). There is considerable information available to the general

population, which supports dietary enrichment of trace metals and minerals through supplementation. As much as half of the U.S. population takes daily vitamins enhanced with copper, iron, zinc, and other minerals, with the idea that there is no such thing as too much supplementation (Radimer et al., 2004). This is an alarming misconception, as researchers have shown that alterations in homeostatic levels of these trace metals not only cause abnormalities in plaque load, but they can also cause or exacerbate memory impairment. To examine the effect of dietary metal supplementation on metal content in Alzheimer's plaques, CRND8 animals (n=16) were administered enhanced drinking water for 5 months: Fe (10ppm FeNO3), Fe+Cu (10ppm FeNO3 + 0.2ppm CuNO3), Cu (0.2ppm CuNO3), and lab tap water. Water was analyzed regularly using inductively coupled plasma-optical emission spectroscopy and ion chromatography at the United States Geological Survey (USGS, Reston, VA) to confirm metal content. Congo red staining was first performed in these animals in order to locate and confirm plaques. Upon confirmation of plaques, slides were taken to National Synchrotron Light Source at Brookhaven National Laboratory for analysis of both bound and free metal content. With the use of beamline X-26A total zinc load was measured at levels below 100 ppm in each of the four water conditions. Statistical analysis of zinc content showed significantly higher levels of zinc in CRND8 animals supplemented with copper water ($p= 0.014$) compared to iron water. Additional analyses are ongoing.

Title: Concurrence of mild cognitive impairment and increased cerebral iron load, as measured by quantitative susceptibility mapping, is associated with increased frontotemporal functional connectivity at rest

Authors: *J. VAN BERGEN[1,2], X. LI[2], M. WYSS[3], J. HUA[2], S. SCHREINER[1], S. STEININGER[1], F. QUEVENCO[1], S. LEH[1], A. GIETL[1], R. NITSCH[1], K. PRUESSMANN[3], P. C. M. VAN ZIJL[2], C. HOCK[1], P. G. UNSCHULD[1];

Abstract: Introduction Altered functional connectivity during preclinical Alzheimer's Disease (AD) has been shown to be a robust finding by several resting state fMRI (rs-fMRI) studies. Various cognitive networks are implicated in brain change associated with AD-pathology and alterations of the default mode network (DMN) are considered to particularly reflect compensatory mechanisms for neuronal damage. On the other hand increases in cerebral iron may reflect pathological alteration in a context of neurodegeneration. Developments in the field of Quantitative Susceptibility Mapping (QSM) have made it possible to directly map brain tissue magnetic susceptibility, which has been shown to correlate well with tissue iron concentration in most brain gray matters. This study aims to assess a potential functional signature of iron accumulation during the stage of Mild Cognitive Impairment (MCI). **Methods** Eighteen subjects with MCI (11 male, 7 female; age 75.0 ± 7.2) and twenty-two cognitively normal elderly controls (14 male, 8 female; age 72.0 ± 5.3 were scanned on a 7T Philips Achieva System. All participants received psychiatric examination and were categorized as cognitively normal or MCI. rs-fMRI was acquired using a 3D T2-prep GRE sequence (TR = 2s, TR_{GRE}/TE_{GRE} = 3.08/1.6ms, 1.5x1.5x1.5 mm^3). Phase data for susceptibility measurements was acquired using a multi-echo 3D GRE scans (TR/TE/ΔTE=23/6/6ms, 0.5x0.5x0.5mm^3). Susceptibility maps were reconstructed by sequentially applying Laplacian based phase unwrapping, sophisticated harmonic artifact reduction for phase data (SHARP) and LSQR based minimization. Classification in “high” and “low” cerebral iron content was performed by a median split of the average cortical grey matter susceptibility in frontal, parietal, temporal and occipital lobes. The iron classification and MCI status were used as the covariates in connectivity analysis using the CONN MATLAB toolbox. **Results** Strong (p-FDR-corrected < 0.001, $T_{1,23}$=4.32) increase of activity in a frontotemperal region for the combined effect of MCI status and “high” iron load was observed. Prominent structures in these region include Frontal Pole and Gyrus, Temporal Pole and Gyrus, Cingulate Gyrus, Paracingulate Gyrus, Amygdala and Nucleus Accumbens. **Discussion and Conclusion** Our data demonstrate increased frontotemporal connectivity in a context of high cerebral iron, as indicated by QSM, and MCI. Further research on the relationship between susceptibility and pathological correlates of AD, such as Amyloid beta plaque density, appears promising for investigation of physiological correlates of altered functional connectivity during preclinical AD.

Abstract: Background: Parental family history (FH) of Alzheimer's disease is associated with greater risk for developing the disease, as well as several preclinical brain changes. Previous work from our laboratory has found an effect of maternal family history on cerebral white matter, but it is unknown if the effect is due to axonal or myelin degeneration. The objective of the current study was to assess the effect of FH on myelin, using novel Multi-component Driven Equilibrium Single-Pulse Observation of T1 and T2 (mcDESPOT) imaging, which is sensitive to myelin content. We hypothesized that FH, particularly maternal FH would have a negative effect on myelin. **Methods:** 128 participants (mean age: 61.72 ± 6.32 years; range 45-74 years) from the Wisconsin Registry for Alzheimer's Prevention underwent mcDESPOT on a GE MR750 3T to calculate myelin water fraction (MWF) maps. Parental FH of AD was based on probable or confirmed AD of one or both parents determined through structured interview or determined through autopsy and reviewed by a multidisciplinary diagnostic consensus panel. Absence of parental FH required that the participant's father survive to at least age 70 and the mother to age 75 without incurring a formal diagnosis of dementia or exhibiting cognitive deterioration. A voxel-wise two-sample t-test in SPM12 was used to compare positive family history and

negative family history, in addition to specifically examining the effect of maternal family history on MWF, adjusting for age and sex. **Results:** Positive parental family history was associated with higher MWF. Affected regions were localized primarily to frontal, parietal, and occipital cortical regions. Participants with maternal family history specifically, showed higher WMF compared to participants without FH, in addition to higher WMF compared to participants with paternal FH. **Conclusions:** Prior studies suggest that parental FH of AD is associated with brain differences, even in asymptomatic individuals. This is the first study to suggest myelin differences based on parental FH. Contrary to our hypothesis, we found evidence for higher myelin levels among individuals with parental FH, particularly maternal family history. Given the strong risk for AD associated with maternal FH, further study is needed to determine the mechanism which underlies increased myelin content among participants who are vulnerable to AD.

Title: Genetic risk scores for Alzheimer’s disease are associated with thinning of hippocampal complex subregions

Authors: *T. M. HARRISON[1], E. P. LAU[2], Z. MAHMOOD[2], A. C. BURGGREN[2], G. W. SMALL[2], S. Y. BOOKHEIMER[2];
[1]Semel Inst. for Neurosci. and Human Behavior, [2]UCLA, Los Angeles, CA

Abstract: Twenty-one genetic loci have been identified for which specific variants increase an individual’s risk for sporadic, late-onset Alzheimer Disease (AD). Many of these risk genes have been identified using genome-wide association studies. An important unresolved question is whether or not polygenic risk scores that use combinations of risk loci increase power to detect

changes in neuroimaging biomarkers for AD. Further, the optimal method to calculate polygenic risk scores is an active field of research. In a pilot study, we acquired high-resolution structural images of the hippocampus in 47 healthy, older subjects. For 15 of these subjects, longitudinal two-year follow-up data were also available. Unweighted and weighted polygenic risk scores for AD were calculated for each subject. The unweighted risk score (URS) was the sum of family history of AD (0 if negative history or 1 if positive history), APOE4 alleles (0,1, or 2), CLU risk alleles (0,1, or 2) and PICALM risk alleles (0,1, or 2). The weighted risk scores (WRS) used published odds ratios (OR) to weight the relative contribution of these risk factors before summing: positive family history OR=2, APOE4 OR=3, CLU minor allele OR=0.9, PICALM minor allele OR=0.9. For the cross-sectional cohort, both URS and WRS showed no relationship to thickness in any hippocampal subregion. For the longitudinal cohort, URS and WRS correlated strongly to percent change in thickness across the whole hippocampus (URS r=-0.85, p=0.0001; WRS r=-0.63, p=0.015), driven by strong relationships in the entorhinal cortex (URS r=-0.66, p=0.01; WRS r=-0.73, p=0.003) and CA23/dentate gyrus (URS r=-0.66, p=0.01; WRS r=-0.65, p=0.01), two anterior subregions of the hippocampal complex. In a multiple regression including age and sex as predictors, models with URS (beta=-2.16, p=0.0003) and WRS (beta=-7.01, p=0.014) predicting percent change in thickness across the whole hippocampus were significant (URS model p=0.009; WRS model p=0.03). These results provide compelling evidence that polygenic AD-risk scores may be especially sensitive to structural change over time in regions affected early in AD, like the hippocampus. Our findings also show that the relationships between our polygenic risk score and hippocampal thinning are not mediated by weighting risk score components with published ORs.

Abstract: INTRODUCTION: Although viewed as separate clinical entities, the line between Alzheimer's disease (AD) and vascular dementia is becoming increasingly blurred, and research on the vascular contributions to AD is of utmost importance as they may exacerbate AD pathology and clinical symptoms. 4D Flow MRI with phase contrast vastly undersampled isotropic projection imaging (pcVIPR) allows researchers to obtain comprehensive measurements of intracranial vascular health, such as mean flow in the arteries of the Circle of Willis. It remains to be determined if and how pcVIPR metrics correlate with perfusion-weighted imaging using Arterial Spin Labeling (ASL). Evidence indicates that cerebral blood flow (CBF) is lower in AD, and hypoperfusion is also present in similar regions in individuals with mild cognitive impairment and/or with genetic risk for AD. However, the relationship between perfusion weighted CBF and metrics of cerebral artery flow and health has not been clearly established *in vivo* across the spectrum of AD severity. METHODS: 130 middle aged adults, 42 cognitively healthy older adults, 28 MCI patients, and 18 AD patients (N = 218, mean age 63.2, SD: 9.8) underwent 4D Flow MRI using pcVIPR as well as ASL imaging with a 1525 tagging delay. Statistical parametric mapping version 12 (SPM12) software was used for voxel-wise regression analysis, with middle cerebral artery (MCA) mean flow as the predictor variable, age and gender as covariates, and CBF measured via ASL as the outcome variable. RESULTS: Average bilateral MCA mean flow was positively associated with ASL whole brain perfusion (max t = 7.61) in frontoparietal regions, including the precuneus, a brain region known to be involved in the pathogenesis of AD. All significant clusters survived familywise error (FWE) correction with p values < 0.05 using a critical t-value of 4.24. CONCLUSION: With any novel technology, it is important to determine how it may inform or add to existing methods. ASL is a commonly used technique in AD research, and this study helps to link intracranial arterial flow measured via pcVIPR to local cerebral perfusion delivered to capillary beds measured in ASL. These data demonstrate a consistent pattern of disrupted blood flow, using two different techniques, across the AD spectrum. Further characterization of ASL and pcVIPR metrics are needed to clarify the relationship between vascular health and AD.

Title: Local shape differences are associated with amyloid beta load and neuropsychological performance in cognitively normal elderly individuals

Authors: *C. SCHROEDER[1], A. GIETL[1], M. M. CHAKRAVARTY[2], M. M. PARK[2], L. MICHELS[3], S. KOLLIAS[3], P. G. UNSCHULD[1], S. L. KROLL[1], A. M. KÄLIN[1], C. HOCK[1], S. E. LEH-SEAL[1];

Abstract: Amyloid plaque and tangle formation is a hallmark of Alzheimer disease (AD). Pittsburgh compound B positron emission tomography (PiB-PET) measures amyloid beta (Aβ) load, which increases substantially before clinical symptoms appear in AD. Aβ load has been shown to be associated with risk of conversion to very mild AD in cognitively normal elderly individuals. Changes in amyloid PET are thought to precede volumetric changes assessed by structural (T1) magnetic resonance imaging (MRI) such as hippocampal atrophy. Because of the vast and growing number of at-risk individuals in our society, a biomarker derived from T1 data that becomes abnormal comparably early to amyloid PET would be highly valuable given the ready availability and non-invasive nature of MRI. Our sample comprised 69 cognitively normal elderly subjects (age 55-80 years, 32 female). Our measures included standardized uptake value ratio (SUVR) from dynamic PiB-PET imaging, volumes of numerous brain regions from 3 Tesla MRI, cortical thickness (CT), shapes of subcortical structures, and performance in neuropsychological tests. Segmentation of subcortical structures was performed using the MAGeT Brain algorithm. We tested associations between those measures controlling for the influence of age. We found bilateral negative associations between SUVR and CT in the entorhinal cortex (EC) ($p = 0.05$, FDR-corrected) and within these regions, EC CT predicted performance in a test of executive function (EF). Left-hemispheric associations between SUVR and shape were present in the globus pallidus (GP) and thalamus ($p = 0.1$, FDR-corrected): In the GP, associations were present in the posterior medial nucleus for outward and in the anterior lateral nucleus for inward displacements. Within this region of the medial nucleus, inward displacements predicted performance in a test of EF. In the thalamus, associations were present

in the anterior, medial, and lateral dorsal nucleus for inward and in the pulvinar and ventral posterior nucleus for outward displacements. The EC is affected early by AD pathology and CT in this region was bilaterally associated with SUVR in healthy elderly individuals. Shapes of subcortical structures showed left-hemispheric associations with SUVR, in line with findings of stronger left- versus right-hemispheric abnormalities in mild AD. Shape in the left medial pallidal nucleus, which is involved in EF, was associated with SUVR and performance in a test of EF, as was CT of bilateral EC. These findings suggest that local shape differences parallel behaviorally relevant pathological states at the presymptomatic stage of neurodegenerative diseases.

Title: Comparison of diffusion weighted imaging protocols for investigating Alzheimer’s disease in ADNI

Authors: *A. ZAVALIANGOS-PETROPULU[1], N. JAHANSHAD[1], C. JACK[2], M. WEINER[3], M. A. BERNSTEIN[2], R. I. REID[2], P. M. THOMPSON[1];

Abstract: Diffusion weighted imaging (DWI) is a popular neuroimaging tool in clinical research to identify biomarkers for neurodegenerative diseases. In preparation for its third phase and to allow improved processing and tractography methods, the Alzheimer’s Disease Neuroimaging Initiative (ADNI) has begun acquiring higher directional resolution enhanced DWIs (eDWI; 68 diffusion-weighted and 8 b0 images) in addition to its original DWI scanning protocol (oDWI; 46 diffusion-weighted and 5 b0 images) during the same MRI session. While the protocol

changes are considered improvements, it is crucial to characterize any differences across scan protocols to maintain empirical integrity. We used identical processing methods for both the eDWI and oDWI scans according to the ENIGMA-DTI protocol, which is designed to generate robust measures across DWI acquisition schemes. We assessed the sensitivity to protocol changes of diffusion tensor imaging (DTI)-derived scalar measures of white matter microstructure in 34 subjects from the ADNI dataset (age: 74±6.8; M/F: 22/13; 12 CN, 12 eMCI, 8 lMCI, 2 AD). Fractional anisotropy (FA) and mean diffusivity (MD) measures were extracted from the white matter skeleton and averaged across regions of interest (ROIs). With a paired t-test, we compared the enhanced and original DTI data at each ROI. 7 of the 63 ROIs studied yielded significantly different measurements of FA, and 49 of 63 were significantly different for MD (after controlling for the multiple tests with the false discovery rate procedure; $q = 0.05$; Table 1). FA measurements may be less sensitive to the protocol change than MD measurements as the DWI's angular resolution increases. Average FA ROIs were generally higher in the oDWI than the eDWI. In this small sample, no significant differences were detected between controls and those with lMCI and AD when testing each protocol individually. These preliminary results suggest the need to further assess differences between the two types of images with a larger data set. More enhanced DWI scans are currently being acquired as part of ADNI and should make for an insightful comparison of protocols.

Abstract: The abnormal aggregation of amyloidogenic proteins characterizes many neurodegenerative diseases and underlies the formation of the canonical pathological features of Alzheimer's disease (AD). Recent findings suggest that the amyloid-β (Aβ) peptide, which constitutes one of the principal aggregating proteins in AD, can adopt distinct structural conformations, reminiscent of prion strains. Indeed, in transgenic mouse models, strain-like variations of Aβ lesions can be seeded and propagated. However, the origin of these diverse structural characteristics and their relation to the clinical phenotype in AD patients remains obscure. With the aim of further analyzing variant molecular conformations among aggregated Aβ species, we used novel, conformation-sensitive methods to probe the molecular architecture of multimeric Aβ in an unusual case of AD that showed abnormally reduced high-affinity binding of Pittsburgh compound B (PIB). Specialized fluorescent dyes (luminescent conjugated oligothiophenes) as well as a novel flow cytometry assay, both designed to discriminate different amyloid structures, reliably distinguished between the PIB-refractory case and PIB-positive AD cases. These results provide evidence for the structural diversity of Aβ conformers among AD patients, which may be at the root of individual disease phenotypes.

Title: Differences in inmunosignal distribution pattern for Aβ and pTau between late-onset sporadic and early-onset familial Alzheimer's disease

Authors: *D. M. TRUJILLO[1], H. ARBOLEDA[2], F. LOPERA[3];
[2]Sch. of Med., [1]Univ. Nacional De Colombia, Bogota D.C, Colombia; [3]Univ. de Antioquia, Medellin, Colombia

Abstract: Neuropathologically, early-onset familial Alzheimer's disease (EOFAD) shows severe Aβ pathology, pronounced brain atrophy and a distinct hyperphosphorylated tau-related pathology that extends to cerebellar cells. In this case series study, a comparative neuropathologycal analysis was made from one group of EOFAD patients and one group with late-onset sporadic Alzheimer's disease (SAD). Deparaffinized slides from the cerebral cortex and cerebellum of EOFAD and SAD patients were obtained from the Brain Bank of the

Neurosciences group of the Universidad de Antioquia. This region in northwestern Colombia, currently comprises the largest population of EOFAD subjects that carries the E280A mutation in PS1. It was observed that EOFAD cases present larger deposits in frontal, temporal, parietal and cerebellar areas; together with higher Aβ immunosignal in the cerebellum. Additionally, SAD cases present smaller Aβ deposits, but in greater quantity, in the temporal and occipital cortex compared with EOFAD. The morphometric analysis of the total immunoreactive burden and Aβ deposits also show that in general, both familial and sporadic patients have a higher immunoreactive Aβ burden in the frontal cortex when compared to the other regions analyzed. Compared with sporadic Alzheimer's disease, EOFAD has some distinctive features. The accumulation of amyloid peptide in familial patients is higher than in sporadic patients matched during CERAD and Braak staging, especially in the form of diffuse plaques. Regarding neurofibril pathology quantification, EOFAD presents itself with higher levels of hyperphosphorylated Tau (pTau) in frontal, parietal, occipital and cerebellar areas. In conclusion, there are neuropathological differences between EOFAD and SAD that could be related with the pathophysiological mechanisms of aggregation and distribution of abnormal deposits in the hereditary variant of Alzheimer's disease. These findings could have further implications on clinicopathological correlations and may also have differential therapeutic impact on those patients.

Abstract: The aim of this study was to evaluate the effect produced by a dopamine releasing implant in striatum in a hemiparkinsonism rat model on motor impairment, 11C-Dihydrotetrabenazine (11[C]DTBZ) uptake by Positron Emission Tomography (PET) to determine the correlation between the DTBZ to VMAT2 binding levels in the striatum, due is widely considered to be a stable marker of dopamine neurone integrity. Methods: 50 male Wistar rats divided in three groups: A) 8 control rats, B) 12 injured rats by administration of the dopaminergic specific neurotoxin 6-OHDA (8µg/4µl) by stereoscopic surgery in left median forebrain bundle (Lx), C) 20 rats with the same lesion and the colocation of a dopamine continuous release titanium dioxide implant (Lx+TiO2DA) and D) 10 rats only with the colocation of implant (TiO2DA). 21 days after the implantation all the groups were underwent to apomorphine spin-induced test (SIT) to determine damage in dopaminergic system. PET scans were performed on left and right striatum measuring the 11[C]-DHTZ uptake. Brains were obtained and mashed to analyze the dopamine content in Striatum by HPLC. Data were analyzed by one-way ANOVA; p values < 0.001 were considered significant. Results: SIT showed an increase of spins in injured animals compared to control and implanted rats: Lx vs control: 289.1 ± 26.32 vs 3.778 ± 2.682, Lx vs Lx+TiO2DA: 289.1 ±26.32 vs 29.89 ±12.33, Lx vs TiO2DA: 289.1 ±26.32 vs 13.67± 7.890. Nevertheless Lx+TiO2DA had an increased vs control: 29.89 12.33 vs 3.778 ± 2.682. PET scans disclosed on the left striatum an increase of uptake in the injured animals compared to implanted animals: Control vs Lx: 4403±1204 vs 8767 ±1422, Lx vs Lx+TiO2DA: 8767±1422 vs 1842±604.6, Lx vs TiO2DA: 8767±1422 vs 3348 ±1427. There is no difference between Control vs Lx+TiO2DA, TiO2DA and Lx+TiO2DA vs TiO2DA. The

right striatum displayed the same pattern: Control vs Lx: 4248±1157 vs 8577±1213, Lx vs Lx+TiO2DA: 1957± 683.1 vs 8577±1213 Lx vs TiO2DA: 3396 ±1547 vs 8577±1213. Here also is no any evident difference between Control vs Lx+TiO2DA, TiO2DA and Lx+TiO2DA vs TiO2DA. HPLC analysis disclosed that striatal dopamine in control animals was: 170.1 ±292.9 ng; in Lx rats: 24.66± 27.34ng, Lx+TiO2DA animals: 29.15± 43.35ng; and TiO2DA rats:123.9± 116.6ng. Conclusion: We conclude that the application of the TiO2DA implant after 21 days could improve the motor function evidenced by the spin-induced test, and this improvement is also evident with the diminishment of 11[C]DTBZ uptake by the implanted animals. In both cases this improvement was not total, but significant.

Abstract: 6-OHDA (6-hydroxydopamine) animal model is widely used in the drug development for Parkinson's disease. Intrastriatal administration of 6-OHDA induces immediate degeneration of the dopaminergic nerve terminals in close proximity of the injection site accompanied by more slowly progressing retrograde cell loss in substantia nigra. Therefore it provides a therapeutic window suitable for neuroprotection and neurorestoration studies. We compared eight different experimental 6-OHDA injection set-ups to find the stable and highly reproducible low dose partial 6-OHDA model of PD. We tested seven different doses from 3 µg to 28 µg of 6-OHDA, three microinjection needles and different striatal injection sites in order to find injection

paradigm better suited for neuroprotection or neurorestoration studies and to reduce the number of used laboratory animals. The progress of lesions was evaluated by amphetamine-induced rotations and the severity of the lesions was assessed by tyrosine hydroxylase (TH) and dopamine transporter (DAT) immunohistochemistry. According to our results, a stable and highly reproducible lesion model can be induced with low doses of 6-OHDA distributed evenly into multiple injection sites (3 x 1 μg , 3 x 2 μg or 3 x 3 μg). Loss of striatal TH- and DAT positive neurites induced by these low doses is at the same level as the loss induced by higher doses (2 x 10 μg and 3 x 7 μg). The stability and reproducibility of the lesion can be enhanced by using a microinjection needle with small outer diameter and small injection volume. Furthermore, injecting the 6-OHDA in 10 degree angle can improve the anatomical targeting into striatum. Together all these factors account for the stability and reproducibility of the lesion and further decrease the number of used animals in the experiments.

Title: Frontocortical overexpression of alpha-synuclein in adult rats reproduces executive cognitive deficits related to Parkinson´s disease

Authors: H. S. LINDGREN[1], D. S. TAIT[3], V. FRANCARDO[1], Z. BIMPISIDIS[1], M. LUNDBLAD[2], V. J. BROWN[3], S. B. DUNNETT[4], *M. A. CENCI[1];

Abstract: Cognitive and psychiatric symptoms are a major cause of disability in Parkinson´s Disease (PD) and do not respond to current treatments. These features are likely to depend on an

interaction between cortical alpha (α)-synuclein-related pathology, aminergic deficits, and neurovascular abnormalities. The relative contribution of different cortical regions and pathogenic factors is poorly understood. In this study, we set out to develop a rat model of frontocortical α-synuclein overexpression and related cognitive deficits that would facilitate future pathophysiological investigations. Methods: Rats received injections of adeno-associated viral (AAV) vectors coding for human wild-type α-synuclein into the medial prefrontal cortex. Transgene expression was driven by a strong neuron-specific promoter (synapsin-1). Rats injected with a control vector (AAV-GFP) and rats with an ibotenic acid lesion of the same prefrontal region served as controls. Eight weeks post AAV-injection, rats were tested in an attentional set-shifting task and in an operant delayed matching-to-position task. In parallel, animals were used to study the dynamics of potassium-evoked glutamate release in the striatum. Results: AAV- α-syn injections resulted in strong expression of human α-syn in neuronal cell bodies within the medial prefrontal cortex, and in axons within the target regions of prefrontocortical projections. Compared to AAV-GFP-injected rats, α-synuclein overexpressing animals were impaired in the ability to shift attentional sets and to acquire a delayed matching-to-position task. *In vivo* amperometry revealed attenuated potassium-evoked glutamate release, and altered kinetics of both glutamate uptake and release in the striatum. Similar though more pronounced behavioural-neurochemical findings were obtained in rats injected with ibotenic acid into the same prefrontal region. Conclusion: Frontocortical overexpression of α-synuclein causes executive cognitive deficits and pathological features relevant to PD. This model may therefore have face validity for translational research on mechanisms and treatment approaches to cognitive dysfunction in PD.

Title: Effects of melatonin on non-motor symptoms and oxidative stress induced by a single intranasal administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in mice, an animal model of Parkinson's disease

Authors: *J. M. MACK[1], T. M. MOURA[1], C. L. GONÇALVES[2], A. L. DAFRE[2], M. FARINA[2], R. D. S. PREDIGER[1];
[1]Pharmacol., [2]Biochem., Univ. Federal De Santa Catarina, Florianópolis, Brazil

Abstract: Parkinson's disease (PD) is characterized by motor and non-motor symptoms that are related with the progressive degeneration of dopaminergic neurons in the nigrostriatal pathway. Our research group previously demonstrated that a single intranasal (i.n.) administration of the pro-neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is able to induce olfactory, emotional, cognitive and motor impairments in rodents associated with time-dependent loss of dopaminergic neurons in different brain areas. The aim of the present study was to evaluate the potential of the repeated administration of exogenous melatonin, a neurohormone produced and released by the pineal gland that has been associated with neuroprotective effects in PD, to prevent behavioral and neurochemical changes induced by a single i.n. MPTP administration in mice. All procedures were approved by local Ethical Committee in Animal Research (PP0830/2012). Male C57BL/6 mice (6 months-old) received melatonin (30 mg/kg) or vehicle (saline) by intraperitoneal route during 25 consecutive days. On the 5th day of treatment animals were anaesthetized with isoflurane (0.96%) and subject to a single i.n. administration of MPTP (1 mg/nostril) or vehicle (saline). The animals were submitted to a battery of behavioral paradigms after MPTP administration that included olfactory discrimination (3rd day), social recognition (5th day), splash test (11th day) and open field (20th day) tasks. On the 21th day after MPTP injection, animals were euthanized and brain structures were collected for Western blotting assays. In order to assess the antioxidant status in the striatum, we evaluated the activity of antioxidant enzymes: CAT, GPx and GR through spectrophotometric methods. Tissues were collected 6 h after MPTP administration. The administration of MPTP induced impairments in olfactory discrimination ability and social recognition memory, anhedonic-like behavior and increased locomotor activity that was accompanied by a significant reduction of striatal tyrosine hydroxylase (TH) levels. Melatonin treatment protected selectively the olfactory deficits without changing the TH levels. Pre-treatment with vehicle plus MPTP and pre-treatment with melatonin plus vehicle induced an increase in CAT and GR activities in striatum. However, pre-treatment with melatonin prevented the MPTP-induced alterations in CAT and GR activities. These results reinforce and extend the potential of melatonin on treatment of PD and these findings can be explained, at least in part, by the known properties of melatonin to increase the cellular antioxidant defenses and act directly as free radical scavenger.

Title: Comparison of striatum and substantia nigra site of CDNF administration in rat 6-OHDA model of Parkinson's disease

Authors: *K. ALBERT, M. H. VOUTILAINEN, A. PANHELAINEN, R. K. TUOMINEN, M. AIRAVAARA, M. SAARMA;
Univ. of Helsinki, Helsinki, Finland

Abstract: Neurotrophic factors (NTF) regulate development of neurons, maintain adult neurons and have been shown to protect and repair damaged neurons in animals. Previous work has been done with NTFs and the neurodegenerative disorder Parkinson's disease (PD) in order to produce neurorestorative therapies, as none exist currently. Recently discovered cerebral dopamine neurotrophic factor (CDNF) has shown therapeutic potential in the rodent 6-OHDA and MPTP models of PD, showing it is a potent NTF to protect dopamine (DA) neurons and restore their function. Experiments were performed to test whether CDNF would have a neurorestorative effect on a 6-OHDA model of PD when given at different doses and injected to different locations in the rat brain. Two weeks after unilateral 6-OHDA lesion (2x10μg) to the striatum, recombinant human CDNF protein was injected into striatum, or substantia nigra, or both areas at varying doses. Amphetamine-induced rotations and cylinder test were used for motor asymmetry evaluation. Optical density of tyrosine hydroxylase fibres in the striatum and substantia nigra were measured to evaluate the severity of the lesion. Behavioural results and immunohistochemistry data indicated that the CDNF dose to the striatum (10μg) or substantia nigra (3μg) on their own were effective in restoring DA neurons. However, the combination of delivery into striatum and substantia nigra had an equally robust neurorestorative effect compared to the single injection into striatum or substantia nigra. Therefore, these injection paradigms work equally efficiently to restore DA neurons and bring about functional recovery.

Title: Synergistic damage of commercially available environmental toxins in Parkinson's disease models

Authors: *E. M. JANEZIC, J. E. CAVINESS, S. G. KANDA, Y.-H. KIM;
Biol., Delaware State Univ., Dover, DE

Abstract: Parkinson's Disease (PD) is the most common motor neurodegenerative disease. It is an age-related disease that affects 1-2% of the population over 60 years of age. The hallmark of PD pathology is the protein aggregation, known as Lewy Bodies, and loss of dopaminergic neurons in the Substantia Nigra pars compacta (SNpc). Although several genetic mutations have been identified to cause PD, they only account for 5-10% of cases. The vast majority of cases are considered to be sporadic, or due to multifactorial reasons. Interestingly, there have been epidemiological studies that have shown that PD is more prevalent amongst farmers and rural populations. It has been suggested that exposure to pesticides and other environmental toxins may increase the risk of PD. In support of this notion, the pesticide rotenone is known to cause PD symptoms in flies and mice. Furthermore, it has been shown that the herbicide, paraquat, and the fungicide, maneb, can cause motor deficits individually, but cause synergistic damage when used together. Since this discovery, these pesticides have been banned in the US and EU. Here we propose that commercially available pesticides, when used together, can cause additive or synergistic damage in *in vitro* and mouse models of PD. We exposed rat dopaminergic N27 cells to commercially used pesticides such as acephate, alachlor, atrazine, chlorothalonil, diuron, glyphosate, imazethapyr, MCPA, and mecoprop at varying concentrations and measured cell viability using the MTT assay. Following single pesticide treatments, we measured cell viability when exposed to different combinations of these pesticides. Our results showed that only high concentrations of single pesticide treatments (e.g. $\geq$ 62.5 μM of chlorothalonil) caused a significant decrease in cell viability. However, when we examined the effect of the combined pesticides (starting with 14 combinations) at concentrations that did not show damage

individually, we identified eight combinations that caused additive damage and three that displayed synergistic damage. Our results suggest that exposure to multiple combinations of pesticides may cause dopaminergic toxicity and further lead to the PD pathology. Currently we are assessing the mechanism of action of toxicity *in vitro*, and analyzing the mouse brain, especially the striatum and the midbrain, after IP injections of a combination of pesticides for two weeks. The objectives of this study are to warn the public of the potential danger of using numerous combinations of pesticides and to impact on changes in policy for approval of pesticides. The results from this study may reveal potential causes for PD and reduce the prevalence of PD.

Title: Pramipexole combined with non-viral transfection of BDNF recovers motor behavior in unilateral 6-OHDA-lesioned rats

Authors: L. R. QUINTERO[1], L. F. RAZGADO[1], A. J. ESPADAS[1], P. E. REYNA[1], A. SIERRA[1], V. ANAYA[3], I. JIMENEZ[1], D. MARTINEZ-FONG[1], *J. ACEVES[2]; [1]Physiol., [2]Ctr. Investigacion Del IPN, Mexico DF 07000, Mexico; [3]Morphology, Estudios Superiores de Iztacala UNAM, Mexico DF, Mexico

Abstract: The chronic (4 ½ months) and continuous (osmotic pump infusion) activation of dopamine D3 receptors combined with the selective and non-viral transfection of the BDNF gene to the remaining dopamine neurons restored nigrostriatal innervation and motor behavior in rats with 6-OHDA-induced degeneration of the nigral neurons (Razgado-Hernandez et al., 2015). Here we explored whether the chronic activation of D3R with Pramipexole (D3R-agonist widely used in clinics) orally administered combined with the BDNF transfection restores motor behavior in this model of PD. We used rats with unilateral lesions of the DA innervation induced

by intrastriatal 6-OHDA injected in three sites (7 µg/site). We evaluated gait (angle of the ankle), motor coordination (beam test), posture (rotarod), akinesia (cylinder test) and muscle rigidity (EMG). Pramipexole was given twice (1 mg/Kg) for 5 months and BDNF was transfected into the DA neurons using the NT-Poliplex (Martinez-Fong et al., 2012), a method that exclusively transfect DA neurons. The combined treatment restored gait, motor coordination and posture and eliminated akinesia and muscle rigidity. The recovery of motor behavior persisted even three months after the end of the treatment, suggesting a trophic effect. The recovery was associated with a partial (about 40 %) recovery of the striatal DA innervation (judged by densitometry) and a partial (about 30%) recovery of the number of DA neurons of the pars compacta. The recovery was also associated with a high (about 80%) expression of the BDNF gene (or protein) and with the expression of BrdU (suggesting neurogenesis) in the TH(+) neurons of the pars compacta. Neither Pramipexole nor BDNF alone recovered motor behavior. Thus, the BDNF transfection to dopamine neurons associated with oral Pramipexole offers a promising strategy for the treatment of Parkinson´s disease.

Title: Body and facial pain in an animal model of Parkinson’s diseases and its possible mechanism and treatment

Authors: *A. TRUONG[1], G. G. ACOSTA[2], R. SHI[2];
[1]BME, [2]Purdue Univ., West Lafayette, IN

Abstract: Parkinson’s disease (PD) is a neurodegenerative movement disorder in which dopaminergic neurons are progressively lost from the brain. The classic symptoms of PD consist of tremor, rigidity, bradykinesia, and postural instability. However, there are also non-motor symptoms of PD that may be even more troublesome than the motor abnormalities. One of the important and under-appreciated complaints among these non-motor symptoms is pain, which is

estimated to be present in more than half of PD patients in various forms and locations. Using a bilateral 6-OHDA/DSP-4 lesion model of PD in rats, we show that parkinsonian rats had increased mechanical sensitivity in the von Frey test of allodynia in hind paw compared to sham-lesioned rats, indicating an increased mechanical pain response in the body extremities in this animal PD model. We also performed the periorbital tactile sensitivity test in these rats to determine the extent of headache and facial pain. Lesioned rats exhibited reduced periorbital pain thresholds compared to sham-lesioned rats indicating increased periorbital sensitivity in parkinsonian rats. While the mechanisms of such neuropathic pain in PD have not been investigated in detail, we have discovered that acrolein, a highly reactive unsaturated aldehyde that has previously been shown to be involved in establishing and maintaining neuropathic pain in spinal cord injury (SCI), was elevated in the lesioned rats. Furthermore, acrolein injection could produce motor behavioral deficits that resemble those associated with the 6-OHDA rats, indicating a probable pathological role of acrolein in this animal model. Interestingly, administration of the acrolein scavenger hydralazine after manifestation of both body and facial pain can reduce acrolein levels and more importantly, mitigate pain sensitivity of parkinsonian rats in both types of pain, in addition to alleviating motor deficits. Acrolein injection to the brain has also produced noticeable neuroinflammation, a process well-known to contribute to neuropathic pain, further supporting a possible role of acrolein in PD pain. Taken together, we have established a model of quantifying neuropathic pain in both body extremities and in facial area associated with a well-established 6-OHDA animal PD model. Further, we have gathered initial evidence that a known pain inducer, acrolein, likely plays an algesic role in pain in a 6-OHDA rat model of PD. Furthermore, anti-acrolein treatment appears to be an effective strategy for pain mitigation in this model.

Title: Symptomatology in Parkinson’s disease: a translational behavioural study in two different 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse models

Authors: *M. SANTORO[1], V. MELIS[2], P.-H. MOREAU[2], J. V. FORRESTER[3], G. RIEDEL[3], P. TEISMANN[3];
[1]Col. of Life Sci. and Med., [2]Sch. of Med. and Dent., [3]Sch. of Med. Sci., Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Background - Nigrostriatal dopaminergic neuronal loss and presence of Lewy bodies are two pathological hallmarks of Parkinson's disease (PD). Intoxication with MPTP is the only example of toxin induced neurodegeneration recapitulating different hallmarks of the disease in human, primates and rodents. PD symptomatology presents with motor and non-motor manifestations. Diagnosis of the disease is based on the onset of motor symptoms, whilst non-motor manifestations are often prodromal to the diagnosis of the disease and observed in 60 % of PD patients. **Objective -** Complete behavioural characterization of two MPTP mouse models of PD has been performed to identify behavioural endpoints valid as translational biomarkers that can discriminate at a sufficiently robust level between saline controls and MPTP lesioned mice. **Methods -** Male C57BL/6J mice ten weeks old were injected i.p. with a sub-acute (30 mg/kg once a day for 5 consecutive days) and acute (4 injections of 20 mg/kg each 2 hours) regimen of the neurotoxin MPTP, control mice received an equivalent volume of saline. Eight behavioural tests were performed chronologically: light-dark box (anxiety), Rotarod, balance beam and CatWalk (gait analysis), PhenoTyper (homecage activity, circadian rhythm), olfactory discrimination and sucrose preference (depression), and Barnes maze (cognition). Behavioural readouts are correlated with dopaminergic neurons in the substantia nigra (stereological cell counting) and, dopaminergic fibres in the striatum (optical density quantification). **Results -** Differences in motor-coordination were detected with balance beam test (latency to traverse) in the sub-acute model, but no fatigue-induced phenotype was revealed in the Rotarod. In the sub-acute MPTP group, marked hyperactivity was observed in olfactory discrimination test (path length), which also affected the habituation to a novel environment (path length per time bin, PhenoTyper). By contrast, acute MPTP administration severely disrupted the animal's gait quantified with CatWalk (stance, stride length, and swing speed). Again, the sub-acute but not the acute MPTP injection regimen yielded a mild cognitive deficit (Barnes maze). **Conclusions -** We have identified behavioural translational biomarkers for PD symptomatology in two MPTP mouse models; greater impairment was achieved using the sub-acute dosing regimen, which affected all disease-relevant symptom domains. This raises two issues: i) Does sub-acute MPTP treatment also conform with the molecular anomalies underlying PD? ii) How does sub-acute MPTP compare to a chronic administration protocol in terms of symptoms?

Title: Characterisation of cognitive dysfunction in an alpha-synuclein rodent model of Parkinson's disease

Authors: *E. K. DOLAN, Y. M. NOLAN, A. M. SULLIVAN;
Anat. and Neurosci., Univ. Col. Cork, Cork, Ireland

Abstract: Background: Viral vector-mediated overexpression of α-synuclein in rodent brains *in vivo* is a newly-developed animal model of Parkinson's disease (PD). It has been shown to reproduce many of the clinical features of PD, including nigral dopaminergic neuron degeneration, decreased striatal dopamine levels and significant motor impairment. In addition to the characteristic motor symptoms seen in PD, cognitive dysfunction such as depression, dementia and dysexecutive syndrome can manifest as the disease progresses. Our study aims to investigate and characterise late-stage cognitive and motor dysfunction using the α-synuclein rat model of PD. **Methods:** Adult male Sprague Dawley rats received into the substantia nigra either unilateral ($3.1x10^8$gc/3µl) or bilateral (two injections of $1.6x10^8$gc/3µl) injection of an adeno-associated viral vector serotype 2/6 overexpressing either human wildtype α-synuclein (n=10 per group) or GFP (n=8 per group). An additional cohort of control animals did not undergo surgery (n=8). Animals underwent a series of motor and cognitive tests at various time points throughout the experiment. **Results:** α-synuclein-lesioned animals exhibited significant motor dysfunction in the stepping test (p=0.001) 20 weeks post-surgery. Early results indicate the onset of cognitive deficits in bilaterally-injected α-synuclein animals at 30 weeks post-surgery, where they showed significant impairment in performance in an olfactory discrimination task and a conditioned taste aversion protocol. Interestingly, there was no difference across the groups after measuring spontaneous alternations in a Y maze. Further immunohistochemical and HPLC analysis is being carried out to examine the progression of the neurodegeneration and α-synuclein pathology in various brain regions. **Future work:** An increasing amount of evidence points to beneficial effects of exercise on both motor and cognitive symptoms in PD, and we are currently running further studies to examine the protective effects of exercise on cognitive dysfunction seen in the α-synuclein model.

Title: *In vivo* μPET imaging of neuroinflammation in a rat model exhibiting Parkinsonian-like pathology

Authors: *C. CORWIN[1,3], M. NUNEZ-SANTOS[1], A. NIKOLOPOULOU[4], Y. KANG[4], S. VALLABHAJOSULA[4], P. SERRANO[2], J. BABICH[4], M. FIGUEIREDO-PEREIRA[1]; [1]Biol., [2]Psychology, Hunter College, CUNY, New York, NY; [3]The Grad. Center, CUNY, New York, NY; [4]Radiology, Weill Cornell Med. Col., New York, NY

Abstract: Chronic neuroinflammation is a critical factor in the pathogenesis of Parkinson's disease (PD). *In vivo* detection of the early stages of brain inflammation could provide an optimal strategy to establish the most effective time for therapeutic intervention prior to a point of no return in PD. To test *in vivo* brain imaging of neuroinflammation in PD, we established a mouse model of inflammation with subchronic microinfusion of prostaglandin J2 (PGJ2) into the nigral/striatal area of adult FVB male mice. PGJ2 is a highly toxic endogenous product of inflammation that impairs the ubiquitin/proteasome pathway and triggers the accumulation/aggregation of ubiquitinated proteins and caspase activation. Thus, PGJ2 induces many of the pathological processes involved in PD. The PGJ2-treated mice exhibited a dose-dependent (a) reduction of dopaminergic neurons in the substantia nigra pars compacta (SNpc) with little damage to local GABAergic interneurons, (b) activation of microglia and astrocytes, (c) neuronal Lewy-like bodies and (d) impairment of gait and balance mimicking PD behavior. We also evaluated microglia activation *in vivo* by performing μPET imaging with [11C](R)PK11195. The latter binds to the mitochondrial translocator protein (TSPO) that is overexpressed upon microglia activation. We observed a qualitative increase in [11C](R)PK11195 signal in the SNpc of PGJ2-treated compared to DMSO-treated mice, confirming that PGJ2 induces microglia activation. To improve resolution and image quality of

μPET imaging, we are establishing a PGJ2-induced rat model of inflammation relevant to PD. Adult Sprague Dawley male rats received four unilateral injections of PGJ2 or DMSO into the right SN. Behavioral assays measuring asymmetry and hypokinetic symptoms and μPET imaging were performed over time. The intact contralateral side served as the basal level for each rat. To provide a correlation between microglia and astrocyte activation in brain inflammation, we used the microglia marker [11C](R)PK11195 and the aromatase inhibitor [11C]vorozole in μPET imaging. Vorozole was used as a marker for astrocyte activation, as it binds to aromatase that is rapidly up-regulated in astrocytes upon brain injury. Aromatase induces estrogen synthesis in the brain. All μPET imaging was compared to immunohistochemistry analyses including aromatase expression. The use of both TSPO and aromatase tracers to image neuroinflammation in the same biological model is novel. Moreover, *in vivo* imaging of both astrocyte and microglial activation is critical to understanding the role of inflammation and its detection in neurodegenerative diseases such as PD.

Title: Decoupled involvement of the dorsolateral striatum and of the pre-frontal cortex in depressive symptoms in 6-hydroxydopamine rat model of Parkinson’s disease

Authors: *F. C. MATHEUS[1], D. RIAL[1], J. I. REAL[2], C. LEMOS[2], R. N. TAKAHASHI[1], L. J. BERTOGLIO[1], R. A. CUNHA[2], R. D. PREDIGER[1];
[1]Pharmacol., Federal Univ. of Santa Catarina, Florianópolis, Brazil; [2]Univ. of Coimbra, Coimbra, Portugal

Abstract: The dorsolateral striatum (DLS) is involved with motor and non-motor behavioral functions and undergoes extensive dopaminergic degeneration in Parkinson`s disease (PD). This dopaminergic neurodegeneration also disrupts other brain areas as the prefrontal cortex (PFC), which has been associated with the appearance of non-motor symptoms of PD. Using behavioral, neurochemical and electrophysiological approaches, we evaluated the structural and temporal dissociation between the role of the DLS and of the PFC in the appearance of depressive-like

behaviors in rats submitted to bilateral DLS lesions with the neurotoxin 6-hydroxydopamine (6-OHDA). The 6-OHDA generated a partial dopaminergic nigrostriatal lesion with motor impairments being observed only at the highest tested dose (20 μg/site). However, the lower 6-OHDA doses (5 and 10 μg/site) did not induce such impairments. Anhedonic-like behaviors were observed in the splash and sucrose consumption tests at 7 days after 6-OHDA lesion. In contrast, helplessness behaviors, as evaluated in the forced swimming and social interaction tests only emerged 21 days after 6-OHDA lesion when anhedonia was no longer present. These temporally dissociated behavioral alterations were coupled to temporal- and structure-dependent alterations in dopaminergic markers such as dopamine D1 and D2 receptors and dopamine transporter (DAT), leading to altered dopamine sensitivity in DLS and PFC circuits, evaluated electrophysiologically. Pharmacological treatments during 7 or 21 days with fluoxetine (10 mg/kg), bupropion (10 mg/kg) or quinpirole (0.1 mg/kg) prevented the onset of anhedonic-like and helplessness-like behaviors. These results provide the first demonstration of a dissociated involvement of the DLS and PFC in anhedonic- and helplessness behaviors in an animal model of PD, which was related with temporal fluctuations in density and functionality of dopaminergic receptors. Leading to altered dopaminergic system sensitivity in these two brain structures. This study sheds new light to the duality between different types of depressive symptoms in PD.

Abstract: L-DOPA-induced dyskinesia (LID) is a frequent adverse side effect of the treatment for Parkinson’s disease (PD). Understanding the mechanisms underlying the development of

these motor disorders is needed to reduce or prevent them. We investigated the role of TrkB receptor in L-DOPA-induced dyskinesia in hemi-parkinsonian mice rendered dyskinetic by chronic L-DOPA administration. L-DOPA treatment specifically increased TrkB receptor mRNA and protein levels in the dopamine-depleted dorsal striatum as compared to the contralateral unlesioned striatum or to the striatum of sham-operated animals. The dopamine depletion alone or acute L-DOPA treatment did not significantly increase TrkB protein levels. In addition to increasing TrkB protein levels, chronic L-DOPA treatment activated TrkB receptor leading to increased tyrosine phosphorylation of TrkB and PLCγ. These results indicate that BDNF/TrkB-dependent pathway is highly up-regulated by chronic L-DOPA treatment in dopamine-depleted striatum and could be involved in the development of abnormal movements, typical of dyskinesia. In support of this hypothesis, we found that targeted invalidation of TrkB gene in the striatum reduced the development of L-DOPA-induced dyskinesia. Our study suggests that interfering with BDNF/TrkB signalling could be a valuable approach to reduce the side effects of L-DOPA treatment in Parkinsonian patients.

Abstract: Parkinson’s disease (PD) is a devastating age-related neurodegenerative disease that affects primarily the dopamine (DA) neurons of the nigrostriatal pathway and results in debilitating motor, and sometimes, emotional and cognitive deficits. Current treatments only manage symptom severity, and there exists no treatment that is able to reverse or even appreciably slow down the neurodegenerative course of the disease. With this in mind, there is an urgent need to promote neuroregenerative or recovery processes. Additionally, it is our belief that therapeutic intervention must occur in the early stages of the disease. As such, the following studies demonstrate how administration of low-dose 6-hydroxydopamine (6-OHDA) can be used

to model the early stages of PD. Furthermore, we found that the neurotrophic cytokines erythropoietin (EPO) and granulocyte macrophage-colony stimulating factor (GM-CSF) may have important therapeutic potential for PD. From our series of experiments, we found that low doses of 6-OHDA administered into the anterior dorsal striatum were able to induce a mild partial lesion that progressed over 30 days with no significant loss of DA cells in the substantia nigra (SNc). Additionally, 21 days after neurotoxin administration there was a decrease in structural phosphatidylcholine lipids and a large increase in inflammatory and immune system related lysophosphatidylcholines. We also observed motor dysfunction that progressed over time in a dose-dependent manner that was related to overall striatal DA loss. Finally, we have shown that treatment with the trophic cytokines EPO or GM-CSF induced striatal re-innervation when administered long after the neurotoxic insult. Taken together, low doses of 6-OHDA were able to induce some of the hallmark behavioural and pathophysiological markers of early stage PD. Additionally, treatment with GM-CSF and EPO may provide novel therapeutic agents aimed at fostering neural recovery.

Title: Long-term effect of sub-anesthetic ketamine infusion in reducing L-DOPA-induced dyskinesias

Authors: **M. J. BARTLETT**[1], L. M. LEPOIDEVIN[1], R. M. JOSEPH[1], K. L. PARENT[2], N. D. LAUDE[2], L. B. LAZARUS[2], M. L. HEIEN[2], M. ESTEVEZ[3], S. J. SHERMAN[1], *T. FALK[1]; [1]Dept. Of Neurol., Univ. of Arizona Col. of Med., Tucson, AZ; [2]Chem. & Biochem., Univ. of Arizona, Tucson, AZ; [3]Neurometrica, LLC, Eugene, OR

Abstract: Low-dose sub-anesthetic ketamine infusion treatment has led to a long-term reduction of treatment-resistant depression and posttraumatic stress disorder (PTSD) symptom severity, as well as reduction of chronic pain states, including migraine headaches. Ketamine also is known

to change oscillatory electric brain activity. Repurposing drugs that have already been proven safe in humans has the potential to offer new therapies at a fraction of the time required to develop new drug treatments. One commonality between migraine headaches, depression, PTSD, Parkinson's disease (PD) and L-DOPA-induced dyskinesia (LID) is hypersynchrony of electric activity in the brain, including the basal ganglia. An effective treatment of LID to extend the useful lifetime of L-DOPA treatment is a critical unmet need in PD therapy. Therefore, we investigated the use of low-dose ketamine in the treatment of PD and LID. We show a long-term therapeutic effect of low-dose ketamine infusion (0.15 - 0.3 mg/kg/hr for 72 hrs) from five PD patient case studies identified by a retrospective chart review (reduced dyskinesia, improved on time, and reduced depression). Additionally, in the standard preclinical rodent model of LID (using 7 mg/kg L-DOPA to prime unilaterally 6-hydroxydopamine-lesioned rats), ketamine (5 - 20 mg/kg) led to long-term dose-dependent reduction of abnormal involuntary movements (AIMs), only when sub-anesthetic low-dose ketamine was given for ten hrs (n=5) and not with a single acute (n=10) low-dose ketamine injection (one way ANOVAs vs baselines, followed by Tukey post hoc tests). To mimic the patient infusion for the 10 hr paradigm ketamine was injected 5 x i.p. two hrs apart, 7 mg/kg L-DOPA was co-injected at the 5th injection, and then the AIMs scores were evaluated. For the ketamine 'infusion' doses the anti-dyskinetic effects lasted days to weeks past the 'infusion' day. A significant anti-dyskinetic effect of the 20 mg/kg ketamine 'infusion' paradigm remained apparent 55 days later, and an additional 10 mg/kg infusion did not show sensitization. To gather pharmacokinetic data tail vain blood was collected at time points during and up to 10 days post a 15 mg/kg 'infusion' protocol, and levels of ketamine and the major metabolite norketamine are currently analyzed (n=10). This novel use of low-dose sub-anesthetic ketamine infusion could lead to fast clinical translation, and since depression and comorbid pain states are critical problems for many Parkinson's disease patients could open up the road to a new dual therapy for patients with L-DOPA-induced dyskinesias. Title: An age- and time-course study of the responses to nigrostriatal lesions and dopaminergic treatments in mice

Authors: *F. BEZ[1], V. FRANCARDO[2], M. A. CENCI[2];
[1]Exptl. Med. Science, Basal Ganglia Pathophysiology Unit, [2]Lund Univ., Lund, Sweden

Abstract: Mice with 6-OHDA lesions are widely used as a model to study L-DOPA-induced dyskinesia (LID), a major therapy complication in Parkinson´s disease. These studies generally utilize young adult mice with relatively acute 6-OHDA lesions. However, studies of LID in genetic mouse models of PD utilize older animals where a parkinsonian-like phenotype has become manifest (Brehm et al. Mol Neurobiol 2014). Ageing affects several pathways of neuroplasticity in the brain, and may therefore impact on an animal´s response to chronic dopaminergic treatments. We have therefore undertaken to compare behavioral and histopathological phenotypes at short- or long-term intervals after 6-OHDA lesions in mice. At 2 months of age, mice sustained unilateral intrastriatal injections of 6-OHDA (2 µl x 2, cf. Francardo et al. Neurobiol Dis 2011). Baseline motor deficits (cylinder test and overall activity) and responses to L-DOPA and apomorphine were evaluated at 3 weeks and 21 months after the 6-OHDA lesion. A video-based methodology was used for simultaneous quantification of abnormal involuntary movements (AIMs) and motor stereotypies, as well as other behavioral items (e.g. horizontal and vertical activity, rearings and rotations). Striatal monoaminergic innervation densities were studied immunohistochemically. A three-weeks treatment with ascending doses of L-DOPA (12-48 mg/kg/day) was used to induce AIMs. This treatment induced severe axial, limb and orolingual AIMs when given 3-5 weeks after the 6-OHDA lesion. In contrast, the same treatment did not induce any dyskinetic behavior when given 21 months post-lesion. However, these old mice exhibited stereotypic behaviors in response to apomorphine (0.25-3.0 mg/kg). Significant differences between the two ages/post-lesion intervals were detected also on measures of rotational behavior, vertical activity, and stereotypies. The immunohistochemical analysis revealed prominent sprouting of both dopaminergic and serotonergic fibers in the lateral striatum ipsilateral to the lesion at 21 months. This is the first study to examine the profiles of behavioral deficits and responses to dopaminergic treatments in 6-OHDA-lesioned mice that reached an advanced age. We report dramatic differences in the response to L-DOPA between young and old mice, possibly related to the occurrence of a pronounced compensatory axon sprouting in the striatum at long post-lesion intervals. These results are part of a larger ongoing study, and we are now studying the effects of 6-OHDA lesions in already old mice.

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder that leads to degeneration of dopaminergic neurons of the substantia nigra. Respiratory disorders occur in most patients with PD, causing a decrease in compliance of the rib cage by increased stiffness, reduced air volume and flow rates of inspired air, fatigue and incoordination of diaphragmatic and accessory muscles. Furthermore, the mechanical restriction of diaphragmatic mobility promotes an imbalance in the ventilation/perfusion ratio, causing hypoventilation in pulmonary ventilation-dependent areas. It has been proposed that such changes are secondary to changes in posture and osteoarticular degeneration, leading to an alteration in the spinal axis that in turn could affect breathing mechanics. Nevertheless, clinical studies have failed to show a clear relationship between respiratory symptoms and the stage of the disease. In this study, we aimed of testing changes the in respiratory funcion in relation to the degree of nigrostrial degeneration. We employed a murine models of mild and severe hemi-Parkinson's Disease. C57BL/6J mice were used. Under surgical anesthesia, PD mice received an injection of different doses of 6-OHDA solution to the right nigro-striatal pathway though a stereotaxically driven microsyringe. These two groups were compared to control mice, which received an injection of saline under the same conditions. Two weeks after surgery, all mice had their respiratory movements recorded by video x-rays without any restraint. Parameters of respiratory function (diaphragm displacement, costophrenic angle, distance between costophrenic angles, and respiratory rate) showed a different patterns of alterations between mild and severe PD. These results suggest a different nature of respiratory alterations in early vs. late stage PD.

Title: The neuroprotective effect of GDNF Family Ligand Mimetics in unilateral 6-hydroxydopamine-model of Parkinson´s disease in rats

Authors: *J.-M. RENKO[1], Y. SIDOROVA[1], M. VOUTILAINEN[1], J. SAKKI[1], M. KARELSON[2], M. SAARMA[1], R. K. TUOMINEN[1];
[1]Univ. of Helsinki, Helsinki, Finland; [2]Tartu Univ. & GeneCode Ltd., Tartu, Estonia

Abstract: Background Neurotrophic factors (NTFs) are secreted proteins supporting the survival and regeneration of neurons. Therefore, NTFs might be beneficial for the treatment of neurodegenerative disorders such as Parkinson´s disease (PD). Glial cell line-derived neurotrophic factor (GDNF) has shown neuroprotective and neurorestorative effects on dopaminergic neurons in animal models of PD. As GDNF is a protein, there are several problems to be solved before it can be used clinically e.g. i) it is expensive to produce in quantities sufficient for clinical use, ii) the effects and adverse effect profile of GDNF have been contradictory in clinical studies and iii) systemic delivery of the protein is problematic. GeneCode Ltd. has developed small molecular weight compounds, which activate GDNF Family Ligand (GFL) receptors (GFRα-RET) and downstream signaling pathways similar to GFL proteins both *in vitro* and *in vivo*. The aim of this study was to test the neuroprotective effect of one GFL mimetic (GFLM) *in vivo* in the 6-hydroxydopamine (6-OHDA) model of PD. **Methods** In the first stereotaxic operation 6-OHDA (16 µg/4 µl) was injected into the left *striatum* of male Wistar rats (n=6-13/treatment group). One hour later osmotic mini-pumps were implanted s.c. and cannulas were placed into the left *striatum*. GFLM (1 µg/24h, 3 µg/24h or 6 µg/24h), GDNF (3 µg/24h) or vehicle (propylene glycol or phosphate buffered saline) was infused for 7 days at the rate of 0.5 µl/h. The mini-pumps were removed in the second stereotaxic operation. Amphetamine-induced (2.5 mg/kg, i.p.) rotational behavior was tested 2, 4 and 6 weeks after the

6-OHDA lesion. Forelimb asymmetry test was performed at 4 weeks time point. After the last rotational behavior test rats were perfused and coronal brain sections were made. Tyrosine hydroxylase (TH) immunostaining will be analyzed from *substantia nigra* and *striatum.* **Results** The GFLM (1, 3 and 6 µg/24h) dose-dependently reduced amphetamine-induced rotations four and six weeks after the 6-OHDA lesion. The effect was comparable to what was observed in animals treated with GDNF protein (3 µg/24h). The analyses of the number of TH-positive cells in *substantia nigra pars compacta* and the optical density of TH-positive fibers in *striatum* are still ongoing. **Conclusions** The results suggest that the GFLM tested here has similar activity as GDNF protein in unilateral 6-OHDA-model of PD in rats. Thus, small molecules that activate GFL receptors and their signaling pathways may have potential as a new disease modifying therapy of PD. Because of small molecular weight, GFLMs could be more suitable for pharmaceutical industry and for clinical use than NTF proteins.

Title: Zolpidem ameliorates motor impairments in unilateral 6-OHDA rodent model of Parkinson's disease

Authors: *R. ASSINI, E. D. ABERCROMBIE;
Ctr. for Mol. & Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: Nodes within the basal ganglia, such as the globus pallidus external segment (GPe) and subthalamic nucleus (STN), have been shown to exhibit increased firing as well as synchronous bursting activity entrained to excessive cortical beta oscillations in unilateral 6-OHDA rodent models of Parkinson's disease (PD). Ionotropic GABA-A receptors are expressed ubiquitously throughout the basal ganglia, but exhibit disparate subunit expression in a nucleus-specific manner. The distribution of alpha subunit types between basal ganglia nuclei confers differential sensitivity to benzodiazepine-like compounds between each node of the circuit. Zolpidem is an imidazopyridine that acts as a positive allosteric modulator of GABA-A receptors, potentiating iPSCs with binding selectivity for receptors expressing the alpha-1 subunit. Coincidentally, the nuclei expressing the alpha-1 subunit within the basal ganglia are also those that have been shown to have increased bursting activity in a dopamine-depleted state. Using rotarod and cylinder test, we investigated whether differential expression of the alpha-1 subunit between basal ganglia nuclei indicates that zolpidem may be a potential non-dopaminergic therapeutic option in the treatment of motor symptoms of PD. Male Sprague-Dawley rats were tested for baseline/pre-lesion performance on the tasks, then lesioned using unilateral infusion of 6-OHDA into the right medial forebrain bundle (MFB). Animals with confirmed lesions were subsequently tested for post-lesion performance on the tasks, then tested for performance following acute intraperitoneal (IP) injection of zolpidem (0.1, 0.25, 0.5 mg/kg) or vehicle. Using the rotarod balance beam task, an improvement (~60%) in performance was found following acute IP administration of 0.1 mg/kg zolpidem compared to undrugged post-lesion performance as well as vehicle. Using the cylinder test, it was found that acute IP administration of 0.1 mg/kg zolpidem reduced unilateral forelimb use bias compared to post-lesion performance as well as vehicle. From this data, it can be concluded that zolpidem may be a potential therapeutic option in the treatment of motor symptoms of PD.

Title: Subthalamic deep brain stimulation reduces pathological information transmission to the thalamus in a rat model of Parkinsonism

Authors: *C. ANDERSON, A. DORVAL;
Univ. of Utah, Salt Lake City, UT

Abstract: The degeneration of dopaminergic neurons in the substantia nigra pars compacta leads to parkinsonian motor symptoms via changes in electrophysiological activity throughout the basal ganglia. High- frequency deep brain stimulation (DBS) partially treats these symptoms, but the mechanisms are unclear. We hypothesize that motor symptoms of Parkinson's disease are associated with increased information transmission between the substantia nigra reticulata (SNr) in the ventral basal ganglia and the ventral anterior thalamus (VA), and that therapeutic DBS treats these symptoms by reducing this extraneous information transmission. We tested these hypotheses in a unilateral, 6-hydroxydopamine- lesioned rodent model of hemiparkinsonism. In the hemiparkinsonian condition, information transfer between SNr and VA was significantly increased in both the orthodromic and antidromic directions, and these changes were reversed by behaviorally therapeutic DBS. Omnidirectional information increases in the parkinsonian state underscore the detrimental nature of that pathological information, and suggest a loss of information channel independence. Therapeutic DBS reduced that pathological information, suggesting an effective increase in the number of independent information channels. We interpret these data with a model in which pathological information and fewer information channels diminishes the scope of possible motor activities, driving parkinsonian symptoms. In this model, DBS restores information-channel independence by eliminating or masking the parkinsonism associated information, and thus enlarges the scope of possible motor activities, alleviating parkinsonian symptoms.

Title: Vagus nerve stimulation paired with motor training does not improve forelimb function or strength in 6-hydroxydopamine-lesioned rats

Authors: *A. NGUYEN[1], A. RUIZ[1], S. HAYS[2], M. KILGARD[2], R. RENNAKER[2];
[2]Brain and Behavioral Sciences, Neurosci., [1]Univ. of Texas At Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) is a safe, tolerable treatment that has been shown to drive powerful, long-lasting plasticity especially when paired with somatosensory inputs. VNS is being investigated as an adjunct treatment to physical rehabilitation and has been shown to improve recovery rates in models of stroke, traumatic brain injury, and tinnitus. VNS paired with forelimb motor training has been shown to increase the forelimb representation area in primary motor cortex (M1). Increases in motor map size and reorganization of motor map topography after neurological injury correlate with functional recovery. Parkinson's Disease is a neurodegenerative disorder involving motor dysfunction and maladaptive plasticity in motor circuitry. To model parkinsonism in rats, researchers use a neurotoxin called 6-hydroxydopamine (6-OHDA) to cause selective depletion of catecholaminergic cells, particularly dopamine cells in the substantia nigra. Administration of 6-OHDA in rats causes motor dysfunction and has been shown to reduce the size of motor maps in M1. The aims of this study were to investigate whether VNS-paired with motor training can induce plasticity in M1 of 6-OHDA lesioned rats, whether VNS can improve motor performance on multiple assays of motor function, and whether changes in motor map size and topography correlate with functional recovery or force generation in these rats. To investigate this, rats were trained to proficiency on an automated force generation task, in which the goal for the rats was to pull a stationary handle with a predetermined amount of force to receive a food pellet reward. Rats were then administered 6-OHDA unilaterally into four sites within the striatum and implanted with a vagus nerve stimulation cuff on the left vagus nerve. After 1 week of post surgical recovery, rats performed the force generation task as physical rehabilitation over the course of 6 weeks with ("VNS Rehab" group) or without VNS ("Rehab Only" group). In the VNS Rehab group, VNS was delivered as brief pulses of electrical current during correct trials (pull attempts that exceeded the 120g force threshold required for a hit and subsequent delivery of a food pellet). Cylinder and forelimb placing tests were employed before and 1 week after the induction of the lesion, and at the end of therapy. At all timepoints during therapy, post lesion performance was significantly impaired when compared to pre-lesion levels, however there was no difference between the groups on either a measure of hit rate or force generation.

Abstract: Parkinson's disease (PD) is a multifaceted disorder affecting motor movement, emotionality, and cognition. The predominance of the motor deficits, resulting from the degeneration of dopaminergic neurons of the substantia nigra pars compacta, has been the major focus of research efforts. However, degeneration of extranigral brain regions, such as the locus coeruleus (LC) and the dorsal raphe nucleus (DRN), also significantly impact disease pathology. Cell loss in these extranigral areas likely contributes to the non-motor symptoms of PD, including depression, anxiety, cognitive impairment, and olfactory dysfunction. The recent development of new genetic animal models of Parkinson's has allowed for a more in-depth examination of regions outside the nigrostriatal pathway involved in the disease state. In particular, our group has examined the novel DJ-1 knockout (KO) rat. The loss of DJ-1 in humans leads to an autosomal recessive, early onset, familial form of PD. We have previously found that DJ-1 KO rats, in general, exhibit motor hyperactivity compared to wild-type (WT) rats. The goal of this study was to determine the viability of using the novel model to study extranigral areas and their associated behaviors. DJ-1 KO and WT animals were assessed for non-motor deficits via a battery of behavioral tasks, including the elevated plus maze (EPM), novel object recognition task (NOR), and buried pellet test. Animals were then sacrificed, processed for immunohistochemistry, and unbiased stereological cell counts of the LC and DRN were conducted. At 8 and 16.5 months of age, no differences in anxiety-like behavior occurred between DJ-1 KO rats and their WT counterparts in the EPM task. At 15 months of age, DJ-1 KO rats displayed alterations in attention and memory compared to WT animals in the NOR task. At 16 months of age, in the buried pellet test, DJ-1 KO animals demonstrated an increase in

olfactory acuity compared to WT animals. Stereological cell counts of tyrosine hydroxylase-positive (TH+) neurons in the LC showed a reduction of TH+ cells in the DJ-1 KO rats versus WT counterparts. In the DRN, cell counts of tryptophan hydroxylase-positive (TPH+) cells exhibited a strong trend toward a loss of TPH+ cells in DJ-1 KO animals. Overall, DJ-1 KO rats display alterations in non-motor behavior, loss of TH+ cells in the LC, and a trend toward a loss of TPH+ cells in the DRN. While it remains necessary to perform behavioral testing and cell counts on younger DJ-1 KO animals, these results underscore the utility of the DJ-1 KO animals for evaluation of non-motor symptoms and corresponding neurodegeneration in a genetic rat model of PD.

Title: Admixing of two mice strains with differential susceptibility to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) positively modulates the nigral dopaminergic phenotype

Authors: *V. D. J, H. YARREIPHANG, T. R. RAJU, P. A. ALLADI;
Neurophysiol., Natl. Inst. of Mental Hlth. and Neuro Scie, Bangalore, India

Abstract: An interesting aspect of Parkinson’s disease (PD) is that it has differential prevalence among different ethnic groups. For example, PD is less prevalent in Asian-Indians compared to Caucasians. Further, the Anglo-Indians who are the admixed population of European and Asian-Indian origin are 5 times lesser susceptible to PD than the latter. We intend to understand this phenomenon of differential prevalence using mice strains, which have differential susceptibility to develop Parkinsonian features upon MPTP administration. We performed systematic neuroanatomical evaluation of dopaminergic neurons of substantia nigra pars compacta (SNpc) in C57BL/6 mice (MPTP susceptible), CD-1 mice (MPTP resistant) and their crossbreds to understand the phenomenon of differential susceptibility to MPTP induced neurotoxicity. The dopaminergic neurons of the SNpc of adult C57BL/6, CD-1 mice and the first filial generation of their reciprocal crosses namely F1X1 and F1X2 were studied at 15-17 weeks (n=6/group). F1X1

were the progeny of female C57BL/6 and male CD-1 mice whereas the F1X2 progeny were that of male C57BL/6 and female CD-1 mice. Unbiased stereology on tyrosine hydroxylase (TH) immunostained serial midbrain sections (40µ) provided the absolute neuronal numbers; densitometry based image analysis and Western blotting revealed protein expression levels; and morphometry revealed their cellular characteristics. Stereological quantification showed significantly higher number of nigral dopaminergic neurons in CD-1 and the crossbred mice compared to C57BL/6. Further, there were insignificant differences in the neuronal densities except for the F1X2 crossbreds. Both, densitometric analysis and immunoblots revealed significantly higher TH expression in the crossbreds compared to C57BL/6. The neuronal nuclear and soma area of the F1X1 and C57BL/6 matched well; while those of FIX2 and CD-1 were similar. The presence of higher number of nigral neurons in CD-1 mice provides the anatomical evidence for its resistance to MPTP induced toxicity. The comparability of numbers in crossbreds and CD-1 mice, complemented by higher TH expression, argue for similar neuroprotection in the crossbreds too. The morphological differences in dopaminergic neurons of susceptible and resistant strains indicate that neuronal size may be a significant factor of vulnerability. Thus, our study provides neuroanatomical evidence of differential susceptibility in mice and the subsequent crossing provides an interesting experimental paradigm to study the human phenomenon of differential prevalence of Parkinson's disease.

Title: Intranasal insulin protects against 6-OHDA-induced dopaminergic neuron loss in the substantia nigra and alleviates motor behavioral deficits in rats

Authors: *Y. PANG[1], S. LIN[2], L.-T. TIEN[3], J. SHEN[1], C. WRIGHT[1], L.-W. FAN[1], A. BHATT[1], R. SAVICH[1];

Abstract: Intranasal administration of insulin has been demonstrated to reach brain parenchyma and improve cognitive functions in both animal models and human subjects. Since insulin can activate both insulin and insulin-like growth factor-1 (IGF-1) receptors, which are expressed in the brain and linked to cell survival signaling, we wanted to test whether intranasal insulin could protect against dopaminergic (DA) neuronal damage and motor behavioral impairment in the 6-OHDA neurotoxic rat model of Parkinson's disease. Method: 6-OHDA was injected stereotactically into the right striatum of male adult rats, and the control rats received the same amount of vehicle. Starting from 24 h post 6-OHDA lesion, rats were treated intranasally with recombinant human insulin once a day, until day 14. Neurobehavioral tests were conducted from day 8 to 15 to assess the integrity of nigrostriatal dopamine system. After completion of behavioral tests, brain sections were prepared for stereological estimation of DA neuron numbers in the substantia nigra SN (SN). Results: Exposure to 6-OHDA led to significant motor deficits and a 50% loss of DA neurons (immunostained with tyrosine hydrolase, TH) in the ipsilateral SN pars compacta in rats. Intranasal insulin treatment significantly ameliorated 6-OHDA-induced motor behavioral impairments including locomotor activity ($p<0.05$), tapered/ledged beam walking performance ($P<0.05$), Vibrissa-elicited forelimb-placing ($p<0.05$), initial step ($p<0.05$), and methamphetamine-induced rotational behavior ($P<0.05$). Stereological cell counting showed that intranasal insulin significantly protected against 6-OHDA-induced loss of loss of TH+ DA neurons in the SN pars compacta ($p<0.05$). Intranasal insulin did not affect body weight and blood glucose levels. Conclusion: This study showed that intranasal insulin provides a strong protection against 6-OHDA-induced DA neuronal loss in rats, suggesting that insulin signaling may be a novel therapeutic target in a broad neurodegenerative disorders.

Title: Unilateral nigrostriatal dopamine lesions produce transient changes in urinary and motor function in a rat model of Parkinson's disease

Authors: *W. F. COLLINS, III, O. Y. WANG, N. P. PHAGU, Y. KAMMILI, M. F. KRITZER;
Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Previous studies utilizing unilateral 6-hydroxydopamine (6-OHDA) lesion of the nigrostriatal pathway in rats implicate dopamine (DA) loss in the basal ganglia as contributing to the bladder overactivity seen in Parkinson's Disease. The goal of this study is to further characterize this 6-OHDA-lesion model system focusing on the time course of changes induced in lower urinary tract (LUT) and motor function. Under isoflurane anesthesia, adult female Sprague-Dawley rats (225-250 g) received unilateral microinjections of 6-OHDA (2 ul; 4.8 mg/ml) or vehicle into the substantia nigra pars compacta (SNc). Two or four weeks following the injection/lesion, rats were anesthetized with urethane (1.4 g/kg) and set up for cystometry (via bladder dome) and external urethral sphincter (EUS) EMG recording. Following recording, rats were perfused transcardially with 4% paraformaldehyde, and brains were removed and processed for tyrosine hydroxylase immunocytochemistry to confirm lesions. Urine output was measured (overnight in metabolic chamber) and rotation behavior was quantified (open field scoring) every 4-7 days prior to and following the 6-OHDA or sham surgeries and immediately before the cystometry. At two weeks post SNc lesion, increases in voiding frequency were observed both in awake rats (22% decrease in time between voids and 20% increase in number of voids) and during cystometry (46% decrease in threshold volume) compared to sham-operated controls (data are consistent with earlier work (1)). However, at 4 weeks, no difference in bladder function (voiding frequency or void volume) was seen between 6-OHDA-lesioned and sham rats. Further, there was no effect of 6-OHDA lesion on other measures of bladder function (pressure threshold, maximum contraction pressure) or measures of EUS function (duration of EUS bursting, EUS bursting frequency, sustained EUS activity) at either the 2 or 4 week time point. In contrast, 6-OHDA-lesioned rats exhibited strong turning and rotational behavior toward the lesioned side at both 2 and 4 weeks post-lesion. In sum, unilateral nigrostriatal DA depletion in adult female rats has sustained effects on rotational behavior, but only transient effects on LUT function that are limited to increases in voiding frequency. The return of voiding frequency to control levels at the longer survival time suggests that compensatory mechanisms have been activated. Given the medial positions of midbrain, brainstem and spinal circuits that are engaged in LUT function, some sort of sprouting response from the intact side should be considered among candidate mechanisms. 1. Title: Cognitive and motor deficits in a rodent model of Parkinson's disease displaying concurrent dopamine and acetylcholine loss

Authors: *C. Y. OSTOCK[1], M. M. CONTI[2], T. LAROSE[1], S. MEADOWS[2], C. BISHOP[2]; [1]Freshman Res. Immersion/ Psychology, [2]Psychology, Binghamton Univ., Binghamton, NY

Abstract: Dopamine (DA) loss in Parkinson's disease (PD) is frequently accompanied by degeneration of acetylcholine neurons within the basal forebrain (BF) and the pedunculopontine nucleus (PPN). Recently, Ach neurons in these nuclei have been implicated in both the motor and non-motor symptoms of PD. However, few rodent models of PD actually account for Ach loss in both the BF and PPN. Here, we evaluated the effects of concurrent BF and PPN Ach loss alone and in combination with striatal DA loss on motor and cognitive performance in a rat model of PD. Sprague-Dawley rats (N = 44) received bilateral: striatal 6-OHDA lesions to deplete DA (DA-lesioned; n = 14), BF (192 IgG-Saporin) and PPN (anti-ChAT Saporin) saporin lesions to deplete Ach (Ach-lesioned; n = 10), combined 6-OHDA + saporin lesions (dual-lesioned; n = 6) , or sham lesions (n = 14). Following recovery from surgery, rats underwent a battery of motor and cognitive behavioral tests. Results indicated that Ach-lesioned and dual-lesioned rats displayed spatial memory deficits on the Morris Water Maze and Spontaneous Alternation tests. DA and Ach lesions alone impaired stepping for the forepaw adjusting steps and vibrissae-elicited paw placement tests and this deficit was exacerbated in dual-lesioned rats. However, only rats with Ach or dual lesions showed motor deficits on the rotarod tests. Collectively, these findings demonstrate that Ach loss may exacerbate cognitive and motor symptoms in PD and highlight the importance of including Ach loss in preclinical models of PD.

Title: Fundamental differences in Parkinsonian rat limbic regions contribute to anxious behavior and diminished responsiveness to diazepam

Authors: *K. A. O'CONNOR[1], A. RAMIREZ-ZAMORA[2], E. MOLHO[2], J. G. PILITSIS[3], D. SHIN[1];

Abstract: There is growing recognition that anxiety has a greater impact on the quality of life in Parkinson's disease (PD) than motor symptoms. Yet, little is known about the pathophysiology underlying anxiety present in 25-51% of PD patients, posing a considerable barrier in developing effective treatment strategies. As an important first step, we examine whether anxiety-like behavior is more prevalent in parkinsonian compared to non-parkinsonian rats, mirroring what is observed in the clinic. We used the unilateral, medial forebrain bundle 6-hydroxydopamine (6-OHDA) rat model of PD ('PD rat') and noted that these rats had higher baseline anxiety-like behavior than sham or naïve rats based on their performance in the elevated plus maze (EPM). Next, we administered diazepam, a commonly used acute anxiolytic, prior to EPM, open field test (OFT), and marble burying testing to unmask differences in efficacy between sham and PD rats. We found that diazepam (1.5 mg/kg) loses efficacy in high anxiety PD rats in the EPM and OFT compared to high anxiety sham rats, suggesting differences in neurocircuits involved in anxiety. Lastly, we monitored neuronal spiking activity in the anterior cingulate cortex (ACC), the bed nucleus of the stria terminalis (BNST) and the basolateral amygdala (BLA), all key regions in the limbic circuit, during administration of either yohimbine alone, or diazepam pre-treatment followed by yohimbine in sham and PD animals. Diazepam is able to prevent yohimbine-induced increases in activity in sham rats, but not in PD rats. Altogether, our findings posit that anxiety in PD and non-PD may differ due to differences in neurocircuits in limbic brain areas.

Title: Parkin knockout rats are hypersensitive to the neurotoxic effects of methamphetamine

Authors: *B. A. KILLINGER[1], A. MOSZCZYNSKA[2];
[1]Dept. of Pharmaceut. Sciences, EACHPS, [2]Wayne State Univ., Detroit, MI

Abstract: Parkinson's disease (PD) is a neurodegenerative disease characterized by the progressive loss of nigrostriatal dopamine neurons, which produces symptomatic motor disturbances. Loss-of-function mutations of Park2, a gene encoding the E3 ligase parkin, have been found in patients with familial PD. Despite intense investigation, the exact role of parkin in the development of PD is still unclear. It is not known whether loss of parkin influences dopamine signaling and/or increases the susceptibility of dopamine neurons to environmental neurotoxic insult. Here we tested the hypothesis that parkin knockout (PKO) rats display abnormal dopaminergic neurotransmission, without gross dopamine loss, in the nigrostriatal pathway. To test this hypothesis we administered both toxic (6 mg/kg, 4 injections, 2 h apart, i.p.) and non-toxic (2 mg/kg, 1 injection, i.p.) doses of the potent dopamine agonist methamphetamine (METH) to PKO rats and measured open-field locomotor behavior. We have found that PKO rats develop acute motor behavior abnormalities both during and following binge METH. These motor behavior abnormalities are consistent with those seen in animal PD models and manifest themselves following the third administration of toxic METH. Strikingly, several animals (40%) displayed a complete loss of motor control following the fourth dose of

METH. Although these PKO rats recovered, they continued to display long-term motor deficits, including rigidity, tremors, difficulty initiating movement, and uncoordinated movements. Such abnormalities in motor behavior are consistent with large deficits (>70%) in striatal dopamine. In agreement, we observed significant reductions (-75%) in striatal dopamine content in PKO rats treated with binge METH. We also found that PKO rats display an abnormal locomotor response to a single injection of low-dose METH. In general, low doses of METH transiently increase locomotor activity while high dose METH suppresses locomotor activity. Here, PKO rats displayed the inverse reaction to single injection of METH. Drug naïve PKO rats had a blunted locomotor response to a single low dose of METH while displaying an exacerbated response to a single-high dose METH. Despite the apparent insensitivity of PKO rats to METH-induced hyperlocomotion these animals did not have reductions in striatal dopamine or its metabolites. In summary, we demonstrate that PKO rats are hypersensitive to the neurotoxic effects of METH while conversely being hyposensitive to METH-induced hyperlocomotion. This suggests that dopamine signaling in the nigrostriatal pathway is likely impaired in PKO rats, which may predispose them to neurodegeneration.

Title: Mechanisms of alpha-synuclein mediated toxicity in the aged rat brain

Authors: *I. M. SANDOVAL, N. K. POLINSKI, B. DALEY, N. MARCKINI, F. P. MANFREDSSON, C. E. SORTWELL, T. J. COLLIER;
Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI

Abstract: Parkinson’s disease is a neurodegenerative disorder associated with the abnormal accumulation of alpha-synuclein (α-syn) in protein aggregates, and the subsequent death of the dopaminergic (DA) neurons of the *substantia nigra* (SN). Although aging has been singled out

as the major risk factor for the development of the disease, very little is known about the mechanisms of α-syn mediated toxicity in the context of the aged brain. Previous work from our group determined that significantly less α-syn protein is required to cause equivalent dopaminergic cell death in young and old rats; suggesting a higher vulnerability of the aged nigrostriatal system to α-syn induced toxicity. We hypothesized that equal α-syn overexpression will cause significantly more neurotoxicity in the SN in the brain of aged rats when compared to the young rats. Further, a recent study showed that nuclear pore permeability is compromised in neurons of the aged brain. Therefore, we aim to determine whether age influences the localization and accumulation of α-syn to the nucleus, possibly interfering with normal cellular processes, consequently increasing the vulnerability of DA neurons. To this end, young (2 month) and old (20 month) male Fischer rats received a single intranigral injection of rAAV2/9 expressing human wildtype α-syn (rAAV2/9-α-syn) into the SN. Immunostaining of brain sections collected at 30 days post-injection showed robust and similar α-syn expression in both: young and old rats. Stereological counts of tyrosine hydroxylase immunoreactive (THir) neurons revealed that α-syn overexpression resulted in significantly fewer surviving THir neurons in the SN of aged rats (52%) as compared to young rats (86%). Experiments are underway to elucidate the subcellular localization of α-syn in DA neurons of young and old rAAV2/9-α-syn treated rats, and potential aberrant interaction with nuclear components. Results from these studies will help define aging as a key contributor to neuronal cell death and possibly shed light on the molecular mechanisms underlying the pathophysiology of PD.

Title: Bpoz-2 gene therapy ameliorates alpha-synucleinopathy in a53t transgenic mouse model of Parkinson’s disease

Authors: *A. ROY[1], S. B. RANGASAMY[2], M. KUNDU[1], K. PAHAN[1];
[2]Neurolog. Sci., [1]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Ankyrin-rich BTB/POZ domain containing protein-2 or BPOZ-2 has been recently shown to control ubiquitination of many biological proteins ranging from embryonic development to tumor progression. However, its role in the process of neuronal diseases has not been properly explored. Previously, we reported that BPOZ-2 could play a crucial role in the amelioration of alpha-synuclein (AS) in the cultured dopaminergic (DA) neurons. However, this observation cannot be warranted until its role is tested *in vivo* in the animal model of PD. Here we report that lentiviral administration of bpoz-2 gene indeed lowers the burden of AS in DA neurons in the nigra of A53T transgenic (Tg) mouse. Our detailed immunohistochemical and immunoblot analyses have clearly shown that the overexpression of bpoz-2 dramatically improves both the somatic and neuritic AS pathologies in the nigral DA neurons. Similarly, the specific ablation of bpoz-2 by lentiviral-shRNA fails to ameliorate, but strongly increases the load of monomeric and polymeric forms of AS in the nigral DA neurons of A53T Tg mice as revealed by different immunological analyses. Our results have demonstrated that bpoz-2 gene therapy could be prospective in the amelioration of alpha-synucleinopathy in PD and other Lewy body diseases.

Title: The Ubc9 SUMO-conjugase associates with and regulates α-synuclein SUMOylation, enhancing its half-life and aggregate formation

Authors: *E. CARTIER, H. KIM;
Delaware State Univ., Dover, DE

Abstract: Parkinson’s disease (PD) is the most common motor neurodegenerative disorders characterized by deterioration of the nigrostriatal pathway and loss of dopaminergic neurons in the substantia nigra. Accumulation of toxic aggregates of the synaptic protein α-synuclein is

critical to cause PD pathology. Abnormally oligomerized or aggregated α-synuclein leads to the formation of distinctive Lewy bodies which are the histological hallmark for PD. α-synuclein misfolding and aggregation can be produced by missense mutations and increase in gene dosage both causing familial forms of PD. On the other hand, α-synuclein clearance is determined by degradation through both the proteasome and lysosome systems and its impaired degradation appears to underlie the accumulation of potentially toxic aggregates. In addition, α-synuclein postranslational modifications including ubiquitination, phosphorylation, and nitrosylation have been reported to play a key role in its toxicity. More recently, α-synuclein has been found to be SUMOylated in cultured cells and mouse brain. Small Ubiquitin-like modifier (SUMO) can be targeted to several lysine residues within the molecule, although lysines 96 and 102 have been identified as the main SUMOylation sites. It is still controversialwhether α-synuclein SUMOylation triggers α-synuclein-mediated protein aggregation or it enhances its solubility. Hence, the relationship between SUMOylation and protein solubility/aggregation, and the relevance of SUMOylation to α-synuclein toxicity need to be further investigated. Here, we developed N27 rat dopaminergic immortalized cell lines over-expressing the human E2 SUMO-conjugase enzyme: Ubc9 that increases SUMOylated species, and the Sentrin-specific protease 1 (SENP1), SUMO peptidase that cleaves SUMO from its targets. We found that Ubc9 is able to strongly associate with α-synuclein assessed by co-immunoprecipitation. Moreover, Ubc9 over-expression is able to enhance α-synuclein overall expression by increasing its protein half-life which leads to the accumulation of α-synuclein aggregates. Overall, our data suggest that SUMOylation is a prominent post-translational modification, which extends α-synuclein half-life and its accumulation may lead to potentially toxic aggregates. Our goal of this study is to identify that SUMOylation of α-synuclein can be a potential therapeutic target to modify the PD pathology.

Title: Developing novel α-synuclein binding peptides to identify, monitor, and inhibit α-synuclein fibril formation

Authors: *A. R. BRAUN[1], D. R. WOLDRING[2], B. HACKEL[2], M. K. LEE[3];
[1]Dept. of Neurosci., Univ. of Minnesota, Plymouth, MN; [2]Chem. Engin., [3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Parkinson's disease (PD) pathology is characterized by the deposition of insoluble α-synuclein (αS) fibrils. Recent studies, both *in vitro* and *in vivo*, have shown that synthetic αS preformed-fibrils (PFFs) are capable of inducing αS associated pathology; supporting a "prion-like" hypothesis for the spread and progression of PD. In addition to PFFs, on-pathway oligomers, which precede and contribute to αS fibril formation, have been shown to seed fibrilization *in vitro* and exhibit acute cytotoxicity when transfected into cells. Because αS aggregates are thought to be pathogenic in PD, reducing αS aggregation or monitoring the distribution of αS aggregation is considered an important target for disease modifying therapy. Therapeutic targeting of αS aggregates for PD necessitates reliable quantitative biomarkers for αS pathology. Using yeast surface display (YSD) we are engineering a series of novel αS-binding peptides that specifically target αS fibrils and oligomers. Using YSD library based on two different protein scaffolds, fibronectin (14kD) and gp2 (4kD), we identified positive binding clones. The identified clones are being evolved using cycles of mutagenesis and binder screening to obtain peptides with a range of different binding affinities. These positive binding peptides will be evaluated for their capacity to bind, track, and potentially inhibit aggregation of αS in a variety of *in vitro* and *in vivo* models. Strong performing peptides may provide a novel lead for additional modifications for use in future therapy development.

Abstract: In Parkinson's disease (PD) brain, the protein alpha-synuclein (alpha-syn) accumulates to form intra- and extracellular amyloid aggregates called Lewy bodies (LB) and Lewy neurites. The aggregation process occurs progressively through the production of intermediary (e.g., oligomeric) species that form mature and insoluble fibrillary structures. Two sort of arguments suggest that he multifunctional enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) may intervene in the aggregation process: (i) GAPDH colocalizes with α-syn in amyloid deposits from PD brains and (ii) it also promotes the formation of LB-like aggregates in cell culture models. Still consistent with this view, we have shown previously that heparin-induced GAPDH prefibrillar species (HI-GAPDHpf) strongly modify alpha-syn aggregation kinetics and reduce the neurotoxicity of alpha-syn species by accelerating the conversion of toxic oligomers (alpha-syn-oli) into less toxic fibrils (Avila et al, J Biol Chem, 2014). In the present work, we aimed to evaluate the ability of HI-GAPDHpf to modulate brain inflammatory processes in response to alpha-syn-oli (samples prepared according to procedures described by Avila et al, 2014) through the use of a model system of microglial cells in culture. Microglial cells activated by alpha-syn-oli (500 nM; 24h) displayed a hypertrophic morphology and showed increased expression of the ionized calcium-binding adapter molecule 1. Moreover, alpha-syn-oli treatment led to increased production and release of two pro-inflammatory cytokines (TNF-alpha and IL-1beta) and to enhanced generation of intracellular radical oxygen species. We will describe how inflammatory processes are modulated by HI-GAPDHpf in alpha-syn-oli-activated microglial cells.

Title: Lewy Body extracts from Parkinson's disease Brains as models for high-throughput screens of neurotoxicity and α-synuclein spreading from cell-to-cell through endocytosis

Authors: *E. BEZARD[1], F. CAVALIERE[2], L. CERF[3], B. DEHAY[1], M. BOURDENX[1], P. RAMOS-GONZALEZ[2], J. OBESO[4], C. MATUTE[2], F. ICHAS[3];

Abstract: The anatomo-pathological landmark of Parkinson's disease (PD) is the deposit of aggregated proteins of aberrant conformation into Lewy bodies (LB). Misfolded α-synuclein (α-syn) is a major protein component of LB. Recent data suggest that α-syn can act like a prion-like protein in PD. Recently, through an innovative strategy based on the purification of aggregated α-syn from the Substantia Nigra pars compacta (SNpc) of PD patients, we assessed the prion-like properties of endogenous α-syn assemblies in an elegant ascending series of animal models, ranging from wild-type mice and non-human primates (Recasens et al. Ann. Neurol. 2014). Besides validating the infectious nature of aggregated α-syn, our approach allowed establishing that authentic α-syn assemblies, e.g. LB, possess "pathological" characteristics absent in α-syn assemblies made *in vitro* that account for the specific infectivity of assemblies. Nevertheless, the actual type of neurotoxic insult wreaked upon neurons by α-syn assemblies, the mechanism of passage from cell-to-cell as well as the cellular identity of cells amenable to α-syn assemblies transfer remains unknown. Using human LB-derived α-syn assemblies proven to induce both nigrostriatal damage and spreading all over the brain in wild-type mice, we found that those α-syn assemblies applied to cortical neuron primary culture in 96 well-plates exhibited a modest cytotoxicity but dose-dependently inhibited the growth of neurite length as well as the number of branching points using high-content time-lapse imaging. We then studied the passage from neuron-to-neuron, neuron-to-glia, glia-to-neuron and glia-to-glia in microfluidic experiments. Those experiments demonstrated that human LB-derived α-syn assemblies are uptaken by all cell type by endocytosis and passed from neuron to neuron, from glia to glia, from glia to neuron and from neuron to glia, grounding the mechanism for spreading both in interconnected regions (neuronal transfer) and within large structures (glial cells might cover large territories within a nucleus). In conclusion, we demonstrated the unique behaviour of human LB-derived α-syn assemblies and developed an *in vitro* high-throughput screening platform for identification of potential therapeutics against α-syn assemblies-induced toxicity and spreading.

Title: Alpha-synuclein and heavy metals: Examining the neuromodulatory role of human native alpha-synuclein in cadmium transport dynamics and homeostasis using a dopaminergic cell model of Parkinson's disease

Authors: *W. CHONG[1], G. KWAKYE[2];
[2]Neurosci., [1]Oberlin Col., Oberlin, OH

Abstract: Despite the idiopathic nature of most forms of Parkinson's disease (PD), animal models and postmortem PD tissues exhibit degeneration and concurrent appearance of protein aggregates known as Lewy bodies (LBs). The protein alpha-synuclein (α-syn) comprises 60% of LBs, implicating α-syn in PD neuropathology. While research has revealed mutant α-syn's role in PD, the function of native α-syn, which is expressed throughout the neurotypical brain, remains ill-defined. Here, we examined α-syn's neuromodulation of metal-induced toxicity via a gene-metal screen by utilizing an established dopaminergic N27 cell line that stably expresses α-syn or a vector control (vec). We report that the 10 metals tested (Cd(II), Fe(III), Zn(II), Se, Co(II), Cu(II), Ni(II), Pb(II), Mn(II) and Al(III)) induce varying levels of toxicity in both genotypes. Depending on the metal, toxicity was attenuated or enhanced in α-syn cells relative to vec. We found a novel gene-metal interaction in which 24h cadmium exposure (Cd(II)) causes a concentration-dependent increase in neurotoxicity for α-syn cells compared to vec. Furthermore, we demonstrate that α-syn cells exhibited reduced levels of the antioxidant glutathione and a concomitant increase in intracellular reactive oxygen species (ROS) compared to vec, thus implicating oxidative stress pathways in α-syn-mediated cell death. Expression levels of proteins involved in oxidative stress pathways (including nuclear-factor (erythroid-derived 2)-like 2 (Nrf2) and heme oxygenase 1 (HO-1)) were measured to determine upstream oxidative stress inducers in α-syn - Cd(II) interaction. We observed a decrease in Nrf2 and an increase in HO-1 levels in α-syn cells compared to vec cells after 6h exposure to 100 μM Cd(II). We also hypothesized that α-syn might regulate metal homeostasis via metal transporter neuromodulation and thus we examined the protein expression levels of metal transporters divalent metal transporter 1 (DMT1) and transferrin. Following that, we hypothesize that increased transporter activity will cause greater Cd(II) influx to α-syn cells compared to vec cells. Thus, we sought to

quantify intracellular Cd(II) levels following a 6h and 24 h 110Cd(II) exposure in N27 cells. We utilized inductively coupled plasma mass spectrometry (ICP-MS) to demonstrate that intracellular α-syn cells accumulate more Cd(II) than vec cells, even at non-toxic concentrations (as low as 25nM). Together, these findings have established the role of human native α-syn in heavy metal homeostasis especially Cd transport dynamics. In summary, we have identified a novel gene-environment interaction between Cd exposure and Parkinson's disease.

Title: Contrasting homeostatic failure of *in vivo* activity by dopamine substantia nigra neurons in response to aging or mutant alpha-synuclein

Authors: *M. SUBRAMANIAM, J. ROEPER;
Inst. For Neurophysiol., Frankfurt am Main, Germany

Abstract: Dopamine (DA) neurons in the substantia nigra (SN) compacta are selectively vulnerable in Parkinson disease (PD) resulting in progressive neurodegeneration. While multiple stressors such as ageing, environmental toxins (e.g. rotenone, MPTP) and genetic predispositions (e.g. A53T-SNCA) have been identified as key risk factors for PD (Sulzer, 2007), the pathophysiological responses to these stressors by DA SN neurons are less well understood. We have recently shown that DA SN neurons selectively increase their *in vivo* firing frequencies in response to mutant a-synuclein expression or proteasome inhibition (Subramaniam et. al., 2014a/b). In both models, neighboring DA neurons in the ventral tegmental area (VTA) were not affected. In contrast, our recent comparison of *in vivo* firing of DA SN neurons in adult (3-4 month) and aged (22-25 month) C57BL6 mice showed no significant differences in the spontaneous frequency within the two groups. However, the data revealed a significant reduction of median firing frequencies in caudal compared to rostral DA neurons from old mice. As seen in our PD models, only the median frequencies of DA neurons were different within the SN subpopulations (caudal and rostral DA SN neurons) of the old mice, but not their median burstiness or action potential duration. Also, the *in vivo* properties of the DA VTA neurons were

not changed. We also extend our proteasome-inhibition model (Subramaniam et. al., 2014b) to include caudal DA SN neurons. In contrast to the significant increase of *in vivo* firing frequencies in rostral DA SN neurons (Subramaniam et. al., 2014b), DA neurons located caudal SN showed no differences in their median *in vivo* firing frequencies compared to controls although they degenerated more severely (~70% loss of TH positive neurons) in response to expoxomicin. Together our data shows that aging and other PD risk factors do not act in a simply unidirectional fashion on the functional properties of DA SN neurons, but induce an opposed homeostatic activity failure (increase/decrease) with sub-regional specificity. We are currently studying the underlying biophysical mechanisms underlying the frequency changes in the caudal and rostral DA SN neurons.

Title: Alpha-synuclein affects trace metal content in primary neuronal cultures

Authors: *E. CARBONI[1], P. LINGOR[1], A. CARMONA[2], S. RODEAU[2], E. BARSKI[1], R. ORTEGA[2];

Abstract: Parkinson's disease (PD) is the most frequent neurodegenerative movement disorder worldwide and it affects about 1% of the population over 65 years of age. The protein alpha-synuclein (aSyn) is the major component of proteinaceous inclusions, so-called Lewy bodies (LB), which are the hallmark of the disease. Interestingly, there is also an increase of iron in the LB and there is evidence for a disturbed metal homeostasis in PD patients' brains, but these mechanisms are still poorly understood. In this study we asked, whether aSyn itself could affect the distribution of trace metals in primary neurons and if aSyn regulates the expression of proteins involved in metal transport. To this, aSyn was overexpressed in primary cell cultures of rat midbrain neurons and the medium was supplemented with iron to mimic the metal dyshomeostasis of PD patients' brains. Cultures were then subjected to highly sensitive particle-induced X-ray emission (PIXE) imaging allowing for spatial localization of a given element within the cell and the quantification of its absolute concentration. Cells overexpressing aSyn

showed higher concentrations of intracellular calcium and iron after iron supplementation compared to controls. In the absence of iron supplementation, cells overexpressing aSyn showed significantly higher levels of copper compared to control. We then characterized the regulation of proteins involved in the cellular transport of trace elements, such as the Divalent Metal Transporter 1 (DMT1), the Copper Transporter 1 (Ctr1) and the Transferrin Receptor (TfR). Our data suggest that aSyn can influence the expression levels of metal transport proteins, like the copper importer Ctr1. In conclusion, our study shows that the increased levels of aSyn alter the intracellular concentrations of transition metals and the expression patterns of metal transport proteins. Transition metals and/or it's transport proteins can thus be promising therapeutic targets for the treatment of Parkinson's disease.

Title: Modulation of synaptoneurosome glutamate release by aggregated proteoforms of α-synuclein

Authors: *J. B. WATSON[1], K. LITTLEJOHN[1], S. YUAN[1], B.-K. KOO[2], J. P. WHITELEGGE[1], T. A. SARAFIAN[1];

Abstract: α-Synuclein, a central protein involved in Parkinson's disease (PD), exists *in vivo* in a variety of modified and aggregated forms associated with progressive PD pathology. However, the specific proteoform structures involved with neuropathological disease mechanisms are not clearly defined. Since α-synuclein is known to play a role in presynaptic vesicle dynamics, we developed an *in vitro* assay to measure glutamate neurotransmitter release using mouse brain synaptoneurosomes (SNs). Using this approach, we observed previously that transgenic mice overexpressing human α-synuclein did not display detectable fibril or oligomer formation but had enhanced SN glutamate release relative to wildtype (WT) controls [T Sarafian et al, 2013 PLoS ONE 8(5): 1-15. doi: 10.1371/journal.pone.0063557; JB Watson et al, 2014, Soc Neurosci Abstr 413.230]. To examine more systematically the presynaptic role of aggregated proteoforms,

fibrils were first prepared *in vitro* by prolonged agitation of recombinant human α-synuclein in a Fluoroskan plate-reader in the presence of either NaCl or GdnHCl and analyzed by fluorescence (TFT, DCVJ, ANS probes), Native/SDS-PAGE, and electron microscopy. Relative to a histone control and monomeric α-synuclein, functional experiments show that pre-incorporation of fibrillated forms of human α-synuclein enhanced potassium/calcium-stimulated glutamate release from WT mouse SNs. Experiments in progress will address the ability of the more physiologically relevant, amino-terminally acetylated α-synuclein to form oligomers and fibrils and to modulate SN glutamate release. Overall results suggest that fibrillated forms of α-synuclein increase glutamate neurotransmitter release and may cause excitotoxicity as one component of their neuropathology in PD.

Title: The oxysterol 27-hydroxycholesterol-induced epigenetic regulation of α-synuclein

Authors: *O. GHRIBI, J. SCHOMMER;
Basic Sci., Univ. of North Dakota Sch. of Med., Grand Forks, ND

Abstract: Accumulation of the α-synuclein (α-Syn) protein in Lewy body inclusions is a hallmark of synucleinopathies. Despite extensive research, no disease-modifying therapy is currently available forsynucleinopathies and the search for diagnostic tests and biomarkers are still under development. The search for disease-modifying therapies or diagnostic markers would benefit from identification of factors that promote over-production of α-Syn protein and elucidation of new cellular mechanisms that regulate the transcription of α-Syn. The role of α-Syn in the pathogenesis of synucleinopathies is not understood, but experimental studies point to a potential neurotoxic role of high levels of this protein in either its soluble or aggregated form. The causes of synucleinopathies are likely multi-factorial with genetic susceptibility and non-genetic factors potentially participating in the increase in the expression levels of α-Syn. While genetic mutations are responsible for about 5 to 10% of all the forms of Parkinson’s disease, the most prevalent synucleinopathy, the vast majority of the cases are sporadic, with epigenetic modifications potentially playing a role in the α-Syn accumulation. Of high relevance to the

regulation of α-Syn expression levels are our findings showing that the cholesterol metabolite27-hydroxycholesterol (27-OHC) increases α-Syn expression levels *in vitro*. While epigenetic modifications, such as DNA methylation, alter α-Syn transcription, the extent to which 27-OHC regulates α-Syn through methylation is yet to be determined. α-Syn gene (SNCA) has two CpG islands, one located in the first axon and the second in the first intron. We determined the methylation status of CpG1 and 2 using Bisulfite Sequencing method in SH-SY5Y cells treated with various concentrations of 27-OHC. Bisulfite specific PCR based sequencing demonstrated that the CpG-2 sequences are methylated under vehicle treatments and the methylation dose-dependently decreases with 27-OHC treatments. Bisulfite analysis showed no changes in CpG-1 methylation with addition of 27-OHC. We also found that increased α-Syn levels is not associated with cellular stress. The causes of accumulation of α-Syn in synucleinopathies are not known.Our results may help in understanding aspects of the cellular mechanisms involved in the pathogenesis of diseases related to α-Syn accumulation.

Title: Identification of protein interactions regulated by alpha-synuclein Serine 129 phosphorylation

Authors: M. M. MARANO, K.-C. HAN, M. S. FRASER, T. F. LANGMAN, *A. TANDON; Tanz Ctr. for Res. in Neurodegenerative Dis., Univ. of Toronto, Toronto, ON, Canada

Abstract: The objective of this study is to identify and characterize novel protein interactions with alpha-synuclein (α-syn), the central protein involved in neurodegenerative disorders broadly classified as synucleinopathies (Parkinson’s disease, multiple systems atrophy, Dementia with Lewy bodies). In these diseases, α-syn aggregates into cytoplasmic inclusions located in neurons

or glial cells, ultimately resulting in cell death. Over 90% of aggregated α-syn in protein inclusions is phosphorylated at the serine 129 position, while less than 10% of α-syn is phosphorylated in healthy controls. It is believed this phosphorylation is involved in the pathogenicity of α-syn. To assess the effects of α-syn phosphorylation, an α-syn interaction screen was performed using homogenates from whole brain or brain synaptosomes obtained from B6129x1-Snca tmlRos1/J α-syn knockout mice. These lysates were eluted through columns containing agarose beads cross-linked to either non-phosphorylated or phosphorylated wild-type human α-syn that had been phosphorylated by polo-like kinase 2, which phosphorylates α-syn at the Ser129 position. Proteins bound specifically to the column were eluted and then analyzed by mass spectrometry to yield a list of potential interacting proteins. These findings have important significance, as they identify novel protein interactions that are differentially regulated by α-syn phosphorylation. Using these preliminary results, candidate proteins were selected from this list and will be further investigated. Interactions will be confirmed using reciprocal co-immunoprecipitation and the interactions will be characterized by assessing for co-localization with α-syn. Following these initial studies this project will be extended to more focused work relating to the candidate protein to examine how phospho-Ser129 α-syn may regulate its function. The increased prevalence of phospho-Ser129 α-syn in disease pathology suggests it is related to protein aggregation, although it remains unclear if it is involved in the initiation of α-syn aggregation or merely a downstream effect. Examining proteins that interact with phospho-Ser129 α-syn may provide clues as to the role of α-syn phosphorylation in normal and pathological conditions, potentially leading to novel therapeutic targets.

Title: Secretion and uptake of alpha-synuclein via extracellular vesicles in cultured cells

Authors: *C. I. LÖÖV[1], L. BALAJ[1], J. BERGSTROM[2], X. O. BREAKEFIELD[1], B. T. HYMAN[1], M. INGELSSON[1,2];

[1]Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [2]Publ. Hlth. and Caring Sci., Uppsala Univ., Uppsala, Sweden

Abstract: Background Observations both *in vivo* and on cell culture indicate that propagation of pathology in the Parkinson's disease brain may be caused by cell to cell spreading of α-synuclein. The underlying mechanisms are largely unknown, although recent evidence suggests that exosomes or other extracellular vesicles may be involved. Here, we investigated release and uptake of different α-synuclein species via vesicle-related mechanisms. **Objective** To assess, in cultured cells, whether different forms of α-synuclein can be secreted and taken up via extracellular vesicles (EVs). **Methods** The human neuroblastoma SH-SY5Y cell line, cultured in media with vesicle-depleted serum, was either non-transfected or transfected with non-tagged α-synuclein or α-synuclein:hemi-YFP. Ultracentrifugation at 100,000x*g* generated EV-fractions and supernatants, which were measured for total α-synuclein levels by ELISA. Western blot and Nanosight tracking analysis were used to assess the presence of vesicles in the respective fractions. To study α-synuclein uptake, non-transfected SH-SY5Y cells were incubated with the EVs or supernatants from transfected and non-transfected cells or with recombinant α-synuclein. **Results** Nano- to picomolar levels of α-synuclein could be detected in cell lysates and in the secreted fractions from transfected cells. Transfection with α-synuclein:hemi-YFP displayed a significantly higher ratio of secreted vs retained protein compared to cells transfected with untagged α-synuclein. Moreover, the α-synuclein:hemi-YFP transfected cells displayed a higher proportion of α-synuclein in the EV fraction than in the supernatant compared to cells transfected with non-tagged α-synuclein. However, only a small amount of the extracellular α-synuclein was internalized independent of source. Western blot and Nanosight tracking analysis indicated that the vesicular fractions were enriched for flotilin-1 positive exosomes. **Conclusions** Our data suggest that human neuroblastoma cells secrete α-synuclein both as free-floating protein and via vesicles that are characteristic of exosomes. The α-synuclein:hemi-YFP fusion protein are secreted to a larger extent than untagged α-synuclein and seem to be particularly directed towards vesicular secretion. Finally, cellular uptake of α-synuclein in this model is modest and does not seem to differ between proteins that have been released from transfected cells or that have a recombinant origin.

Title: α-Synuclein disrupts the intracellular trafficking of iron import proteins (Fet3, Ftr1) in Saccharomyces cerevisiae

Authors: *S. N. WITT, D. PATEL;
LSU Hlth. Sci. Ctr. / Biochem., Shreveport, LA

Abstract: The main culprits in Parkinson's disease (PD) are elevated levels of both the neuronal protein α-synuclein (α-syn) and iron. Our hypothesis is that elevated levels of α-syn disrupt the normal intracellular trafficking of iron export proteins to the plasma membrane; instead, in cells with α-syn, the iron transporters divert to the lysosome for degradation. Aberrant trafficking of the iron export proteins leads to iron accumulation and cell death. We have been studying how α-syn disrupts iron homeostasis in yeast cells, and because yeast and humans have similar proteins that mediate iron uptake/export, our results will likely be relevant to humans. In humans, ceruloplasmin (Cp), which is a soluble ferrooxidase that mediates iron export from cells, has been genetically linked to PD. Another human protein, hephaestin, which is a membrane-bound ferroxidase, also mediates iron export. Yeast express Fet3, which is an ortholog of Cp and Hp. Fet3 with its binding partner Ftr1 mediate iron import into yeast cells. A soluble form of Fet3 fully complements for the loss of Cp in aceruloplasminemic mice (Cp-/- mice), and Hp complements for the loss of Fet3 in budding yeast. The experiments described here sought to determine whether human α-syn disrupts the intracellular trafficking of Fet3-Ftr1 complexes in yeast. We found that α-syn dramatically shortens the life span of non-dividing, stationary-phase yeast cells. For example, the median lifetime (t1/2) was 13.5 ± 5 d and 4.0 ± 1 d without and with α-syn expression, respectively. Probing the mechanism underlying this accelerated cell death, we discovered that the stationary-phase cells expressing α-syn have approximately 30% less iron than the same cells without α-syn expression, and the level of Fet3 was signficiantly lower in cells expressing α-syn than in contreol cells without α-syn. These results show that low iron may be the cause of the shortened lifespan of cells expressing α-syn. To further test this hypothesis, WT cells were grown in medium supplemented with iron (10 μM FeCl3) and then we performed the aging assay (±α-syn). Supplemental iron partially rescued accelerated aging of those cells expressing α-syn; specifically t1/2 increased from 4.0 d to 7.8 d. Lastly, we also co-expressed mouse Hp and human α-syn in yeast cells and found that α-syn decreases the level of Hp. These results indicate that α-syn disrupts the intracellular trafficking of Fet3/Hp, which causes iron deficiency and cell death. Experiments are underway to test whether α-syn drives Hp to the lysosome in human cells.

Title: Activated Microglia Modulate α-synuclein secretion via JNK activation in α-synucleinopathic PC12 catecholaminergic neurons

Authors: *D. P. CHRISTENSEN[1,3], P. EJLERSKOV[4], I. RASMUSSEN[2], F. VILHARDT[2]; [1]Univ. of Copenhagen, Cambridge, MA; [2]Univ. of Copenhagen, Copenhagen, Denmark; [3]Dept. of Cell. and Mol. Med., Copenhagen, Denmark; [4]Biotech Res. & Innovation Ctr., Copenhagen, Denmark

Abstract: Although α-SNC lacks a secretory signal it can be released both as mono- and oligomeric forms by unconventional secretion pathways during cellular stress, possibly to be taken up by neighboring cells (neurons or glia). Microglia (the resident brain macrophages) are essential for PD development and we hypothesize that they play an hitherto unappreciated role in PD pathogenesis. In PD numerous activated microglia have been found in, but not limited to, the vicinity of degenerating neurons. Upon activation microglia can induce severe neurotoxic effects by excess production of cytotoxic factors such as superoxide and tumor necrosis factor alpha (TNFα). Recently, we have established a cell culture system modeling PD with NGF-differentiated PC12 neurons conditionally expressing the Lewy body associated protein tubulin polymerization-promoting protein (TPPP/p25α) and α-SNC (wt or A30P). In this culture model α-SNC is secreted by the exocytosis of α-SNC containing autophagosomes and amphisomes (exophagy). We investigated mediators of neuronal α-SNC secretion and if neurons and microglia interact to influence neuronal α-SNC secretion. Pharmacologic (SP600125) and genetic (shRNA) JNK knockdown decreases, whereas constitutive active JNK signaling (fusion construct transfections) increases neuronal α-SNC release (assessed by protein precipitation and immunoblotting of conditioned media). Lipopolysaccharide (LPS) activated inflammatory microglia increase neuronal α-SNC release in co-culture and TNFα (classically derived from activated microglia) exposure of neurons in monoculture mimics the effect of activated inflammatory microglia. Thus activated microglia may not only inflict bystander damage to neighboring neurons, but could also mediate proteopathic spreading of α-SNC from neuron to

neuron.Collectively, our data support a critical role for activated inflammatory microglia in the proposed hypothesis for PD spreading throughout the brain.

Title: Fyn kinase mediates aggregated α-synuclein import and priming of the NLRP3 inflammasome in microglia

Authors: *N. PANICKER, S. SARKAR, M. NEAL, D. HARISCHANDRA, H. JIN, H. SAMINATHAN, V. ANANTHARAM, A. KANTHASAMY, A. KANTHASAMY; Biomed. Sci., Iowa State Univ., Ames, IA

Abstract: Persistent neuroinflammation is recognized as a key pathophysiological contributor to many neurodegenerative diseases, including Parkinson’s disease (PD). Resident brain microglia mediate chronic neuroinflammation through the production of pro-inflammatory factors. Identifying the key molecular signaling events perpetuating microglial activation could unravel novel mechanisms that contribute to progressive neurodegeneration in PD. The NLRP3 inflammasome, traditionally shown to be involved in the innate immune response to microbial pathogens and particulate entities, has recently been implicated in neurodegenerative diseases. However, its role in PD pathogenesis is yet to be established. Herein, we show that aggregated human α-synuclein, the major component of Lewy bodies, can activate the inflammasome pathway in microglia. Aggregated α-synuclein treatment amplified LPS-induced priming of the NLRP3 inflammasome in mouse primary microglia, synergistically promoting NLRP3 and pro-IL-1β induction, as well as subsequent IL-1β processing and caspase-1 activation, culminating in the secretion of cleaved IL-1β into the supernatant. This inflammasome activation was accompanied by significantly increased nitrite production and NOS2 expression. Pre-treatment of the cells with pan caspase or caspase-1 specific inhibitors significantly blocked aggregated α-

synuclein-induced IL-1β production in primary microglia. We then demonstrate that aggregated α-synuclein can mediate both priming and maturation of the NLRP3 inflammasome independent of LPS stimulation. Next, we examined the role that the non-receptor Src family tyrosine kinase Fyn plays in aggregated α-synuclein-mediated inflammasome activation. Fyn was found to be rapidly activated in microglial cells by aggregated α-synuclein and it contributed to NF-κB activation, which induced pro-IL-1β and NLRP3 message levels. Strikingly, Fyn was also found to play a role in the import of α-synuclein into microglial cells. Finally, we observed diminished production of IL-1β and other pro-inflammatory cytokines from Fyn-deficient microglia in response to aggregated α-synuclein stimulation. Collectively, our results demonstrate that the NLRP3 inflammasome plays a role in the inflammatory response during α-synuclein and other protein misfolding and that Fyn may regulate NLRP3 inflammasome-signaling in PD. (Supported by NS078247 and NS088206).

Abstract: Alpha-synuclein (-SYN) is a central molecule in the pathogenesis of Parkinson’s disease (PD). We have recently found that regulation of α-SYN could occur at mRNA level in

the 3'UTR de-pendent manner. Human α-SYN transcripts have relatively long 3'-untranslated regions (3'-UTRs) compared to other species and transcripts having various composition of the 3'-UTR have been reported. However, the precise contribution of the 3'-UTRs to healthy physiology and pathological processes in PD is largely unknown. Here, we show that α-SYN mRNA is translocated into neurites of fully differentiated human dopaminergic neuronal cells, supporting its physiological role in neurites. RNA-binding protein Pum2 is responsible for neuritic localization and translational repression by recognizing a conserved binding motif in the α-SYN 3'-UTR. Mi-tochondrial reactive oxygen species relieve Pum2-mediated translational repression, increasing α-SYN level in neurites. Interestingly, α-SYN mRNA is highly enriched in mitochondria and pro-motes local protein translation, increasing mitochondrial oxygen consumption and ATP generation. Collectively, Pum2-dependent translational control of α-SYN near mitochondria contributes to the fine-tuning of mitochondrial respiratory functions in neurites. Dysfunction of these mechanisms may contribute to PD pathogenesis.

Title: De-repression of TET1 by oxidative stress regulates alpha-synuclein expression in dopaminergic neurons

Authors: *S. GUHATHAKURTA[1], S. BASU[2], E. BOK[2], G. JE[3], Y.-S. KIM[2];
[1]Burnett Sch. of Biomed. Sci., Orlando, FL; [2]Burnett Sch. of Biomed. Sci., Univ. of Central Florida, Orlando, FL; [3]Col. of Med., Kyung-Hee Univ., Seoul, Korea, Republic of

Abstract: In human, the gene (SNCA) coding for alpha-synuclein (α-SYN) contains high CpG rich region around transcription start site encompassing promoter and intron1. Hypomethylation of this intron1 CpG island has been shown to be associated with deregulated higher expression of α-SYN in Parkinson's disease (PD). However, this finding remains controversial across different studies and also the detailed mechanism behind this regulation has not been explored. SNCA being a high CpG containing gene is bound by active histone modification H3K4me3 which

favors transcription. Interestingly, we found that in matured dopaminergic neuronal cell line, SNCA expression level is significantly less as compared to non-neuronal cells such as HEK-293T. To understand the underlying reason of this less expression of SNCA in dopaminergic neuronal cell line, we found that this gene is also co-occupied by histone repression modification H3K27me3. This peculiar presence of both the activation and repression marks together made this gene promoter “bivalent” in the neuron which supports its lesser expression. Based on this gene's epigenetic structure i.e. presence of CpG island and promoter bivalency, we hypothesized that SNCA could be regulated by Ten Eleven Translocase 1 (TET1). Expectedly, we observed that TET1 binds to SNCA promoter and knocking down of TET1 leads to huge expression of α-SYN whereas the basal expression of α-SYN further goes down upon overexpression of the cysteine rich DNA binding CXXC domain of TET1. This finding demonstrated that TET1 acts as a major repressor for α-SYN in dopaminergic neurons. It is already known that α-SYN can be regulated by Reactive Oxygen Species or ROS. To understand how ROS can regulate this gene's expression, we checked the SNCA promoter driven luciferase activity in presence of TET1-CXXC domain with or without known ROS inducers like Paraquat and H2O2. We found that the repression of SNCA promoter driven luciferase activity by TET1-CXXC is reversed in presence of oxidative stress. In order to understand how this de-repression of TET1 or release of its binding to SNCA happens, we measured the cysteine oxidation status of this protein. Since, TET1 is a cysteine rich protein and 8 of them are involved in its DNA binding, there is a high chance that these residues could get oxidized to its sulphenylated forms. Interestingly, we found that TET1 cysteine sulphenylation is increased in presence of ROS which might be the cause for this de-repression of TET1 from the SNCA gene promoter and allow its transcription.

Title: Implication of 8-oxodG-mediated Transcriptional Mutagenesis in sporadic Parkinson’s disease

Authors: *S. BASU[1], S. GUHATHAKURTA[2], E. BOK[3], G. JE[4], A. CRISTOVAO[5], Y.-S. KIM[2];

Abstract: Oxidative stress-mediated DNA damage in the form of 8-oxo-7,8-dihydroguanine (8-oxodG, oxidized guanine), has been shown to accumulate under several disease like Cancer and neurodegeneration including Parkinson's disease (PD). In post-mitotic cells like neurons, where fidelity of transcription and translation is key to maintaining physiological activity, 8-oxodG-mediated misincorporation of adenine instead of cytosine in mRNA chain during transcription (transcriptional mutagenesis, TM) can lead to significant phenotypical and functional alterations. Sporadic PD is classically characterized by aggregation of a synaptic protein called alpha-synuclein (α-SYN), which forms intraneuronal inclusion in dopaminergic neurons. Genomic mutations that can alter the conformation of α-SYN to β-sheet structure are known to accelerate the aggregation. We hypothesized using SNCA (alpha-synuclein) gene as a model, that TM can generate novel variants at the mRNA level which can accelerate the aggregation process. We predicted the generation of 43 possible mutants of α-SYN through Transcriptional Mutagenesis (TM), but focused on a few which had the highest potential for making the molecule more prone towards aggregation based on prediction by a structural analysis algorithm, TANGO. We confirmed the presence of two of the predicted mutations (Serine42Tyrosine(S42Y) and Alanine53Glutamate(A53E)) in SNCA mRNA from the substantia nigra region of human post-mortem PD brain using RNaseH2 based PCR technique. S42Y and A53E mutations when present accelerate oligomerization of α-SYN compared to wild-type protein using protein complementation system. To our knowledge, this is the first report showing the presence of TM related mutations in Parkinsonian tissue and their role in the pathogenesis of the disease.

Title: Alpha-synuclein overexpression negatively regulates insulin receptor substrate 1 by activating mTORC1/S6K1 signaling

Authors: *H. YANG;
Neurobio., Parkinson's Dis. Center, Capital Med. Univer, Beijing, China

Abstract: Alpha-synuclein (α-Syn) is a major component of Lewy bodies, a pathological feature of Parkinson's and other neurodegenerative diseases collectively known as synucleinopathies. Among the possible mechanisms of α-Syn-mediated neurotoxicity is interference with cytoprotective pathways such as insulin signaling. Insulin receptor substrate (IRS)-1 is a docking protein linking IRs to downstream signaling pathways such as phosphatidylinositol 3-kinase/Akt and mammalian target of rapamycin (mTOR)/ribosomal protein S6 kinase (S6K)1; the latter exerts negative feedback control on insulin signaling, which is impaired in Alzheimer's disease. Our previous study found that α-Syn overexpression can inhibit protein phosphatase (PP)2A activity, which is involved in the protective mechanism of insulin signaling. In this study, we found an increase in IRS-1 phosphorylation at Ser636 and downregulation of tyrosine phosphorylation, which accelerated IRS-1 turnover and reduced insulin-Akt signaling in α-Syn-overexpressing SK-N-SH cells and transgenic mice. The mTOR complex (C)1/S6K1 blocker rapamycin prevented the phosphorylation of IRS-1 at Ser636 in cells overexpressing α-Syn, suggesting that mTORC1/S6K1 activation by α-Syn causes feedback inhibition of insulin signaling via suppression of IRS-1 function. α-Syn overexpression also inhibited PP2A activity, while the PP2A agonist C2 ceramide reversed both S6K1 activation and IRS-1 Ser636 phosphorylation upon α-Syn overexpression. Thus, α-Syn overexpression negatively regulated IRS-1 via mTORC1/S6K1 signaling while activation of PP2A reverses this process. These results provide evidence for a link between α-Syn and IRS-1 that may represent a novel mechanism for α-Syn-associated pathogenesis.

Title: Heparan sulfate is involved in cellular uptake of alpha-synuclein amyloid fibrils but not oligomers

Authors: *E. IHSE[1], J. D. ESKO[2], E. MASLIAH[3];
[1]Dept of Cell. and Molecuar Med., Univ. of California San Diego, La Jolla, CA; [2]Dept of Cell. and Mol. Med., [3]Dept of Neurosciences, UCSD, La Jolla, CA

Abstract: Objectives: Spreading of the pathology to increasingly larger areas of the brain in neurodegenerative diseases like Alzheimer´s and Parkinson´s disease has been proposed to be caused by a prion-like seeding mechanism. It has been shown that protein aggregates involved in these diseases can transfer from one cell to another, but not much is known about how the secretion or internalization occurs. The glycosaminoglycan heparan sulfate is known to interact with protein aggregates that are having the amyloid fold, as it has been found in protein deposits of essentially every amyloid disease regardless of the aggregating protein. It has also recently been shown that heparan sulfate is involved in the cellular uptake of A-beta, tau and prion protein aggregates. The objective of the present project was to investigate if heparan sulfate are involved in cellular internalization of alpha-synuclein aggregates, and if this is true only for aggregates with an amyloid fibril conformation or also for oligomeric species. Methods: Alpha-synuclein in oligomeric or fibrillar conformation was added to the cell media of rat neuroblastoma B103 cells or CHO-cells deficient in heparan sulfate all together or in N- or 2-O-sulfation of the heparan sulfate chains. Cellular uptake was determined by ELISA on cell lysates. Colocalization of heparan sulfate and alpha-synuclein aggregates was studied through confocal microscopy. Results: Cellular uptake of fibrillar alpha-synuclein was almost completely abolished by the addition of heparin to the cell media of B103 cells, while uptake of oligomers were only slightly inhibited. In the microscope, both oligomeric and fibrillar alpha-synuclein were seen to colocalize with heparan sulfate in the B103 cells, in what seems to be endocytic vesicles. All of the CHO mutants showed strongly inhibited uptake of fibrillar alpha-synuclein compared to wt cells, but there was no significant difference in uptake ability between the different mutants. In contrast, no significant difference of uptake was seen between the CHO wt and mutant cells for oligomeric alpha-synuclein. Conclusions: Heparan sulfate is involved in the cellular uptake of some, but not all, types of alpha-synuclein aggregates, and the amyloid fibrillar conformation is likely important for this interaction.

Title: Inclusion seeding by mutant α-synuclein fibrils in primary neuronal cultures and in transgenic mice

Authors: *N. J. RUTHERFORD, M. BROOKS, B. I. GIASSON;
Dept. of Neuroscience, Univ. of Florida, Gainesville, FL

Abstract: α-synuclein (αS) is a major player in the pathogenesis of Parkinson's disease (PD) as the protein is found to be aggregated within Lewy body inclusions in the brains of PD patients. Additionally, missense mutations in, or increased copy number of the gene that encodes αS (SNCA) have been identified in PD families. Some of these missense mutations have been shown to accelerate aggregation *in vitro*, however this is not always the case. Interestingly, two recently identified mutations, G51D and A53E, were reported to slow down the rate at which αS forms fibrils, but increased cellular toxicity under mitochondrial stress conditions and, for A53E, reduced aggregation in cell culture. Previous studies have shown that αS fibrils produced from the PD-causing A53T and E46K αS mutant proteins can induce morphologically distinct inclusions in primary neuronal-glial cultures overexpressing αS, producing flame-like and rounded inclusions respectively. Furthermore, this phenomenon is mirrored in mice transgenic for A53T or E46K αS. It has also been reported that the species of αS fibril, whether wild-type, A53T or E46K, is the determining factor as to which type of inclusion is formed. Therefore our ongoing studies are designed to further investigate the effect of treating αS overexpressing primary neuronal-glial cultures with fibrils produced from all of the identified αS mutants. Quantification of the induction of inclusion pathology and morphological analyses of inclusions will provide information on the abilities of the αS mutants to induce αS inclusion pathology in this cell culture model. In addition, the intramuscular injection seeding followed by CNS transmission model is being utilized in αS transgenic mice, allowing us to assess the physiological relevance of these findings as well as determine the effects of the mutant αS fibrils on toxicity by examining the survival of motor neurons within the lumbar spine. These studies will help to define the inclusion driving capabilities and toxic nature of the different αS mutations in a disease relevant model, providing potential clues to the pathogenesis of this devastating disease.

Title: Genetic and size determinants of alpha-synuclein mediated vesicle rupture

Authors: W. P. FLAVIN[1], O. I. ZHURBICH[2], S. SKARPATHIOTIS[3], *E. CAMPBELL[4]; [1]Integrative Cell Biol., [2]Microbiology and Immunol., [3]Stritch Sch. of Med., [4]Cell Biology, Neurobio. and Anat., Loyola Univ. Chicago, Maywood, IL

Abstract: Numerous recent studies have increasingly implicated smaller aggregates of alpha-synuclein (a-syn) as the pathological cause of Parkinson’s disease. It is now becoming appreciated that a-syn can spread from cell to cell in a prion-like fashion, propagating its misfolded, aggregated conformation from affected to neighboring cells in much the same way as a spreading infection. Our lab previously demonstrated that a-syn aggregates disruptively enter cells by inducing rupture of lysosomal membranes following endocytosis, causing cathepsin-mediated oxidative stress and inflammasome activation. In order to further investigate the ability of a-syn to induce vesicle rupture, and to test the hypothesis that familial missense mutations can differentially affect the efficacy of a-syn entry in this manner, we generated aggregates of purified WT and mutant forms of a-syn, characterized the aggregate size distribution of these preparations, and measured the ability of these species to induce vesicle rupture. We determined that amine-reactive FITC fluorophore labeling of aggregated a-syn preparations increases the proportion of smaller, single a-syn fibrils in the sample compared to larger, grouped fibrils, and that these smaller, labeled aggregates are able to significantly induce vesicle rupture regardless of a-syn type. Additionally, we demonstrated that cells exposed to insult by different types of a-syn exhibit rupture of distinct intracellular compartments, and that aggregates of missense mutant G51D a-syn demonstrate a significantly increased propensity for inducing rupture of larger vesicles. This work provides further mechanistic insight into the movement of a-syn within and between cells, as well as the detrimental consequences of this spread for affected neurons. Understanding the cellular and molecular mechanisms responsible for intercellular

transfer of a-syn pathology is critical for developing treatments designed to arrest or prevent Parkinson's disease progression.

Title: Neuroprotective effects of zonisamide against lactacystin-induced neurodegeneration do not involve changes in system xc- expression

Authors: *E. BENTEA[1], J. VAN LIEFFERINGE[1], T. DEMUYSER[1], S. KOBAYASHI[2], L. DENEYER[1], G. ALBERTINI[1], E. MERCKX[1], K. MAES[1], H. SATO[3], I. SMOLDERS[1], J. LEWERENZ[4], A. MASSIE[1];

Abstract: Zonisamide (ZNS), an anti-epileptic drug used in the symptomatic treatment of Parkinson's disease (PD), has been recently linked with neuroprotective properties in toxin- and genetic-based models of PD. One of the mechanisms proposed to mediate the neuroprotective effects of ZNS involve an increase in expression of the cystine/glutamate antiporter system xc-, leading to enhanced cystine supply for astrocytic glutathione synthesis (Asanuma et al. Ann Neurol 2010 67(2):239-49). At the same time, however, enhancement of system xc- might trigger excitotoxicity due to pathological astrocytic glutamate release, leading to non-cell autonomous neuronal death (Massie et al. FASEB J 2011 25(4):1359-69). In order to gain further insights into the neuroprotective properties of ZNS and elucidate the role of system xc-, we have employed the lactacystin (proteasome inhibition) mouse model of PD. Our findings indicate that chronic treatment with ZNS (30mg/kg; i.p.) protects against lactacystin-induced neurodegeneration, confirming the neuroprotective properties of ZNS, for the first time in a model based on proteasome inhibition. The neuroprotective effects of ZNS were accompanied by an improvement in sensorimotor function, as evaluated using the adhesive removal test. ZNS treatment failed, however, to modulate the expression of system xc- in midbrain and striatum of

lactacystin treated mice, indicating that the neuroprotective action of ZNS do not involve changes in system xc- expression. Similarly, we found that chronic treatment with ZNS did not influence system xc- expression or glutathione levels in the basal ganglia of control (untreated) mice. Finally, *in vitro* studies indicated that ZNS treatment did not change system xc- activity in HT22 cells or primary astrocytes, and did not influence glutathione levels in astroglial C6 cells. In conclusion, our study revealed neuroprotective and symptomatic effects of chronic ZNS treatment in a PD model based on proteasome inhibition. Our top-down approach investigating the effect of ZNS treatment in pathological and physiological conditions and in cell culture, failed to reveal any significant effect on system xc- expression or activity. We thereby propose that the neuroprotective actions of ZNS are not mediated via system xc-. Instead, other pathways are likely to be involved, such as the proposed anti-inflammatory, anti-oxidant and neurotrophic properties of ZNS. Future studies in this regard will be important in understanding the mechanisms of neuroprotection of ZNS. Nevertheless, our findings support the use of ZNS as a symptomatic and possible disease-modifying therapy in PD.

Title: A novel neuroprotective aurimmed compound as a potential therapeutic for Parkinson’s disease

Authors: *J. E. CAVINESS;
Delaware State Univ., Dover, DE

Abstract: Parkinson’s disease (PD) is the second most prominent neurodegenerative disorder to date affecting over 1% of the U.S. population over the age of 65. PD pathology is characterized by protein aggregation known as Lewy bodies and the depletion of dopaminergic neurons in the substantia nigra (SN). Currently, most commonly used therapeutics focus on alleviating PD symptoms, however, there is no known effective therapeutic that shows neuroprotective or

recovery effects for PD patients. Using cell viability and toxicity (MTT and LDH) assays, we have identified that the lead AurimMed compound: AMP-X-0079 showed a significant neuroprotective and recovery effect on oxidative stress induced toxicity (MPP+ and H_2O_2) in rat dopaminergic N27 cells. In addition to our preliminary *in vitro* studies, we found that AMP-X-0079 increased the survival rate as well as the mobility rate in the rotenone induced *Drosophila* PD model. Furthermore, we assessed the effect of oral AMP-X-0079 treatment in the MPTP-lesioned C57/Bl6 mouse model. Our behavioral data suggest that the oral treatment of AMP-X-0079 (50 µg/gram body weight) for two weeks was sufficient to improve their movement from MPTP-induced damage. In multiple behavioral studies including hindlimb clasping, cross-beam and grooming tests, we found that the compound treated mice showed significantly improved movement, compared with the MPTP and vehicle-treated mice. The following immunohistochemical analysis of the striatum and the SN verified that there is a significant increase in the tyrosine hydroxylase-positive cells in both the striatum and the SN from AMP-X-0079 treated animals when compared to MPTP/Vehicle treated animals. Although we may need to identify the optimal dose for the treatment, the oral treatment of the novel compound already displayed a promising efficacy in mice. We are currently validating over 10 identified target genes in the mechanism of action from mass spectrometry-based protein profile, compared with the vehicle group. We believe that there is a great potential to develop the novel AurimMed compound as an effective therapeutic, not only because it alleviates the PD symptoms and slows the disease progression, but also because it shows neuroprotective/recovery effects in PD models.

Title: The neuroprotective effects of near infrared light (670nm) when applied at different periods in relation to MPTP insult

Authors: *F. REINHART[1,2], N. EL MASSRI[3], N. TORRES-MARTINEZ[1,2], F. DARLOT[1,2], C. CHABROL[1,2], D. M. JOHNSTONE[3], J. STONE[3], J. MITROFANIS[3], A.-L. BENABID[1,2], C. MORO[1,2];

Abstract: Parkinson's disease (PD) is the second most widespread neurodegenerative disease around the world. It is characterised by the signs of resting tremor, bradykinesia and rigidity. The standard treatments for PD are effective at attenuating the motor signs at least at their onset. However they do not efficiently slow the progression of the PD. In another hand, a growing number of studies illustrate the interest of near-infrared (NIr) treatment to preserve the motor capacities and to protect the dopaminergic cells in animal models of the PD. We assess here if a NIr therapy could be used to prevent the PD and/or stays efficient even when the disease is well established. We used an acute mouse MPTP model. Briefly, the mice received 2 injections in 2 days (50mg/kg global dose). They also received (or not) a 90s light (670 nm) treatment, extra-cerebrally, twice a day, within 2 days. According to the various groups, the mice received the light treatment either the 2 days before the MPTP injections (pre-treated), or during the MPTP injections (simultaneously treated), or the 2 days after the MPTP injections (post-treated). The motor capacities were assessed in an open field daily. After the MPTP days, the mice were allowed to survive during one week, then a histological analysis have been realised to determine the number of dopaminergic cells preserved. Behaviour: the MPTP group has a 60% decrease of its motor capacities after the MPTP injections and remains very sick the days after. We show here that a pre-treatment preserves the motor capacities as well as a simultaneous treatment, during the entire MPTP time (50% better). The days after the MPTP injections, these two groups recovered their complete motor capacities. In the post-treated group, the mice were very affected before the treatment (60% loss). Only 20min after the light application, this group recovered its complete motor capacities. Histology: the pre- and simultaneous treatment showed a higher number of dopaminergic cells preserved (≈100%) than the MPTP group (≈70%). However, if the post-treatment has a higher number of cells preserved than MPTP (≈ 20% better), this result does not reach the significant limit. We show here that, (1) a 670 nm pre-treatment is protective against the MPTP insult and, (2) a post-treatment improves the motor capacities of parkinsonian mice. To conclude, we can suppose two distinct mechanisms of action of NIr light. (1) A short term effect (a few minutes) leading to motor capacities improvement; (2) a longer term effect, maintained at least 48h, which preserves cells form death. These results confirm the interest of a NIr therapy against the disease and allow us to seriously consider this strategy in human.

Title: Development of a novel brain penetrant multifunctional iron chelator dopamine agonist for symptomatic and neuroprotective therapy of Parkinson's disease

Authors: *A. K. DUTTA, Dr[1], B. DAS[1], L. XU[1], T. ANTONIO[2], M. REITH[2];
[1]Wayne State Univ., Detroit, MI; [2]New York Univ., New York, NY

Abstract: Parkinson's disease (PD) is a major neurodegenerative disorder affecting 1-2% of the elderly population, causing profound motor impairments that include tremors at rest, rigidity, bradykinesia, and postural instability along with non-motoric symptoms such as autonomic, cognitive and psychiatric problems. It is believed that environmental factors converging on oxidative stress, nigral iron elevation, mitochondrial dysfunction, inflammation and aberrant protein aggregation, account for most cases of PD. For the successful treatment of multifactorial CNS diseases, like PD, a new paradigm has arisen to address the underlying pathogenesis pathways, according to which multifunctional drugs having multiple pharmacological activities can be employed to target more than one pathological factor to slow the disease progression and alleviate motor dysfunction at the same time. Unfortunately, no neuroprotective drugs have been identified or approved by the FDA so far for the treatment of PD, thereby, necessitating research for such agents. To address this yet unmet medical need and considering the implication of free iron (II) in PD, we have designed, synthesized and evaluated a novel hybrid iron chelator, D-607, as a multitarget-directed ligand against PD. In the GTPγS functional assay, the compound revealed full agonist activity at both D2 and D3 receptors (EC50 (GTPγS); D2 = 51.6 and D3 = 13.5 nM). *In vitro*, the molecule displayed potent antioxidant and efficient iron chelation properties along with preferential affinity for the reactive form of the metal (Fe2+) that induces oxidative stress in PD brain. In reserpinized PD animal model, D-607 also exhibited potent *in vivo* activity in reversing hypolocomotion delineating its blood brain barrier crossing ability. Pre-treatment with D-607 *in vitro* was found to rescue dopaminergic PC12 cells from toxicity induced by both 6-hydroxydopamine and iron administration in a dose-dependent manner, thereby, producing neuroprotection effect. These observations strongly suggest that compound D-607 might be an excellent multifunctional agent for a novel viable therapy of PD. This work is supported by grants from NINDS (NS 047198, AKD).

Title: Chronic caffeine mitigates aberrant motor learning: Insights into reduced Parkinson's disease risk in caffeine drinking populations

Authors: *A. C. KROK[1], J. L. KORANDA[1], J. A. BEELER[2], X. ZHUANG[1];
[1]Univ. of Chicago, Chicago, IL; [2]Queens Col. CUNY, Queens, NY

Abstract: Epidemiological studies have consistently shown that heavy caffeine consumption reduces the risk of Parkinson's disease (PD); however, the mechanism of such protective effects remains unknown. In recent studies, we provide evidence that dopamine (DA) blockade can induce motor inhibition through corticostriatal LTP in the indirect pathway. We have proposed that aberrant plasticity (i.e. aberrant learning) may degrade established motor skills and contribute to PD motor symptoms. Additionally, we have shown that the xanthine theophylline, a non-selective adenosine receptor antagonist similar to caffeine, can mitigate both aberrant motor learning and underlying abnormal corticostriatal plasticity. In the current study, we predicted chronic caffeine exposure could also mitigate aberrant motor learning due to its A2A antagonist activity. To test the effects of chronic caffeine on aberrant motor learning, mice were pretreated with caffeine in their drinking water for 2 weeks and then trained on the accelerating rotorod. We found chronic caffeine exposure partially rescued rotorod performance during an initial acquisition phase of training in which DA receptors were pharmacologically blocked. We then retrained the same mice on the rotorod in the absence of dopamine blockade (i.e. recovery phase). Performance of mice withdrawn from caffeine, but not those maintained on caffeine, recovered to levels of control mice that were previously trained with saline rather than dopamine blockade. This result is consistent with an earlier study that showed theophylline diminishes initial acquisition of aberrant motor learning, but theophylline administered after aberrant learning actually impairs recovery. We also found that chronic caffeine reduced the sensitization of haloperidol-induced catalepsy, reinforcing the idea that chronic caffeine may mitigate D2R blockade-induced impairments in motor learning. These results suggest that chronic caffeine exposure may protect against the acquisition of aberrant motor learning, providing protection

against aberrant motor learning that may delay the onset and severity of PD motor symptoms in caffeine drinking populations.

Title: Pre- and post-synaptic mechanisms for nicotine's protective effect against Parkinson's disease

Authors: ***J. KORANDA**[1], A. C. KROK[1], D. S. MCGEHEE[2], J. A. BEELER[3], X. ZHUANG[1]; [1]Neurobio., [2]Anesthesia, The Univ. of Chicago, Chicago, IL; [3]Queens Col. CUNY, Queens, NY

Abstract: Nicotine use has long been associated with decreased risk of Parkinson's disease (PD), but the potential protective mechanisms are unknown. Recently, we reported that dopamine (DA) D2 receptor (D2R) blockade induces an experience-dependent learned inhibition of movement and suggested that this 'aberrant motor learning' contributes to PD symptoms. We have found that chronic nicotine treatment can reduce aberrant motor learning in mice, suggesting that chronic nicotine may exert a PD protective effect through reducing aberrant learning and aberrant corticostriatal plasticity. In the current study, we found that the specific deletion of β2 nicotinic subunits in DA neurons is sufficient to reduce stimulated DA release in anesthetized mice and mitigate aberrant motor learning, similar to chronic nicotine treatment. We also found that chronic nicotine treatment and β2 deletion reduce the phosphorylation of extracellular regulated kinase (pERK) following repeated D2R antagonism paired with the motor learning paradigm. These results suggest that the striatal network may become adapted to non-pathologically low DA levels following chronic nicotine treatment. These neuroadaptations, in turn, may protect against dopamine denervation-induced aberrant motor learning. The current data suggest one possible mechanism that might underlie the protective effects of chronic nicotine against PD.

Title: Modeling Parkinson's disease in aged rats: the neuroprotective effects of caffeine against the neurotoxicity of 6-hydroxydopamine

Authors: *G. H. BEAGLEY[1], C. O. HALEY[2];
[1]Dept Psychology, [2]Psychology, Alma Col., Alma, MI

Abstract: Parkinson's disease (PD) involves the degeneration of dopaminergic neurons in the substantia nigra (SN). Researchers have hypothesized that the caffeine in coffee is neuroprotective, and is associated with the prevention and treatment of PD. This study investigated whether caffeinated coffee and/or caffeine tablets reduce behavioral and/or cognitive impairment of PD. Two year old male Sprague Dawley rats were stereotaxically injected with 6 - hydroxydopamine (6 - OHDA) producing bilateral lesions in the SN; generating an animal model of PD. Rats were treated with caffeinated coffee and caffeine tablets for at least 2 weeks before surgery and continued on their assigned regimen after surgery. Rats were then tested for cognitive and motor impairment using the Morris Water Maze (MWM). Results indicate, on average, that the rats treated with caffeine were faster at locating the platform than the rats treated with coffee (tablets (1:30 seconds vs 1:53 seconds) and both were faster than rats with no caffeine treatment (2:00 seconds). In addition, behavioral observations indicate that coffee may be better at reducing motor dysfunction. Histological results suggest that caffeinated coffee was better than caffeine tablets at increasing neuronal viability in the substantia nigra in comparison to no treatment. Other bioactive properties of coffee, independent of caffeine, are suspected to play a role in neuroprotection and the treatment of PD.

Title: Glycyrrhizic acid attenuates dopaminergic neurodegeneration in rotenone model of Parkinson's disease

Authors: ***E. HAQUE**[1,2], H. JAVED[2], S. ABUL KHAIR[2], S. AZIMULLAH[3], S. OJHA[3]; [2]Dept. of Biochem., [3]Dept. of Pharmacol. and Therapeut., [1]UAE Univ., Al Ain, United Arab Emirates

Abstract: Parkinson disease (PD) is the second most common neurodegenerative disorder characterized by loss of dopaminergic neurons in the SNc area. Numerous studies suggest that oxidative stress and inflammation play a critical role in the etiopathogenesis of PD. The current study was undertaken to assess the neuroprotective potential of glycyrrhizic acid (GA), one of the active components present in licorice against rotenone-induced rat model of PD. Since, PD is a progressive chronic neurodegenerative disorder; we have used chronic protocol for four weeks at a dose of 50 mg/kg prior to rotenone (3 mg/kg) challenge. The administration of rotenone caused significant reduction in antioxidant activities as evidenced by reduced activity of superoxide dismutase, catalase and depletion of glutathione with a concomitant rise in the lipid peroxidation product, malondialdehyde. A significant enhancement in the levels of pro-inflammatory cytokines and elevation in the inflammatory mediators like cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) was observed in the midbrain region. The immunohistochemistry revealed that following rotenone challenge, a significant increase in the expression of ionized calcium binding adaptor molecule-1 (Iba-1), and glial fibrillary acidic protein (GFAP), which are indicative of microglial and astrocyte activation accompanied by loss of dopamine neurons in the SNc. Interestingly, GA treatment significantly protected the dopamine neuron and normalized the Iba-1 and GFAP activation from the rotenone insult. GA also improved antioxidant enzymes, prevented glutathione depletion and inhibited lipid peroxidation along with attenuation of induction of pro-inflammatory cytokines. Subsequently, GA also attenuated the increased levels of inflammatory mediators such as COX-2 and iNOS. Based on the results of our study we conclude that GA protects against rotenone-induced PD and the neuroprotective effects are attributed to its potent antioxidant and anti-inflammatory properties.

Title: The effect of flavonoids against paraquat induced oxidative stress and neurotoxicity in *Drosophila* melanogaster

Authors: *D. R. JHONSA, L. BADGUJAR, B. SUTARIYA, M. SARAF;
Pharmacol., Bombay Col. of Pharm., Mumbai, India

Abstract: Parkinson's disease is a chronic, progressive neurodegenerative disorder with a multifactorial etiology involving advancing age, environmental and genetic factors. The exact cause of PD is unknown as well as its cure; dopamine (in the form of levodopa or mucuna pruriens) being the gold standard of PD treatment since the discovery of the disorder. But it only provides symptomatic relief from the disease and is unsuccessful in halting the progression of the disease. *Drosophila* melanogaster has widely been used as a model to study a number of neurodegenerative diseases. Exposure to environmental toxin paraquat is employed to induce oxidative stress induced neurotoxicity and sporadic Parkinson's disease. Flavonoids are an important class of phenolic phytochemicals exerting a multiplicity of neuroprotective actions within the brain. In this study, the therapeutic anti-oxidant properties of two flavonoids, fisetin and hesperidin against paraquat induced oxidative damage and neurotoxicity in *Drosophila* melanogaster has been examined. Adult female and male flies (CsBz strain) exposed to 7 and 12 mM paraquat solution for 12 hours showed significant mortality and locomotor disability. The life span was extended and the locomotor activity of flies was enhanced in paraquat exposed flies when treated with fisetin and hesperidin for 24 hours. Fisetin and hesperidin treatment also ameliorated oxidative stress factors such as intracellular ROS levels, superoxide dismutase and catalase. They also reduced acetylcholine esterase activity which was increased by paraquat. Also, the levels of the endogenous anti-oxidant, reduced glutathione which were diminished by paraquat were also enhanced by fisetin and hesperidin. Thus, this study demonstrated that feeding flies with fisetin and hesperidin after exposure to paraquat showed anti-oxidant and neural protective effects leading to recovery of locomotor behaviour and extension of life span in fruitflies. The project also confirmed the utility of *Drosophila* melanogaster as a model in screening putative therapeutic molecules prior to their use in mammalian models.

Abstract: We recently reported that treatment with naringin, a major flavonoid found in grapefruit and citrus fruits, attenuated neurodegeneration in a rat model of Parkinson's disease (PD) *in vivo*. In order to investigate whether its effects are universally applied to a different model of PD, and whether its treatment induces restorative effects on the lesioned nigrostriatal dopaminergic (DA) projection, we observed the effects of pre-treatment or post-treatment with naringin in a mouse model of PD. For neuroprotective effects, 6-hydroxydopamine (6-OHDA) was unilaterally injected into the striatum of mouse brains for a neurotoxin model of PD in the presence or absence of naringin by daily intraperitoneal injection. Our results showed that naringin protected the nigrostriatal DA projection from 6-OHDA-induced neurotoxicity. Moreover, similar to the effects in rat brains, this treatment induced the activation of mammalian target of rapamycin complex 1 (mTORC1), which is well known as an important survival factor for DA neurons, and inhibited microglial activation in the substantia nigra (SN) of 6-OHDA-treated mice. However, there was no significant change of DA phenotypes in the SN and striatum post-treated with naringin compared with 6-OHDA-lesioned mice, despite the treatment being continued for 12 weeks. These results suggest that post-treatment with naringin alone may not be enough to restore the nigrostriatal DA projection in a mouse model of PD. However, our results apparently suggest that naringin is a beneficial natural product to prevent DA degeneration, which is involved in PD. Title: Protective effects of pyrroloquinoline quinone against the cell death caused by 6-hydroxydopamine and hydrogen peroxide

Authors: *Y. YAMADA, M. NAKAMICHI;
Dept of Biotech and Chem Fac of Engin. Kinki Univ., Higashi-Hiroshima, Japan

Abstract: Parkinson's disease (PD) is one of most common neurodegenerative diseases with progressive neurodegeneration of the nigrostriatal pathway. Reactive oxygen species (ROS) has been implicated in the etiology of PD. 6-Hydroxydopamine (6-OHDA) is a neurotoxin that acts specifically on nerve cells, are taken up by dopaminergic neurons. It is thought that ROS and endoplasmic reticulum stress (ERS) involved in toxicity of 6-OHDA. Pyrroloquinoline quinone (PQQ) is reported to participate in a range of biological function such as antioxidant and cell growth-promoting effect. It was reported that PQQ rich feed increased mice liver mitochondria. However, the mechanism of these actions is not known in detail. On the other hand, PQQ which has a very high reactivity and readily reacts with the amino group-containing substance has been reported to change imidazol pyrroloquinoline (IPQ) by forming an imidazole skeleton. In this study, we compared the protective effect of PQQ2Na (oxidized form), PQQH2 (reduced form), IPQNa (oxidized form) and IPQ (reduced form) against 6-OHDA and H2O2 using human neuroblastoma cell line SK-N-SH. The cells incubated in the presence of 6-OHDA for 24 hrs with the four forms of PQQ in CO2 incubator or H2O2 for 10 min at room temperature. After incubation, the cell viability rates were measured by MTT assay. In addition, the effects of PQQ2Na, PQQH2, IPQNa and IPQ against mitochondria formation were examined. The expression levels of human cytochrome c oxidase subunit IV isoform 1 (COXIV-1) that is known as one of mitochondria marker genes were measured by RT-PCR using Taq Man probes. All PQQs used in this experiment showed protective effects against the toxicity of 6-OHDA and H2O2. PQQ2Na, PQQH2, IPQNa and IPQ show a trend of protection at concentrations as low as 1 nM and 100 nM against 6-OHDA and H2O2, respectively. PQQ and amino acid adduct IPQ showed the almost same biological activity. PQQ might act as the adduct form *in vivo*. PQQ2Na, PQQH, IPQ and IPQNa increased the expression of COXIV-1 in SK-N-SH. These results suggest that PQQ may play the fundamental role in metabolism of the neuron and will be useful for the development of therapeutic agents of PD.

Title: Multi-therapeutic potentials of silibinin for the treatment and prevention of Parkinson's disease

Authors: ***Y. LEE**;
Dept. of Pharm., Busan, Korea, Republic of

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disease, and induced by a selective loss of dopaminergic neurons in the nigrostriatal pathway. The lipophile MPTP can cross the blood-brain barrier, and is subsequently metabolized into toxic MPP+, which causes mitochondrial dysfunction and the selective cell death of dopaminergic neurons, and thus causes PD pathologies. The flavonoid silibinin is the major active constituent of silymarin, an extract of the milk thistle seeds and known to have hepatoprotective, anti-cancer, anti-oxidative effects and neuroprotective effects. In the present study, we reported the neuroprotective effects of silibinin in both acute and sub-chronic MPTP model of PD. Pre- and post-treatments of silibinin were effective to attenuate motor deficit and dopaminergic neuronal loss caused by acute and sub-chronic PD model, respectively. Glial activation was observed in striatum and in substantia nigra of mice treated with both MPTP-induced PD models. Silibinin had modulatory roles on neuroinflammation in acute PD mice model, but not in sub-chronic PD mice model. In addition, *in vitro* study confirmed that silibinin suppressed MPP+-induced astroglial activation and ERK phosphorylation in primary astrocytes, and also prevented MPP+-induced cell death and disruption on mitochondrial membrane potential in primary cultured neurons. Taken together, the present study indicates that silibinin has multi-therapeutic potentials for treatment and prevention of PD and other neurodegenerative diseases associated with mitochondrial dysfunction or neuroinflammation.

Title: Neuroprotective effects of antidepressants via upregulation of neurotrophic factors

Authors: *S. SHADFAR, D.-Y. CHOI;
Yeungnam Univ., Gyeongsan, Korea, Republic of

Abstract: Neurotrophic factors are essential for neuronal survival, plasticity and development, and have been implicated in the mechanism of the action of antidepressant drugs (ADs). In an attempt to investigate the effects of three different antidepressant drugs on expression of neurotrophic factors and their related signaling pathways, we injected C57Bl6/J mice with ADs including fluoxetine, imipramine and milnacipran (i.p., 20 mg/kg/day for 1 week or 3 weeks). We also measured concentration of monoamines (dopamine, 3,4-dihydroxyphenylacetic acid, serotonin, homovanillic acid) in the striatum of mice after injection of ADs. Our results revealed that all of the drugs upregulated the concentration of brain-derived neurotrophic factor in the striatum both at one week and three weeks after treatment. In contrast, an increase in glial-derived neurotrophic factor was more obvious at three weeks after the antidepressants treatment. Specifically, fluoxetine and imipramine more clearly increased expression of neurotrophic factors than milnacipran. In addition, we found that the ADs raised the phosphorylation of extracellular signal-regulated-protein kinase (Phospho-Erk1/2) and the serine/threonine kinase Akt protein. Moreover, ADs slightly increased monoamine neurotransmitters in the striatum. Therefore, we carefully propose that ADs might have neuroprotective properties and could be employed as novel therapeutic agents for neurodegenerative diseases such as Parkinson’s disease and Alzheimer’s disease.

Title: Neuroprotective effects of DNP on the MPTP-induced Parkinson's disease mouse model

Authors: *A. KIM;
Pusan Natl. Univ., Pusan-City, Korea, Republic of

Abstract: Parkinson's disease (PD) is progressive neurodegenerative disorder characterized by loss of dopaminergic neurons in substantia nigra (SN) of the brain. 2.4-Dinitrophenol (DNP) is well known for a mitochondrial uncoupler which inhibits efficient energy production in mitochondria. Mounting evidences suggest the beneficial effects of DNP on neural plasticity and neurodegeneration, thus the present study tested effects of DNP on the MPTP-induced PD mouse model. Mice were pretreated with DNP (1 mg/kg or 5 mg/kg) for thirteen consecutive days. Then four times of MPTP (20 mg/kg) was administered into mice to introduce PD pathologies. MPTP caused significant motor deficits and DA neuronal loss in SN of PD mice. However, DNP pretreatment ameliorated MPTP-induced motor dysfunction and dopaminergic neuronal loss in striatum (STR) and substantia nigra (SN). Moreover, we observed that DNP prevented the MPP+-induced cell death and reduction of mitochondrial membrane potentials in SH-SY5Y cells and primary cultured neurons. The present study showed that DNP-mediated mild inhibition of oxidative phosphorylation can be neuroprotective on the MPTP-induced PD mouse model. Current findings suggest that DNP could protect dopaminergic neurons and maintain the integrity of mitochondrial membrane potential in PD through activating adaptive stress responses.

Title: Pretreatment of morin alleviates neurotoxicity in Parkinson's disease mouse model

Authors: *J. LEE;
Pusan Natl. Univ., Busan, Korea, Republic of

Abstract: Parkinson's disease (PD) is one of the most common neurodegenerative disorders and progressive neurodegenerative diseases, and characterized by loss of dopaminergic (DA) neurons in substantia nigra (SN). Morin (3,5,7,2',4'-pentahydroxyflavone), a member of flavonols, is a constituent of many herbs, fruits and wine. Previous studies have shown that morin has antioxidant, anti-inflammatory, and antiproliferative effect *in vivo* models of cancer. In addition its neuroprotective effects are also well reported in neurodegenerative diseases model including Alzheimer's disease. Here we reported the neuroprotective effects of morin in the MPTP-induced PD mouse model. Mice were pre-treated with morin (5mg/kg or 50mg/kg) for twelve consecutive days. Then four times MPTP (20 mg/kg) was given to mice to introduce PD pathologies. MPTP induced significant motor deficits and DA neuronal loss in SN of PD mice. Morin attenuated motor dysfunction induced the PD model, and tyrosine hydroxylase (TH) immunostaining showed that morin protected DA neuronal loss from MPTP-induced PD model in substantia nigra (SN) and striatum (STR). Morin also alleviated MPTP-mediated neuroinflammation in SN and STR. Furthermore, we found that morin pretreatment protected neurons against toxic MPP(+)-mediated cell death in primary cultured neurons. The present study provides *in vivo* and *in vitro* evidences that morin is a potent neuroprotective agent in a model of PD. Further study will be focused on revealing neuroprotective mechanism of morin.

Title: Traditional medicines: mechanisms of neuroprotection and the Nrf-2 antioxidant pathway in Parkinson's disease models

Authors: *A. JACQUET, S. Y. MA, J.-C. ROCHET;
Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN

Abstract: As our population ages, the economical and social burden of neurodegenerative diseases such as Parkinson's disease (PD) affects an increasing number of families. Despites global efforts, there are still no treatments to stop or slow the neurodegenerative process underlying PD. We therefore initiated an ethnopharmacological study to identify medicinal plants used in Nepalese and Native American traditional medicine to treat PD and PD-related symptoms. Among the 50+ plants documented, we identified six promising candidates including the isoflavone-rich red clover extract. The neuroprotective activities of these extracts were assessed in immortalized and primary neuronal cell cultures. We showed that our plant extracts (including red clover) and individual isoflavones alleviate toxicity elicited by rotenone, paraquat and/or the α-synuclein mutant A53T as determined by monitoring dopaminergic neuron survival and the preservation of neurite lengths. The plant extracts showed the ability to increase the cellular antioxidant response via activation of the Nrf-2/ARE pathway, as determined in primary cortical astrocytes and mixed primary midbrain cultures transduced with an Nrf-2 reporter adenovirus encoding EGFP downstream of the antioxidant response element (ARE). The extracts also interfered with a loss of mitochondrial function triggered by the complex I inhibitor rotenone in SH-SY5Y cells maintained in galactose-containing media to ensure that they were dependent on oxidative phosphorylation for their energy production. Finally, the red clover extract was found to inhibit proteasomal function as monitored using GFP-U, an unstable form of GFP, as a substrate protein to study ubiquitination-dependent proteasomal degradation. Current efforts are aimed at determining whether the inhibitory effect of the red clover extract on the ubiquitin-proteasome system results in an activation of lysosomal autophagy. Collectively, our results suggest that red clover and other polyphenol-rich botanical extracts protect against toxicity elicited by PD-related insults by activating the cellular antioxidant response, ameliorating mitochondrial dysfunction, and modulating protein degradation. These insights about the neuroprotective mechanisms of botanical extracts take us a step closer to the design of herbal remedies for PD. With 80% of the world population using medicinal plants as a primary source of healthcare, the development of plant-based therapies would critically impact the lives of these patients.

Abstract: The Parkinson's Desease (PD) is a neuromotor disorder characterized by the lost of the dopaminergic cells, specifically in the substance nigra (SNpc) pars compacta in mild brain. Nigral dopaminergic cells are particularly vulnerable to oxidative stress which is a key stimulator of microglia activation, which produce reactive oxygen species (ROS) from microglia, and the subsequently dopaminergic cells death to propagate and propel feed forward cycle of neuronal death and inflammation underlying the progression of cell death. Exist evidence that the inflammation which are produced by microglia activation amplify the cell death.In this years, the cannabinoid CB2 receptor (CB2r) , has a new roll like a pharmacological target by the modulation of neuroinflammation because it is upregulated on activated microglia an has a numerous functional effects on these cells. Beta-Caryophyllene is a strongly CB2 agonist which has emerged in recent years. We investigate if beta-caryophyllene can modulate the neuroinflammation response by activation of CB2r in Parkinsonism. We administrated v.i.p MPTP (30mg/kg/d) for 3 days, and beta-caryophyllene (10mg/kg/d) 5 days before MPTP. Groups were: CTL, MPTP, B+MPTP, Beta. After 72h of treatment we sacrificed by decapitation or perfusion, quickly remove SNpc and striatium. Inmunohistochemistry with tyrosine hydroxilase (TH), Iba1 and GFAP. Quantify levels by ELISA of TNFa, IL-6, IL-1b which are related with inflammation. We obtained that immunoreactivity of TH in MPTP group decrease in SNpc and striatum, but this were revert in the beta-caryophyllene group. The inmunoreactivity of Iba1 and GFAP increase in MPTP group and significantly decrease on beta-caryophyllene group. Our results suggest that mice treated with beta-caryophyllene were significant different compared whit the other groups for all techniques.

Title: Is Liraglutide effective in 6-hydroxydopamine induced rat model of Parkinson's disease?

Authors: ***M. K. SHARMA**, J. JALEWA, C. HOLSCHER;
Lancaster Univ., Lancaster, United Kingdom

Abstract: Type 2 diabetes is a risk factor in the development of Parkinson's disease (PD) and the insulin signalling in the brains of PD patients is impaired. Currently, the treatments available cannot repair or prevent further damage in the brain, thus there is urgent need to develop novel treatments. Liraglutide (Victoza®), a long-lasting GLP-1 analogue is on the market as treatment for diabetes. Previous research has shown neuroprotective and growth factor properties of Liraglutide in the brain. Liraglutide crosses the blood-brain barrier and increases synaptic plasticity and cognitive function. The current study aims to answer whether Liraglutide will exhibit neuroprotective effects in 6-OHDA induced rat model of PD. Sprague Dawley rats were injected with Liraglutide (25nm/kgbw) or saline (0.9%w/v). The effect of Liraglutide treatment will be assessed on motor behaviour using rotarod and grip strength meter. In addition, we will study the dynamic gait signals of the rat on Digigait and analyse the parameters of animal posture and kinematics. Tyrosine hydroxylase immunopositive neurons will be counted in the substantia nigra (SNpc) and striatum (caudate putamen). Here, for the first time we test the effect of intraperitoneal (i.p.) administration of Liraglutide as a treatment for the motor impairment suffered by 6-hydroxydopamine (6-OHDA) injected rat PD models. Results will be disclosed at the meeting.

Title: Alaskan blueberry and Sirtuin 1-mediated neuroprotection in a Caenorhabditis elegans model of Parkinson's disease

Authors: *M. MAULIK[1,2], S. KUHN[3], B. E. TAYLOR[4];
[2]Dept. of Chem. and Biochem., [3]Dept. of Biol. and Wildlife, [4]Dept. of Biol. and Wildlife, Dept. of Chem. and Biochem., [1]Univ. of Alaska Fairbanks, Fairbanks, AK

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by the loss of dopaminergic neurons and aggregation of alpha-synuclein (AS) protein leading to motor and cognitive impairment. The current study investigates the role of Alaskan bog blueberry (*Vaccinum uliginosum),* on alpha synuclein aggregation using a transgenic model of *Caenorhabditis elegans* expressing human alpha-synuclein [NL5901 (P(unc-54)::alpha-synuclein::YFP+unc-119)].The current study also examines the role of Sirtuin 1, a histone deacetylase, in reducing the toxicity of alpha-synuclein aggregates and whether this effect is mediated via expression of molecular chaperones, HSP1 and HSP70. The Alaskan bog blueberry was chosen for its high phenolic content, because phenolics have been shown to modulate sirtuin-mediated molecular pathways. Our experiments showed that the crude extract of low bog blueberry (400 and 800 ug/ml) reduced alpha-synuclein aggregation. For high-dose blueberry extract (800 ug/ml), the protection was mediated by sirtuin and HSF-1, which is independent of HSP 70. These findings encourage further studies on these Alaskan botanicals as possible therapeutic agents for Parkinson's disease, specifically of interest are the identification of active ingredients within the extracts and their optimal doses.

Title: N-acetyl-cysteine in combination with igf-1 enhances neuroprotection against proteasome dysfunction-induced neurotoxicity in sh-sy5y cells

Authors: *B. CHENG[1], A. ROMAN[2], A. KUANG[2], E. CASILLAS[1];
[1]Univ. Texas Hlth. Sci. Ctr., Edinburg, TX; [2]Biol., UT-PAN-American, Edinburg, TX

Abstract: The ubiquitin proteasome system (UPS) dysfunction has been implicated in the development of many neuronal disorders, including Parkinson's disease (PD). Previous studies focused on individual neuroprotective agents and their respective abilities to prevent neurotoxicity following a variety of toxic insults. However, the effects of the antioxidant N-acetyl cysteine (NAC) on proteasome impairment-induced apoptosis have not been well characterized in human neuronal cells. The aim of this study was to determine whether co-treatment of NAC and insulin-like growth factor (IGF)-1 efficiently protected against proteasome inhibitor-induced cytotoxicity in SH-SY5Y cells. Our results demonstrate that the proteasome inhibitor, MG132, initiates poly (ADP) ribose polymerase (PARP) cleavage, caspase-3 activation, and nuclear condensation and fragmentation. In addition, MG132 treatment leads to endoplasmic reticulum (ER) stress and autophagy-mediated cell death. All of these events can be attenuated without obvious reduction of MG132-induced protein ubiquitination by first treating the cells with NAC and IGF-1 separately, or simultaneously prior to exposure to MG132. Moreover, our data demonstrated that the combination of the two, rather than used individually, proved to be significantly more effective for neuronal protection. Therefore, we conclude that the simultaneous use of growth/neurotrophic factors and a free radical scavenger may increase overall protection against UPS dysfunction-mediated cytotoxicity and neurodegeneration.

Title: Beta-Caryophyllene ameliorates oxidative stress and neuroinflammation in rat model of rotenone-induced Parkinson's disease

Authors: *S. K. OJHA[1], C. SHARMA[2], H. JAVED[3], S. AZIMULLAH[4], S. BEGUM[3], E. HAQUE[3];
[1]UAE UNIVERSITY, AL AIN, United Arab Emirates; [2]Intrnl. Med., [3]Biochem., [4]Pharmacol. and Therapeut., UAE Univ., Al Ain, UAE, United Arab Emirates

Abstract: Parkinson disease (PD) is the second most common neurodegenerative disorder characterized by loss of dopaminergic neurons in the substantia niagra (SNc) of brain. A large number of studies demonstrate that oxidative stress and inflammation play a critical role in the etiopathogenesis of PD. The current study was undertaken to determine the neuroprotective potential of beta-caryophyllene (BCP), a phytocannabinoid and natural sesquiterpene of wide occurrence. Recent approved by FDA for its use as food additive and flavoring agent encouraged investigated its medicinal properties. Following the chronic and progressive nature of PD pathogenesis, BCP (50 mg/kg) and rotenone (3 mg/kg) were administered to rats for four weeks, as rotenone-induced PD recapitulates human PD pathogenesis. Rotenone challenge caused a significant decrease in activities of antioxidants as evidenced by reduced superoxide dismutase, catalase and reduced glutathione with a concomitant increase in the lipid peroxidation product, malondialdehyde. Rotenone injections also significantly induced pro-inflammatory cytokines; IL-1β, IL-6 and TNF-α and enhanced the expression of inflammatory mediators; cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) in the midbrain. Immunohistochemical studies reveal a significant increase in the expression of ionized calcium binding adaptor molecule-1 (Iba-1) and glial fibrillary acidic protein (GFAP) indicative of microglia activation and astrocyte activation, respectively with loss of dopamine neurons in the SNc following rotenone exposure. However, in our study, treatment with BCP significantly protected the dopaminergic neurons, improved antioxidant enzymes and stabilized the activation of Iba-1 and GFAP resulted from the rotenone challenge. BCP also prevented glutathione depletion and inhibited lipid peroxidation along with significant attenuation of the induction of pro-inflammatory cytokines. Further, BCP treatment also attenuated the increased levels of other inflammatory mediators; COX-2 and iNOS. Based on the results of the present study, it is concluded that BCP protects against rotenone-induced neurodegeneration in PD. The neuroprotective effects of BCP, a naturally available phytocannabinoid could be promising for neuroprotection and the neuroprotective potential could be attributed to its potent antioxidant and anti-inflammatory properties.

Title: Necdin promotes mitochondrial biogenesis to prevent neurodegeneration in experimental Parkinson's disease

Authors: *K. HASEGAWA[1], T. YASUDA[2], C. SHIRAISHI[1], K. FUJIWARA[1], H. MOCHIZUKI[1], K. YOSHIKAWA[1];

Abstract: Mitochondria play a pivotal role in neuronal survival and function. Mitochondrial dysfunction causes neurodegenerative diseases such as Parkinson's disease (PD). Necdin is predominantly expressed in postmitotic neurons and promotes neuronal differentiation and survival. We have previously shown that necdin binds to Sirt1, an NAD+-dependent protein deacetylase involved in the regulation of energy homeostasis and cell survival, and facilitates Sirt1-mediated deacetylation of its substrates p53 and FoxO1 in neurons (J Neurosci, 28:8772-8784, 2008; ibid., 32:5562-5572, 2012). In the present study, we examined whether necdin affects neuronal mitochondrial biogenesis using necdin-null mice. Microarray-based gene expression profiling and quantitative real-time PCR analysis revealed that expression of mitochondria-specific and mitochondrial biogenesis-related genes was significantly low in necdin-null cortical neurons. Furthermore, the amounts of mitochondria and ATP were reduced in necdin-null neurons, which expressed low protein levels of PGC-1α, a master regulator of mitochondrial biogenesis and function. Coimmunoprecipitation assay revealed that necdin bound and stabilized PGC-1α by preventing its ubiquitin-dependent degradation. Forced expression of necdin in primary cortical neurons and human neuroblastoma SH-SY5Y cells promoted mitochondrial function via PGC-1α stabilization and suppressed their mitochondrial toxin-induced degeneration. Furthermore, necdin gene transfer into the substantia nigra *in vivo* of adult mice prevented MPTP-induced degeneration of dopaminergic neurons. These results suggest that necdin stabilizes PGC-1α to promote neuronal mitochondrial biogenesis and prevents mitochondrial dysfunction-associated neurodegeneration.

Biomed. Sci., The Aga Khan Univ., Karachi, Pakistan; [6]Biochemistery, The Univ. of Karachi, Karachi, Pakistan

Abstract: The symptoms of Parkinsonism and oral dyskinesia have been showing to be induced by neuroleptics that significantly affect its clinical use. In this study, we investigate whether Nigella sativa-oil (NS) (black cumin seeds) - a traditional medicine used for the seizure treatment in eastern country- may reduce the haloperidol (HAL) - induced extrapyramidal symptoms (EPS) - like behavior in rats. After combine treatment with HAL (1mg/kg) on NS (0.2ml/rat), rats displayed a significant decreased EPS-like behavior including movement disorders and oral dyskinesia as compared to controls. Immunohistochemical analysis indicates that NS reduced astrogliosis in Caudate and Accumbens Nuclei. These results suggest that NS may consider as an adjunct to antipsychotics to reduce the EPS-like side effect. **Figure 1: Striatal Histopathology (GFAP) at the Dorso-Lateral Region of Caudate Figure: 2 Active Microglia in the Bilateral Striata.**

Title: DA-9805, mixture of herbal extracts, promotes the degradation of α-synuclein in SH-SY5Y cells via autophagy activation

Authors: *H.-R. BYUN[1], H. KIM[1], J. KIM[1], J. KOH[2];
[1]Neural Injury Res. Ctr., Asan Inst. For Life Sci., Seoul, Korea, Republic of; [2]Neurol., Asan Med. Ctr., SEOUL, Korea, Republic of

Abstract: Accumulation of α-synuclein in Lewy bodies and neurites is a pathological hallmark of Parkinson disease (PD). Mutations in α-synuclein cause familial PD, suggesting that altered α-synuclein function can trigger the neurodegenerative process. The formation of cytoplasmic α-synuclein pathologies in PD has been attributed to the dysfunction of protein degradation pathways such as proteasome and autophagy/lysosome systems. DA-9805 is a mixture of herbal extracts prepared by Dong-A ST with PD as a disease target. Although precise pharmacological mechanisms are yet to be characterized, its targets in PD models seem to include inflammation, oxidative stress and autophagy. One of the factors that regulate autophagy flux may be cAMP that has been reported to boost autophagy flux. Of interest, a significant decrease in cAMP levels was observed in patients with PD (Nishino et al. Rev. Neurosci. 1993). Since preliminary data suggested that DA-9805 interacted with PDE1, in the present study, we examined the possibility that DA-9805 reduces α-synuclein accumulation in SH-SY5Y cells through the activation of autophagy. As we predicted, DA-9805 inhibited PDEs and increased cAMP levels in SH-SY5Y cells. Indicating that DA-9805 thus increased autophagy flux, it decreased levels of LC3 and p62 in SH-SY5Y cells. Furthermore, it promoted α-synuclein protein degradation in an autophagy-dependent manner. Present results indicate that DA-9805, likely by increasing the cAMP levels, is an activator of autophagy in SH-SY5Y cells, and by this mechanism, may reduce α-synuclein accumulation. Taken together, our results suggest that DA-9805 may prove useful as a therapeutic agent against neurodegenerative proteinopathies such as PD and AD.

Title: Because it does not influence MAO-B and DAT activities, the Near Infrared light therapy is a promising protective strategy against Parkinson's disease

Authors: F. REINHART[1,2], F. DARLOT[1,2], C. CHABROL[1,2], C. GAUDE[1,2], D. RATEL[1,2], N. TORRES-MARTINEZ[1,2], A.-L. BENABID[1,2], *C. MORO[1,2];
[1]Cea-Grenoble, Leti-Clinatec, Grenoble, France; [2]Univ. Grenoble Alpes, Grenoble, France

Abstract: Parkinson's disease (PD) is a major movement disorder and neurodegenerative disease. The current therapies are effective against symptoms but cannot protect the patient against the cells degeneration. It exists several preclinical models using toxins or genetic that can mimic the parkinsonian physiopathology and help us to find new therapies agains PD. The most used or them, the 1-methyl-4-phenyl-1,2,3,6- tetrahydropyridine (MPTP) is well known to mimic the human PD because of its capacity to specifically intoxicate the dopaminergic structures, like in substancia nigra pars compacta. Firstly, the MPTP is oxidised in MPP+ (which is the neurotoxic form of MPTP) by the monoamine oxidase B (MAO-B). Secondly, the MPP+ crosses the plasmic membrane of the dopaminergic cells through the dopamine transporter (DAT). Obviously, any neuroprotective strategy tested in these different models must be proven to not modulate neither the MAO-B activity, nor the DAT activity. We assess here that a new neuroprotective strategy using near infrared (NIr) illumination is not influencing the MAO-B and DAT activities. Indeed, a growing number of recent studies in MPTP models of Parkinson's disease have reported that a NIr light therapy (λ = 600-1000 nm) can be neuroprotective in PD. The MAO-B and DAT activities have been measured *in vitro* respectively by the kits MAO-Glo assay® (PromegaTM) and Neurotransmitter Transporter Uptake Assay Kit® (Molecular

DeviceTM). Briefly, the principles are to present the MAO-B or the DAT to a substrate coupled with a blinded luminophore (MAO-B) or fluorophore (DAT). After the reaction, we can measure the quantity of luminophore or fluorophore freed by a measurement of the light emitted by the medium of interest, and thus to deduce the MAO-B or DAT activities. We had several conditions here: (1) MAO-B or DAT + substrate in darkness and (2) MAO-B or DAT + substrate under different NIr illuminations. We show here that a NIr exposure, used as a therapeutical strategy against the PD does not modulate neither the MAO-B, nor the DAT activity. Thus, the results demonstrating a protective effect of NIr therapy in MPTP models are actually due to a real neuroprotective effect and not to an experimental bias. Our results confirm the interest of a NIr therapy against the disease and allow us to seriously consider this strategy in human.

Title: Neuroprotective effect of Korea Red Ginseng extract on 1-methyl-4-phenylpyridinium ion (MPP^+)-induced apoptosis in PC12 cells

Authors: *S. RYU, S. T. KIM;
Sch. of Korean Medicine, Pusan Natl. Universi, Yangsan-si/gyeongnam,28 Yongon-Dong, Korea, Republic of

Abstract: Red ginseng is valuable herb in Asian countries as a crude substance to enhance vitality, health and longevity. The water extract of red ginseng has been used to promote immunity and inhibiting inflammation. To further explore its actions, the present study evaluated protective effects of Korean red ginseng (KRG) extract against 1-methyl-4-phenylpyridine (MPP^+)-induced apoptosis in dopaminergic neurons. KRG extract was pretreated on PC12 cells for 24hours prior to MPP^+ expose to cells and live cell viability assay, flow cytometry, quantitative real-time PCR, and TUNEL staining were performed on PC12 neuronal cells. KRG treatment significantly enhance cell viability, reduced Annexin V-FITC and propidium iodide double staining cells and TUNEL-positive cells indicated that KRG treatment reduced MPP^+-

induced apoptosis in PC12 cells. KRG treatment also reduced caspase-3, -8, and -9 activities. These results suggest that KRG treatment exert a protective effect against MPP+-induced apoptosis in dopaminergic neurons.

Title: Longitudinal characterization of microglial gene expression profile and behavioral, morphological and neurophysiological abnormalities in a mouse model of autism spectrum disorder

Authors: *M. E. WOODBURY[1], S. IKEZU[2], J. I. LUEBKE[3], P.-H. CHAO[2], T. IKEZU[2]; [1]Grad. Program in Neuroscience; Pharmacol. and Exptl. Therapeut., [2]Pharmacol. and Exptl. Therapeutics; Neurol., [3]Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Mounting evidence implicates a role of peripheral and central innate immunity in neuropsychiatric disorders, including autism spectrum disorder (ASD). Microglia, the innate immune cells of the CNS, show changes in density, morphology, and/or activation phenotype in post-mortem ASD brains and recently by [11C] PK11195 PET imaging of young patients with ASD. Maternal immune activation (MIA) is significantly associated with higher incidence of autism in children in multiple large-cohort studies. We hypothesize that MIA dysregulates microglial homeostasis of the offspring, which in turn leads to spine dysgenesis, abnormal neuronal excitability, and ASD-like behavior. Using a MIA animal model induced by intraperitoneal injection of the innate immunity ligand polyinosinic:polycytidylic acid [poly(I:C)],on embryonic day 9.5 (E9.5), we profiled microglial gene expression in the offspring at several time points and associated this with behavioral and neuroanatomical findings as a

longitudinal study. We found that microglia highly expressed molecules associated with neural differentiation, neurite outgrowth, and synaptogenesis, which were enhanced at prenatal and postnatal time points in offspring following poly(I:C) injection to pregnant dams. *In vitro,* knockdown of key molecules in microglia was associated with reduced neural differentiation, neurite outgrowth and expression of synaptic markers in co-cultured neural precursor cells, assessed using transwells and our custom microfluidic cell culture system. Following dysregulation of microglial gene expression at embryonic and early postnatal stages, MIA induced ASD-like behavior in the offspring, including reduced maternal approach and decreased sociability, observed from postnatal week 3 to 8. Whole-cell patch clamp recordings of prefrontal layer V cortical pyramidal neurons at 8 weeks of age revealed enhanced excitatory synaptic activity as evidenced by increased frequency and reduced amplitude of miniature and spontaneous excitatory postsynaptic currents. This was associated with increased spine density and abnormal spine subtype distribution in apical dendrites of biocytin-filled layer V cortical pyramidal neurons, assessed by laser-scanning confocal microscopy. Our findings highlight the role of microglia in ASD pathogenesis, and suggest that microglial gene expression is a promising target for pharmacological intervention in ASD.

Abstract: Mutations in the *Autism susceptibility candidate 2 gene* (*AUTS2*), whose protein is believed to act in neuronal cell nuclei, have been shown to be associated with multiple psychiatric illnesses including autism spectrum disorders (ASD), intellectual disability (ID), schizophrenia, epilepsy and ADHD. Here we reveal a novel function of cytoplasmic AUTS2 in

the regulation of cytoskeleton and neural development. Immunohistochemistry and fractionation studies show that AUTS2 localizes not only in nuclei, but also in the cytoplasm, including growth cones in the developing brain. AUTS2 activates Rac1 to induce lamellipodia via interacting with P-Rex1 and Elmo2/Dock180, both of which are guanine nucleotide exchange factors (GEF) for Rac1. On the other hand, AUTS2 downregulates Cdc42 to suppress filopodia via interacting with Intersectin 1 and Intersectin 2, specific GEFs for Cdc42. Our loss-of-function and rescue experiments show that a cytoplasmic AUTS2-Rac1 pathway is involved in cortical neuronal migration and neuritogenesis in the developing brain. Moreover, *Auts2*-deficient mice display behavioral abnormalities including anxiety-related emotion and memory formation. These findings suggest that cytoplasmic AUTS2 acts as a novel regulator for Rho family GTPases contributing to brain development and give good insights into the pathology of human psychiatric disorders with *AUTS2* mutations.

Abstract: Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental disorder that is increasing in prevalence and is defined by impaired sociability, deficits in communication skills, and restricted and/or stereotyped behaviors. Recent studies involving young ASD patients (between 1-3 years old) have shown larger brain volumes compared to age-matched controls, suggesting that early neurodevelopment may be altered and may contribute to disease pathogenesis. Here, we investigated the development of dendritic arbors and neuronal densities of hippocampal pyramidal neurons in the BTBR mouse model of autism, which displays all three core behavioral symptoms of this disorder. Our preliminary studies using Golgi staining revealed that at the neonatal stage (postnatal day 8), the total lengths of both apical and basal dendrites of pyramidal neurons in the hippocampal CA1 region of the BTBR animals were greater than that in the B6 control animals, a strain commonly used as a control for the BTBR animals in ASD studies (B6 total apical: 298±20 μm, total basal: 330±43 μm; BTBR total apical: 381±18 μm, total basal: 401±28 μm). Dendritic branching was further analyzed by using Sholl analysis that measures the number of dendrites crossing concentric circles as a function of distance from the soma. Preliminary results revealed that there were more dendritic intersections at 40 to 60 mm distances from the soma in the BTBR compared to B6 animals (B6: 4.3±0.5 intersections at 40 mm and 1.8±0.5 intersections at 60 mm; BTBR: 5.4±0.4 intersections at 40 mm and 2.9±0.3 intersections at 60 mm). In contrast, Nissl staining demonstrated a similar density of CA1 pyramidal neurons between the BTBR and B6 pups (B6: 0.0072±0.0003 cells/μm^2; BTBR: 0.0068±0.0003 cells/μm^2), and a similar thickness of the CA1 pyramidal neuron layer between the two strains (B6: 106±2 μm; BTBR: 100±2 μm). At the adult stage, the thickness of the pyramidal neuron layer was reduced compared with neonates (B6: 52±1 μm; BTBR: 51±0.5 μm), whereas the densities of pyramidal neurons remained similar between the BTBR and C57 animals (B6: 0.0075±0.0004 cells/μm^2; BTBR: 0.0085±0.0003 cells/μm^2). Further experiments to quantify dendritic structure in adult animals are required to determine whether the BTBR model has larger and more complex dendritic arbors, or whether the development of dendritic arbor is accelerated in these animals. Considering the significance of dendritic structure in information processing, our results suggest that altered dendritic structure may contribute to abnormal behaviors seen in this animal model of ASD.

Title: RNA-binding protein Celf6 regulates actively translated mRNAs enriched in neuromodulatory neurotransmitter cell populations

Authors: *M. A. RIEGER[1], J. D. DOUGHERTY[2];
[1]Washington Univ. St. Louis, Saint Louis, MO; [2]Genet., Washington Univ. St. Louis, St. Louis, MO

Abstract: A growing body of literature has highlighted the importance of RNA-binding proteins (RBPs) in the development and maintenance of the central nervous system. The functional roles of these proteins are implicated in the etiologies of psychiatric disorder and neurodegenerative disease. The mechanism by which RBPs regulate their targets is diverse: including splicing, stability, localization and rate of translation. These in turn have consequences for neuronal cellular phenotypes such a differentiation and synaptic plasticity. Our laboratory uses the Translating Ribosome Affinity Purification (TRAP) methodology which allows us to profile mRNAs in a cell-type specific manner. Using TRAP to identify mRNA species enriched in serotonergic neurons, we identified the RNA-binding protein Celf6 and later found it to be associated with autism spectrum disorder risk. A homozygous null mutation in this gene in mice presented with reductions to both post-natal ultrasonic vocalization behavior and levels of neuromodulatory neurotransmitters such as serotonin. To understand the molecular role of Celf6 in serotonergic neurons, we profiled these cells using TRAP in the context of a Celf6 null animal. The abundance of a number of mRNAs on ribosomes were found to differ between Celf6 wild-type and null animals using this approach. We examined these species for commonalities at the level of sequence and structure. These mRNAs contained cytosine and uracil-rich stem-loop motifs identified in silico within the 3' untranslated region (3' UTR). To better understand their regulation, we are next turning to an *in vitro* culture system. Using cells expressing epitope-tagged Celf6 we will be able to determine the specificity of interaction between Celf6 and putative targets by cloning 3' UTRs into a fluorescent reporter and assessing the Celf6-dependence of reporter levels as well as evidence of direct binding using cross-linking

immunoprecipitation. We will test whether structural integrity of motifs in the 3' UTR affects mRNA stability and efficiency of translation in a Celf6-dependent manner. Using the information obtained *in vitro*, we can then make predictions as to which mRNAs would be differentially regulated in an independent population of cells and use TRAP to validate these predictions. Taken together we outline a pipeline of techniques that powerfully combines *in vivo* and *in vitro* methods. Using these methods we hope to gain insight into the role of key regulatory molecules in the brain that affect behavior and cellular function.

Title: Regulation of synaptic function in hippocampal CA1 pyramidal cells by neuroligins

Authors: *M. JIANG[1], J. S. POLEPALLI[2], R. C. MALENKA[2], T. C. SÜDHOF[1,3];
[1]Mol. and Cell. Physiol., [2]Nancy Pritzker Laboratory, Dept. of Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA; [3]Mol. and Cell. Physiol., Howard Hughes Med. Inst., Stanford, CA

Abstract: Neuroligins (NL) are postsynaptic adhesion molecules, which have been implicated in autism spectrum disorders (ASD). Despite a large body of work, their detailed synaptic functions remain unknown and controversial. To begin to address the requisite synaptic functions of NLs precisely, we generated mutant mice carrying conditional knockout (cKO) alleles of the three major NLs (NL1, 2, and 3). Injection of viruses expressing Cre *in vivo* at postnatal day 0 (P0) and day 21 (P21) followed by acute slice electrophysiology ~2 weeks later allowed us to study the consequences of genetically deleting NL1-3 *in vivo* at different developmental stages on inhibitory and excitatory synaptic function in hippocampal CA1 pyramidal neurons. Deletion of NL1-3 at P0 caused a clear decrease in inhibitory synaptic transmission; an effect that was

phenocopied by deletion of NL2 alone. In contrast, P0 deletion of NL1-3 had no detectable effect on AMPA receptor-mediated miniature EPSCs and no effect on dendritic spine density. However, triple NL1-3 cKO as well as NL1 cKO alone (but not NL3 cKO) at both P0 and P21 significantly decreased NMDA receptor-mediated synaptic responses. In addition, NL1 cKO but not NL3 cKO abolished long term potentiation (LTP) at both P0 and P21. Several lines of evidence suggest that the block of LTP by NL1 deletion is not due to the impairment in NMDA receptor-mediated synaptic function. These results confirm a critical role for NL2 in inhibitory synapse formation, a critical role for NL1 in maintaining normal NMDA receptor-mediated synaptic transmission, and an unexpected critical role for NL1 in LTP. These single and triple cKO mice will be valuable tools for furthering our understanding of the roles of these ubiquitous postsynaptic cell adhesion proteins in synaptic and circuit function.

Title: The role of Neuroligins on synaptic transmission at Calyx of Held during development

Authors: *B. ZHANG, L. CHEN, T. SUDHOF;
Dept. of Mol. & Cell. Physiol., Stanford medical school, Stanford, CA

Abstract: Autism spectrum disorders (ASDs), also designated as Autism, is a heterogeneous cognitive syndrome characterized by impairment in reciprocal social interaction, impairment with verbal and nonverbal communication, and repetitive behaviors with narrow interests. Genome-wide associate studies have identified transsynaptic cell adhesion molecules neuroligins (NLs) are associated with autism. Neuroligins (NLs) are synaptic cell adhesion molecules, includes family members NL 1, -2, -3, and -4 in rodent. NL1 and NL3 function at excitatory synapse, where NL 2 and NL3 function at inhibitory synapse, while NL4 function in glycinergic synapse. Due to its perinatal lethal phenotype of constitute triple knockout NL1/2/3, it is impossible to study the role of NLs at a synapse during the development with this constitute

NL1/2/3 triple KO mice. Besides, knockdown strategy used for determining the role of NLs suffer from off-target effect. Therefore, the role of NLs in synapse formation/maturation in a mammalian CNS synapse is largely unknown. The calyx of Held in the auditory system is a giant and fast-transmitting synapse with hundreds of active zones covering half of the postsynaptic principal neuron in the medial nucleus of the trapezoid body. The development of calyx of Held synapses is characterized sequentially by, 1): an initially small glutamatergic nerve terminals contacted by several fibers, 2), the emerging of protocalyces after elimination of redundant synapses being, and 3), calyces formed with faster transmitter release and postsynaptic receptor kinetics. However, the molecular mechanisms that drive synapses elimination and synapse maturation of the calyx of Held synapses, remain largely unknown. Here we used the large calyx of Held synapse as a model synapse to study the role of NLs in synapse formation/maturation in the mammalian CNS. Using mouse genetics (conditional NLs knockout mice), stereotactic virus injection, electrophysiology, and immunostaining, we demonstrate a specific and essential role of NLs for the development of these large auditory relay synapses.

Abstract: The advent of induced pluripotent stem cell (iPSC) technology provides new avenues to generate neural precursors and neurons from patients with CNS disorders. The study of autism etiology has been hampered by both the inability to study human neurons and the heterogeneity of the disorder. While mechanistic analyses in model systems are useful, it is likely that definition of the fundamental pathophysiology will demand study of human neuronal development and function. While iPSC technology was thought of limited use in complex and heterogeneous disorders, we (NJ Autism Center of Excellence; PI Millonig) have now successfully applied these techniques to autism. To reduce heterogeneity between samples, we employed three strategies: 1) families were recruited for language phenotypes including idiopathic autism and another language disorder called Specific Language Impairment; 2) autism cases are compared to unaffected brothers as controls; 3) male sibpairs were deliberately chosen where the affected individual has a narrow autism diagnosis with either no or severely limited language. We have now generated iPSCs from 8 brother-brother sibpairs using Sendai virus expressing the Yamanaka factors. ICC demonstrates that all clones express iPSC markers (TRA160, NANOG, OCT4). iPSC pluripotency was demonstrated by embryoid body formation followed by QRTPCR for lineage-specific markers. To identify developmental phenotypes, neural stem cells (NSCs) and inducible neurons (iNs) have been generated. We have found reproducible differences in NSC development in one family. ICC and QRTPCR demonstrates that the autism NSCs abnormally express genes (e.g. SOX2, ZIC1, ID2) that function in NSC development (P<.001). These NSCs also display additional neurite outgrowth and migration defects (see Prem; Williams)(P<.001). Strikingly some of the NSC phenotypes are rescued by the addition of biologically relevant small molecules (P<.001). For another family ICC for MAP2 and other differentiation markers demonstrate abnormal iN differentiation including dendritic spine deficits. We plan to further analyze molecular and cellular mechanisms underlying these patient-specific phenotypes to identify pathways and targets as well as complete analysis of the 8 sibling pairs in hand.

Title: effect of co-ultramicronized PEALut treatment in a murine model of autism spectrum disorder

Authors: *R. CRUPI[1], D. IMPELLIZZERI[1], G. BRUSCHETTA[1], R. SIRACUSA[1], M. CORDARO[1], E. ESPOSITO[1], S. CUZZOCREA[1,2];
[1]Biol. and Envrn. Sci., Univ. of Messina, Messina, Italy; [2]2Manchester Biomed. Res. Ctr., Univ. of Manchester, Manchester, United Kingdom

Abstract: Autism spectrum disorders (ASDs) are pervasive neurodevelopmental disorders characterized by neurological deficits, especially as related to cognitive function. Although its pathogenesis remains unknown, the major hypothesis at present posits that autism is a multifactorial disorder with a genetic predisposition. Brain inflammation can be a key element in the pathogenesis of neuropsychiatric disorders, including a significant proportion of subjects with ASD. N-palmitoylethanolamide (PEA) is considered to be the parent molecule of ALIAmides, known for its anti-inflammatory, analgesic and neuroprotective properties. PEA inhibits peripheral and central neuroinflammation as well as associated symptomatology. Flavonoids, such as luteolin, possess neuroprotective actions in central nervous pathophysiological conditions. Moreover, the association of PEA with Luteolin (co-ultra PEALut) is more effective in eliciting neuroprotective and anti-inflammatory actions in different models of CNS pathologies, than the molecule taken alone. Our goal was to evaluate the effects evoked by orally administration of co-ultra PEALut in the management of inflammatory and neuroregenerative events associated with ASD using a well established experimental model. A multidisciplinary approach was employed to study: behavioral taks; neuroinflammatory pathways; neurogenesis and neuroplasticity alterations. On P14, C57BL/6 mice were injected with 400 mg/kg sodium valproate. Two different set of experiments were conducted. In the first, on P15 mice were administered with co-ultraPEALut (1mg/kg, daily) and on P30 the behavioral and neuroinflammatory studies were assessed. In the second, at P120, mice started treatment with co-ultraPEALut (2 weeks) and then were sacrified for neurogenesis and neuroplasticity investigations. Co-ultraPEALut ameliorated aggressive behavior and improved spatial learning memory in the valproic acid-induced autistic mice. Moreover, our results revealed the ability of co-ultraPEALut to reduce the level expression of NF-κB, GFAP and nitrotyrosine; also modulate apoptosis in hippocampus and cerebellum. Moreover co-ultraPEALut increases neurogenesis and neuroplasticity in the hippocampus of the autistic mice.

Title: NSF interacts with SERT and modulates its trafficking: implications for path ophysiology in autism

Authors: *K. IWATA[1], H. MATSUZAKI[1], T. TACHIBANA[2], K. NAKAMURA[3], T. KATAYAMA[4], N. MORI[5];

Abstract: Change in serotonin transporter (SERT) function has been implicated in autism. SERT function is influenced by the number of transporter molecules present at the cell surface, which is regulated by various cellular mechanisms including interactions with other proteins. Thus, we searched for novel SERT-binding proteins and investigated whether the expression of one such protein w as affected in subjects with autism. We identified N-ethylmaleimide-sensitive factor (NSF) as a candidate SERT-binding protein by a pull-down system. NSF co-localized with SERT at the plasma membrane, and NSF knockdown resulted in decreased SERT expression at the cell membranes and its uptake function in HEK293-hSERT cells. NSF endogenously co-localized with SERT and interacted with SERT in mouse brain. We measured SERT (SLC6A4) and NSF mRNA expression levels in post-mortem brains and lymphocytes from autistic and control individuals. While SLC6A4 expression was not significantly changed, NSF expression tended to be reduced in post-mortem brains, however this potential trend is not statistically significant, and was significantly reduced and correlated with the severity of the clinical symptom in lymphocytes of autistic subjects. These data clearly show that NSF interacts with SERT under physiological conditions and is required for SERT membrane trafficking and uptake function. A possible role for NSF in the pathophysiology of autism, through modulation of SERT trafficking, is suggested.

Title: Disruption of circuit formation and refinement in a mouse model of autism

Authors: ***N. CHENG**, M. KHANBABAEI, E. HUGHES, R. TOBIAS, K. MURARI, J. M. RHO;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Autism is a complex neurodevelopmental disorder, characterized by deficits in socio-emotional functions and language development, as well as repetitive and/or restrictive behaviours. Because higher-order cognitive abilities are disproportionately affected in autism, it has been hypothesized that disruption in the wiring of the brain, especially in long-range connections, contributes to the pathophysiology of the disease. Here, we investigated circuit formation and refinement during retino-geniculate segregation in the BTBR mouse model of autism, which displays all of the three defining behavioural features of the disorder. The adult lateral geniculate nucleus (LGN) is characterized by its laminated organization into distinct eye-specific layers, which are non-overlapping regions receiving afferents from either the left or the right eye. During normal development, the retino-geniculate afferents from the two eyes are initially overlapping before gradually segregating into eye-specific regions observed at the mature stage. This eye-specific 'map' in the LGN thus has served as a model system to study circuit formation and refinement in the brain. Utilizing this system, we labelled retinal afferents from both eyes of the BTBR mice with an anterograde tracer conjugated with different fluorophores, and compared eye-specific segregation in the LGN between the BTBR model and the B6 animals, a strain commonly used as a control for the BTBR mice in autism studies. We found that in postnatal day 8 animals, the total area of dorsal LGN occupied by retinal afferents from both eyes was significantly smaller in the BTBR mice compared to B6 controls (B6: 0.26±0.04 mm^2, n=5; BTBR: 0.17±0.01 mm^2, n=7; p=0.04). In addition, the degree of overlap between the ipsi- and contralateral afferents was significantly greater in the BTBR than B6 mice. In the B6 animals, the percentage of overlapping area to total dorsal LGN area was between 12.5% to 18.9% using four different thresholds (n=5), while in the BTBR animals, the percentage of overlapping was between 22.2% to 32.3% using the same four thresholds (n=7; p=0.017 to 0.033 corresponding to the four thresholds used). Moreover, these abnormalities in

retino-geniculate input continued into adulthood in the BTBR animals. Taken together, these results indicate that eye-specific projection and segregation in the LGN is impaired in the BTBR animals, suggesting that aberrant circuit formation and refinement may be a feature of this animal model of autism.

Title: Characterization of heritable small nucleotide variations in GCN2: implications for autism spectrum disorder

Authors: *A. G. VOROBYEVA[1], A. BHATTACHARYA[1], I. IOSSIFOV[2], T. DEVER[3], E. KLANN[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Cold Spring Harbor, Cold Spring Harbor, NY; [3]NIH, Bethesda, MD

Abstract: Autism spectrum disorder (ASD) is a heritable neurodevelopmental disorder characterized by the early onset of social deficits, communication impairments, repetitive behaviors, and cognitive inflexibility. Multiple lines of evidence suggest that dysregulated translational control is a common molecular anomaly in ASD pathophysiology. Exome sequencing of families with a child affected by autism revealed numerous heritable autism-associated single nucleotide variations (SNVs) within genes encoding for proteins responsible for controlling protein synthesis. One affected gene is the evolutionarily conserved *EIF2AK4*, which encodes the general control nonderepressible 2 (GCN2) kinase. Upon amino acid starvation, GCN2 preferentially binds uncharged tRNAs resulting in kinase activation and downstream phosphorylation of the α subunit of initiation factor eIF2. The phosphorylation of eIF2 α terminates global translation and enhances the translation of mRNAs containing 5'UTRs with unread open reading frames, including the transcription factor ATF4. We hypothesized that heritable ASD-associated SNVs in *EIF2AK4* alter the kinase function of GCN2. We discovered that multiple heritable SNVs in *EIF2AK4* results in altered GCN2 activity as measured by alterations in eIF2 α phosphorylation, global protein synthesis, and expression of ATF4. Our findings suggest that impaired GCN2 function occurs in multiple individuals with ASD

Title: Using exogenous factor treatments to define differences in autism patient-derived neural stem cells

Authors: *M. WILLIAMS[1,2], S. PREM[2], X. ZHOU[2], P. MATTESON[2], P. YEUNG[2], C. LU[2], Z. PANG[2], L. BRZUSTOWICZ[1], J. MILLONIG[2], E. DICICCO-BLOOM[2];
[1]Neurosci., Rutgers Univ., Piscataway, NJ; [2]Neurosci., Rutgers, Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by abnormalities in social interactions and stereotyped/restrictive behavior. The study of ASD has been hindered by disease heterogeneity and difficulties in creating representative mouse models. To examine deficits in sporadic autism, we (NJ Autism Center of Excellence; PI Millonig) generated iPSC lines from 8 severely affected males with ASD and their unaffected brothers (Sib) and derived neural stem cells (NSCs) for study. By applying exogenous factors (EFs) to NSCs we can challenge ASD relevant biological processes such as proliferation and early neuronal maturation. We have examined an array of developmentally relevant EFs including FGF, pituitary adenylate cyclase-activating peptide, BDNF, NT3, insulin, H2O2 and MeHg. Here we focus on FGF due to its role in regulating neurogenesis. To define effects, cells were grown at high density (50K cells/cm2) without and with EFs. At 48h, cells were labeled with tritiated thymidine to assess DNA synthesis and EdU for S phase entry. In parallel, single cell analyses were conducted by acutely dissociating high-density cultures, plating at low density (10K/cm2) and fixed at 2 or 4h for immunostaining. Further, sister cultures were dissociated every 48h for 6 days to quantify live cell numbers via hemocytometer. Comparisons of culture

conditions found that select media and substrate were required to enhance reproducibility and magnitude of response to EFs. As might be expected, FGF induced increases in DNA synthesis and S-phase entry by 50-100% by 48h. Further, FGF mitogenic stimulation at 48h reliably predicted progressive 50% - 100% increases in cell numbers at 4 and 6 days. Conversely, FGF mitogenic stimulation was accompanied by ~60% reductions in proportions of cells expressing β-III tubulin, suggesting FGF maintained the NSC state. Preliminary results in one ASD-Sib pair identified an abnormal ASD-NSC proliferative response, associated with 70% reduction ($p<0.001$) in cellular levels of SOX2 expression. Reduced SOX2 expression may be associated with changes in proliferation as well as restricted lineage differentiation. In aggregate, our results indicate that we are able to employ EFs to discover differences in ASD-implicated biological processes. FGF stimulates proliferation and likely maintains a NSC-like state. In comparison of an ASD-Sib pair, this experimental paradigm has begun to uncover patient-specific differences in cellular phenotypes, as might be expected in idiopathic ASD.

Abstract: Autism spectrum disorders (ASD) are developmental disorders defined by abnormal social interactions and repetitive behaviors. Elucidation of ASD etiology has been hampered by inability to study human neurons, disorder heterogeneity and relevance of model systems. Recently, induced pluripotent stem cell (iPSC) studies in monogenic autism and sporadic schizophrenia uncovered abnormalities in synaptic function and neuronal migration in human neurons. To examine deficits in sporadic autism, we (NJ Autism Center of Excellence; PI Millonig) generated iPSC lines from 8 severely affected males with ASD and their unaffected brothers (Sib) and derived NSCs for study. We are comparing neurite extension and cell migration in ASD and Sib lines in control media and media with relevant growth factors such as PACAP, serotonin and neurotrophins. Growth factor stimulation of signaling pathways may allow identification of defects in idiopathic autism. To quantify neurite outgrowth, confluent NSCs were dissociated and plated on fibronectin coated plates in control or PACAP (10nM) media at low density. At 48h, cells bearing neurites >2 cell diameters were counted in 10 fields. To define migration, neurospheres were formed by plating NSCs in absence of substrate. After 48-96h, spheres were plated on Matrigel with control or PACAP media and fixed at 48h. Using phase contrast images, the areas of the inner cell mass and total sphere outgrowth were measured. Migration: total neurosphere area-inner cell mass area. In one Sib, 13% of cells had neurites in control media while 21% had neurites in PACAP reflecting a 58% increase ($p=0.007$). However in ASD, only 7.3% of cells had neurites in control, a significant reduction compared to their Sib ($p=0.001$). Further, PACAP elicited no change in neurite outgrowth in ASD (PACAP; 7.4%). Similarly, Sib neurosphere migration was increased 77% by PACAP (Con=1318; PACAP=2107; $p<0.001$), whereas ASD exhibited reduced migration compared to their Sib ($p=0.001$) and no PACAP response (Con= 855; PACAP=962, $p=0.15$). While ASD NSCs display absent neurite outgrowth with PACAP, preliminary studies suggest other factors overcome outgrowth deficiency, suggesting pathway specific deficits in this individual. Thus, baseline and PACAP induced migration and neurite extension are significantly reduced in ASD NSCs in one family. Characterization of other sibpairs will determine if these results are generalizable. While heterogeneity of ASD reduces the chances of identical phenotypes, our studies show the value of utilizing relevant growth factors to uncover impaired and patient specific developmental pathways which may lead to personalized ASD therapies.

Title: Testosterone and the Brain: A molecular study into Autism Spectrum Disorders using a human stem cell model

Authors: *D. ADHYA[1], K. JOZWIK[2], J. CARROLL[2], J. PRICE[3], D. P. SRIVASTAVA[3], S. BARON-COHEN[1];
[1]Psychiatry, [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Inst. of Psychiatry, King's College, London, London, United Kingdom

Abstract: Hans Asperger first described autism in 1944 as an extreme variant of male intelligence. Individuals with this condition show difficulty in empathising - in making sense of and predicting another's feelings, thoughts and behaviour, and excel in systemising - a preference for rule-based, structured, factual information. Studies have shown this extreme variant of male intelligence in autism spectrum disorders (ASD) to be correlated with elevated foetal steroidogenic activity, suggesting a role for steroids such as testosterone in the development of the ASD pathology during foetal development. The purpose of this study was to determine the effect of testosterone on cellular and molecular pathways in the ASD brain, and how it differs from the typically developing (TD) brain. This was achieved using a human induced pluripotent stem cell (hiPSC) model of this condition. Keratinocytes from healthy individuals, and individuals diagnosed with ASD were reprogrammed into iPSCs, then differentiated into cortical neurons using the dual SMAD signalling inhibition strategy. Testosterone was administered to these neurons at an early stage of development at the physiological and supra-physiological levels. Preliminary data indicates that ASD neurons seem to develop precociously, while being more responsive to testosterone than healthy neurons. The androgen receptor (AR) and some of its putative downstream genes such as gonadotropin-releasing hormone (GnRH) and p38 (a class of mitogen-activated protein kinases) were

differentially expressed in ASD neurons compared to TD neurons, predicting differential structural and functional outcomes of neurons in the two groups. Genes indicating neuron cell fates such as T-box brain 1 (TBR1) and BRN2 were also differentially expressed in ASD neurons, demonstrating altered characteristics of developing ASD neurons. These data suggests that the ASD phenotype starts developing *in utero* at very early stages of brain development, and that neurons of ASD individuals are programmed, at a molecular level, to react differently to sex steroids such as testosterone.

Title: Characterization of zinc biology in the Autism Spectrum associated Disorder Phelan McDermid Syndrome using patient biosamples and iPS derived cells

Authors: *S. PFAENDER[1], A. GRABRUCKER[2], T. BOECKERS[1];
[1]Inst. for Anat. and Cell Biol., Ulm Univ., Ulm, Germany; [2]Mol. Analysis of Synaptopathies, Neurocenter, Ulm University, Germany

Abstract: Phelan McDermid Syndrome (PMDS) is a neurodevelopmental disease characterized by infantile hypotonia, developmental delay, impaired or absent speech, seizures and features of Autism Spectrum Disorders (ASD). The major cause for the observed phenotype is a 22q13.3 deletion involving the SH3 domain and ankyrin repeat containing protein 3 (Shank3), a scaffolding protein that forms highly organized multimeric platforms at the postsynaptic density (PSD) of excitatory synapses upon zinc-binding. Since zinc deficiency has been reported repeatedly in ASDs, here we examined a cohort of PMDS patients for zinc levels in blood and hair along with the assessment of a range of symptoms. We found an increased incidence rate of zinc deficiency, which is associated with the occurrence of certain symptoms. To understand the possible reasons for zinc deficiency in this patient group, we screened the expression of zinc and

other metal homeostasis proteins in enterocytes differentiated from human induced pluripotent stem (iPS) cells from both PMDS patients and healthy controls. Our results indicate an impaired cellular zinc absorption in PMDS patients. Since recruitment and multimerization of soluble Shank3 at the PSD are zinc dependent, disruption of zinc homeostasis in neurons might alter neuronal development and function in various ways. For example, given that zinc plays a major role in the function of several proteins involved in proliferation and apoptosis of neuronal precursors as well as neuronal development and function, we also examined expression of zinc transporters in differentiated and differentiating neurons of iPS cells. Since we are particularly interested in hypotonia and motor development, we chose motor neurons for our model system. Here, we analyzed zinc homeostasis in different stages of neuronal differentiation and examined the effects of zinc deficiency on both morphology and function of motor neurons differentiated from iPS cells from PMDS patients and healthy controls. Furthermore, we evaluated whether alterations in PMDS motor neurons can be rescued by targeted manipulation of biometal homeostasis as novel treatment strategy for PMDS.

Title: Comprehensive approach with an analytical battery to elucidate pathophysiological role of RBFOX1/A2BP1, a "hub" gene in the ASD gene transcriptome network

Authors: *K.-I. NAGATA[1], N. HAMADA[2], H. ITO[2], H. TABATA[2];
[1]Inst. For Developmental Research, Aichi Human Service Ctr., Kasugai, Japan; [2]Inst. for Developmental Research, Aichi Human Service Ctr., Kasugai, Japan

Abstract: While many different biological causes have been implicated in the etiologies of neurodevelopmental disorders such as autism-spectrum disorder (ASD) and intellectual disability (ID), genetic factors are considered to be the most important. Thus, it is essential to clarify the pathophysiological significance of respective disease-related genes in brain development. To address this issue, we have established a battery of *in utero* electroporation-based *ex vivo* and *in vitro* observations including cortical neuron migration, axon elongation, dendrite development,

spine morphogenesis and live-imaging as well as cell biological and biochemical analyses. RBFOX1/A2BP1 is a neuron-specific splicing factor predicted to regulate neuronal splicing networks clinically implicated in neurodevelopmental disorders including ASD. Since RBFOX1 has been recently identified as a "hub" in the ASD gene transcriptome network, we performed comprehensive analyses of RBFOX1 by with the above-mentioned analytical battery. Knockdown of RBFOX1 using *in utero* electroporation caused abnormal cortical neuron positioning during corticogenesis, which was most likely to be attributed to impaired cell migration. Based on the confocal laser microscope-associated live-imaging analyses, migration defects were found to occur in the radial migration and terminal translocation, perhaps due to impaired nucleokinesis. Notably, RBFOX1-deficient neurons frequently showed abnormal polarity during corticogenesis. On the other hand, the cell cycle of neuronal progenitor cells was not affected by RBFOX1-silencing. RBFOX1 was also found to regulate axon/dendrite development since axon extension to the opposite hemisphere as well as dendritic arborization was suppressed in RBFOX1-deficient cortical neurons. Effects of RBFOX1 knockdown on the neuronal morphology were further confirmed in *in vitro* analyses. RBFOX1-silencing in primary cultured hippocampal neurons resulted in the reduction of primary axon length and total length of dendrites, and abnormal spine morphogenesis. Taken together, impaired cortical neuron migration, disturbed interhemispheric axon development and dendritic arborization, and defective synapse formation may induce structural and functional defects of the cerebral cortex, and consequently contribute to emergence of the clinical symptoms of neurodevelopmental disorders.

Abstract: Our laboratory recently characterized a novel autism spectrum disorder (ASD)-associated de novo missense mutation in the human dopamine transporter (hDAT) gene SLC6A3 (hDAT T356M). This hDAT variant exhibits dysfunctional forward and reverse transport properties that may contribute to DA dysfunction in ASD. Here, we report that Zn2+ reverses, at least in part, the functional deficits of ASD-associated hDAT variant T356M. These data suggest that the molecular mechanism targeted by Zn2+ to restore partial function in hDAT T356M may be a novel therapeutic target to rescue functional deficits in hDAT variants associated with ASD.

Title: Effects of trace metal imbalances on excitatory synapses of hippocampal neurons

Authors: *S. HAGMEYER[1], J. CRISTÓVÃO[2], K. MANGUS[1], C. M. GOMES[2], A. M. GRABRUCKER[1];
[1]WG Mol. Analysis of Synaptopathies, Neurol. Department, Neurocenter of Ul, Univ. Ulm, Ulm, Germany; [2]BioISI – Biosystems & Integrative Sci. Inst., Faculdade de Ciências da Univ. de Lisboa, Lisboa, Portugal

Abstract: Recent studies revealed that biometal dyshomeostasis plays a crucial role in the pathogenesis of neurological disorders such as autism spectrum disorders (ASD). This deregulation can be caused either by environmental factors such as diet, malabsorption of essential trace metals, exposure to putative toxic metals, infection, stress, or by pathological abnormalities in the brain such as the accumulation of metal binding proteins like Amyloid beta (Aβ) or S100B. Disrupted neuronal trace metal homeostasis in turn may mediate synaptic dysfunction and impair synapse formation and maturation. Here, we investigated the consequences of an imbalance of transition metals on glutamatergic synapses of hippocampal neurons *in vitro*. We analyzed whether an imbalance of any one metal ion alters synapse

formation and subsequently established a biometal profile in the culture medium that mimicked the characteristic changes in trace metals reported in ASD patients. Furthermore, we manipulated trace metal levels by the exposure of neurons to calcium and zinc binding S100B protein aggregates and/or copper and zinc binding Aβ aggregates. To investigate the impact of these alterations on synapses, we evaluated synapse formation and maturation, and composition regarding NMDA receptor subunits and Shank proteins. Our results show that a biometal profile characteristic for ASD patients leads to a reduction of NMDAR subunit 1 and 2a levels as well as synaptic Shank protein family members (Shank2, Shank3) along with a reduction of synapse density. Moreover, exposure to putative toxic protein aggregates leads to trace metal imbalances and similarly affects synapses and synaptic proteins supporting the hypothesis that a part of the pathology of these aggregating proteins is a consequence of altered synaptic metal homeostasis. Thus, we conclude that balancing trace metal levels in synaptopathies such as ASD and Alzheimer's Disease might be a prime target to normalize synaptic alterations.

Title: Integrative analysis of RNA-seq and whole genome sequencing reveals perturbed gene co-expression networks in autism

Authors: *G. COPPOLA[1], K. ARDHANAREESWARAN[1], J. MARIANI[1], A. ABYZOV[2], F. VACCARINO[1];
[1]Child Study Ctr., Yale Univ., New Haven, CT; [2]Div. of Biomed. Statistics and Informatics and Dept. of Hlth. Sci. Res., Mayo Clin., Harwick, MN

Abstract: In our recently published work (Mariani et al, 2015) we exploited iPSCs-derived telencephalic organoids to model idiopathic ASD. We analyzed the transcriptome of the

organoids from patients (PB) and their unaffected fathers (NC). ASD-derived organoids demonstrate an accelerated cell cycle and an overproduction of GABAergic inhibitory neurons and synapses. Transcription factor (TF) analysis highlighted the Forkhead TF family as possible driver of gene upregulation and FOXG1 was among the top upregulated genes in ASD-derived neurons. Using RNA interference, we show that by normalizing the expression of FOXG1 we recover the GABA/glutamate balance. We therefore identified in the strong up-regulation of FOXG1, a key driver of the GABA/glutamate imbalance. We performed whole genome sequencing (WGS) in the same set of PBs and identified rare SNVs in regulatory regions associated to FOXG1, albeit not in every PB. We then extended the analysis to FOXG1 centric gene co-expression networks (GCN). We identified: 1) a set of genes strongly correlated to FOXG1 in NC and weakly correlated in PB, i.e. loss-of-correlation network (LCN); 2) a set of genes showing weakly correlated to FOXG1 in NC and strong correlation in PB, i.e. gain-of-correlation network (GCN). The LCN contains several genes crucial for glutamatergic differentiation. The GCN contains several genes crucial for GABAergic differentiation. This is consistent with our recently published work, and reflects the identified GABA/glutamate imbalance in probands, strengthening the role of FOXG1 as key driver of this phenotype. We used FunSeq2 to functionally associate SNVs to genes, score them for their potential disruptive impact and filter out any variant with a score < 1.5. We identified 205 genes recurrent in all 4 probands. Functional annotation highlighted splicing, synaptic transmission and immune system. We tested the FOXG1 centric networks for enrichment in the entire set of gene involved by the 4 probands and found significant overlap with the LCN (p-value=$6.78\ 10^{-8}$). Finally, to validate our findings, we performed WGS of four more patients, infer the set of rare SNVs and tested them again for convergence and overlap with the FOXG1-centric networks. We found 219 genes recurrent in all 4 probands. Functional annotation highlighted a strong involvement of immune system related gene. Again, we found significant overlap with the LCN (p-value=$1.56\ 10^{-15}$). Our integrative analysis strengthens our previous finding of the involvement of FOXG1, strongly involving its potential regulatory network and highlights the importance of the non-coding regions in disease etiology.

Title: A neuroenergetic model of the autism brain predicts clinical results from postmortem donors

Authors: *Z. SACCOMANO[1], E. C. AZMITIA[2];
[1]Biol. and Psychology, New York Univ., New York, NY; [2]Biology, Psychiatry, Ctr. for Neural Sci., New York Univ., New York City, NY

Abstract: Autism spectrum disorders are diagnosed by clinical assessments aimed to identify individuals with an abnormal behavioral phenotype marked by social and communication deficits as well as stereotyped or repetitive rituals. Autism is also associated with a range of cellular abnormalities such as accelerated perinatal brain growth (Shen et al., 2013; Courchesne et al., 2011), glial hyperactivation and inflammation (Vargas et al., 2005; Tetreault N.A. et al., 2012), increased electrical activity (Rumsey and Ernst, 2000), brain hypoperfusion (Burroni et al., 2008; Boddaert et al., 2002), and persistent neurovascular reorganization (Azmitia et al., 2015). Furthermore, some evidence suggests situations that increase energy flow into the brain may promote normative behaviors in autism patients through hyperbaric oxygen therapy (Rossignol et al., 2006) and, interestingly, when patients experience fevers, which increases cerebral blood flow (Good, 2011). These results indicate that changes in neuroenergetic maintenance maybe more central to generating autistic behaviors than altered morphology. Here, we present a model of energy propagation amongst vascular cells, astrocytes and neurons in the autism brain by measuring the integrity of their interfaces in human postmortem samples. Morphometric analyses of these networks were conducted in human postmortem tissue and we demonstrate that the integrity of the neurovascular unit in superior temporal cortex (layers II-VI) predicts clinical results specific to that region from the postmortem brain donors. Currently, developing models of this kind is the only method capable of correlating altered cellular networking through direct microscopy in human postmortem tissue with dynamic brain activity measured in living patients.

Title: Annotation and curation of autism-related protein-protein interaction datasets into AutDB, a genetic database for autism

Authors: *W. PEREANU, C. CROFT SWANWICK, S. MUEND, S. BANERJEE-BASU; Mindspec, Mc Lean, VA

Abstract: Research over the last few decades has linked hundreds of genes with diverse roles to autism spectrum disorder (ASD). The autism-related genes encode proteins with roles that include ion channels, cell adhesion molecules, chromatin remodelers, transcription factors, RNA binding proteins and many others. Understanding how such a large and diverse set of genes contribute to ASD will require a bioinformatics approach and a well annotated dataset sourced from the works of multiple research groups. To this end, we have developed an ASD-specific database (PIN) that integrates evidence of protein-protein interactions from publish papers. The PIN database includes all high-priority ASD-linked genes as scored by the Gene Scoring module of SFARI Gene (https://gene.sfari.org/autdb/GS_Home.do). Specifically, we annotate all ASD-linked genes that are scored as high confidence (category 1), strong evidence (category 2), syndromic and genes that have both functional and genetic evidence (Category 3). Because of the diverse protein roles that ASD-linked genes take part in, we have developed an inclusive ontology that captures the experimental techniques used and the tissue types tested. We also categorize the type of protein interaction using a set of six terms that cover physical binding and functional regulation, these are “Protein Binding”, “DNA Binding”, “RNA Binding”, “Protein Modification” and “Autoregulation”. The PIN database is updated on a quarterly basis (December, March, June and September). As of the March, 2015 release, the PIN database includes 339 ASD-linked genes that have 30,780 interactions from 29 species that have been sourced from 2,274 primary research articles. The PIN database has been integrated into our genetic autism database, AutDB and can be found here: http://autism.mindspec.org/autdb/PINHome.do. In addition, we have licensed the database and it may also be accessed through SFARI Gene (https://gene.sfari.org/autdb/PINHome.do).

Title: The neural substrate of autism spectrum disorder and attention hyperactivity disorder

Authors: *H. OHTA[1], T. ITAHASHI[1], C. KANAI[1], M. NAKAMURA[3,1], K. KANJI[1], H. YAMADA[2], A. IWANAMI[2], N. KATO[1], R. HASHIMOTO[1,4];
[1]Clin. Res. Ctr. for Neurodevelopmental Disorders, [2]Neuropsychiatry, Showa Univ., Tokyo, Japan; [3]Kanagawa Psychiatric Ctr., Kanagawa, Japan; [4]Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: [Introduction] Autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are neurodevelopmental disorders. Previous researches have shown high rate of ADHD comorbidity (30-50%) in individuals with ASD. According to the Diagnostic and Statistical Manual of Mental Disorders_5th edition (DSM-5), ASD and ADHD can be diagnosed together. There are, however, only a few studies investigate the commonality and/or difference of biological characteristics between the two disorders. Structural and functional magnetic resonance imaging (MRI) has shown brain abnormalities in ASD and ADHD. Recent neuroimaging technique makes it possible to investigate white matter fiber structure using Diffusion Tenor Imaging (DTI). Not only the localized brain abnormality, but impaired structural brain connectivity are considered to be related the core feature of ASD and ADHD. So far, there is no study that compared the two disorders regarding the characteristics of white matter tract. The aim of the present study is to reveal the commonality and/or difference of white matter microstructure between the two disorders. [Method] Twelve adults with ASD, five adults with ADHD and eight age- and gender- matched healthy controls participated in this study. Individuals who have mental retardation were excluded from this study. MRI scans were conducted to all participants. The DTI data were compared between groups. [Result] Disorder-specific white matter alternations were found in some regions. However, the differences between groups were not significant statistically ($p > 0.05$). [Conclusion] Due to the small sample size, significant difference was not found between groups. This is on going study, so we will recruit more participants to reveal the commonality and/or difference of white matter microstructure between the two disorders.

Ctr., Beijing, China

Abstract: Autism is a developmental disorder with characteristic deficiency in social behavior and communication skills and the presence of stereotypical behavior. Several lines of evidence suggest that oxytocin (OXT) and arginine-vasopressin (AVP) system were aberrant in the autistic patients, and administration of exogenous OXT and AVP could partially and temporarily relief the clinical symptoms. Our previous studies also demonstrated that transcutaneous electrical acupoint stimulation (TEAS) improved autistic behaviors accompanied by changes of plasma levels of OXT/AVP. Certain brain regions such as hypothalamus, amygdala and hippocampus are known to contain OXT/AVP neurons/terminals and play important roles in regulation of complex social behaviors. Thus, we designed a clinical study to investigate the correlations between the autistic symptoms, circulating OXT/AVP levels and brain structural and functional abnormalities as assessed by MRI techniques. The results showed: (1) the volume of hypothalamus was decreased, and the left amygdala and left hippocampus increased in children with autism compared to typically developing children. (2) The functional connectivity between amygdala (AMG) and supramarginal gyrus (SMG) was decreased in children with autism compared to typically developing children. An attenuation of the functional connectivity between AMG and SMG was negatively correlated with increased clinical Autism Behavior Checklist (ABC) scores (total and sensory scores). (3) The functional connectivity between the left

hippocampus and right basal ganglia/right thalamus areas was increased in children with autism compared to the typically developing children. (4) A lowering of the blood OXT/AVP concentration was positively correlated with a decrease of the connectivity between AMG and ISMG. These results strongly suggest that changes in structure and activity of intrinsic OXT/AVP system may be involved in the development of autism.

Abstract: Several studies have linked glutamate alterations to autism spectrum disorder (ASD). Magnetic resonance spectroscopy (MRS) is a useful technique to non-invasively measure glutamate concentrations in-vivo. To our knowledge, this is the first study to apply MRS to the measurement of glutamate concentrations in adults with high-functioning ASD in the dorsal anterior cingulate cortex (dACC), a region high in glutamatergic signalling and previously shown to function abnormally in participants with ASD. We hypothesized that glutamate concentrations, as measured by single-voxel spectroscopy (SVS), would be altered in the dACC

in participants with ASD and would correlate with autistic symptoms as measured by the Autism Diagnostic Observation Schedule (ADOS). All participants underwent neuropsychological testing, structural Magnetic Resonance Imaging and SVS. Structural scans were analysed with whole brain voxel based morphometry (VBM). We used a SVS protocol that was designed for the optimised assessment of the glutamate peak. Additional metabolite measurements included N-acetylaspartate (NAA), glutamate/glutamine (Glx), creatine, phosphocholine and myo-inositol. Lastly, we ran bivariate Pearson correlations between glutamate concentrations, demographic (age, IQ) and clinical scores (ADOS). SVS was acquired in 19 participants with ASD (ADOS > 6) and 19 neurotypical controls (NC). There were no significant differences between groups for age, IQ, tissue composition in the dACC or whole brain grey matter volume as measured by VBM. Participants with ASD had, on average, a non-significant reduction in glutamate and Glx concentrations compared to NC. NAA, an indicator of neuronal function, was significantly reduced in participants with ASD ($p<0.05$). There was no support for the inter-relationship between glutamate concentrations and the ADOS in participants with ASD. We conducted a second analysis which excluded four participants with ASD due to factors which may have confounded glutamate concentrations (three participants on anticonvulsant medications and one participant with a reported history of seizures). The second analysis replicated all of the findings from the full group analysis, except for a significant reduction in glutamate ($p<0.05$) and Glx ($p<0.05$) concentrations for participants with ASD relative to NC. In conclusion, we provide evidence of altered glutamate and NAA concentrations in adults with ASD. Glutamate may be a potential target for therapeutic intervention but further investigation is required to gain insight into how glutamate is linked to both the pathophysiology and behavioural manifestations of ASD.

Title: Transdiagnostic neural basis for impaired phonological working memory across reading disability and autism spectrum disorder

Authors: *Z. QI[1], C. LU[2], A. HARRIS[3], L. W. WEIL[3], M. HAN[1], K. HALVERSON[1], T. K. PERRACHIONE[3], M. KJELGAARD[1], W. KENNETH[1], H. TAGER-FLUSBERG[3], J. D. E. GABRIELI[1];
[1]MIT, Cambridge, MA; [2]Beijing Normal Univ., Beijing, China; [3]Boston Univ., Boston, MA

Abstract: Individuals with reading disability or autism spectrum disorder (ASD) have, respectively, distinct disorders of language and social communication, but often exhibit common impairment in phonological abilities. It is unknown, however, whether the impaired phonological abilities reflect distinct or shared neuroanatomical bases in these two diagnostic groups. Here, we examined white-matter structural connectivity via diffusion-weighted imaging in children with reading disability, or ASD, or typical development (TD) matched in age, non-verbal IQ and gender. Phonological working memory is assessed by a combination of phonological awareness and verbal short-term memory tasks. Compared with TD, both reading disability and ASD groups exhibited reduced phonological working memory. Both groups displayed lower fractional anisotropy and higher radial diffusivity in the temporo-parietal part of the left arcuate fasciculus (TP-AF). ASD group additionally exhibited white-matter anomalies at the temporo-occipital part of the right inferior longitudinal fasciculus (TO-ILF). No group difference was found between reading disability and ASD. The fractional anisotropy of the left AF and right ILF correlated with ability in phonological working memory across all participants. In particular the microstructural features of the right ILF only correlated with phonological working memory in the two diagnostic groups, but not the typically developing counterparts. Thus, impaired phonological working memory was transdiagnostically associated with a similar neuroanatomical endophenotype.

Title: Local resting state functional connectivity in autism: Multisite variability and effect of eye status

Authors: *S. NAIR[1], M. M. BERKEBILE[1], C. P. CHEN[1], J. O. MAXIMO[2], R. A. MÜLLER[1,3]; [1]San Diego State Univ., San Diego, CA; [2]Univ. of Alabama, Birmingham, Birmingham, AL; [3]UCSD, San Diego, CA

Abstract: Despite growing evidence of abnormal long distance connectivity in autism spectrum disorder (ASD), findings for local connectivity have been limited and inconsistent. A regional homogeneity (ReHo) study by Maximo et al. (2013) reported local overconnectivity in posterior visual cortices in ASD. This was not confirmed in a large-sample study by the Autism Brain Imaging Data Exchange (ABIDE; DiMartino et al., 2013). However, eye status (open vs. closed) was not considered in these studies. Using high-quality data from ABIDE and our own group, we aimed to resolve these inconsistencies. Resting state fMRI data from ABIDE and SDSU (in-house) were processed. Time points with motion >.2mm were censored, and participants with <80% time points remaining after censoring were excluded. Nuisance regressors included six rigid-body motion parameters, signal from white matter and ventricles, and derivatives. Analyses were performed with and without global signal regression (GSR). Voxel-wise ReHo (local connectivity) maps were obtained using AFNI's 3dReHo. Five separate, low motion datasets were analyzed: a Grand Total group including all data (ABIDE and SDSU combined; N=331), SDSU (eyes open [EO]; N=53), NYU (eyes open; N=63), ABIDE-EO (eyes open, excluding SDSU and NYU; N=141), and ABIDE-EC (eyes closed; N=72). All subsamples were matched on head motion (p>.96), age (p>.87), and nonverbal IQ (p>.96). Despite large high-quality subsamples, between-group effects differed across datasets. Only a single effect, ASD overconnectivity in visual cortex, was seen across 4 datasets (Grand Total, SDSU, NYU, ABIDE-EO). Consistent effects for ≥2 datasets included underconnectivity in pericentral and inferior premotor regions (Grand Total, SDSU, ABIDE-EC), in mid/posterior cingulate cortex (Grand Total, SDSU), and in medial prefrontal cortex (Grand Total, NYU). Results from the non-GSR pipeline were largely similar. Local overconnectivity in visual cortex was the most consistent finding across multiple datasets, including a Grand Total with N=331. The finding is in agreement with previous reports (Maximo et al., 2013; Keown et al., 2013) and may relate to atypically increased visual activity often seen in the ASD imaging literature. The divergent finding in DiMartino et al. (2013) can be attributed to inclusion of eyes-closed data - the only dataset not showing this finding. Despite several other partly consistent findings, the differences across datasets suggest that ReHo may be highly sensitive to between-site variability, even in high-quality low-motion datasets.

Title: Abnormal cerebellar functional connectivity in children with autism spectrum disorder

Authors: *R. HANAIE[1], I. MOHRI[1], K. KAGITANI-SHIMONO[1], I. HIRATA[2], J. MATSUZAKI[1], F. NAGATANI[1], Y. WATANABE[3], M. TANIIKE[1];

Abstract: The cerebellum is one of the brain regions that has been most consistently reported to have neuropathological findings in patients with autism spectrum disorder (ASD). In recent years, many studies have reported that the cerebellum contributes not only to motor function but also to various cognitive functions. Aim of this study was to investigate cerebellar functional connectivity in children with ASD using resting state functional magnetic resonance imaging and to know whether its abnormalities were related to motor deficits, socio-communicative deficits, and executive dysfunction in children with ASD. Echo planar imaging functional volume and T1-weighted images of 15 children diagnosed with ASD (all males; age: 11.1 ± 2.1 years) and 20 typically developing (TD) children (19 males/1 female; age: 10.7 ± 2.4 years) were acquired on a 3 tesla scanner. The diagnosis of ASD was made according to the DSM-IV criteria and confirmed by autism diagnostic schedule-generic (ADOS-G). The Movement Assessment Battery for Children 2 (M-ABC 2) was used to assess motor function of the participants. In addition, Social Responsiveness Scale (SRS) and Behavior Rating Inventory of Executive Function (BRIEF) were used to assess socio-communicative function and executive function, respectively. Seed-based resting state functional connectivity analysis was performed using the CONN toolbox (http://www.nitrc.Org/projects/conn/). Cerebellar ROIs were created using the probabilistic MR Atlas of the human cerebellum (Diedrichsen, 2009). Children with ASD showed overall decreased cerebellar connectivity relative to TD children. The decreased functional connectivities between several cerebellar subregions and brainstem, thalamus, insula, prefrontal, premotor, and parietal cortex were found. In the ASD group, connectivity between the left dentate nucleus and brainstem was positively related to the total score of the M-ABC 2, and connectivity between the left VIIIa and left thalamus was positively related to the Restricted/Repetitive Behavior (RRB) score of the SRS. In addition, connectivity between the

right VIIb and right insula was negatively related to the Behavioral Regulation Index (BRI) score of the BRIEF. This study clearly showed that there were abnormalities in connectivity between cerebellum and various other brain regions, and abnormal cerebellar connectivity contribute to motor, executive and socio-communicative deficits in children with ASD.

Title: Atypical intrinsic functional connectivity of FFA is associated with social communication deficit in ASD

Authors: *W. ZHAO, I. FISHMAN, A. LEGENKAYA, S. NAIR, M. SULLIVAN, Y. GAO, M. BERKEBILE, R.-A. MUELLER;
Psychology, SDSU, San Diego, CA

Abstract: Among the core symptoms of Autism Spectrum Disorder (ASD) are deficits in social communication. There is large body of evidence demonstrating that individuals with ASD have impairments in face processing, a crucial component of reciprocal social interactions, including deficits in gaze processing, face identification and recognition of facial expressions of emotion. Fusiform face area (FFA), located in the ventral occipital cortex, is essential for face perception and has been shown to have reduced activation to faces in individuals with ASD compared to typically developing (TD) controls. Given the prevalent theory that ASD is a disorder of network dysfunction and abnormal brain connectivity, we investigated functional network organization of FFA in individuals with ASD, using intrinsic functional connectivity (iFC), a functional imaging method assessing the synchronicity of spontaneous low-frequency activity fluctuations between

different brain areas. We performed whole-brain iFC analysis using right FFA as a seed region in 35 children and adolescents with ASD (ages 8-17 years) and 36 TD participants matched for age, gender, IQ, and in-scanner head motion. Direct group comparisons revealed that the ASD group showed two clusters of greater connectivity (compared to the TD group): with a region in the inferior portion of the medial frontal gyri (medial frontopolar cortex) and with posterior cingulate cortex (PCC). Reduced connectivity in ASD was observed between FFA and the right supplementary motor area (SMA). Within the ASD group, the degree of overconnectivity (mean z-score) between FFA and the medial frontal cluster was significantly correlated with social impairment, as measured by the Social Responsiveness Scale (SRS), i.e., participants with greater sociocommunicative symptoms had more excessive connections. The findings show atypical iFC patterns of a brain region crucially involved in face processing in children and adolescents with ASD. Namely, greater connectivity was observed between FFA and regions outside of the canonical face processing network (e.g., PCC, medial frontopolar cortex), suggesting atypical network organization of the neural circuit underlying face perception in ASD. The link between excessive out-of-network functional connectivity of the FFA and ASD social communication symptoms suggests that inefficient face processing circuitry may contribute to social deficits observed in ASD. Consistent with a previous study (Fishman et al., JAMA Psychiatry 2014), the finding suggests that autistic symptomatology may be tied to functional overconnectivity.

Title: Delineating adaptive neural mechanisms in individuals with autism when processing unimodal vs. bimodal real-world stimuli using functional MRI

Authors: ***P. J. WEBSTER**[1], C. FRUM[2], A. KURKOWSKI-BURT[3], J. W. LEWIS[1]; [1]Neurobio. & Anat., [2]Physiol. and Pharmacol., [3]Occup. Therapy, West Virginia Univ., Morgantown, WV

Abstract: The rate of autism diagnosis has been steadily increasing in the U.S. according to the Centers for Disease Control. Sensory processing dysfunction is a core feature of autism that can cause an individual to over-respond or under-respond to everyday sensory stimuli. The inability to effectively manage non-noxious stimuli can be socially isolating, increase anxiety, and impact a person's ability to attend to what's pertinent in their environment. Neuroimaging studies investigating sensory processing in autism have shown differential structural and functional connectivity depending on the age of the participants, level of stimulus complexity, and task demands. In addition, the timeframe within which information is perceived is altered in individuals with autism. Despite these differences--and in spite of the fact that cortical activation patterns in this group may be seen in different brain regions and with greater variability--autistic children and adults often perform at or above the level of their peers on many tasks. Exactly how individuals with a spectrum of autism phenotypes develop adaptive neuronal mechanisms to process and integrate sensory information has not been determined. The objective of this research is to depict cortical processing systems engaged during a simple selective attention task using real world (complex) audiovisual stimuli in high-functioning individuals with autism. We hypothesize that differences in structural and functional connectivity induce adaptive neural mechanisms that impact the timing of incoming sensory inputs and alter neuronal processing when integrating sensory information. We used functional magnetic resonance imaging (fMRI) to characterize these putative adaptive brain mechanisms when processing one source of sensory input (visual) vs. integrating two types of sensory information (audiovisual). The preliminary data indicate that adolescents and young adults with autism show differential activation in the cingulate region of the brain when integrating audiovisual information compared to adolescents and adults without autism. Differences in activation in this brain region may contribute to the high comorbidity of ADHD in individuals with autism as well as in emotional dysregulation, often seen in autism. This research is significant because it utilizes real world stimuli to investigate cortical activation differences across two developmental time points (adolescents and young adults), thus will inform models of plasticity in this heterogeneous disorder and will aid in the refinement of targeted interventions and their efficacy.

Title: Hyper-synchronization of brain activity in ASD during face-to-face conversation

Authors: *K. JASMIN[1,2], S. J. GOTTS[2], Y. XU[3], S. LIU[3], C. RIDDELL[2], J. INGEHOLM[2], A. R. BRAUN[3], A. MARTIN[2];

Abstract: People with autism spectrum disorders (ASD) find face-to-face communication difficult. While previous neuroimaging studies have examined brain function in ASD during task and rest conditions and found abnormal differences in sensory, motor, social, and language networks, little is known about the function of these networks in an on-line, naturalistic conversation task. Here, we scanned 19 high-functioning autistics and 20 matched controls with fMRI while they conversed with an experimenter about their interests, hobbies, work and school life. Microphones, headsets and cameras were used to support face-to-face interaction. Using an unbiased, data-drive approach we found that the ASD participants showed greater whole-brain synchronization (timeseries co-variation) than the typically developed (TD) participants (voxelwise PTD) between all 24 regions revealed that most of the hyper-synchronization occurred within Network 2, and between Networks 2 and 3 ($P<.05$, two-tailed, Bonferroni corrected). Our results suggest that ASD brains may be less differentiated or functionally specialized than TD brains and that abnormal sensorimotor processing may relate to the difficulties ASDs have with face-to-face conversation.

Title: Developmental differences in functional connectivity in autism

Authors: *T. K. MCALLISTER-DAY[1], T. MADHYASTHA[1], M. REITER[1], M. K. ASKREN[1], N. KLEINHANS[1], W. A. CHAOVALITWONGSE[1,2], T. GRABOWSKI, Jr.[1,3]; [1]Radiology, [2]Industrial & Systems Engin., [3]Neurol., Univ. of Washington, Seattle, WA

Abstract: Autism is a developmental disorder known to affect brain structure and function, but how it affects functional connectivity is not well understood. There is evidence for long-range hypoconnectivity and short range hyperconnectivity, but results are dependent upon control of motion, subject age, and methodological approach. In this study we synthesize two methodological approaches, graph-based functional connectivity (FC) and a novel method called network kernel analysis, to analyze within- and between-network connectivity of large-scale intrinsic functional networks. Our population consists of a cross-sectional sample (N=360) drawn from the Autism Brain Imaging Data Exchange (ABIDE) repository, selected based on root mean squared mean absolute motion < 0.5 mm, and individually matched for motion, full scale IQ, and age (7-35). We used literature-defined coordinates to identify nodes in the default mode network (DMN), dorsal attention network (DAN), frontal-parietal task control network (FPTC) and networks involved in emotional processing (SELF and OTHER)1. We censored motion-tainted frames. Using a graph approach, we found that within-network FC declined with age within the DAN, FPTC, and SELF networks. There was no main effect of diagnostic group on FC in any network after correction for multiple comparisons; however, the effect on OTHER approached significance (pcor = 0.056). There was no effect of age on between-network FC between SELF and OTHER and the remaining networks. Using network kernel analysis, and including nodes involved in salience, somotosensory and visual processing networks, we identified nine intrinsic network kernels whose structure was identical across five evenly distributed age bins and diagnostic group. A subsequent GLM using the network scores as regressors allowed us to map linear age-related developmental differences for each intrinsic network and examine group-related differences in slope. In general, network level developmental changes involved cortical specialization, lower cross-network correlation, and changes in cortical/subcortical connectivity. Developmental differences in ASD involve slower development of right-sided language-related homologues. We conclude that the network kernel approach allows us to consider group differences in connectivity in the context of substantial developmental network changes. References 1. Murray, R. Title: Association between age and rich-club structure in autistic and neurotypical human brains

Authors: *T. WATANABE[1], G. REES[1,2];
[1]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom; [2]Wellcome Trust Ctr. for Neuroimaging, UCL, London, United Kingdom

Abstract: Recent studies have shown the existence of rich-club organisation in large-scale anatomical human brain networks. The organisation consists of highly-connected regions and sparsely connected peripheral regions, and is supposed to contribute efficient information processing. In addition, disruption of this network organisation has been found in several psychiatric disorders including schizophrenia. In this study, using a publicly shared diffusion tensor imaging dataset, we found that brains of neurotypical individuals showed increases in rich-club architecture and network functionality during adolescence, whilst individuals with autism spectrum disorders did not. Moreover, this typical development of rich-club organisation was related with progressive involvement of the right anterior insula. In contrast, in autistic individuals, the anterior insula did not show typical increases in grey matter volume, and this anatomical immaturity was correlated with social symptoms of autism. These observations suggest that rich-club organisation is one of the bases of functionally efficient brain networks that enable complex cognitive functions in adult human brains, and imply that immature rich-club architecture might underlie some neurodevelopmental disorders.

Title: White matter microstructure differences in adolescents with autism, psychosis and 22q11.2 deletion syndrome

Authors: *J. GALVIS[1], J. E. VILLALON[1], G. PRASAD[1], C. CORBIN[3], T. M. NIR[1], L. KUSHAN-WELLS[4], C. E. BEARDEN[4], P. M. THOMPSON[2];

Abstract: 22q11.2 deletion syndrome (22q) is a neurogenetic disorder that can affect the heart, face, and brain. Many adolescents with 22q develop autism spectrum disorder (ASD), psychotic disorders (PS) or both. It is vital to understand which brain differences distinguish 22q from healthy developing adolescents and which pathological processes increase risk for ASD or PS. Here we analyzed white matter microstructural differences between 22q youth with (1) both ASD and Psychotic disorders, and (2) ASD only. We analyzed diffusion-weighted MRI (dMRI) scans using diffusion tensor imaging (DTI) and Q-ball imaging models to assess microstructural changes in the white matter. We computed DTI measures including axial, radial and mean diffusivity (AD, RD, MD), fractional anisotropy (FA), sphericity, linearity, planarity, and one orientation distribution function (ODF) based measure - the generalized fractional anisotropy - for all subjects (50 controls; mean age=12.48 years, M/F 29/21; and 46 22q patients; mean age=15.76 years, M/F 23/23). We computed the mean of each DWI derived measure in each of 100 white matter regions of interest, segmented using the Johns Hopkins white matter atlas. Support vector machines (SVMs) were used to classify individuals as 22q or healthy controls, and determine which ROIs had highest weight for classification. We obtained 92% accuracy with 10 fold cross validation. We performed a linear regression on each of the DWI measures within the ROIs ranked highest by the SVM algorithm to determine differences between 22q-ASD and PS. 22q youth with PS (n=12: mean age=16.25, M/F 5/7) had higher AD in the left posterior limb of the internal capsule, compared to ASD (n=12: mean age=12.91, M/F 8/4; FDR correction; $p < 7E-7$). For all other measures, we detected no significant differences between 22q individuals with and without psychosis. Higher AD in psychotic patients may be related to reduced axonal development. Via a new consortium, ENIGMA-22q, substantially increased sample sizes should identify more subtle but robust differences between these groups.

Title: Relationship between language network connectivity and language deficits in children with Autism Spectrum Disorder

Authors: ***Y. GAO**[1], S. NAIR[2], A. LEGENKAYA[2], S. PUNYAMURTHULA[2], I. FISHMAN[2], R.-A. MÜLLER[2];
[1]Clin. Psychology, San Diego State University/ Univ. of Californ, San Diego, CA; [2]Psychology, San Diego State Univ., San Diego, CA

Abstract: Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by sociocommunicative deficits. Studies suggest that atypical neural connectivity in ASD contributes to behavioral symptoms. However, evidence relating functional connectivity

of the language network to clinical measures of language in ASD remains limited. The present study examined links between intrinsic functional connectivity (iFC) of the language network and language abilities in children with ASD. Methods: We included 6-minute resting state fMRI scans from 31 ASD and 30 typically developing (TD) participants, ages 8-17 years. Groups were matched on age, non-verbal IQ, and head motion (all *p*s>.83). Data were preprocessed using nuisance regressors from six motion parameters, white matter and ventricles, and derivatives. Time points with motion >0.5mm and two subsequent time points were censored. All subjects included had >80% time points. Whole-brain iFC analyses were performed for seed in Broca's and Wernicke's areas in the left hemisphere (with coordinates adopted from Tomasi & Volkow, *Mol. Psychiatry* 2012). IFC maps were directly compared between the groups. Mean *z*-scores extracted from significant between-group clusters were correlated with scores from the Clinical Evaluation of Language Fundamentals (CELF). Results: Although within-group maps were mostly similar, direct group comparisons revealed significant iFC differences between ASD and TD groups (corrected $p<0.05$), with greater iFC (ASD > TD) between Broca's area and right middle temporal gyrus, and weaker iFC (ASD < TD) between Broca's area and right insula/frontal operculum. For Wernicke's area, extensive underconnectivity was detected in bilateral visual cortex. The latter was correlated with CELF Core Language scores ($r= -0.52$, $p<0.05$) and Expressive Language scores ($r= -0.51$, $p<0.05$) in the ASD group; i.e., greater iFC was associated with lower language scores. Conclusion: Patterns of atypical iFC in the ASD group differed between anterior and posterior perisylvian seeds. While overconnectivity between Broca's area and right middle temporal gyrus may relate to atypical functional asymmetry (increased right hemisphere participation) for language observed in some previous studies, extensive underconnectivity for Wernicke's area with striate and extrastriate visual cortices was a novel finding. Its potential significance was underscored by links with language ability. In particular, the link with expressive language was unexpected (given the primarily receptive role of Wernicke's area) and will require further investigation.

Title: Deficits in the brain's reading network in children with autism ameliorated by language remediation

Authors: *J. O. MAXIMO, D. L. MURDAUGH, A. R. LEMELMAN, C. E. CRIDER, S. E. O'KELLEY, R. K. KANA;
Psychology, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Background: Individuals with autism spectrum disorders (ASD) may rely on intact or enhanced visuospatial skills to better facilitate language comprehension. Such compensation may underlie the engagement of neural circuitry that differs from typically developing individuals, or an underuse of the typical language-specialized regions in the brain. While attempts have been made to target language deficits in ASD using behavioral interventions, limited attention has been given to assessing intervention-related changes in brain functioning. **Objectives:** The objective of this study was to test the impact of an intensive visual imagery-based reading intervention on brain responses underlying language comprehension in children with ASD. **Methods:** The ASD participants were randomly assigned to a Wait-list control group (ASD-WLC; n = 10) and an Experimental group (ASD-EXP; n = 12). Both groups were scanned pre- and post-intervention, with only the ASD-EXP group receiving the intervention before their second scan. Participants went through a reading intervention program (Visualizing and Verbalizing for Language Comprehension and Thinking; 10-weeks, 200 hours of instruction). In the fMRI scanner, the participants performed 3 tasks: word comprehension, sentence comprehension, and verbal absurdity. **Results:** Across the 3 experiments: I) the ASD-EXP group showed an increase in bilateral motor, occipital and parietal activation compared to the ASD-WLC group post-intervention; II) intervention-related changes in brain activation were observed in the ASD-EXP group post-intervention in right cuneus, calcarine, and superior parietal lobule; and III) improvement (pre-to-post) in Gray Oral Reading Test scores significantly predicted changes in activation in the ASD-EXP group in precuneus, left angular, right IFG, and right insula. **Conclusions:** The findings of this study revealed that the reading intervention increased the brain activity in ASD-EXP children in regions associated with language and visual imagery. It should be noted that these results were accompanied by improvement in language comprehension in these participants. These findings underscore the potential of rigorous and structured interventions in targeting brain plasticity and improving functions in children with autism.

Title: Global and modular resting state network topology in autism, phenylketonuria, and traumatic brain injury

Authors: *R. M. ZAMZOW, J. P. HEGARTY II, K. R. BELLESHEIM, M. H. PRICE, J. D. JOHNSON, G. YAO, D. Q. BEVERSDORF, S. E. CHRIST;
Univ. of Missouri, Columbia, MO

Abstract: It has previously been suggested that functional connectivity, as measured by functional magnetic resonance imaging (fMRI), is altered in individuals with neurodevelopmental disorders or neurological syndromes. In the present study, we used graph theoretical analysis to examine how the topology of functional networks differs based on diagnosis. Resting state fMRI data was collected from 61 individuals with autism spectrum disorder (ASD) (mean age = 15.4), 12 individuals with phenylketonuria (PKU) (mean age = 23.6), 18 individuals with traumatic brain injury (TBI) (mean age = 39.4), and a comparison group of 61 typically developing individuals (TD) (mean age = 15.4). Partial correlation matrices for 90 cortical and subcortical regions were generated and thresholded across a range of network densities: $.05 \leq k \leq .48$. Topological properties were then compared between diagnostic groups and the TD group via area under the curve analyses. Statistical analysis revealed that the ASD group demonstrated reduced clustering coefficient ($p < .01$) as well as a trend toward increased characteristic path length ($p < .10$), as compared to the TD group. This pattern suggests disruptions in network efficiency at both the local and global levels in ASD. The PKU and TBI groups, however, displayed the opposite pattern. Both groups showed increased clustering coefficient ($p < .001$, in both instances) and reduced characteristic path length ($p < .001$, in both instances), as compared to controls, suggesting network-wide over-connectivity. In subsequent analyses, 13 functional subnetworks were identified for each group using a community detection algorithm and compared between groups for topological organization. In particular, as compared to the TD group, the ASD group demonstrated a reduced number of connections at each node within a subnetwork containing temporal cortical regions ($p < .01$). The PKU group showed reduced network efficiency and connection strength in a large subnetwork containing frontoparietal connections, as compared to the TD group ($p < .01$). Lastly, the TBI group displayed reduced network efficiency and connection strength in 9 of the 13 functional

subnetworks ($p < .01$ in all instances). The results of the present study indicate alterations in functional network and subnetwork topology that are distinct to specific diagnoses. Future studies are needed to characterize these alterations within the contexts of development and symptom severity.

Title: Motor imagery induced event-related desynchronization(ERD) of mu rhythm in ASD

Authors: ***Y.-T. CHEN**[1], K.-S. TSOU[2], C.-C. WONG[2], H.-L. CHEN[1], Y.-T. FAN[3], C.-T. WU[1,4];

Taiwan Hosp. & Col. of Med., Taipei City, Taiwan

Abstract: Current evidence regarding whether the action representation is impaired in ASD remains inconclusive. While some studies showed that individuals with ASD demonstrate deficient action representation when performing action observation or imitation tasks, other studies showed the opposite results. In one of our recent behavioral study, we investigated the characteristic of action representation in ASD through motor imagery (MI) and showed that ASD is capable of performing kinesthetic MI but with a more inefficient way, reflecting preserved action representation in ASD. In the current study, we aimed to further investigate the neurophysiological mechanisms underlying MI in ASD through measuring MI-induced event-related desynchronization (ERD) in the mu rhythm (8-13 Hz). We recruited 16 individuals with ASD and 16 typically developing control (TDC) participants to perform a hand-rotation and an object-rotation task during EEG recording. In the hand-rotation task (involves kinesthetic MI), participants were required to judge the laterality of a 3-D model image of a bare-hand (the intransitive condition) or a hand-with-spoon (the transitive condition) that rotates with different

angles. In the object rotation task (involves object-based visual imagery), they were required to judge whether the drawer is on the right or on the left side of a desk that rotates with different angles. Specifically, to prevent contamination of mu power change induced by motor preparation and execution of manual responses, we modified our previous behavioral paradigm into a delayed response design. Based on the previous findings, we hypothesized that there would be positive biomechanical effects in which the medial rotation condition (comfortable position) would induce more mu ERD than the lateral rotation condition (awkward position), since the former is easier to imagine with kinesthetic information. For the hand rotation task, our results reveal that both groups demonstrated 'biomechanical effect' over the central scalp regions in the transitive condition. However, the mu power attenuations over the central regions of the ASD group were smaller than that of the TDC group both in the intransitive and transitive condition, for both medial (group difference for bare-hand: 8.6%; for hand-with-spoon:14.2%) and lateral rotation(group difference for bare-hand:12.4%; for hand-with-spoon, C3:11.6%). Our findings implicate that the inefficient performance of MI in individuals with ASD might result from reduced ERD in the mu rhythm over sensorimotor cortices.

Title: Links between thalamocortical and cerebrocerebellar intrinsic functional connectivity in autism spectrum disorder

Authors: *M. M. BERKEBILE[1], A. NAIR[2,1], A. J. KHAN[4], S. NAIR[1], M. DATKO[3], R.-A. MUELLER[1];

[1]Psychology, San Diego State Univ., San Diego, CA; [2]Clin. Psychology, [3]Cognitive Sci., UCSD, La Jolla, CA; [4]Clin. Psychology, Suffolk Univ., Boston, MA

Abstract: Introduction Research on autism spectrum disorder (ASD) has indicated atypical connectivity between cerebral cortex and deep structures such as thalamus and cerebellum. Recent intrinsic functional connectivity (iFC) work has shown predominant thalamocortical (TC) underconnectivity (Nair et al., Brain 2013), but cerebrocerebellar (CC) overconnectivity in ASD (Khan et al., Biol. Psychiatry 2015). However, these studies suggested similar domain-specific patterns of stronger iFC for sensorimotor (SM) and weaker iFC for supramodal (SU) connections. The present study examined these relationships by testing whether differential effects for SM and SU domains might be linked between TC and CC iFC. Methods 22 ASD and 27 typically developing (TD) participants, 7-17 years old, completed a 6 minute resting state scan (3T GE). Data were preprocessed in AFNI, with motion and fieldmap correction, spatial smoothing to 6mm3 FWHM, and Talairach normalization. Cortical regions of interest (ROIs) were obtained from the Jülich histological and Harvard-Oxford atlases. Partial correlation analyses were performed between mean time series from each unilateral cerebral cortical ROI and each ipsilateral thalamic and each contralateral cerebellar voxel. Results Our hypothesis linking domain-specific iFC patterns for TC and CC connectivity in ASD was not confirmed. One TC-CC correlation ($p<.05$) was found for left SM in the TD group (iFC between left SM cortex and left thalamus being positively correlated with iFC between left SM cortex and right cerebellum). The ASD group showed no such pattern. Examining individual ROIs, we found that this left SM correlation in the TD group was driven by perirolandic connectivity (M1, S1). In the ASD group, we found negative correlations ($r>.6$; $p<.005$) between CC iFC for right inferior/middle temporal cortex with TC iFC for right occipital and left S1 cortices; and a positive correlation between TC iFC for right posterior parietal and CC iFC for left superior temporal cortex. Conclusions Findings suggest that atypical TC and CC connectivity in ASD is not governed by a single principle of increased sensorimotor vs. reduced supramodal iFC. In fact, one link seen in the TD group for left SM was absent in the ASD group. Several atypical links were also seen in the ASD group. One of these showed that reduced cerebellar iFC with ventral visual stream (right inferior/middle temporal cortex) was linked to relatively increased thalamic iFC with right occipital cortex. This finding suggests that atypically increased activity and connectivity of early visual cortex observed in previous studies may be related to unusual subcortical and cerebellar connectivity.

Title: Attention-based learning deficits in individuals with autism suggest constitutively elevated norepinephrine levels

Authors: *M. C. GRANOVETTER[1], E. ELDAR[2], Y. NIV[1];
[1]Dept. of Psychology and Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Autism spectrum disorders comprise a class of conditions characterized in part by a deficit in sensory integration (Lai, Lombardo, & Baron-Cohen, 2013). Previous work suggests that the degree to which learning about environmental stimuli integrates over different stimulus features is modulated by neural gain. High gain corresponds to tonic activity of the locus coeruleus (LC) and increased global levels of norepinephrine (NE) levels in the brain, and has been associated with a less integrative mode of learning and processing. In contrast, low gain correlates with LC phasic activity, resulting in decreased NE concentrations. That is, when neurotypical individuals are in a high gain state, they have a tendency to narrow their attentional breadth and learn from few stimulus dimensions that they are particularly predisposed to, whereas in a state of low gain they are able to learn from multiple stimulus features simultaneously (Eldar, Cohen, & Niv, 2013). Given autistic individuals' deficits in attention-based learning and relatively large baseline pupil diameters (an indicator of enhanced NE release from LC terminals), we tested the behavioral performance and pupillary responses of autistic and neurotypical teenagers on a task measuring the extent of learning from multidimensional stimuli. While autistic participants' pupillary responses were consistent with a high gain state, the behavioral data suggested that autistic individuals were more likely to learn from multiple stimulus dimensions, as compared to neurotypical controls. To reconcile these opposing findings, we propose that in the autistic brain, chronically elevated levels of NE cause desensitization of adrenergic receptors, thereby resulting both in a significant diminishment of gain and a decrease in NE's capability of modulating the signal-to-noise ratio of a range of neural circuits. In contrast, adrenergic receptors controlling pupil dilation are less susceptible to desensitization

(Heck & Bylund, 1998), and thus reveal the elevated NE levels more directly. Our results thereby support a possible neural basis for deficits in attention-based learning in autistic individuals, while also accounting for several classic autistic features. Title: Resting-state functional connectivity predicts prospective change in social functioning and adaptive behaviors

Authors: *M. PLITT[1], K. A. BARNES[2], G. L. WALLACE[2], L. KENWORTHY[2], A. MARTIN[2];
[1]Lab. of Brain and Cognition, Natl. Instit, Bethesda, MD; [2]Lab. of Brain and Cognition, NIMH, Bethesda, MD

Abstract: Though typically identified in early childhood, the social communication symptoms and adaptive behavior deficits that are characteristic of autism spectrum disorder (ASD) persist throughout the lifespan. Despite this persistence, even high-functioning individuals show substantial heterogeneity in outcomes. Previous studies have found various behavioral assessments such as IQ, early language ability, and baseline social functioning and adaptive behavior scores to be predictive of outcome, but most of the variance in functioning remains unexplained by such variables. In this study, we investigated to what extent functional brain connectivity measures obtained from resting-state functional connectivity MRI (rs-fcMRI) could predict the variance left unexplained by behavior (age, follow-up latency, and baseline social

functioning and adaptive behavior scores) in two measures of outcome—adaptive behaviors and social functioning at least one year post-scan (mean follow-up latency = 2 years 10 months). We found that connectivity involving the so-called salience network (SN), default-mode network (DMN), and frontoparietal task control network (FPTCN) was highly predictive of future social functioning and the change in social functioning and adaptive behavior over the same time period. Furthermore, functional connectivity involving the SN, which is predominantly composed of the anterior insula and the dorsal anterior cingulate, predicted reliable improvement in adaptive behaviors with 100% sensitivity and 70.59% precision (the ability of a model to not label a scan as positive when the true label is negative). Our study successfully predicted heterogeneity in outcomes for individuals with ASD from rs-fcMRI data that was unaccounted for by simple behavioral metrics and provides novel evidence for networks underlying long-term symptom abatement.

Title: Investigating the effects of Neuro Feedback training on the functional brain connectivity of children on the autism spectrum

Authors: ***A. COURELLI**[1], H. COURELLIS[1], E. FRIEDRICH[2], J. A. PINEDA[2];
[1]Bioengineering, [2]Cognitive Sci., UCSD, San Diego, CA

Abstract: Neuro feedback training (NFT) constitutes a promising treatment for ASD that has been shown to produce positive behavioral changes. The majority of the analyses regarding the effects of NFT on the behavior of autistic children have relied on caretaker surveys and changes in the power of EEG frequency bands. While such analyses provide benchmarks regarding NFT effectiveness, they do not provide information about changes in functional brain connectivity that can be used to explain behavioral changes. To investigate changes in functional brain

connectivity, we computed Granger Causality spectral estimates using filtered EEG signals recorded from pediatric ASD patients before and after NFT. Closed loop NFT was conducted on 13 autistic children, ages 8-17, with the aim to upregulate mu-rhythms, 8-13 Hz rhythms in the sensorimotor cortex, and suppress beta and theta rhythms. Prior to the beginning of the NFT and after 16 sessions were completed, an emotion recognition test was conducted and EEG data were recorded using a 32 electrode full cap EEG. Patients were shown a series of video clips of individuals making happy, fearful, or angry faces. The videos were categorized into two stimulus classes according to the type of emotion they presented: positive (happy) and negative (fearful/angry).The acquired data were processed by applying artifact rejection, the cleaned data were epoched to encompass only the video presentation stimuli, and Independent Component Analysis (ICA) was conducted to identify sources of electrical activity during the epoch. Non-artifactual Independent Components (IC's) selected for the positive and negative stimulus class served as nodes for the functional brain connectivity networks associated with each stimulus class. Using the selected ICs, a Multivariate Autoregressive model was constructed for each stimulus class and spectrotemporal Granger causality (GC) was computed among all possible pairs of the selected IC's. Changes in the strength of the causal connections were subsequently determined by averaging spectral GC power within the trained frequency bands across the entire epoch. Key brain regions associated with ICs that exhibited change in causal connection strength for each stimulus class corresponded to centers for self-regulation and social cognition, visual processing centers, and the pre motor cortex. Caretaker evaluations of the patients' performance pre and post NFT (Social Responsiveness Scale and Autism Treatment Evaluation Checklist) suggested that the observed changes in functional brain connectivity were accompanied by improvement in social responsiveness and a decrease in autistic symptoms.

Title: Are sensory problems in autism really sensory?

Authors: M. ZINNI[1,4], M. WESTERFIELD[2], S. WEE[3], L. CHUKOSKIE[2], *J. TOWNSEND[1]; [1]Dept Of Neurosci, [2]Inst. Neural Computation, [3]Dept. Neurosciences, UCSD, La Jolla, CA; [4]Neuroverse, Inc., San Diego, CA

Abstract: Abnormal responses to sensory stimulation are a commonly reported clinical feature of autism spectrum disorder (ASD). Both over- and under-responsiveness have been reported in all sensory modalities, although the nature and affected sensory modality of these abnormalities varies greatly between individuals. Despite the general consensus that sensory abnormalities are an important clinical symptom in autism, there is little or no understanding of the underlying mechanisms. Because the vast majority of evidence regarding these sensory symptoms in ASD are based solely on behavioral descriptions, it is not clear whether these symptoms are related to differences in function at a basic sensory level or whether these symptoms result instead from the influence of poorly modulated arousal and attention on sensory responsiveness. The present study examined these factors in adults with ASD compared to typically developing (TD) adults. Participants completed three experiments utilizing behavioral, event-related brain potential (ERP) and heart-rate (HR & HRV) measures to collectively examine electroencephalographic (EEG) sensory responses to: auditory stimulation; changes in intensity of auditory stimulation; repeated auditory stimulation (refractory and habituation responses). During these experiments we also examined the effects of physiological arousal and attention on brain responses to sensory stimulation. We found significant sensory problems on the Sensory Profile Questionnaire in ASD adults, suggesting that sensory difficulties persist throughout the lifespan. While ASD participants reported more sensory difficulties, our physiological measures did not support a true sensory origin of these difficulties. The ERP responses to auditory stimuli of varying intensity were similar in amplitude between ASD and TD groups. Also, ASD adults, like TD adults showed the expected refractory response to a repeated sensory stimulus (i.e., the response to the second of a pair of stimuli with differing inter-stimulus intervals was smaller). However, gradual habituation over time was atypical in ASD, but only when sensory stimulation was unattended. Additionally, baseline arousal differed between groups as measured by HR & HRV as well as greater arousal in the ASD group during the presentation of auditory tones. These findings suggest that in adults with ASD, sensory difficulties that are experienced in daily life may be a function of differences in the modulation of general arousal and the effects of attentional state rather than abnormalities in basic sensory response.

Title: Relationship between neural coherence and attention in autism spectrum disorder

Authors: A.-M. FLORES[1], T. ANDERSEN[1], C. SWICK[1], R. GOODCASE[1], J. BRENNAN[2], I. KOVELMAN[2], S. BOWYER[3], *R. LAJINESS-O'NEILL[1];
[1]Eastern Michigan Univ., Ypsilanti, MI; [2]Univ. of Michigan, Ann Arbor, MI; [3]Henry Ford Hlth. Systems, Detroit, MI

Abstract: Autism Spectrum Disorder (ASD) is characterized by atypical attentional functioning. Aberrant neural synchrony may be a neurophysiological mechanism underlying this characteristic. This study investigated relationships between synchrony and attention. Twelve ASD (Age: M = 8.9; SD= 1.0) and 13 neurotypical (NT) children (Age: M = 9.3; SD = 1.3) underwent magnetoencephalography (MEG) at rest. Synchronization was quantified by calculating coherence between cortical sites. Kendall Tau correlations were computed to examine relationships between coherence and auditory attention (AA). Alpha-band: In ASD, coherence between cingulate and orbitofrontal regions was positively related to shifting errors (τ=-0.73- -0.60). In NT, higher coherence between frontal and subcortical regions, and from the cingulate to fronto-parietal regions, was related to better AA (τ=0.48- 0.74). Gamma-band: In ASD, coherence between fronto-temporal regions, and temporal lobes, was positively related to AA (τ=0.47- 0.51). Coherence between temporal and pre/postcentral regions was negatively related to AA inhibition (τ=-0.47). Increased connectivity was related to better AA, shown by fewer omission errors (τ=0.45-0.65). Connectivity from orbitofrontal to all other regions was related to higher impulsivity on set shifting tasks (τ=-0.66- -0.47). In NT, increased coherence between fronto-parietal regions was related to less AA inhibition (τ=-0.63- -0.48); coherence between orbitofrontal and temporal regions was positively related to inhibition (τ=0.48- 0.56). Higher coherence between fronto-temporal regions was related to more omission errors on a set shifting task (τ=-0.61- -0.50). Coherence between bilateral temporo-parieto-occipital regions was negatively related to AA impulsivity (τ=-0.60- -0.48). Enhanced alpha connectivity between cingulate and orbitofrontal regions suggested poor regulation in ASD. Enhanced alpha connectivity in NT between frontal and subcortical regions and from cingulate to fronto-parietal regions, enhanced AA. Better AA performance in ASD were related to increased gamma connectivity between temporal and fronto-temporal regions. Poor inhibition was differentially associated in ASD and NT with increased gamma connectivity between temporal and pre/postcentral regions and frontoparietal regions, respectively. Better inhibition was associated with increased gamma connectivity between orbitofrontal and temporal regions in NT. Overall,

posterior connectivity was associated with impulsivity. Findings suggest differential cortical connectivity in ASD and NT associated with auditory attention.

Title: Brainstem morphometry in individuals with and without autism spectrum disorders

Authors: *S. E. CHRIST, M. C. ABRAHAM, G. YAO, D. Q. BEVERSDORF;
Univ. of Missouri, Columbia, MO

Abstract: Objective: Previous studies of brainstem morphometry in individuals with autism spectrum disorder (ASD) have yielded mixed results. Whereas some studies (e.g., Gaffney et al. 1988, Jou et al. 2013) have found ASD-related abnormalities, others (e.g., Elia et al, 2000) have reported no significant differences between individuals with and without ASD. The objective of the present study was to further examine this issue while also investigating the relationship between morphometry and autistic symptomatology. To this end, structural volume of the midbrain, pons, and medulla were studied in a sample of adolescents and young adults with and without ASD. Methods: High resolution T1-weighted MRI structural images were acquired from 20 individuals with ASD (male/female: 18/2; mean age: 13.0 yrs) and an age- and gender-matched comparison group of 21 typically developing individuals without ASD (male/female: 20/1; mean age: 13.1 yrs). All data processing was conducted by individuals who were masked to the group status of the participants. Following acquisition, the structural MR image data for each participant was rotated into AC-PC coordinates, and the brainstem structures of interest (i.e., midbrain, pons, and medulla) were then manually segmented in a standardized fashion to obtain precise volumetric measurements. Manual segmentation, while time-consuming, is considered the “gold-standard” by most investigators for detecting subtle volumetric differences

(Harms et al., 2010). Results & Conclusions: Overall, there was a trend towards larger total brain stem volume in the ASD group (M = 29.43 cm^3) compared to the typically developing non-ASD group (M = 28.05 cm^3); however, this difference did not rise to statistical significance, $t(39)$ = 1.57, p = .13, d = .50. Similar non-significant trends were observed for all three individual structures of the brainstem (midbrain, pons, and medulla). Of note, within the ASD group, a relationship (r = .54, p = .02) between brainstem volume and autistic symptomatology (as measured by the Social Communication Questionnaire; Rutter et al., 2003) was evident. This relationship held for all three individual structures (midbrain: r = .52; pons: r = .44; medulla: r = .53). The present findings replicate and extend previous studies which have reported ASD-related abnormalities in brainstem morphometry (Gaffney et al. 1988, Jou et al. 2013). Additional research is needed to examine the extent to which the presently the observed relationship between brainstem volume and autistic symptoms may be driven by a particular aspect of symptomatology (e.g., sensory abnormalities).

Title: Gamma band oscillations to reveal neural network cortical coherence dysfunction in autism spectrum disorder

Authors: *K. HUANG[1,2], Y.-T. LIN[3], S. S. F. GAU[2,4];
[1]Natl. Taiwan Univ. Hosp., Taipei, Taiwan; [2]Grad. Inst. of Brain and Mind Sciences, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Psychiatry, Natl. Taiwan Univ. Hospital, Taipei, Taiwan, Taipei, Taiwan; [4]Dept. of Psychiatry, Natl. Taiwan Univ. Hospital, Taipei, Taiwan, Taipei, Taiwan, Taipei, Taiwan

Abstract: Objective: Autism spectrum disorder (ASD) is a neurodevelopment disorder involving γ-aminobutyric acid (GABA). Sensory abnormalities, particularly in the auditory modality, are commonly seen in individuals with ASD. Since GABA system plays a key role in generating neuronal gamma oscillations, this study aims to investigate whether ASD patients have impairments in gamma-band auditory steady-state response (ASSR) which is an auditory event-related potential. **Method**: Twenty-nine children and adolescents with ASD, and twenty-

eight typical developing (TD) children and adolescents were recruited. Subjects were presented three click trains with rates of stimulation at 20, 30 and 40 Hz, respectively. The ASSR was recorded through a 32-channel electrode cap. Single-electrode ERSP (Event-Related Spectral Perturbation) and ITC (Inter-Trial phase Coherence) indices were derived from the electroencephalogram (EEG) signals. **Results**: The ASD group showed higher ERSP power in the frontal and parieto-occipital region and smaller ITC in right temporal area, in response to 20 Hz click trains. Regarding 30 Hz click train stimulation, lower ERSP at electrode CP3 and smaller ITC at F4, T4, were observed in ASD group. The mean of ERSP to 40 Hz click train was higher at C4 and P4 in ASD group. **Conclusion**: These findings suggested different auditory responses to train stimulation in subjects with ASD. However, group differences in the gamma-band EEG responses were not that obvious. Larger sample is needed to better explore the ASSR in ASD subjects.

Title: An altered divisive normalization model of autism

Authors: *J. PATTERSON, A. ROSENBERG, D. ANGELAKI;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Autism is a neurodevelopmental disorder marked by a diverse set of symptoms including perceptual, social, and cognitive atypicalities. This heterogeneity presents a significant challenge to establishing a comprehensive characterization of the disorder. The widespread effect of the disorder on neural systems suggests that autism may broadly impact neural computations as opposed to isolated systems. As such, we hypothesize that alterations in canonical computations that occur throughout the brain may underlie the behavioral characteristics of autism. Here we focus on one computation in particular, divisive normalization, which balances a neuron's net excitation with inhibition reflecting the combined activity of a population of

neurons. Divisive normalization inherently reflects the ratio of neural excitation to inhibition, which is believed to be abnormally elevated in autism. In the present work, we show that an altered divisive normalization signal which elevates the excitatory/inhibitory ratio can account for perceptual findings in autism. Specifically, we develop a neural network model of primary visual cortex (V1) in which individual units are selective for stimulus location and orientation. An increased E/I ratio is simulated in the model by reducing the strength of the inhibitory divisive normalization signal reflecting the population activity. To examine how this alteration might give rise to perceptual autism symptomatology, we simulate two perceptual studies comparing the behavior of typically developing controls and individuals with autism on tasks that strongly engage V1. The first, a motion discrimination task employing stimuli of different sizes and contrasts, revealed reduced surround suppression and overall better discrimination performance in autism for high contrast stimuli, but equivalent performance across the groups at low contrasts. The second, a feature detection task investigating the facilitating effect of an attentional cue, reported a sharper gradient of attention in autism than in controls. Interestingly, we find that the results of both studies could be accounted for by the same alteration in divisive normalization. Our results suggest that the divisive normalization framework can provide novel insights into the neural basis autism and generate hypotheses that are readily testable by psychophysics experiments. In future work, it should be possible to adapt this framework to other sensory modalities as well as more complex operations such as facial processing which require hierarchical processing.

Title: Environmental and pharmacological intervention restores cognitive impairment in a mouse model of Down syndrome

Authors: *M. DIERSSEN, S. CATUARA;
CRG - Ctr. For Genomic Regulation, Barcelona, Spain

Abstract: Down syndrome (DS) is caused by trisomy of chromosome 21 (HSA21) leading to cognitive disability and high prevalence of Alzheimer-type dementia. Currently there is no effective therapy to improve learning and memory or to prevent/delay neurodegeneration later in life. Studies in a trisomic mouse model of DS (Ts65Dn) have indicated that environmental enrichment (EE), a housing condition that enhances social, sensorimotor and cognitive abilities, promotes neuroplasticity effects that can partially rescue cognitive impairments but the effects are limited and temporary. The dual specificity tyrosine-phosphorylation-regulated kinase 1A (Dyrk1A) has been postulated as a primary candidate gene located in chromosome 21 and implicated in multiple DS phenotypes. It encodes a serine-threonine kinase that phosphorylates critical substrates in neuroplasticity, cognitive function and neurodegeneration. We previously showed that Dyrk1A kinase levels and activity are normalized to wild type levels by EE in DS mouse models. Here we tested if the inhibition of Dyrk1A activity using (−)-Epigallocatechin-3-Gallate (EGCG), a potent Dyrk1A inhibitor, potentiates the effects of EE inTs65Dn mice in young animals and at older ages associated with the onset of neurodegeneration by analyzing the effect of a combined EGCG-EE intervention on the cognitive performance of Ts65Dn mice. Our results indicate that the combined use of EGCG-EE significantly improves visuo-spatial and recent memory, a cholinergic-dependent cognitive function in young and middle-age trisomic mice. The data indicate that combined use of EGCG-EE in trisomic mice potentiates the effects of EE, inducing different beneficial effects during lifetime.

Title: Deficits in a radial-arm maze spatial pattern separation task in a mouse model for Down syndrome

Authors: M. E. STRINGER[1], I. ABEYSEKERA[2], R. J. ROPER[2], *C. R. GOODLETT[3]; [1]Psychology, [2]Biol., [3]IUPUI, Indianapolis, IN

Abstract: Down syndrome (DS) is caused by three copies of human chromosome 21 (Hsa21) and results in a constellation of phenotypes including intellectual disability. Ts65Dn mice, the most extensively studied DS model, have three copies of ~50% of the genes on Hsa21 and display many phenotypes associated with DS, including cognitive deficits. DYRK1A is found in three copies in humans with Trisomy 21 and in Ts65Dn mice, and is involved in a number of critical pathways including CNS development and osteoclastogenesis. Epigallocatechin-3-gallate (EGCG), the main polyphenol in green tea, inhibits Dyrk1a activity. We have shown that a three-week EGCG treatment (~10mg/kg/day) during adolescence normalizes skeletal abnormalities in Ts65Dn mice, yet the same dose did not rescue deficits in the Morris water maze (MWM) or novel object recognition (NOR). In contrast, a higher EGCG dose (90mg/kg/day) was reported to improve performance on MWM and NOR in Ts65Dn mice. The current study investigated a spatial memory pattern separation task in Ts65Dn mice, a hippocampal-dependent task that requires differentiation between similar memories acquired during different learning episodes. Distinguishing between these similar memories is thought to depend on distinctive encoding in the hippocampus linked to functional activity of newly generated granule cells in the dentate gyrus. Given that recent studies in Ts65Dn mice have reported significant reductions in adult hippocampal neurogenesis, we hypothesized that Ts65Dn mice would be impaired in the pattern separation task, and that EGCG would alleviate the pattern separation deficits seen in trisomic mice in association with increased adult hippocampal neurogenesis. Mice were given EGCG (~100 mg/kg/day) or water beginning on postnatal day (PD) 24 and trained beginning on PD 75 on a radial-arm maze delayed non-matching-to-place pattern separation task that included three different degrees of spatial separation. Euploid mice performed significantly better over training than Ts65Dn mice, including better performance at each of the three separations. EGCG did not appear to alleviate the deficits in Ts65Dn mice. Assessment of adult neurogenesis in these mice is ongoing. This is the first study to show deficits in Ts65Dn mice on a pattern separation task. To the extent that pattern separation depends on the functional involvement of newly generated neurons in an adult dentate gyrus, this approach in Ts65Dn mice may help identify more targeted pharmacotherapies for cognitive deficits in individuals with DS. Supported by an IUPUI Research Support Funds Grant (to RJR and CRG) and Department of Psychology Internal Support Funds (CRG) from IUPUI.

Title: Delayed maturation of visual system in the mouse model of Down syndrome Ts65Dn

Authors: M. R. STASKO, D. B. VICTORINO, J. J. SCOTT-MCKEAN, B. L. ZAMPIERI, *A. C. COSTA;
Div. of Pediatric Neurology, Dept. of Pediatrics, Case Western Reserve Univ., Cleveland, OH

Abstract: Down syndrome (DS), which is caused by the trisomy of chromosome 21, is the most common genetically defined cause of intellectual disability. This genetic disorder also affects the visual system in a variety of ways, which include high incidence of refractive errors, accommodative inaccuracy, amblyopia, strabismus, nystagmus, abnormal oculomotor and vestibular functions, decreased visual acuity, and decreased color and contrast sensitivities. In a previous study (Scott-McKean et al., IOVS 51: 3300- 3308, 2010), we demonstrated that adult mice Ts65Dn (a murine model of DS) exhibit deficits in luminance threshold, spatial resolution, and contrast threshold, compared with euploid control mice, as assessed electrophysiologically by pattern visual evoked potentials. Here, we investigated visual thresholds of optokinetic tracking (OKT), a fundamental visual behavior that facilitates the relative stabilization of retinal images. Using the methods originally described in detail by Prusky el al. (IOVS 45:4611-4616, 2004), we were able to quantify OKT thresholds in untrained and freely moving Ts65Dn and control euploid mice, daily from eye opening (postnatal day 14) to 35 days of age, and then in longer intervals (5-10 days), until the animals were 60-day old. We found that Ts65Dn mice show a significant delay in the maturation of the visual system. Whereas the mean spatial frequency sensitivity to a 100% contrast grating projected on a virtual cylinder for 14-day old euploid control mice was 0.21 c/deg, the mean value of this measure was 0.08 c/deg for Ts65Dn mice. Ts65Dn mice were only able to achieve a mean spatial frequency sensitivity of 0.21 c/deg at 16 days of age. At age 45 days, the measured values of mean spatial frequency sensitivity were 0.45 and 0.43 c/deg for control euploid and Ts65Dn mice, respectively. The development of contrast sensitivity was also delayed in Ts65Dn mice. At 17 and 35 days of age, contrast sensitivity was 6% and 17% in Ts65Dn mice versus 9% and 26% in control mice, respectively. We are currently comparing these behavioral based findings with *in vivo* electrophysiological assessments by means of patterned visually evoked potentials. In addition, the integrity of the

visual path is being assessed through the investigation of potential lenticular and/or retinal lesions with a slit lamp imaging system and a retinal imaging microscope equipped with optical coherence tomography capabilities. The observed delay in the maturation of the visual system in a mouse model of DS mimics the qualitative features of the same phenomenon seen in young persons with DS.

Title: Spinal cord abnormalities in the Ts65Dn mouse model of Down syndrome

Authors: ***N. M. AZIZ**, J. L. OLMOS-SERRANO, T. F. HAYDAR;
Boston Univ. Sch. of Med., Boston, MA

Abstract: Individuals with Down syndrome (DS) are severely hypotonic at birth and exhibit disturbances in movement production and postural control during early postnatal development. As such, acquisition of motor skills is significantly delayed in DS patients, negatively impacting their gait and fine motor control throughout life. Work in our lab has for the first time elucidated substantial cytoarchitectural as well as gene expression abnormalities in spinal cords (SCs) of Ts65Dn mice. Because the full spectrum of SC deficits in DS is still unknown, the impact of trisomy on motor neurons (MNs), interneurons (INs), and oligodendrocytes (OLs) was analyzed both pre- and postnatally. Our qRT-PCR data show a 144.7±60% increase in expression of the homeodomain transcription factor *Hb9*, which is found in MNs and in a subset of INs, in postnatal day 60 (P60) Ts65Dn mice compared to euploids. This increase was accompanied by a 47.0±13% decrease in the expression of the IN-specific homeodomain transcription factor *Irx3*. Immunohistochemical (IHC) assessment of OL maturation in a spinal white matter tract showed enrichment in immature versus mature OLs at both P30 and P60. Upon further investigation of the white matter, we also found a decrease in the number of nodes of Ranvier at P30 in Ts65Dn mice compared to euploids. Concomitant with these gene expression and histological differences were profound deficits in hanging wire and hindlimb reflex performance in the Ts65Dn mice.

Along with the reported postnatal aberrations, prenatal abnormalities in gene expression were also detected at embryonic day 12.5 (E12.5) and E14.5 in SCs of Ts65Dn mice. This includes a 95.7±26% increase in expression of *oligodendrocyte transcription factor 2* (*Olig2*) and a 24.3±6% increase in *Hb9* expression at E12.5. Olig2+ cell numbers were also significantly increased in T65Dn SCs at this age. At E14.5, expression of *Hb9* and *Olig2* was normalized, yet expression of another patterning transcription factor known as *Nkx2.2* was decreased by 27.1±7% in SCs of trisomic animals. Collectively, our data show that population dynamics and gene expression in spinal MNs, INs and OLs are affected in both postnatal and embryonic Ts65Dn, suggesting that widespread and temporally unrestricted aberrations exist in trisomic SCs. Importantly, data also show that OL maturation and function are adversely impacted, pointing to a novel link between Down syndrome and improper myelination in the SC. These observed defects are accompanied by deficits in reflexive motor tasks such as the hanging wire and hindlimb reflex in Ts65Dn mice.

Title: Endogenous DNA damage and cellular death pathways in Down Syndrome

Authors: *A. PINTO[1], M. M. SERAFINI[1], C. LANNI[1], S. GOVONI[1], M. RACCHI[1], E. PROSPERI[2], D. NECCHI[1];
[1]Univ. of Pavia, Pavia, Italy; [2]Inst. of Mol. Genet. of the Natl. Res. Council, Pavia, Italy

Abstract: Background: Down syndrome (DS) is a genetic disease due to triplication of genes located on chromosome 21. DS phenotype is complex and includes mental retardation, increased incidence of congenital heart disease, hypothyroidism, leukemia and pulmonary hypertension. No single gene or region of human chromosome 21 is responsible for all common features of DS. More likely, interactions between various genes, their altered expression and other factors could better explain the major DS phenotypes and their severity. Moreover, Down syndrome is characterized by genetic instability, neurodegeneration and premature aging. However, the molecular mechanisms leading to this phenotype are not yet well understood. We observed that DS fibroblasts from both fetal and adult donors show the activation of a DNA damage response already during unperturbed growth conditions, as indicated by histone H2AX and

phosphorylation of checkpoint protein. Furthermore, increased levels of p53 protein in untreated DS fibroblasts were observed, although DNA damage was not investigated. Interestingly, we also found an altered conformational state of p53 in Ts65Dn brain, thus resulting in an impaired and dysfunctional response to stressors. **Objective:** To examine the transcriptional function of p53 in the context of neurological disorder and then the consequences of unfolded p53 on its activity in Down Syndrome. Our long-term goal is to elucidate the role of unfolded p53 in human brain disease progression. **Methodology:** Fetal and adult fibroblasts were used to understand whether DNA damage response activation was related to damage accumulation with age or to genetically inherited properties. To study alterations of cell death pathways induced by conformationally altered p53, we used Ts65Dn mouse model, the most investigated DS model with a triplicated segment of orthologous human chromosome 21. Considering the current notion that autophagy plays a critical role in multiple pathological lesions we focused our attention on p53-related autophagy pathways to better understand their involvement in the development of neurodegeneration in DS individuals. **Conclusions:** We have recently investigated the presence of endogenous DNA damage and a defective repair mechanism in fetal and adult DS fibroblasts that could contribute to genome instability in Down Syndrome. Furthermore, animal DS model shows a conformational altered status of p53, a key mediator of the DNA damage response. As a consequence, p53 is not able to induce the expression of a group of target genes involved in several pathways to maintain genome stability in response to stress signals, thus contributing to the system dysfunction.

Title: Microarray analysis of entorhinal cortex stellate cells in the Ts65Dn mouse model of Down syndrome and Alzheimer's disease following maternal choline supplementation (MCS)

Authors: *H. M. CHAO[1], M. J. ALLDRED[2,5], S. LEE[3], E. PETKOVA[4,6], S. D. GINSBERG[2,5,7];
[2]Ctr. for Dementia Res., [3]Med. Physics, [4]Child Psychiatry, [1]Nathan Kline Inst., Orangeburg, NY; [5]Psychiatry, [6]Child & Adolescent Psychiatry, [7]Neurosci. & Physiol., New York Univ. Langone Med. Ctr., New York, NY

Abstract: Down syndrome, caused by trisomy of chromosome 21, is characterized by physical and cognitive impairments, and by early presentation of Alzheimer's disease (AD) pathology. The trisomic Ts65Dn mouse model of Down syndrome (DS) and AD exhibits many key phenotypes of the disorder including learning and memory deficits and basal forebrain cholinergic neuron (BFCN) degeneration. Choline is an essential nutrient required for proper central nervous system development of the fetus, and maternal choline supplementation (MCS) has been shown to be beneficial to both normal disomic (2N) and trisomic (Ts65Dn) offspring with regard to adult hippocampal neurogenesis and performance on attentional and cognitive tasks. The entorhinal cortex, as a gateway to and from the hippocampus, has an essential role in executive function and memory, and has been shown to be particularly vulnerable in aging, DS, and Alzheimer's disease (AD).In the present study we utilize custom-designed microarrays with subsequent Nanostring nCounter and qPCR validation to investigate entorhinal cortex gene expression from layer II/III stellate cells in Ts65Dn and 2N littermates. Specifically, offspring from both choline supplemented dams (~4 times the normal dietary intake of choline) and normal choline fed dams were analyzed at 5-7 months of age.. Briefly, individual stellate cells were microaspirated via laser capture microdissection (LCM) and then subjected to terminal continuation (TC) RNA amplification and analysis on a custom-designed microarray platform with ~576 genes relevant to neurodegeneration and neuroscience. Validation via Nanostring nCounter and qPCR is performed on regional dissections of the entorhinal cortex from Ts65Dn and 2N littermates obtained from dams either treated with MCS or unsupplemented maternal choline (UMC) from pregnancy until weaning. Preliminary results display significant expression level differences based on genotype as well as by maternal diet. Classes of transcripts that show preliminary regulation by MCS include neurotrophins and neurotrophin receptors, synaptic-related markers, and protein phosphatases and kinases. In summary, these datasets will allow us to delineate expression changes associated with the Ts65Dn mouse model and to determine whether they can be mitigated by MCS. In addition, these findings will be compared to the previously reported patterns of gene expression in hippocampal CA1 pyramidal neurons as well as compared and contrasted to molecular fingerprints obtained from human postmortem brain tissues from subjects with DS and AD (along with age-matched non-demented controls) to assess potential translational targets.

Title: Hippocampal network activity in a mouse model for Down syndrome

Authors: *G. J. LEVENGA[1,2], M. ROCHE[2], H. WONG[2], P. CAIN[2], C. A. HOEFFER[2,3]; [1]Dept. of Integrated Physiol., Univ. of Colorado Boulder, Boulder, CO; [2]Inst. for Behavioral Genet., Boulder, CO; [3]Dept. of Integrated Physiol., Boulder, CO

Abstract: Down syndrome (DS), also known as trisomy 21, is a genetic disorder caused by the presence of all or part of a third copy of chromosome 21. Because of better education and improved health care, people with DS are living longer. With this increase in lifespan, it was found that people with DS develop symptoms consistent with early onset Alzheimer's disease (AD). Both AD and DS comorbid with abnormal EEG activity and seizures. In DS, seizures seem to peak at two ages; the first peak occurs in the first two years of age, while the second peak occurs during adulthood. The second peak may be connected with the symptoms of AD. One gene that is located on chromosome 21 called Regulator of Calcineurin 1 (RCAN1) may be involved in the development of hyperexcitability and other accelerated aging symptoms, such as oxidative stress and mitochondrial dysfunction. The goal of our research is to test the hypothesis that a) a mouse model of DS develops epilepsy during aging and b) RCAN1 is involved in DS/AD-related aging phenotypes and hyperexcitability. We use two different transgenic mouse models: Dp161Yey (Dp16) mice and RCAN1TG mice. Dp16 mice have a direct duplication of the entire Mmu16 region that is conserved in HSA21 and RCAN1TG mice only overexpress RCAN1 in excitatory neurons in the brain. To measure network excitability from freely behaving mice, we implanted electrodes in the hippocampus to measure local field potentials (LFPs). We

expect that young Dp16 mice have increased power in gamma frequencies due to excessive inhibition by the GABAergic circuit reported in DS model mice, while spiking frequency may be reduced. This phenotype might reverse in aged Dp16 mice where we expect to find increased hyperexcitability. Since RCAN1 is a major calcineurin (CaN) regulator and CaN KO mice show enhanced gamma frequency, we expect that RCAN1TG mice have similar phenotypes to Dp16 mice. In addition, we expect to find spontaneous epileptic events in aged Dp16 and RCAN1TG mice. This work will be important to better understand circuit dysfunction during aging in Down syndrome.

Title: Effects of monoacylglycerol lipase inhibitor JZL184 on adult neurogenesis in Ts65Dn mice, a model of Down syndrome

Authors: D. FOZOONMAYEH, M. SAWA, J. YU, A. BECKER, *A. M. KLESCHEVNIKOV;
Neurosciences, Univ. of California San Diego, La Jolla, CA

Abstract: Down syndrome (DS) is a developmental genetic disorder characterized by profound cognitive impairment. It was previously shown that one of the causes likely contributing to cognitive impairment in DS is impaired adult neurogenesis. Monoacylglycerol lipase (MAGL) is the key catabolic enzyme of endocannabinoid 2-arachidonoylglycerol (2-AG). Recently we observed that chronic treatment of Ts65Dn mice, a genetic model of DS, with the selective MAGL inhibitor JZL184 increased brain levels of 2-AG and improved hippocampal synaptic

plasticity and cognition. We hypothesized that one possible mechanism by which JZL184-treatment improved synaptic plasticity and cognition is through a restoration of adult neurogenesis. Here we examined the effects of chronic JZL184- treatment of Ts65Dn mice and their littermate WT controls on properties of adult neurogenesis in the dentate gyrus. Adult (8 mo old) male mice were injected with JZL184 (i.p., 8 mg/kg) once a day for 19 days. BrdU was injected once a day for 3 days (i.p., 100 mg/kg) during the chronic phase (days 12-14) of the JZL184 treatment. The brains were collected for immunohistochemistry 6 days after the last BrdU injection. In the vehicle-treated animals, density of BrdU-positive cells was almost three times lower in the Ts65Dn vs. WT mice (WT Veh: 100 ± 36%, Ts65Dn Veh: 33.4 ± 13.1 %). Treatment with JZL184 increased the density of BrdU-positive cells in Ts65Dn mice, but reduced it in WT controls. Expressed in percentage points of the corresponding vehicle-treated controls, the densities of BrdU-positive cells were significantly increased in the JZL184-treated Ts65Dn mice (WT JZL: 45.9 ± 10.3%; Ts65Dn JZL: 143.0 ± 14.1 %, $t(4) = 6.8$, $p = 0.001$). These data show that chronic MAGL inhibition improves neurogenesis in Ts65Dn, but impairs it in WT mice. Thus, restoration of the adult neurogenesis could underlie the improvement of synaptic plasticity and learning in JZL184-treated Ts65Dn mice. This result suggests that chronic MAGL inhibition should be considered as a potential approach for improvement of cognitive impairment in Down syndrome.

Ctr., Chicago, IL

Abstract: Persons with Down syndrome (DS) have intellectual disability and develop Alzheimer's disease (AD) neuropathology in early midlife. Currently, there are no effective treatments for DS or AD. A potential therapeutic strategy is dietary maternal choline supplementation (MCS). The Ts65Dn mouse model recapitulates key features of DS/AD, including cognitive dysfunction and basal forebrain cholinergic neuron (BFCN) degeneration, enabling mechanistic assessments that may be translated to humans. BFCNs are responsive to target-derived neurotrophic support from the hippocampus and neocortex, and MCS is posited to increase levels of nerve growth factor (NGF) and/or brain-derived neurotrophic factor (BDNF) and optimize their respective signaling pathways, which may underlie behavioral benefits seen in offspring from MCS treated dams. We hypothesize that MCS attenuates select neurotrophin and/or neurotrophin receptor changes associated with DS/AD. Here we evaluated homogenates of hippocampal and frontal cortex tissue obtained from offspring from MCS or choline unsupplemented mothers at 12-16 months of age. Immunoblot analysis was performed using antibodies directed against neurotrophins, including proNGF, proBDNF, and mature BDNF, as well as neurotrophin receptors including cognate NGF receptor TrkA, cognate BDNF receptor TrkB, cognate neurotrophin-3 (NTF3) receptor TrkC, and the pan-neurotrophin receptor p75NTR. Preliminary immunoblot analysis indicates a significant effect of maternal diet on offspring expression of proNGF and p75NTR in both hippocampus and frontal cortex. Specifically, MCS upregulates proNGF and p75NTR expression in both regions independent of genotype. Moreover, preliminary results indicate that TrkA expression is downregulated in Ts65Dn cortex compared to 2N littermates, and that MCS increases TrkA expression independent of genotype. These data suggest that MCS primes the brain of adult offspring for increased neurotrophic signaling, both through presumed pro-survival as well as pro-apoptotic pathways, effectively increasing the dynamic range of neurotrophic activity in the forebrain. Ongoing assessments of BDNF & TrkB and NTF3 & TrkC are predicted to show that MCS has a significant effect on the expression of these neurotrophic pathways as well. By understanding mechanisms underlying the beneficial effects of MCS, we may be able to increase the potential for translation to humans, and alterations in neurotrophic support from hippocampus and neocortex may be key areas for intervention in DS and AD.

Title: Lingual and laryngeal myosin heavy chain isoform characterization of the Ts65Dn mouse model of Down syndrome

Authors: ***T. J. GLASS**, N. P. CONNOR;
Surgery, Univ. of Wisconsin, Madison, WI

Abstract: Down syndrome is associated with a high incidence of impairment in vocal communication, feeding, and swallowing. The etiologies of these dysfunctions are unclear. The Ts65Dn mouse model was used to address the hypothesis that alterations in neuromuscular phenotypes underlie behavioral deficits in these critical cranial functions. Lingual and laryngeal muscles were isolated and analyzed by SDS-PAGE to quantify relative myosin heavy chain (MyHC) isoform composition. The following muscles were assayed: genioglossus (a tongue protrusor), sternohyoid (involved in maintaining airway patency), and anterior and posterior digastric (involved in jaw movement and positioning of the hyoid bone). Ts65Dn mice showed significant relative reduction in MyHC 2b in the digastric muscles ($n = 10$ adult mice per group, $p = .03$). Because relative MyHC 2b levels in the murine digastric muscles are known to increase following the developmental transition from weaning to mastication, studies are underway to assess digastric MyHC 2b levels at multiple points during post-natal development and to quantify functional mastication rates. Characterization of neuromuscular junctions in muscles pertinent to lingual and airway functions has also been initiated. In future work, analysis of the developmental trajectory of MyHC isoform changes in conjunction with analysis of neuromuscular junctions in the muscles of vocalization, mastication, and swallowing in Down syndrome mouse models may assist in a better understanding of the etiologies of vocal communication and feeding impairments associated with this syndrome.

Title: Absence of Down syndrome-related prenatal phenotypes in the Dp(16)1Yey/+ mouse model of Down syndrome

Authors: ***J. GOODLIFFE**, T. F. HAYDAR;
Boston Univ. Sch. of Med., Boston, MA

Abstract: Down syndrome (DS) is the most common genetic intellectual disorder and results in malformations of the central nervous system. Fetal studies have reported aberrations in brain developmental including microcephaly and altered cortical lamination. Several mouse models of DS have recapitulated these phenotypes as well as establishing further abnormalities in critical events including neurogenesis and neuronal differentiation. A recently developed model, the Dp(16)1Yey/+ or Dp16, has the largest triplication of the human chromosome 21 (Hsa-21) homologous region located to mouse chromosome 16 (Mmu16) and may better represent DS pathologies. To date, Dp16 studies have focused on adult behavioral, cerebellar and craniofacial abnormalities that mirror other mouse models of DS. Here, we present the first comprehensive study on Dp16 prenatal brain development. Despite the presence of adult phenotypes, our study shows that all measured parameters of Dp16 forebrain development are unchanged from euploid mice. Specifically, several phenotypes previously reported in human fetal neocortex and in the developing forebrains of other mouse models such as microcephaly, altered cortical lamination, reduced neurogenesis, progenitor population abnormalities and abnormal mitotic activity are not present in Dp16. This striking absence of DS-related phenotypes confounds the use of this model for embryonic studies and highlights the differences apparent in segmental models of trisomy 21. Data from this study isolate temporal periods belying observed deficits in the DS brain and for first time show that deficits in embryonic neurogenesis are not necessary for the manifestation of cognitive abnormalities in a mouse model of DS. Title: Mechanism of synaptic vesicle exocytosis in neuronal cell lines derived from the cerebral cortex of and trisomy 16 fetal mouse, an animal model of Down syndrome: Regulation by cortical actin

Authors: J. VASQUEZ[1], A. CARDENAS[1], *P. A. CAVIEDES[2];
[1]Ctr. Interdisciplinario de Neurociencia de Valparaíso, Univ. de Valparaiso, Valparaiso, Chile;
[2]ICBM Fac Medicine, Univ. of Chile, Santiago, Chile

Abstract: Down Syndrome (DS) in man is produced by an extra copy of chromosome 21, and constitutes the most frequent cause of mental retardation for known genetic reasons. The trisomy 16 mouse is an animal model of DS, yet the condition is lethal in such animals, and they do not survive gestation. We have therefore generated cell lines from the cerebral cortex of a fetal Ts16 mouse (named CTb), and a normal littermate (named CNh), to use as control. Cultured brain neurons from TS16 fetuses, as well as the CTb cells, show a decrease in fractional release of [3H]-acetylcholine; compared to normal euploid controls. Therefore, we have explored the possibility that an alteration in the exocytosis of secretory organelles may be responsible for the decrease in acetylcholine (Ach) release. To evaluate this possibility, we used total internal reflection fluorescence microscopy (TIRF) to monitor exocytosis events in cultured CTb and CNh cells transfected with pHluorin fused to the vesicular acetylcholine transporter (VChAT). Our results reveal that, in resting conditions, CNh and CTb cells exhibit 5.6 ± 1.1 (n=37) and 10.1 ± 1.9 (n=26) exocytotic events in 3 min of recording, with fluorescence decay kinetics expressed in time constant values (τ) of 1.5 ± 0.2 and 1.9 ± 0.3 s respectively. The number of events significantly increase in cells stimulated with the Ca+2 ionophore ionomycin (20 μM), being such increment significantly lower in the CTb cells (22.7 ± 3.2, n=8) compared to CNh cells (39.4 ± 4.5, n= 10n= 8; $p<0.05$), while the decay kinetics decelerate similarly in both cell lines (τ of 2.0 ± 0.2 and 2.7 ± 0.3 s for CNh and CTb cells, respectively). Further, τ values increase when the cells are treated with 100 mM HEPES or 100 mM bafilomycin A1 (a vesicular ATPase inhibitor). Both agents delay vesicle acidification after closure of the fusion pore, yet they do not affect vesicles that fuse with the plasma membrane. Therefore, these results suggest that the main mechanism for release of vesicle content in these cell lines is a “kiss and run” type

exocytosis. On the other hand, after evaluating the role of the cytoskeleton in the exocytosis kinetics, we observed that the fluorescence decay kinetics is retarded in cells treated with the inhibitors of actin polymerization wiskostatin or cytochalasin D. Taken together, these results indicate that both cell lines release their vesicular content via a " kiss and run " mechanism that is highly regulated by the cortical actin cytoskeleton. The CTb cell line could represent an adequate model to study secretion impairments related to DS pathophysiology.

Title: Ts65Dn mice exhibit rapid forgetting in the social transmission of food preferences task: Further evidence for impaired hippocampal function

Authors: *N. A. SANTIAGO, S. E. KIM, B. E. POWERS, B. J. STRUPP;
Cornell Univ., Ithaca, NY

Abstract: Down syndrome (DS) is the most common genetic cause of intellectual disability, estimated to affect 1 in 690 live births. Individuals with DS also generally develop Alzheimer's disease (AD) pathology early in life, often including dementia. The Ts65Dn mouse model of DS recapitulates many of the hallmark characteristics of human DS, notably including cognitive dysfunction. Recent studies in our lab have demonstrated that increased maternal intake of choline during pregnancy and lactation in this mouse model significantly reduces cognitive dysfunction, increases hippocampal neurogenesis, and offers protection to cholinergic basal forebrain neurons. Prior to conducting additional experiments to further delineate the nature of the benefit offered by maternal choline supplementation in this model of DS, our goal was to first demonstrate impaired hippocampal function in these mice using a sensitive test of hippocampal function that does not involve food restriction or stress, factors which complicate

interpretation of observed performance impairment of this mouse model. One task with these characteristics is the Social Transmission of Food Preference Task. This task models the natural tendency of rodents to learn about the safety of novel foods through social interaction and has been shown to be sensitive to hippocampal dysfunction. In our first study, a 1 day memory retention interval was used, whereas our second study utilized a 7 day retention test. In the first study it was found that both genotypes exhibited strong social learning and recall one day later ($P< 0.001$). The trisomic mice did not significantly differ from their wildtype counterparts ($P= 0.417$). However, when a 7 day retention interval was used in the second study, group differences were uncovered. The mice overall demonstrated significant social learning and memory ($P= 0.0001$) with the interaction of social learning and genotype being borderline significant ($P= 0.06$), suggesting that the magnitude of the social learning effect varied by genotype. A very strong social learning effect was seen for the 2N mice ($P= 0.0001$), whereas it was not significant for the trisomics, indicating more rapid forgetting of the socially transmitted information. These results have laid the groundwork for using this task in future studies to test whether maternal choline supplementation will alleviate the impairment in hippocampal-dependent explicit memory seen in DS, and gain greater insight into underlying neural and epigenetic mechanisms.

Title: Elucidating the role of metals in the Down syndrome brain

Authors: *N. MALAKOOTI[1,2,3], M. A. PRITCHARD[2], R. C. KIM[3], I. T. LOTT[3], I. VOLITAKAS[1], B. R. ROBERTS[1], D. I. FINKELSTEIN[1], P. A. ADLARD[1];

Abstract: Introduction: Down syndrome (DS) is the most common intellectual disability, with an incidence of 1 in 700 births and is caused by whole or partial trisomy of chromosome 21. All people with DS develop Alzheimer's disease (AD) like neuropathology by the age of 40. One of

the characteristics of AD is dyshomeostasis of metals in brain. Aim: Since one of the characteristics of AD is dyshomeostasis of metals in brain, we tested whether metal homeostasis was also altered in the DS brain. Method: We measured metal levels in the hippocampus, prefrontal and temporal cortices in nineteen post mortem DS brains (55.9 ± 7.2 years of age) and seven control brains (54.2± 3.07 years of age) by inductively coupled plasma mass spectrometry (ICPMS). Result: Iron levels were significantly higher and calcium levels were significantly lower in the hippocampus, prefrontal and temporal cortex in DS. Zinc levels were significantly lower in DS temporal cortex. Conclusion: These data suggest that metals are dysregulated in DS, The underlying cellular mechanisms of this failure in metal ion homeostasis remain to be explored and further interrogation of these samples with liquid chromatography ICPMS is currently underway to further characterize the metalloproteome in the DS brain.

Title: Canonical wnt signalling alterations correlate with hsa21 trisomy and the kinase activity of dyrk1a

Authors: *S. GRANNO[1], D. BERWICK[2], F. WISEMAN[3], V. PLAGNOL[4], M. ZANDA[4], V. TYBULEWICZ[5], E. FISHER[3], K. HARVEY[2];
[1]Sch. of Pharm. / Inst. of Neurol., [2]Sch. of Pharm., [3]Inst. of Neurol., [4]Genet. Inst., UCL, London, United Kingdom; [5]Francis Crick Inst., London, United Kingdom

Abstract: Down syndrome (DS), the most common human aneuploid disorder, is caused by trisomy of chromosome 21 (Hsa21). Recurring features include distinct morphological abnormalities and intellectual disability. In DS, overexpression of the Hsa21 gene dual specificity tyrosine-(Y)-phosphorylation regulated kinase 1A (DYRK1A) is inextricably linked to the DS phenotype, as well as the nearly universal development of an early onset form of Alzheimer's disease (AD). The Wnt pathway is a highly conserved signalling cascade involved in transcriptional regulation of genes with recognised roles in cancer, stem cell differentiation

and neurogenesis. In recent years, aberrant Wnt signalling has been linked to development of AD. Several studies indicate that stabilisation of this signalling pathway may prevent Aβ-mediated neurotoxicity, while its disruption has been found to exert negative effects on synaptic assembly and function. Here, we seek to determine the role of Wnt signalling in the development of DS, combining studies in cell and animal model systems. Because of its documented interaction with the Wnt inhibitor GSK3β, we selected DYRK1A for primary investigation. In a neuroblastoma cell line (SH-SY5Y), we demonstrate DYRK1A's role as a Wnt signalling modulator through inhibition and overexpression studies. Furthermore, we show that DYRK1A overexpression leads to a significant alteration in protein amount of key Wnt signalling components. Taken together, these data suggest a novel modulatory role of DYRK1A on canonical Wnt signalling activity. Concurrently, our *ex vivo* studies on the Tc1 mouse model of DS seek to profile Wnt signalling in the DS cerebral cor-tex and hippocampus. Our results indicate that the Tc1 hippocampus and cortex display significant changes in expression levels of Wnt agonists, antagonists and negative modulators. Some of these are reportedly involved in hippocampal development and adult neurogenesis. Taken together, these results suggest an overall imbalance in canonical Wnt signalling in the Tc1 mouse model. Overall, our data indicate that aberrant Wnt signalling may significantly correlate with Hsa21 trisomy, both through DYRK1A-mediated modulation and changes in Wnt signaling component expression and activation levels. For the first time, Wnt signalling may be established as a key contributor to DS, opening new avenues for therapeutic strategies aimed at restoring physiological Wnt signaling function.

Title: Maternal choline supplementation (MCS) alters CA1 pyramidal neuron gene expression in adult Ts65Dn and normal disomic (2N) offspring

Authors: *M. J. ALLDRED[1,4], S. LEE[2], E. PETKOVA[3,5], S. D. GINSBERG[1,4,6];
[1]Ctr. for Dementia Res., [2]Med. Physics, [3]Child Psychiatry, Nathan Kline Inst., Orangeburg, NY;
[4]Psychiatry, [5]Child & Adolescent Psychiatry, [6]Neurosci. & Physiol., New York Univ. Langone Med. Ctr., New York, NY

Abstract: Down syndrome (DS) is the most frequent genetic cause of intellectual disability (ID). Individuals with DS have decreased cognitive function seen by impairments in hippocampal learning and memory, degeneration of cholinergic basal forebrain neurons (BFCNs), and language and communication skills. In addition to abnormal CNS function during development and adult life, individuals with DS develop Alzheimer's disease (AD) neuropathological hallmarks early in mid-life, including senile plaques, neurofibrillary tangles, and early endosomal abnormalities. To examine gene expression changes associated with DS/AD and test a putative treatment paradigm, we are using the Ts65Dn mouse model. Ts65Dn mice recapitulate several critical components of DS/AD, including cognitive dysfunction and BFCN degeneration, providing mechanistic assessments for translation to humans. We tested a maternal choline supplementation (MCS) dietary paradigm and examined Ts65Dn and normal disomic (2N) offspring at the start of the BFCN degeneration (after ~4 months of age), postulating that MCS will improve cognition and could delay the septohippocampal degeneration seen in Ts65Dn mice, specifically by assessing CA1 pyramidal neurons. We tested whether MCS treatment could ameliorate some of the gene expression deficits found in Ts65Dn mice within the BFCN pathway and track pathways that may elucidate the underpinnings of cognitive decline and AD pathology. Microarray results on a custom-designed platform indicate that MCS produces significant gene expression level changes compared to age-matched unsupplemented maternal choline (UMC) offspring in CA1 pyramidal neurons both independent and dependent of genotype, which is confirmed by Nanostring nCounter and/or qPCR analysis. Specifically, alterations in several classes of transcripts including both glutamatergic neurotransmission and neurotrophin receptor activity, along with AD-related genes and synaptic-related markers were observed in Ts65Dn and 2N littermates. Preliminary genes that are MCS sensitive include App, Syp, Sod2, Ntf5, and Slc6a13. Comparing MCS offspring to UMC offspring in Ts65Dn and 2N littermates will help to elucidate specific genes and signaling pathways that may be responsive to this early intervention. Moreover, these mechanistic studies may help elucidate the link between choline requirements and cognitive development. This approach also has translational viability as a low cost, non-invasive method of cognitive improvement for DS, as well as having a generalized neuroprotective effect that could delay the onset and development of AD and related neurodegenerative disorders.

Title: Netrin-1 induces local translation of Down syndrome cell adhesion molecule in axonal growth cones

Authors: S. JAIN[1], *K. WELSHHANS[2];
[1]Dept of Biol. Sci., [2]Dept of Biol. Sci. & Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: Down syndrome cell adhesion molecule (DSCAM) is known to play an important role in many neurodevelopmental processes such as axon guidance, dendrite arborization and synapse formation. *DSCAM* is located in the Down syndrome trisomic region of human chromosome 21 and implicated as one of the genes directly contributing to the Down syndrome brain phenotype, which includes a reduction in the formation of long-distance connectivity. Here, we find that overexpression of DSCAM in mouse cortical pyramidal neurons results in a decrease in axon outgrowth and branching. This finding directly implicates DSCAM as a contributor to the formation of improper neuronal connectivity in Down syndrome. Thus, it is of significant interest to understand the underlying molecular mechanisms by which *Dscam* regulates axon pathfinding. The local translation of a select group of mRNA transcripts within growth cones is necessary for the formation of appropriate neuronal connectivity. We have found that *Dscam* mRNA is localized to growth cones of C57BL/6J mouse hippocampal pyramidal neurons. Localization of *Dscam* mRNA to growth cones is dynamically regulated in response to the axon guidance molecule, netrin-1. Furthermore, netrin-1 stimulation results in an increase in locally translated DSCAM protein in growth cones. Interestingly, deleted in colorectal cancer (DCC), a netrin-1 receptor, is required for the netrin-1 induced increase in *Dscam* mRNA local translation. Locally translated mRNAs are transported in a translationally dormant state as a part of a ribonucleoprotein complex. We find that two RNA binding proteins, fragile X mental retardation protein (FMRP) and cytoplasmic polyadenylation element binding protein (CPEB), colocalize with *Dscam* mRNA in growth cones, suggesting their regulation of *Dscam* mRNA localization and translation. We are also examining these processes in a mouse model of Down syndrome (Ts65Dn), and have found that the formation of appropriate interhemispheric connectivity during

development is disrupted. Furthermore, the localization and local translation of *Dscam* mRNA in early postnatal neuronal growth cones from Down syndrome mice is also dysregulated. Taken together, these results have implications for Down syndrome, because dysregulated local translation of *Dscam* during embryonic development may contribute to inappropriate neural connectivity and the etiology of this neurodevelopmental disorder.

Title: A novel neurosteroid improves specific phenotypes of the Angelman Syndrome mouse model

Authors: *S. L. BLANKENSHIP[1], J. GRIECO[2], M. ROGAWSKI[3], E. WEEBER[2];
[1]Mol. Pharmacol. & Physiol., Univ. of South Florida Morsani Col. of Med., Tampa, FL; [2]Pharmacol. & Physiol., Univ. of South Florida, Tampa, FL; [3]Neurol., Univ. California, Davis, Davis, CA

Abstract: Angelman Syndrome (AS) is a devastating neurological disorder for which there is no cure. AS presents with ataxia, frequent smiling and laughter, lack of speech, and severe, debilitating seizures that occur in >90% of the AS population. Epilepsy in AS is often refractory to many prescribed medications, and chronic, intractable epilepsy is shown to cause hippocampal damage and is associated with cognitive decline. The severity of seizures and lack of consistently effective anti-epileptic medications for AS patients demonstrates a considerable need for other therapeutic options. Decreases in GABAergic tone and cognition have been observed in the AS mouse model; the use of a GABA agonist lacking significant motor and memory-related side effects may dampen overall neuronal excitability and increase the signal-to-noise ratio in various areas of the brain, which could positively affect the motor, learning, and memory phenotypes. Thus, we examined a novel therapeutic strategy for seizures in AS: a novel neurosteroid with enhanced bioavailability. Ganaxolone, a partial agonist and positive allosteric modulator of GABAA receptors, is a novel synthetic analog of allopregnanolone, an endogenous neurosteroid. This drug has demonstrated success in clinical trials for complex partial seizures and pediatric

epilepsy with limited side effects. Therefore, we hypothesize that Ganaxolone will decrease seizure frequency, increase seizure threshold, and will improve hippocampal-dependent cognition and motor learning deficiencies seen in Ube3a-deficient mice. These mice were implanted with subcutaneous osmotic pumps for either 3 days or 4 weeks in order to evaluate both short- and long-term effects. We report that Ganaxolone improves specific phenotypes in the AS mouse model, and should be investigated further as a potential non-toxic therapy for individuals diagnosed with AS.

Title: Exploring alternative diffusion tensor measures to study atypical development in 22q11.2 deletion syndrome

Authors: *J. VILLALON REINA[1], J. GALVIS[1], C. CORBIN[1], T. NIR[1], L. KUSHAN[2], P. M. THOMPSON[1], C. BEARDEN[2];
[1]Neurol., Imaging Genet. Ctr., Marina Del Rey, CA; [2]Semel Inst. for Neurosci. and Human Behavior, Dept. of Psychiatry and Biobehavioral Sci., Los Angeles, CA

Abstract: Diffusion-weighted MRI (dMRI) is a widely used tool to study brain disease and can describe alterations in white matter microstructure in typical and atypical development. Fractional anisotropy (FA) is a standard dMRI-derived measure sensitive to disrupted white matter microstructure in neurodevelopmental disorders such as 22q11.2 deletion syndrome (22qDS). Many studies report higher FA in several brain regions in adolescents and children with 22qDS, relative to typically developing controls. Most studies of 22qDS patients acquire MRI scans with low angular resolution and lower b-values, which constrain the analysis to measures derived from Diffusion Tensor Imaging (DTI). We used alternative DTI derived metrics to further describe the microstructure of the areas with higher FA in 22qDS. We compared adolescents with 22qDS to typically developing control subjects (56 patients with molecularly confirmed 22q11.2 deletions; mean age=14.96 years, M/F 28/28, 52 controls; mean

age=12.33 years, M/F 31/21). MRI parameters were: 64 gradient directions, one shell of b=1000 s/mm2. Besides FA and mean diffusivity (MD), we also computed mode, linearity, sphericity, and planarity. These describe the geometry of the tensor providing an indirect measure the white matter architecture such as high dispersion of fibers vs. unidirectional single fiber compartments. We compared the two groups with a standard voxel-wise analysis. FA was higher in 22q in the body, isthmus and genu of the corpus callosum (CC) and in the corticospinal tract (CS), particularly on the left side. In the CC, the 22qDS group had higher linearity, lower sphericity and lower MD. In the CS, we found higher mode and lower planarity in the 22qDS group. In both the CC and CS, the tensors had a more elongated shape in 22q versus controls, so the higher FA may imply a less complex white matter architecture. Higher MD has been associated with changes in the extracellular space such as glial cell rearrangements. Even though DTI reconstructions with lower b-values cannot readily distinguish between extra- and intracellular compartments, Gaussianity is characteristic of the extracellular component of diffusion as is assumed in DTI. The higher FA in 22qDS may be caused by lower neurite density with a surrounding highly organized glial architecture along the main axis of the axonal pathways. More studies are required to distinguish between pathological changes of glial and axonal components, which may be facilitated by acquisitions with multiple diffusion-sensitive shells.

Abstract: Background – Angelman Syndrome (AS) is a neurodevelopmental disorder caused by deletions in the chromosomal region 15q11-13. This region is susceptible to genetic imprinting, and therefore maternal and paternal deletions have differing affects, with a maternal deletion causing AS and a paternal deletion causing Prader-Willi Syndrome. Maternal loss of function in the gene *UBE3A*, which is found within 15q11-13, is sufficient to cause AS. *Ube3a*(p+/m-) mice have been previously investigated to study AS, and these studies have reported motor deficits and learning impairments. **Objectives** – The purpose of this study is to use MRI and several behavioural assays to investigate the neuroanatomical phenotype and how it relates to the behavioural phenotype in *Ube3a* (p+/m-) mice. **Methods** – In total 39 mice were assessed,18 mice were *Ube3a*(p+/m-) (10M and 8F) and 21 were wild-type (WT) (11M and 10F). Imaging was performed using a 7T MRI with a T2 weighted, 3D fast spin echo sequence which acquires data at an isotropic resolution of 56 μm (Lerch et al. 2011). Using image registration the brains were aligned, and the volumes of 62 different regions (Dorr et al. 2008) were calculated. Multiple comparisons were controlled using False Discovery Rate (FDR, Genovese et al. 2002). Prior to the *ex vivo* imaging the same group of mice were behaviourally tested. This testing consisted of measuring the righting reflex (at P4-6), USV recordings (P7), eye opening (P10-16), open field (P17), sociability (3 chamber task, P24), self-grooming (P25), and social interaction (P27). At P28 mice were perfusion fixed and prepared for ex-vivo imaging. **Results and Discussion** – For the full group of mice 17 regions were found to be smaller at an FDR of <5% (23 at FDR <15%). The female mice, however, drove those differences, where 17 regions were found to be smaller (FDR <15%). No differences found in the males. Figure 1 shows several coronal slices highlighting the significant voxel-wise differences for the full group. For the behavioural assays of the *Ube3a* mice, no differences found in righting reflex or weight, but there was a delay in eye-opening in both sexes. There was an increase in USV call duration in males as well as differences in call profiles in both sexes. At P17, males had decreased activity, whereas females were not different. Social and grooming behaviours were not different for either sex. **Conclusions** – Interestingly, sex differences were found in both the neuroanatomy and behaviour, but they seem to be inconsistent as the female neuroanatomy and the male behaviour were found to be more abnormal. Future investigation will examine any correlations between the neuroimaging and behaviour.

Title: Role of Arc in plasticity deficits associated with Angelman syndrome

Authors: *E. D. PASTUZYN, J. D. SHEPHERD;
Neurobio. and Anat., Univ. of Utah, Salt Lake City, UT

Abstract: Angelman syndrome is an autism spectrum disorder that is caused by deletion of the maternal allele of the *UBE3A* gene, resulting in a lack of Ube3A protein in the brain. Previous studies have suggested that the neuronal protein Arc is a putative target of Ube3A ligase activity. Arc is an immediate-early gene that is rapidly transcribed in response to neuronal activity and is translated locally at synapses. Arc protein is critical for memory consolidation and multiple forms of synaptic plasticity via trafficking of AMPA receptors at the postsynaptic membrane. Arc levels are increased in the mouse model of Angelman syndrome, $Ube3a^{m-/p+}$ (AS mice), and reducing Arc levels in AS mice ameliorates seizure susceptibility. AS mice have impaired experience-dependent plasticity in visual cortex. Levels of synaptic proteins are tightly regulated; too much or too little protein at the synapse is detrimental for plasticity. Therefore, we hypothesize that increased Arc levels are causative in the plasticity deficits observed in AS mice. In order to verify a direct interaction between Arc and Ube3A protein *in vivo* and *in vitro*, we conducted coimmunoprecipitation experiments from whole brain lysates and from cultured cortical neurons. Our preliminary data suggest that Arc and Ube3A do not directly interact. However, we will also determine if this putative interaction is sensitive to both neuronal activity levels and spatial distribution of protein within neurons, as both Arc and Ube3A expression is activity-dependent. To test this, we will perform subcellular fractionation on whole brain lysates and coimmunoprecipitate Arc and Ube3A to determine if there is an interaction between these two proteins only in specific cellular compartments, such as in the nucleus or at synapses. In addition, we cultured cortical neurons from AS mice and wildtype littermates and performed immunohistochemistry for Arc in conditions of low or high neuronal activity. We found that the increase in Arc protein in AS mouse neurons is exaggerated by enhancing neuronal activity. Ongoing experiments will determine whether surface expression and trafficking dynamics of AMPA receptors are disrupted in AS mouse neurons. These studies will shed light on the putative Arc/Ube3A interaction and whether dysregulation of Arc in AS mice leads to AMPA receptor trafficking and plasticity deficits.

Title: Defining the phenotype: increases in neuronal density and glia-to-neuron ratio in the pre-commissural caudate head in Williams syndrome

Authors: *K. HANSON[1], C. N. BROWN[2], V. A. JUDD[1], H. A. ORFANT[1], U. BELLUGI[3], K. SEMENDEFERI[1];
[1]Anthrop., UCSD, La Jolla, CA; [2]Psychological & Brain Sci., UCSB, Santa Barbara, CA; [3]Salk Inst. for Biol. Res., La Jolla, CA

Abstract: Williams syndrome is a rare neurodevelopmental disorder caused by a hemizygous deletion of 26-28 genes on the seventh chromosome. Among its most notable behavioral phenotypes is a generalized disinhibition of social behavior. A significant decrease in activation is reported in functional imaging studies in frontostriatal regions during go/no-go tasks in individuals with Williams syndrome, with particular deficits in striatal activation. Given these findings in Williams syndrome, and the specific impairment of the caudate nucleus in a wide variety of other neurodevelopmental disorders affecting behavioral control and response inhibition, such as Huntington's disease and ADHD, we sought to examine the head of the caudate nucleus in individuals with Williams syndrome. Our sample included four pairs of age, sex, and hemisphere-matched subjects, including three males and one female (ages 18-45) who prior to death were part of an ongoing study seeking to characterize the behavioral, social, and cognitive effects of Williams syndrome. Coronal sections through the rostral portion of the caudate nucleus, consisting of the pre-commissural head of the caudate, were Nissl stained to examine the distribution of neurons and glia using unbiased stereological methods. We found an overall increase in neuronal density, as well as an increase in the ratio of glial cells to neurons. These data suggest that deficits in inhibitory behavioral control may be linked to dysfunction of local circuitry within the striatum in Willliams syndrome mediated by imbalance between neuronal and glial cell distribution and increased cell packing density. Control specimens and ongoing material support has been provided by the University of Maryland Brain and Tissue Bank.

Title: Using machine learning to identify a cortical neuroanatomic signature of 22q11.2 Deletion Syndrome

Authors: D. SUN[1], R. JONAS[1], E. KRIKORIAN[1], L. KUSHAN[1], M. GUDBRANDSEN[2], E. DALY[2], C. ECKER[2], C. MURPHY[2], D. MURPHY[2], M. CRAIG[2], *C. E. BEARDEN[1]; [1]UCLA, Los Angeles, CA; [2]King's Col. London, London, United Kingdom

Abstract: 22q11.2 Deletion Syndrome (22q11DS) is a neurogenetic disorder caused by a microdeletion of chromosome 22. Patients with 22q11DS exhibit elevated rates of psychiatric disorders including schizophrenia, autism, and ADHD. Thus, studying neuroanatomic changes in 22q11DS may shed light on neural mechanisms underlying the risk for developing psychiatric conditions. Marked brain abnormalities have been found in 22q11DS, but whether they constitute distinct patterns to differentiate patients from healthy individuals is unclear. With a relatively large magnetic resonance imagining (MRI) dataset, we seek to determine if 22q11DS patients can be classified based on cortical anatomical features using machine learning algorithms. MRI scans of 80 22q11DS patients (mean age 14.5; 48.5% female) and 93 demographically comparable healthy controls obtained from two research sites were included in the analysis. Anatomical measures including cortical thickness (CT), surface area (SA), and volume in 68 regions across the cortex were extracted using FreeSurfer's automatic parcellation method. Between-group comparisons were conducted, and Bonferroni correction was used to control multiple comparisons. Classification was done by applying a linear support vector machines algorithm to all cortical measures. Compared with controls, significantly reduced cortical volume was found in 22q11DS patients in parietal, occipital, and temporal regions, as well as in the anterior cingulate. Significantly increased CT was found in patients in the bilateral insula, left pars triangularis and opercularis, and right supramarginal and rostral middle frontal region, while significantly reduced CT was found in patients in the left parahippocampal region. Significantly reduced SA was widespread in patients, found in 45 regions across the cortex. Classification using within-group cross-validations on 70 patients and 57 controls from one site gave an average accuracy of 91.0% (87.1-96.8%). When the classifier derived from one site was applied to cortical measures of 10 patients and 26 controls from the other site, all except one

control were accurately classified, giving a cross-site classification accuracy of 97.2%. This study reveals profound anatomic abnormalities in the cerebral cortex of patients with 22q11DS, involving widespread reduction of cortical surface area and volume in primarily posterior brain regions, with relative preservation of frontal regions. These patterns allow highly accurate classification of patients and controls. Future studies may elucidate the role of these patterns in increasing the risk for 22q11DS-related psychiatric disorders.

Title: Go/NoGo EEG experiment reveals cortical slowing in motor initiation in the children with cerebral palsy

Authors: C.-Y. LI[1], C.-H. CHANG[1], C.-Y. PENG[2], *J.-R. DUANN[3,4];
[1]Natl. Hemei Exptl. Sch., Changhua, Taiwan; [2]Biomed. Engin. Res. Ctr., [4]Grad. Inst. Clin. Med. Sci., [3]China Med. Univ., Taichung, Taiwan

Abstract: Introduction: The study of EEG characteristics of the children with cerebral palsy (CP) has been limited. In this study, we explored the EEG characteristics of the children with CP by finding the P300 evoked by the performance of a Go/NoGo task and comparing it to that of normal subjects. We hypothesized that the slowing in the task performance of the children with CP might be manifested by the slowing in the cortical processes caused by the damage to the motor-related cortices in the brain. As a result, we should see the changes in the shape of the P300s facilitated by the Go/NoGo task performance. The potential alterations included either the overall delay of P300 or the reshaping of the P300 subcomponents (Turetsky et al., 1998), indicating the slowing in perception or the cortical slowing in the motor initiation. Methods: We

collected EEG data from 20 children with CP, performing a visual Go/NoGo task, pressing a red huge round button using their dominant hand when they saw a circle on the screen and holding the button press when they saw a cross. Each visual cue was displayed for 500 ms at the inter-stimulus interval of 3 sec on average. 50 Go and 50 NoGo trials were collected in each EEG run and each subject performed two EEG runs. EEG data were recorded using a wireless 32-channel device with International 10-20 system cap using wet EEG electrodes. Each channel was sampled at 2 KHz and then filtered by a band-pass filter (1 - 50 Hz) and downsampled to 250 Hz for further analysis. We then decomposed the brain EEG into independent sources using independent component analysis and selected the brain EEG activity mainly locating at posterior midline regions for computing the event-related potentials (Jung et al., 2000). Results: The preliminary result showed that the P300 elicited by the Go/NoGo task performance of the children with CP revealed a clear gap between the subcomponents of P300 as compared to the P300 waveforms obtained from a Go/NoGo task performance by normal subjects reported in the literature. However, the early component of the P300 ERP arrived no later than the P300 found in the normal subject. Conclusion: Our results showed that the slowing in the task performance of the children with CP might be caused by the initiation of the motor action in the brain, while the capability of perception of the execution cues in their brain may be relatively intact as. Title: Morphological analysis of TSC-1 deleted pyramidal neurons

Authors: K. DALEEN[1], T. MANGOUBI[3], R. COX[3], *A. YOSHII[2];
[2]Dept of Anat. & Cell Biol., [1]UIC, Chicago, IL; [3]MIT, Cambridge, MA

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous disorder that causes abnormal cellular proliferation, differentiation, and growth in many organ systems including the brain, eyes, heart, lung, liver, kidney, and skin. Afflicted patients have a variety of neurological symptoms such as epilepsy, mental retardation and autistic behavior. Formation of cortical tubers, malformed tissues in the brain, accounts for some forms of seizures in those with TSC. However, it remains unclear whether tubers cause cognitive deficits. It is also possible that cortical neurons themselves are disorganized and that their synapse formation is dysregulated. In this study we analyze neuronal morphology in TSC. Using *in utero* electropolation, we transferred a DNA construct encoding GFP tagged Cre recombinase into embryonic day 15.5 neuronal progenitor cells in a Tsc1loxp/loxp mouse fetal brain. We imaged pyramidal neurons at postnatal day 28-30 with a confocal microscope. In WT cortices, Cre-GFP positive neurons were located in cortical layer 2/3. However, mutant brains showed a scattered distribution of Cre-GFP positive neurons. These Tsc-1 deleted cells also expressed a marker protein for layer 2/3 despite their malpositions. Furthermore, we found that soma size of Tsc1-deleted pyramidal neurons was enlarged as compared with WT pyramidal neurons. Sholl analysis demonstrated that Tsc1-deleted neurons had more arborizations than WT. We are currently analyzing dendritic spine size and number per a defined length. Our ongoing study suggests that Tsc-1 deleted cortical neurons show alterations in cellular organization and differentiation. In the future, we will aim to correlate these morphological changes with the neurological deficits in TSC. DoD TSCRP Career Transition Award (W81XWH-09-1-0088) to A.Y.

Title: Spontaneous epileptiform activity and low seizure threshold in a mouse model of Angelman Syndrome

Authors: ***A. DAO**, H. A. BORN, A. ANDERSON;
Pediatrics Neurol., Baylor Col. of Med., Houston, TX

Abstract: Angelman Syndrome (AS) is a rare neurodevelopmental disorder that affects approximately 1 in 20,000 births. In addition to severe cognitive deficits, epileptic seizures are common in AS cases. These seizures are often refractory to standard anti-epileptic drug treatment. Thus, there is a need to characterize the seizure phenotype and threshold to convulsant to then use to screen novel therapeutics. We investigated the seizure phenotype in a mouse model of AS via deletion of exon 2 on chromosome 15. We utilized long-term video synchronized electroencephalography (v-EEG) and spectral analysis to qualitatively and quantitatively compare between wild-type (WT) and AS mice. We observed spontaneous spike bursting (polyspikes) in the cortex and hippocampus of AS mice on the C57BL/6 background, which correlated with a higher delta power in these regions and higher theta and gamma power in the hippocampus. These findings were not observed in the 129Sv/Ev background mice. We did not capture spontaneous seizures in long-term v-EEG recordings of AS mice in either C57BL/6 or 129Sv/Ev background, so we evaluated seizure threshold in these mice using kainate, a chemoconvulsant. We found that 129 Sv/Ev AS mice showed a lower seizure threshold compared to WT littermates when challenged with kainate, however a seizure threshold comparable to WT littermates was found in the C57BL/6 AS mice. These preliminary findings indicate strain specificity for spontaneous epileptiform activity, spectral changes, and decreased seizure threshold, and provide the fundamental groundwork for further studies into treatment of the critical seizure phenotype in AS.

Title: Motor control during dual-task situations in Williams syndrome

Authors: *K. WUEBBENHORST[1], N. HOLL[2];
[1]EUFH Med. Rostock, Rostock, Germany; [2]Med., Rostock Univ., Rostock, Germany

Abstract: Human motor functions comprise the planning, the realization and the control of movements. The motor functions of patients with Williams-Beuren Syndrome underlie identical mechanisms like their peers. Nevertheless, several alterations in movement execution are existent. Differences in motor execution restrain their everyday life in different ways. The origin of these differences is diverse since there is not one, but many causes for motor deficits. In

particular, difficulties in tasks with motor and cognitive requirements like climbing stairs are attributed to functional deficits in visualspatial processing (Meyer-Lindenberg et al., 2006). However, the often occurring change from hypotonic to hypertonic muscle tone during adolescence can be caused from deficits in processing motor commands. This leads to the high importance of the motor development and the necessity of its comprehensive and long-term promotion. In this study 27 subjects (*) between the ages from 7 to 30 participated for the evaluation of static postural control. We organized the participants in three age groups for better within group comparisons (age group I children 7-13, age group II adolescents 14-17, age group III young adults 18-24). Since patients constitute deficits in visuospatial planning of movements (Hocking et al., 2013) we introduced a motor-cognitive dual-task-situation in addition to a single-task-situation. The measurements of the static postural control were performed on a balance coordination system (GKS-1000, Meditech, Germany). The area represents the surface covered by the displacement of the body's center of gravity. The medial-lateral-velocity (ML-velocity) and the anterior-posterior-velocity (AP-velocity) represent the mean displacement velocity of the body's center of gravity when travelled at equal measuring time. The area increased for every age group when compared with the single-task and dual-task-situation. We found the highest increase with age group I from 5.1 ± 1.7 SE to 9.6 ± 3.2 SE for the dual-task-situation ($p=0.01$). The same results were obtained for the ML-velocity and AP-velocity. For instance, we found an increase of the ML-velocity in age group I from 14.7 ± 1.7 SE to 21.5 ± 2.8 SE ($p<0.001$). These results indicate that when confronted with a motor-cognitive dual-task-situation, the motor task is compromised for the cognitive task. Following these results, training of visualspatial perception along with a combination of sensorimotor training with cognitive involvement might improve the observed deficits in task execution. * matched healthy control subjects are recruited and data will be available for the Neuroscience congress

Title: Strain-specific behavioral deficits in the maternally deficient Ube3a Angelman syndrome mouse model

Authors: *H. A. BORN[1,3], A. T. DAO[1,3], A. E. ANDERSON[2,3];
[1]Pediatrics, [2]Pediatrics, Neurology, and Neurosci., Baylor Col. of Med., Houston, TX; [3]Jan and Dan Duncan Neurolog. Res. Inst., Texas Children's Hosp., Houston, TX

Abstract: Angelman syndrome (AS) is a neurodevelopmental disorder characterized by marked developmental delay, cognitive impairment, movement disorder, and frequently is associated with seizures and abnormal EEG activity. AS is caused by defects in the maternally inherited ubiquitin protein ligase (Ube3a) gene, and a Ube3a maternal deficient mouse model (Ube3am-/p+) is a useful tool for AS therapeutic development. Despite the severity of AS, there is currently no effective treatment. To screen potential therapeutics, we established a behavioral battery and characterized the Ube3am-/p+ model on three different mouse strain backgrounds: C57Bl/6 (C57), 129Sv/Ev (129), and the F1 hybrid of C57 x 129. Previous studies have shown varying behavioral results, and one potential confound is differences from strain background. We assessed motor activity, anxiety, and learning and memory behavior in adult gender-balanced AS and wildtype (WT) littermates from C57, 129, or F1 hybrid background. The battery included open field activity (OFA), elevated plus maze (EPM), marble burying (MARB), inverted grid (IG), wire hang (WH), accelerating rotorod (RR), novel object recognition (NOR), and tone-shock paired fear conditioning (FC). Regardless of strain, AS mice show significantly increased weight and normal performance on the IG test. On a C57 background, AS mice show significantly decreased locomotor activity, rearing episodes, performance on both wire hang and rotorod, marbles buried, and preference for the novel object with a 24 hr test. In contrast, mice on a 129 background show normal locomotor activity, performance on the rotorod, and marble burying when compared to WT. FC-context and wire hang tests reveal deficits in AS 129 mice compared to WT 129 mice. The F1 hybrid AS mice show significantly decreased locomotor activity, rearing episodes, performance on rotorod, and marbles buried. Despite the impaired performance on motor tests of the AS F1 mice, preliminary results show similar performance from AS and WT F1 mice on NOR and FC tests. Our results suggest that AS-like behavioral phenotypes expressed in the Ube3am-/p+ mouse model are strain-specific. The Wt 129 mice perform poorly on the OFA, MARB, and NOR tests, suggesting a 129 background may not be optimal for screening the effect of potential AS treatments on both motor and learning/memory impairments. Overall, the C57 background will be best for screening using a diverse battery of behavioral tests. Future studies will screen potential treatments for rescue of AS-like motor and learning and memory impairments. Title: Dorsal-ventral patterning in a neurodevelopmental model of bipolar disorder

Authors: *M. BAME[1], C. J. DELONG[2], M. G. MCINNIS[3], K. S. O'SHEA[2];
[2]Cell & Developmental Biol., [3]Psychiatry, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Bipolar Disorder is a hereditary neuropsychiatric condition in which patients experience intense mood fluctuations that can lead to extreme behavioral changes. Moods alternate between severe depression and mania and often negatively impact patients' lives. No single gene has been determined to cause Bipolar disorder and the underlying pathological mechanisms remain unclear. It has recently been suggested that disruptions in neural development may play a role in the pathology of psychiatric disorders. To test this hypothesis, we have established a developmental model of Bipolar Disorder in which patient and control somatic cells have been reprogrammed, establishing induced pluripotent stem cells that have been differentiated into neural precursors and neurons. Microarray analysis of RNAs from these cells indicate that neurons derived from Bipolar patients have elevated expression of transcription factors associated with GABAergic interneurons, while those derived from controls have elevated expression of transcription factors associated with excitatory glutamatergic neurons. To examine the mechanisms involved in the production of ventral CNS derivatives (GABAergic interneurons) and dorsal derivatives (excitatory glutamatergic neurons) we have exposed cells at sequential stages of differentiation to Hedgehog pathway agonists and inhibitors and to Wnt pathway stimulation. We found that when treated with an activator of Hedgehog pathway signaling (SAG), neural precursors derived from Bipolar patients respond more strongly than those derived from control patients, increasing expression of GLI1 and PTCH 1 transcripts, as well as the interneuron progenitor transcription factor NKX2.1. We are currently examining the response of neural precursors to Chir99021 (a Wnt pathway activator) and cyclopamine (a Hedgehog inhibitor) on expression of Hedgehog and Wnt target genes. Alterations in early neuronal allocation/differentiation could lead to alterations in patterning and connectivity throughout the cortex and contribute to Bipolar Disorder.

Title: The basic neurobiology of Pitt-Hopkins Syndrome

Authors: *A. J. KENNEDY, J. J. DAY, D. SWEATT;
Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Human haploinsufficiency of the transcription factor Tcf4 (Transcription factor 4, E2-2, ITF2) leads to a rare autism spectrum disorder called Pitt-Hopkins syndrome (PTHS), which is associated with severe language impairment and development delay. However, the neural and transcriptional mechanisms disrupted in Tcf4 deficiency are unknown. Here, we demonstrate that Tcf4 haploinsufficient mice that genetically model PTHS have deficits in social interaction, ultrasonic vocalization, prepulse inhibition, as well as spatial and associative learning and memory. We found that despite learning deficits, Tcf4 (+/-) mice have enhanced long-term potentiation in the CA1 area of the hippocampus. Tcf4 was found to regulate hippocampal CpG methylation of gene bodies and cAMP response elements broadly across the genome, and direct the expression of neuroreceptors and memory associated genes, including Grin2a, Klotho, and Arc. In translationally oriented studies we found that small molecule HDAC inhibitors normalized hippocampal LTP and memory recall in our mouse model. Finally, we observed that antisense oligonucleotide-based HDAC2 isoform-selective knockdown was sufficient to rescue deficits in spatial and associative memory in Tcf4 (+/-) mice.

Abstract: There is a ~30% excess of males with intellectual disability (ID), which can be partly explained by above average, 5-10%, contribution of genes and mutations on the X-chromosome. By X-exome sequencing, we identified mutations in the KLHL15 gene that cause ID in two Australian families. The first mutation deletes two poorly conserved amino acids (F241, Y242) in the middle of the protein, while KLHL15::ACOT9 is the result of a large in-frame chromosomal deletion, fusing the N-terminus of KLHL15 to the C-terminus of the mitochondrial enzyme acyl-CoA thioesterase 9. KLHL15, or Kelch-like 15, is the substrate binding component of an E3 ubiquitin ligase complex that also contains cullin3 (Cul3). We have previously shown that KLHL15 specifically targets the B′β (B56/PR61/PPP2R5B) subunit of protein phosphatase 2A (PP2A) for ubiquitylation and proteasomal degradation. B′β is a brain-specific regulatory subunit and mediates the dephosphorylation and inactivation of tyrosine hydroxylase and Ca^{2+}/calmodulin-dependent protein kinase II. As a first step towards elucidating pathogenic mechanism in XLID caused by mutations in E3 ligases, we have begun to biochemically characterize KLHL15 ΔFY241 and KLHL15::ACOT9. KLHL15 mutant cDNAs were cloned and characterized by expression in HeLa and HEK293 cells. The two XLID mutations did not alter the cytosolic localization of KLHL15, nor did they compromise binding to Cul3 as detected by co-immunoprecipitation. However, both ΔFY241 and ::ACOT9 dramatically decreased KLHL15 binding to PP2A/B′β, 35% and 17% , respectively, in comparison to wild-type

KLHL15. In addition, both XLID mutations impaired PP2A/B′β degradation and KLHL15 auto-degradation. Our results indicate that XLID mutations in KLHL15 are hypomorphic and suggest that regulated turn-over of PP2A/B' β and perhaps other as yet undiscovered substrates of KLHL15 is critical for proper development of the human brain.

Title: Enhanced transmission at the calyx of Held synapse in a mouse model for Angelman syndrome

Authors: ***T. WANG**, Y. ELGERSMA, J. G. G. BORST;
Erasmus Med. Ctr., Rotterdam, Netherlands

Abstract: The neurodevelopmental disorder Angelman syndrome (AS) is characterized by intellectual disability, motor dysfunction, distinct behavioral aspects and epilepsy. AS is caused by a loss of the maternally expressed *UBE3A* gene, and many symptoms can also be observed in

an *Ube3a* mouse model of this syndrome. At the cellular level, changes in the axonal initial segment (AIS) have been reported, and changes in vesicle cycling have indicated the presence of presynaptic deficits. However, the physiological consequences of these changes for synaptic transmission *in vivo* are unknown. Here we studied the role of UBE3A in the auditory system, a pathway which is uniquely suited to study presynaptic function *in vivo*, by recording synaptic transmission at the calyx of Held synapse in the medial nucleus of the trapezoid body (MNTB). The calyx of Held synapse has a relay function in the auditory brainstem; each principal MNTB neuron is contacted by a single, giant terminal from a globular bushy cell of the contralateral AVCN. Because of its large size, both pre- and postsynaptic activity can be recorded *in vivo* with a single pipette. Through *in vivo* whole cell and juxtacellular recordings in *Ube3a* mice, we show that MNTB principal neurons exhibit a hyperpolarized resting membrane potential, an increased action potential (AP) amplitude and a decreased AP halfwidth. Moreover, both the pre- and postsynaptic action potentials in the calyx of Held synapse of AS mice showed significantly faster recovery from spike depression. An increase in AIS length was observed in the principal MNTB neurons of AS mice, providing a possible substrate for these gain-of-function changes. In addition, EPSPs showed decreased short-term synaptic depression (STD) during long sound stimulations in AS mice, and faster recovery from STD following these tones. These findings provide the first *in vivo* evidence for abnormal excitability and changes in synaptic transmission in a mouse model of AS.

Title: The cognitive and behavioral phenotypes of individuals with CHRNA7 duplications

Authors: *M. GILLENTINE[1], C. P. SCHAAF[1,2];
[1]Mol. and Human Genet., Baylor Col. of Med., Houston, TX; [2]Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX

Abstract: Chromosome 15q13 is one of the least stable regions in the genome, due to the presence of low copy repeat elements (LCRs) that cluster into six breakpoints (BP1 to BP6). These LCRs make the region vulnerable to non-allelic homologous recombination (NAHR), resulting in recurrent copy number variants (CNVs). Between BP4 and BP5, multiple recurrent CNVs have been observed. Large deletions of 1.5 Mb to 2 Mb have been well established as pathogenic, with high penetrance of multiple neuropsychiatric phenotypes observed, including intellectual disability (ID), developmental delay (DD), autism spectrum disorder (ASD), schizophrenia, and epilepsy. Smaller deletions encompassing only *CHRNA7* have also been seen in individuals with a similar range of phenotypes and penetrance. However, the significance of duplications spanning *CHRNA7* has been enigmatic, as gains of *CHRNA7* have been found to occur at similar frequencies in individuals with neuropsychiatric disease and controls. Using a genotype-to-phenotype approach, we evaluated 18 individuals, who had been identified to carry a *CHRNA7* duplication by clinical chromosome microarray analysis. Duplication sizes varied from 148 kb to 3.231 Mb. Formal cognitive assessment of the 18 probands (age 2 to 14) revealed an average full scale IQ of 80.2, being significantly lower than the average population. Research reliable testing for autism spectrum disorder was positive in 41% of cases, as determined by the Autism Diagnostic Interview –Revised (ADIR) and Autism Diagnostic Observation Schedule (ADOS). Additional phenotypes included developmental delay, language and speech delay, attention deficit/hyperactivity disorder (ADHD), and epilepsy in a subset of patients. Inheritance was determined in 13 of 18 cases, with just over half of the transmitting parents manifesting a neurological phenotype, indicating that these duplications are incompletely penetrant. This study suggests that *CHRNA7* duplications may be pathogenic, and that affected individuals manifest cognitive and behavioral phenotypes. However, ascertainment bias needs to be considered in this context. A detailed neuropsychological phenotyping of individuals who were not referred as probands, but subsequently identified to carry a *CHRNA7* duplication, or individuals with a prenatal diagnosis of *CHRNA7* duplication could be considered to overcome that bias.

Title: Behavioral and neuroanatomical characterization of mice with a mutation of the candidate dyslexia susceptibility gene Dyx1c1

Authors: *A. R. RENDALL[1], A. TARKAR[2], H. M. CONTRERAS-MORA[1], J. LOTURCO[2], R. H. FITCH[1];

Abstract: Dyslexia is a learning disability characterized by difficulty learning to read and write. The underlying biological and genetic etiology remains poorly understood. One candidate gene, dyslexia susceptibility 1 candidate 1 (DYX1C1), has been shown to be associated with deficits in short-term memory in dyslexic populations. The purpose of the current study was to examine the behavioral and neuroanatomical phenotype of a mouse model with a homozygous conditional (forebrain) knockout of the rodent homolog Dyx1c1. Twelve Dyx1c1 conditional homozygous knockouts, 7 Dyx1c1 conditional heterozygous knockouts and 6 wild-type controls were behaviorally assessed using auditory discrimination, motor, and learning/memory tasks. Mice with the homozygous Dyx1c1 knockout showed deficits on radial-arm and T-maze tasks, but not on auditory or motor tasks. Following behavioral assessment, all brains were extracted and used for histological evaluation. Volume measures of the striatum (caudate putamen, nucleus accumbens), cortex, and hippocampus were recorded and analyzed. These neuroanatomical findings were correlated with behavioral measures to evaluate whether regional anomalies might account for the learning deficits observed in the Dyx1c1 conditional homozygous knockouts. Our findings affirm existing evidence that DYX1C1 may play an underlying role in the development of neural systems important to learning and memory, and disruption of this gene's function could contribute to learning deficits as seen in individuals with dyslexia.

Title: Statistical learning of spatial cues in virtual hebb-williams maze

Authors: L. GUO[1], Y. CHEN[2], *A. BATTISON[3], L. GABEL[4];
[1]Psychology, [2]Computer Sci., [4]Psychology & Neurosci., [3]Lafayette Col., Easton, PA

Abstract: Statistical learning has been shown in different domains of cognitive abilities, including social understanding, logical reasoning, and language acquisition. The current study explored statistical learning in navigation. Navigators often use spatial cues to support their performance. We proposed that cues associated with high reliability would be adopted more readily relative to unreliable cues. The present study investigated the effect of cue reliability on adults' performance in virtual reality mazes. Undergraduate students performed a navigational task in a virtual Hebb-Williams maze. Participants were randomly assigned with the same sets of mazes that either had no cue, a cue (i.e. a checkerboard pattern implemented on a maze wall) that was reliable, or the same cue less reliable in identifying the correct path to a goal. We measured individual performance efficiency as an indicator of the person's maze performance. Our results supported our major prediction such that adults exposed to the reliable cue outperformed those who had no cue and those with the unreliable cue. The current study should provide useful knowledge for future studies of statistical learning in navigational tasks.

Title: Sex-dependent effects of adolescent methylphenidate and guanfacine on impulsive choice and cocaine self-administration

Authors: K. J. NORMAN[1], *J. L. LUKKES[2], B. S. THOMPSON[1], S. L. ANDERSEN[3];
[1]Lab. of Developmental Neuropharm., McLean Hosp., Belmont, MA; [2]Lab. of Developmental Neuropharm., McLean Hospital, Harvard Med. Sch., Belmont, MA; [3]Lab. of Developmental Neuropharm., McLean Hospital/Harvard Med. Sch., Belmont, MA

Abstract: Sex-dependent effects of adolescent methylphenidate and guanfacine on impulsive choice and cocaine self-administration **K. J. NORMAN**, J. L. LUKKES, B. S. THOMPSON, and S.L. ANDERSEN Laboratory of Developmental Neuropharmacology, Dept. of Psychiatry, McLean Hospital/Harvard Medical School, Belmont, MA 02478, USA. Methylphenidate (MPH; a dopamine transporter inhibitor) and guanfacine (GUAN; an α_{2a} noradrenergic receptor agonist) treatments effectively increase attentiveness and decrease impulsivity in clinical populations of adolescent ADHD. However, their long-term effects on different aspects of drug addiction, such as motivation to use drugs or sensitivity shifts, have not been thoroughly characterized. The current studies investigate the effect of juvenile to adolescent exposure to MPH or GUAN on concurrent impulsivity and later cocaine self-administration in adulthood. Male and female Sprague-Dawley rats were given MPH (2 mg/kg, p.o.) or GUAN (0.2mg/kg, i.p.) daily beginning on postnatal day (P) 22 and throughout adolescence. Twenty minutes following treatment, rats were placed into an operant conditioning chamber and impulsive choice was assessed using a delay discounting task (DDT; 0, 10, 20, 40, and 60 sec delay) with food reward. Beginning in adulthood (P90), rats were implanted with a jugular catheter and began cocaine self-administration on a fixed-ratio (FR1 and 5, 0.5 mg/kg) and a progressive ratio (PR, 0.25 mg/kg and 0.75 mg/kg) schedule, followed by an FR5 dose-response (0, 0.03, 0.1, 0.3, and 1 mg/kg) assessment. During DDT, MPH increased the number of large food rewards received at the 20 and 40 sec delay in males, suggesting decreased impulsivity, while both MPH and GUAN increased the number of large rewards received at the 20 sec delay in females. In adulthood, MPH and GUAN decreased cocaine intake in males, but had no effect in females. PR breakpoint was reduced by MPH and GUAN in males, but only MPH was effective in females. A downward shift in FR5 responding at 0.03mg/kg in MPH and GUAN treated male and female rats indicates decreased sensitivity to cocaine. These findings suggest that sex-dependent neural adaptations following dopaminergic and noradrenergic activation during development reduce impulsive choice and later sensitivity to and suppression of cocaine intake during adulthood. The project described was supported by R01 DA-15403 and R01 DA-026485 to SLA.

Title: Neural correlates of phonological and orthographic processing in children with developmental dyslexia

Authors: *X. YAN[1], Y. DENG[2], F. CAO[1];
[1]Communicative Sci. and Disorders, Michigan State Univ., East Lansing, MI; [2]Inst. of Psychology, Chinese Acad. Sci., Beijing, China

Abstract: Introduction: Converging behavioral and neurological evidence from alphabetic languages has demonstrated phonological deficits in children with developmental dyslexia (DD) (Bruck, 1992; Rack, Snowling, & Olson, 1992)). However, whether phonological deficit is also the core problem in children with DD in logographic languages is still a debate (Siok & Fletcher, 2001; Siok, et al., 2004). Our study provides neurological evidence for whether Chinese children with DD also experience phonological deficits in an auditory rhyming task using fMRI. Reading is a complex process and skilled orthographic processing also plays an important role in fluent reading (Siok et al., 2004; Cao et al., 2008), especially in logographic languages such as Chinese. Our study also examined whether there are orthographic deficits in Chinese children with DD. **Method:** 5 dyslexic fifth-graders (DD), 13 typically developing fifth-graders (age control, AC) and 14 typically developing third-graders (reading-matched control, RC) participated in an auditory rhyming task and a visual spelling task during fMRI scanning. During the auditory rhyming task, participants judged if two orally presented words rhymed or not; during the visual spelling task, participants judged if the second character of two visual presented words shared a radical or not. **Result & Discussion**: Behavior results showed no significant differences in reaction time (RT) or accuracy among the three groups in the visual spelling task. For the auditory rhyming task, the AC group was significantly faster and more accurate than the DD group and the RC group. fMRI results indicated that in both tasks AC showed greater activation than DD in two IFG regions: the left dorsal IFG (-48, 8, 34) and the left anterior IFG (-50, 34, 18). These two regions have been found to show developmental increase in our previous studies using the same tasks (Cao et al, 2011, 2012). It suggests that children with DD have a developmental delay in these two regions. We also found DD showed reduced activations in comparison to both AC and RC in left middle occipital gyrus (MOG) for the auditory rhyming task and in left cuneus for the visual spelling task. The reduced activation in MOG suggests a weaker integration of orthography and phonology during the rhyming judgment (Fiebach et al, 2002; Gold et al, 2007); the reduced activation in ceneus suggests less elaborated visual-spatial processing of Chinese words (Kim et al, 2015). Both of these mechanisms are related with the etiology of DD rather than the result of being DD.

Hosp., Seoul, Korea, Republic of; [4]Psychiatry, Chung-Ang Univ. Med. Sch., Seoul, Korea, Republic of

Abstract: Factor analyses of attention-deficit/hyperactivity (ADHD) symptoms divide the behavioral symptoms of ADHD into two separate domains, one reflecting inattention and the other, a combination of hyperactivity and impulsivity. Identifying domain-specific genetic risk variants may aid in the discovery of specific biological risk factors for ADHD. In contrast with data available on genes involved in hyperactivity and impulsivity, there is limited information on the genetic influences of inattention. Transcriptional profiling analysis in animal models of disorders may provide an important tool to identify genetic involvement in behavioral phenotypes. To explore some of the potential genetic underpinnings of ADHD inattention, we examined common differentially expressed genes (DEGs) in the prefrontal cortex of SHR/NCrl, the most validated animal model of ADHD and WKY/NCrl, animal model of ADHD-inattentive type. In contrast with Wistar rats, strain representing the “normal” heterogeneous population, SHR/NCrl and WKY/NCrl showed inattention behavior in the Y-maze task. The common DEGs in the PFC of SHR/NCrl and WKY/NCrl vs. Wistar rats are those involved in transcription, synaptic transmission, neurological system process, and immune response. qRT-PCR analyses validated expression patterns of genes representing the major functional gene families among the DEGs. Although further studies are warranted, the present findings indicate novel genes associated with known functional pathways of relevance to ADHD which are assumed to play important roles in the etiology of ADHD-inattentive subtype.

Title: Thalamic centromedian/parafascicular complex DBS in Tourette syndrome modulates motor and non-motor networks

Authors: *P. TESTINI, W. S. GIBSON, H.-K. MIN, K. R. GORNY, J. P. FELMLEE, K. M. WELKER, C. A. EDWARDS, M. L. SETTELL, E. K. ROSS, B. T. KLASSEN, K. H. LEE; Mayo Clin., Rochester, MN

Abstract: Introduction: Deep brain stimulation (DBS) of the thalamic centromedian/parafascicular complex (CM/Pf) is a therapeutic option for severe, medication-refractory Tourette syndrome (TS). The neural networks that mediate the therapeutic effect have yet to be identified. We performed fMRI in human patients undergoing thalamic DBS for TS to test the hypothesis that DBS of CM and Pf would modulate sensorimotor and limbic networks. Methods: Five patients underwent bilateral stereotactic implantation of DBS electrodes (Medtronic 3387) in the CM/Pf. Electrode location was verified by postoperative CT. Intraoperative 1.5T functional MRI (fMRI) was acquired during DBS of the CM (0-1+ 3V 130Hz 90us) and Pf (2-3+ 3V 130Hz 90us) nuclei. All pulse sequences were previously safety tested in a phantom. At three months post-surgery, a double-blinded tic evaluation using the Rush Video-Based Tic Rating Scale was performed during sham, CM, and Pf stimulation, and these scores were correlated with changes in blood oxygen level-dependent (BOLD) activity. All procedures were approved by the Mayo Clinic Institutional Review Board. Results: Group analysis ($pBonf < 0.001$) showed that CM DBS resulted in an increase in BOLD signal within motor regions including the ipsilateral putamen, pallidum, motor and premotor cortices, thalamus, and contralateral cerebellum. Stimulation of Pf, however, resulted in a decrease in BOLD signal within these same motor regions, as well as in limbic and associative areas including the insula and cingulate cortices. Both CM and Pf DBS caused clinically relevant improvements in Rush scores relative to sham stimulation ($p = 0.12, 0.03$; paired t-test). A positive linear correlation between DBS-evoked improvement in Rush scores and magnitude of BOLD signal change was observed in the ipsilateral motor cortex and contralateral cerebellum.

Conclusions: These results show that CM and Pf DBS exert differential effects on sensorimotor and limbic networks. Notably, the observed effect of both CM and Pf DBS on the motor network BOLD activation, and the correlation between such activation and the clinical outcomes suggest that DBS-evoked modulation of the motor circuitry may play a key role in the therapeutic mechanism of CM/Pf DBS. Title: Disrupted white matter connectivity in dyslexic children: a multivariate pattern analysis

Authors: *Z. CUI, Z. XIA, H. SHU, G. GONG;
State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Sch. of Brain and Cognitive Science, Beijing Nor, Beijing, China

Abstract: Disrupted brain connectivity between reading related regions has been hypothesized to be a critical contributing factor for developmental dyslexia (DD). The existing white matter (WM) studies in dyslexia always treated voxels or tracts as independent variables and have difficulties in detecting subtle and spatially distributed differences. In the present study, we apply a multivariate pattern analysis to test if the DD can be characterized by atypical distributed WM patterns. Twenty-eight dyslexic children and 33 matched typically developing controls were included. For each individual, the mean of WM volume (WMV), fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD) for each White Matter Parcellation Map region were computed and then concatenated into a single feature vector. Then, a linear support vector machine (LSVM) classifier was constructed to discriminate dyslexics and controls (Figure 1). To validate our results, the logistic regression (LR) model was applied to classify the dyslexics and controls with the exact same classification framework. The prediction accuracy of the proposed LSVM classifier was 83.61% (P<0.001; sensitivity=75.00% and specificity=90.91%). The AUC was 0.86 (P<0.001). There are 43 discriminative WM features, which were mainly located within the putative reading system (e.g., the superior longitudinal fasciculus), the limbic system (e.g., the cingulum and fornix), and the motor control system (e.g., the inferior cerebellar peduncle). The prediction accuracy and AUC of the LR classifier were 73.77% and 0.80 (all P<0.001). The weights of the discriminative features for the LR classifier were significantly correlated with that for the LSVM classifier (r=0.73, P<0.001). These results demonstrated a significant WM pattern change in dyslexia, which were mainly associated with WM tracts in the putative reading network, limbic system and motor system, and further highlight the potential of WM connectivity as a biomarker for recognizing brain disorders or diseases.

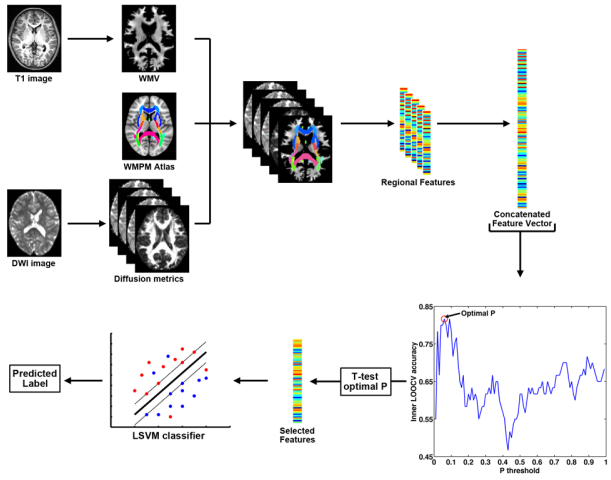

Figure 1. The classification flow based on the combination of white matter volume and diffusion metrics. Two-tailed two sample t-test was used for feature selection and nested LOOCVs were applied for the optimal P threshold.

Title: Reduced electrophysiological connectivity during visual word recognition in dyslexic children

Authors: *G. ŽARIC[1], J. M. CORREIA[1], G. FRAGA GONZÁLEZ[2], J. TIJMS[3], M. W. VAN DER MOLEN[2], L. BLOMERT[1], M. BONTE[1];

Abstract: Reading is a complex cognitive skill subserved by a distributed network of visual and language-related regions. Disruptions of connections within this network are proposed as a possible cause of reading dysfunction in developmental dyslexia. Here we investigated effective connectivity in the reading network of 9-year-old typically reading children (TR; n=20) and two groups of dyslexic children: severely dysfluent dyslexic (SDD; n=20) and moderately dysfluent dyslexic (MDD; n=18). To this end, we used directed transfer function (DTF) to analyze the electroencephalographic (EEG) signal recorded while the children recognized visual words and meaningless letter-like symbol strings. DTF is a spectral multivariate estimator of EEG activity propagation and based on autoregressive models. Here DTF was performed per subject and random-effect statistics were calculated between groups per condition using Wilcoxon tests per frequency bin (FDR<0.05). Our preliminary analysis indicates an expected propagation from posterior to anterior channels in TR children during both the visual word and symbol string recognition task. Similar results were found in the MDD group with significantly weaker connectivity from left parietal to central and frontal channels than in TRs on both tasks. On the other hand, the SDD readers showed significantly weaker propagation from occipital to parietal and central channels on both tasks than both TR and MDD groups. Most interestingly, the SDD group exhibited significantly stronger bilateral anterior to posterior connectivity in both conditions than TR and MDD groups, spanning mostly in the lower gamma, but also alpha and beta bands. This pattern of results suggests that the two groups of dyslexic children use two different compensatory mechanisms: MDD readers rely on qualitatively the same connectivity as TRs; while SDD readers more strongly rely on bilateral anterior to posterior connectivity. This differentiation emphasizes the importance of considering differences in severity of reading

dysfunction within dyslexic population in addition to group differences between typical and dyslexic readers.

Abstract: Human commensal microbial communities in the intestine (i.e. the gut microbiome) have an increasingly recognized impact on human health, including brain functioning. Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder characterized by abnormal brain dopamine; for instance reflected by decreased reward anticipation responses in the ventral striatum in the brain. Of the many etiological factors involved in ADHD, the microbiome might constitute an important one. Here, we investigated the difference in microbiome between ADHD cases and undiagnosed controls, as well as its effects on brain functioning. Using next-generation 454 DNA sequencing of the bacterial 16s rRNA marker gene, we characterized microbial communities of an n = 97 ADHD cases and controls cohort. Firstly, we investigated the differences in abundance of (i) bacterial taxa and (ii) predicted metabolic functions of the microbiome based on the presence and abundance of bacterial taxa. Secondly, we assessed neural reward anticipation responses using fMRI in an n = 87 ADHD cases and

controls cohort. Thirdly, in a sub-set of 28 subjects who participated in both the microbiome and fMRI study, we related differences in microbiome to neural reward anticipation. Many bacterial taxa differed between cases and controls, among which the Bifidobacterium genus that was increased from 12.0% to 20.2% in average relative abundance in ADHD cases ($p = 0.002$, MWU). When we focused our analyses on genes producing monoamine (including dopamine) precursors in the bacteria, we found that a gene involved in the synthesis of the essential amino acid phenylalanine ((KEGG K01713) encoding the enzyme prephenate dehydratase (EC: 4.2.1.51)) was significantly more present in the microbiome of ADHD cases compared with controls. In our larger imaging sample, reward anticipation in the anatomically defined ventral striatum was significantly decreased for ADHD cases relative to controls, replicating previous studies. Strikingly, in our smaller sub-sample, increased abundance of this microbial phenylalanine-related gene was also associated with decreased bilateral ventral striatal BOLD responses for reward anticipation ($pFWE < 0.05$, small search volume: anatomical ventral striatum), independent of ADHD diagnosis. Our results suggest that differences in gut microbiome structure exist between ADHD cases and controls. Importantly, relative abundance of a dopamine-related microbial gene that differed between ADHD cases and controls was associated with altered reward anticipation responses, one of the neural hallmarks of ADHD.

Title: A father’s exposure to nicotine and its surprising consequences for the offspring

Authors: *D. M. MC CARTHY, S. E. LOWE, T. J. MORGAN, Jr, E. N. CANNON, F. FAN, J. ZHU, P. G. BHIDE;
Ctr. for Brain Repair, Biomed. Sci., Florida State University,College of Med., Tallahassee, FL

Abstract: Much attention has been focused on the consequences of tobacco use by pregnant women or women of childbearing age and its effects on the developing fetus. A number of clinical and pre-clinical studies show a relationship between fetal nicotine exposure and premature birth, sudden infant death syndrome, and an increased risk of attention deficit hyperactivity disorder (ADHD). However, in reality, smoking is more prevalent among men (21.6%) than women [(16.5%) (Centers for Disease Control)]. Whether a father's use of tobacco affects cognitive development of the offspring he sires is not clear. To address this issue, we developed a mouse model of paternal nicotine exposure in which adult male mice were exposed to nicotine in drinking water for up to 12 weeks and then bred with drug naïve female mice. The nicotine was dissolved in saccharin sweetened drinking water to mask nicotine's bitter taste. Thus, we created three experimental groups of mice exposed either to plain drinking water, 2% saccharin or nicotine (200 μg/ml) plus 2% saccharin. Since our goal was to determine if paternal exposure to nicotine is associated with ADHD phenotypes in the offspring, we analyzed working memory, attention and spontaneous locomotor activity in the offspring sired by males in each treatment group. Hyperactivity, working memory deficit and attention deficit are major components of the ADHD symptomatology. The offspring of the nicotine exposed males showed significant deficits in working memory and attention but not in locomotor activity. The offspring of the saccharin exposed males showed significant increase in locomotor activity, and did not show significant changes in working memory or attention. Thus, paternal exposure to nicotine or saccharin each produced distinct behavioral consequences for the offspring that are associated with the ADHD phenotype.

Title: Distinct associations between neural speech discrimination responses and verbal cognition in dyslexic and fluently reading children

Authors: *L. KIMPPA[1], E. PARTANEN[3], K. ALHO[4], T. KUJALA[2];
[2]Inst. of Behavioural Sci., [1]Cognitive Brain Res. Unit, University of Helsinki, Finland; [3]Dept. of Clin. Med., MINDLab / Ctr. of Functionally Integrative Neurosci. (CFIN), Aarhus, Denmark; [4]Inst. of Behavioural Sci., Div. of Cognitive Psychology and Neuropsychology, Helsinki, Finland

Abstract: The relationship between the underlying neural deficit and difficulties in cognitive skills in dyslexia is ill-defined. We explored the association of neural indices of auditory discrimination and behavioural-level language and verbal memory functions in dyslexic and fluently reading 9-12-year-old children. Responses to changes in frequency, vowel identity and duration either at the middle or final syllable of a tri-syllabic pseudo-word were recorded in an oddball paradigm. Mismatch negativity (MMN), P3a and late discriminative negativity (LDN) event-related brain potentials (ERPs) were measured in an ignore condition where children focussed on watching a silent cartoon. Correspondingly, N2, P3a and LDN were measured in an attend condition where the children were instructed to attend to the speech stimuli and press a button to a novel target sound. Cognitive skills were tested on several domains: conceptual/abstract verbal reasoning and phonological processing, rapid automatized naming (RAN), verbal working memory, verbal learning and long-term memory, as well as reading fluency and writing. The association between response amplitudes and cognitive performance was assessed using stepwise multiple regression analysis. Group differences were investigated by conducting multiple regression analysis separately for each group and response. In the dyslexics, several connections between early neural discrimination of sounds, indexed by the MMN and N2, and especially RAN time were found, whereas the controls' early responses were linked to verbal reasoning and working memory. The attention-related P3a responses were associated with verbal reasoning and learning in the dyslexics and rapid naming time and working memory in the controls. The LDN, reflecting late discriminative ability and/or reorienting, was related to error-proneness and auditory short-term memory functions in dyslexics; in controls it was most strongly related to verbal learning and later memory retrieval. The only significant relationship with reading fluency was found for duration N2 in dyslexics. In sum, the MMN, N2 and P3a responses predicted verbal working memory performance while the LDN predicted long-term memory performance in the controls but no such pattern was observed in the dyslexics. Significant relationships between the neural responses and measures of language and memory functions were found in both groups, but the couplings differed. These results imply somewhat distinct connections of low-level speech processing and higher-level verbal cognition in dyslexia compared to fluently reading individuals.

Title: The basal ganglia in relation to executive dysfunction in ADHD and reading disorder

Authors: ***A. C. JAGGER**, A. A. OLECHOWSKI, L. ALVES, M. Y. KIBBY;
Psychology, Southern Illinois Univ. - Carbondale, Carbondale, IL

Abstract: The basal ganglia (BG) has strong connections to frontal cortex. There are frontostriatal circuits for motor functioning, executive functioning (EF), and motivation (Tekin & Cummings, 2002). We recently found BG gray matter volume is smaller in children with ADHD, reading disability (RD) and comorbid ADHD and RD (RD/ADHD) compared to controls (Jagger et al., 2015). The frontostriatal network is often atypical in ADHD, particularly in the prefrontal cortex and caudate (Shaw et al., 2014; Cortese et al, 2005) and in white matter tracts (Silk et al., 2009). Individuals with RD show reduced BG function in relation to higher order learning (Howard et al, 2006). Our study examined whether BG gray matter volume may be differentially related to cognitive and behavioral EF measures in RD, ADHD, and RD/ADHD. Over 100 children (30 controls, 22 RD, 15 RD/ADHD and 42 ADHD; 55 males) participated in the study, ranging in age from 8-12 years. T1 weighted MRI scans were collected on all participants and analyzed using voxel-based morphometry (VBM) in SPM 8 with a BG mask. EF was assessed with the Behavior Rating Inventory of Executive Function (BRIEF) questionnaire completed by the parents on the child. A t-test was used to validate the volume difference between controls and the clinical groups. Multiple regressions were then conducted within group in VBM, between BG gray matter volume and cognitive EF measures (BRIEF scores of planning/organizing (P/O) and working memory (WM) and behavioral EF measures (BRIEF scores of emotional control and behavioral regulation) to observe whether there is a relationship between EF and BG volume. The BG was smaller in the clinical groups compared to the control group. For children with ADHD, smaller caudate volume bilaterally was related to worse P/O, and smaller right lenticular nucleus and left globus pallidus volumes were related to poor WM.

For the RD group, smaller right putamen volume was related to worse P/O. In the comorbid group, smaller left putamen and bilateral caudate volume was related to poor WM. In addition, smaller left caudate volume was related to worse P/O. Our results strengthen prior conclusions that alterations in the BG in ADHD are associated with deficits in EF. Based on our findings, these relations are specific to cognitive EF, contributing to current notions of the functions of the dorsolateral prefrontal-striatal circuit. In RD this relation is specific to higher order processing (P/O). Those with comorbid RD/ADHD generally have relationships between BG volume and cognitive EF consistent with having ADHD; however, the hemisphere and specific nucleus involved varied somewhat. Network analysis would be a beneficial next step.

Title: Functional neuroimaging of visuospatial working memory tasks enables accurate identification of attention deficit and hyperactivity disorder

Authors: *R. HAMMER[1,2], G. E. COOKE[3], M. A. STEIN[4], J. R. BOOTH[5]; [2]Interdepartmental Neurosci. Program, [1]Northwestern Univ., Evanston, IL; [3]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois, Urbana-Champaign, Urbana-Champaign, IL; [4]Dept. of Psychiatry and Behavioral Sci., Univ. of Washington Sch. of Med., Seattle, WA; [5]Dept. of Communication Sci. and Disorders, The Univ. of Texas at Austin, Austin, TX

Abstract: Finding neurobiological markers for neurodevelopmental disorders, such as Attention Deficit and Hyperactivity Disorder (ADHD), is a major objective of clinicians and neuroscientists. Here we examined if functional Magnetic Resonance Imaging (fMRI) data from few distinct visuospatial working memory (VSWM) tasks allows accurate identification of cases with ADHD. We tested 20 boys with ADHD combined type and 20 typically developed (TD) boys in four VSWM tasks that differed in feedback availability (no-feedback, feedback) and

reward size (large, small). We used a multimodal analysis based on brain activity in 16 regions of interest, significantly activated or deactivated in the four VSWM tasks (based on the entire participants' sample). Dimensionality of the data was reduced into 10 principal components that were used as the input variables to a logistic regression classifier. We found that fMRI data from the four VSWM tasks enabled classification accuracy of 92.5%, with high predicted ADHD probabilities values for most clinical cases, and low predicted ADHD probabilities for most TDs. This accuracy level was higher than those achieved by using the fMRI data of any single task, or the respective behavioral data. These findings indicate that task-based fMRI data acquired while participants perform few distinct VSWM tasks enables better identification of clinical cases. Our findings also provide an important theoretical contribution, showing that the manifestation of neurocognitive abnormalities in ADHD is context dependent. We suggest that similar approach can be adopted for diagnosing other clinical populations, and possibly also for dissociating between distinct clinical populations who share behavioral symptoms. This would require using cognitive tasks that target the neurocognitive deficits characterizing the clinical condition of interest, or a battery of tasks that may enable dissociating between distinct neurocognitive abnormalities.

Title: Variability in the auditory-evoked neural response as a potential mechanism for dyslexia

Authors: ***T. M. CENTANNI**[1], D. PANTAZIS[1], L. DENNA[2], J. D. E. GABRIELI[1], T. P. HOGAN[2];
[1]MIT, Cambridge, MA; [2]MGH Inst. of Hlth. Professions, Boston, MA

Abstract: Recent work has demonstrated that rat models of dyslexia exhibit increased trial-by-trial variability in the primary auditory cortex response to sound and that this feature is also present in the auditory brainstem response of children with dyslexia. Whether this feature is present in cortex and whether this represents a reliable biomarker for this disorder is still unknown. In the current study, we investigated whether trial-by-trial neural variability is present in auditory and/or visual cortex of children with dyslexia using magnetoencephalography (MEG); a non-invasive brain imaging technique with millisecond temporal precision. Recordings were acquired in response to auditory speech sounds and tones as well as visual presentation of letters and objects. Response consistency was calculated in three ways using Pearson's r; (1) individual trial comparisons to test general variability, (2) trials from the beginning of the session compared with trials from the end of the session to evaluate neural fatigue, and (3) even numbered trials versus odd numbered trials to evaluate consistency of the result. Our results demonstrate that decreased consistency in the neural response is present in cortex of children with dyslexia compared to typically developing children. This effect is present not only when all possible repetitions are compared, but also when responses from the beginning of the session are compared with trials at the end of the session. These results support the recent theory that neural variability could be a neural mechanism for dyslexia.

Neuorological science, Bellaria Hosp. Bologna, Bologna, Italy; [6]Second Univ. of Naples, Sch. of Medicine, Dept. Expt. Med., Naples, Italy

Abstract: Modeling neuropsychiatric problems, such as Attention-Deficit Hyperactivity Disorder (ADHD), autism and others has been useful to the understanding of elementary components of behavior. The aim of the present studies was to compare across various models of ADHD available in the literature, two behavioral traits, namely free rearing or leaning against the walls. The model systems used were the Spontaneously Hypertensive (SHR), Wystar-Kyoto Hyperactive (WK-HA), Wystar-Kyoto Hypertensive (WK-HT) and the Naples High Excitability (NHE) line. The experimental design included young adult male rats that were tested in a spatial novelty test, the Làt-maze, for 10 min. Behaviour was videotaped and analyzed for frequency of corner crossing (HA), frequency and duration of rearing (R) and leaning (L). Duration of rearing and leaning operationally define non-selective attention (NSA). Results showed (i) a higher frequency of rearing and leaning in SHR than in Wystar-Kyoto controls, (ii) a higher frequency of rearing and leaning and longer duration of leaning in WK-HA than in WK-HT rats, (iii) a higher frequency and shorter duration of leaning in NHE rats than in Naples Random-bred controls. Moreover, these studies showed a higher frequency of rearing and leaning in hyperactive SHR and WK-HA rats and a higher frequency of shorter duration leaning in NHE. In conclusion, this series of studies on rearing and leaning in genetic model systems revealed that these are dissociable traits. This, in turn, may help to understand the neural mechanisms of cognitive and non-cognitive aspects of behavior.

Abstract: Dyslexia, or Reading Disability (RD), is a specific impairment in processing written language despite adequate intelligence and educational background. RD, affecting 5-17% of school-aged children, has far-reaching social and economic consequences. Genetic studies have identified multiple candidate dyslexia susceptibility genes (CDGSs). Multiple theories of RD have emerged with the majority of available data pointing to phonological and visual deficits. Genetically altering CDSG expression in mice results in similar visual and auditory processing deficits to those identified in humans. Despite the similarities, it remains unclear whether reported deficits in animal models directly translate to RD in humans. Recent studies have demonstrated that humans using a virtual representation of a Hebb-Williams (vHW) maze task (measure of visual-spatial processing) perform similarly to mice using the standard apparatus in the laboratory. Data from our laboratory demonstrate that adults (18-22 years old) and children (8-13 years old) exhibit similar performance efficiencies on a vHW to mice completing the physical HW maze. These data suggest that humans share common problem solving skills on our vHW maze with mice completing the physical version of the maze. In the current study we examined performance of children (5-6 years of age, and 8-13 years of age) with and without RD on the vHW maze. Children with RD, in both age groups, exhibited impaired performance on this task, similar to animal models of RD. Path analysis results show commonalities in problem solving ability in this impaired group, which may lead to a marker specific to individuals with RD. Preliminary data suggest that typically developing adults (18-23 years of age) use statistical learning strategies to successfully navigate the vHW maze, but it is still unclear what strategies children with RD employ to complete the task. These data, combined with genetic analysis of CDSG expression, will provide powerful information toward our long-term goal of early identification of children at risk for reading disorder.

Title: Animal model of cognitive dysfunction responding to ADHD therapies

Authors: E. ANDRIAMBELOSON[1], E. POIRAUD[1], B. HUYARD[1], L. GORJ[1], *S. M. O'CONNOR[2], S. WAGNER[1];
[1]Neurofit, ILLKIRCH, France; [2]Bionomics Limited, Adelaide, Australia

Abstract: Over 90% of adults and children living with and seeking treatment for Attention Deficit Hyperactivity Disorder (ADHD) manifest cognitive dysfunction, particularly impairments in attention, working memory and executive function which provides support for a cognitive rather than psychomotor basis of ADHD pathology. The existing animal models for ADHD feature psychomotor behavior impairments (impulsivity and hyperactivity) but do not always favorably respond to the psychostimulant drugs used for the treatment of ADHD. In the present study, the potential of ADHD médications (methylphenidate, amphetamine and atomoxetine) to restore cognitive performance (spontaneous and continuous alternation in the T-maze) was tested in mice after pharmacological alteration of the central cholinergic system by injection of scopolamine. Amphetamine, Methylphenidate and Atomoxetine elicited dose-dependent reversion of cognitive deficit in scopolamine -treated mice. Seven days of subchronic treatment was required to obtain the cognitive effect of amphetamine whereas Methylphenidate and Atomoxetine were effective following a single acute or 3-day subchronic dosing regimen. Furthermore, Atomoxetine was effective after a short pretreatment period (0.5h prior to the T-maze task) whereas Amphetamine and Methylphenidate required longer pretreatment times (16h). The above results demonstrate that psychostimulant drugs with differing mechanisms of action have a positive effect in this model of scopolamine-induced cognitive dysfunction, and indicate its utility for evaluating the cognitive enhancing properties of new chemical entities for ADHD.

Title: Prenatal nicotine exposure produces attention deficits in male and female mice

Authors: F. FAN[1], A. GANNON[1], O. N. JACKSON[1], P. S. BOHLEM[1], S. B. STERLING[1], D. MCCATHY[1], T. SPENCER[2], J. BIEDERMAN[2], P. G. BHIDE[1], *J. ZHU[1];
[1]Ctr. for Brain Repair, Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL; [2]Clin. and Res. Programs in Pediatric Psychopharmacology and Adult ADHD, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: Inattention is a major cognitive symptom of attention deficit/hyperactivity disorder (ADHD). Maternal smoking during pregnancy is linked with a significant increase of risk for ADHD in the exposed offspring. Consistent with this, rodent models of prenatal nicotine exposure (PNE) show a number of deficits associated with ADHD. Here we characterized attention performance in a PNE mouse model using an Object-Based Attention test in which mice are exposed to 5 different objects during the training session and to 2 objects, one novel and one familiar, during the test session. Mice appropriately divide attention (time spent exploring an object) among the five objects in the training session, and then in the test session, focus attention preferentially upon the novel object. A mouse with attention deficit is not expected to favor the novel object, but focus equal attention upon familiar and novel objects. We found that male and female mice in the control group (not prenatally exposed to nicotine) spent significantly longer time exploring the novel object during the test session. However male and female mice in the PNE group spent approximately equal length of time exploring novel and familiar objects. Since methylphenidate (MPH) is among the most commonly used stimulant medications in the treatment of ADHD, we examined the effects of MPH on attention in our PNE model. We found that a single oral dose of MPH (0.75 mg/kg) improved attention in male and female mice in the PNE group such that there was no longer a difference between the PNE and control groups in this measurement. Moreover, similar administration of MPH to the control groups did not affect attention in male or female mice, nor did saline administration to male or female mice in the PNE group produce any effects on attention. Our data show that PNE produces attention deficits in both male and female mice and that MPH improves attention in both sexes. Thus, our data further support the value of the PNE mouse model as an animal model of ADHD.

Title: Pattern recognition in stop-signal fMRI classifying ADHD from siblings and controls

Authors: *T. WOLFERS[1,2], D. VAN ROOIJ[1,6], A. MARQUAND[1,7], C. BECKMANN[1,3,8], B. FRANKE[2,4], J. K. BUITELAAR[3,5];
[1]Donders Ctr. for Cognitive Neuroimaging, Radboud Univ., Nijmegen, Netherlands; [2]Dept. of Human Genet., [3]Dept. of Cognitive Neurosci., [4]Dept. of Psychiatry, [5]Karakter Child and Adolescent Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [6]Dept. of Psychiatry, Univ. Med. Ctr. Groningen, Groningen, Netherlands; [7]Inst. of Psychiatry, King's Col., London, United Kingdom; [8]Ctr. for Functional MRI of the Brain (FMRIB), Univ. of Oxford, Oxford, United Kingdom

Abstract: In earlier studies using pattern recognition, attention deficit hyperactivity disorder (ADHD) could be distinguished from healthy controls on the basis of magnet resonance imaging (MRI) derived features with promising but mixed results. These studies were preformed in small cohorts that did not include siblings. In the present study we use pattern recognition to identify functional MRI patterns that distinguish ADHD from unaffected siblings and healthy controls in a large clinical sample. In total 228 participants, belonging to ADHD-, siblings- or control-group, were tested. The groups were balanced and well matched on age and gender. Each participant preformed a stop-signal task adapted for MRI scanning. Beta weights for the main univariate task contrasts were calculated and used as input for a Gaussian process classifier (GPC). GPCs are best described as a distribution over functions. Based on Bayes' rule the posterior distribution of functions which represents the training data is found in an optimal way. This posterior distribution is used to classify new examples according to the rules of probability.

ADHD could reliably be classified from controls (area under the curve (AUC): .68; $p<.05$) as well as from their unaffected siblings (AUC: .8; $p<.05$). Siblings could not significantly be distinguished from controls. Surprisingly, the classification of ADHD from siblings was better than from controls, although siblings share neurobiological alterations related to ADHD. The present results contribute significantly to the investigation of ADHD with pattern recognition, as it is one of the largest studies performed so far and the only one in a cohort including siblings. It presents realistic estimates for the classification of ADHD based on current methodological developments in machine learning and importantly, is the first that shows the potential of pattern recognition for the diagnostics of ADHD from unaffected siblings. The present finding indicates that pattern recognition in stop-signal functional MRI task might hold the potential for the development of biomarkers for ADHD.

Title: The glutamate pathway is associated with hyperactive/impulsive symptoms and autism symptoms in Attention-Deficit/Hyperactivity Disorder

Authors: *J. NAAIJEN[1], J. BRALTEN[1], S. FARAONE[2], J. GLENNON[1], B. FRANKE[1], J. BUITELAAR[1];
[1]Radboud UMC, Nijmegen, Netherlands; [2]State Univ. of New York Upstate Med. Univ., New York, NY

Abstract: Attention/Deficit Hyperactivity Disorder (ADHD) and Autism Spectrum Disorders (ASD) are highly heritable, but finding the contributing genetic risk variants has turned out to be challenging. Many genetic studies have focused on monoaminergic candidate genes. Current

concepts of neurodevelopmental disorders also implicate glutamate, the most abundant excitatory neurotransmitter in the brain. Altered glutamatergic signaling has been implicated in both ASD and ADHD in 1H-MR spectroscopy studies, genome-wide studies of SNPs and CNVs, candidate gene association and linkage studies. As multiple genes with small effects are assumed to play a role in both ADHD and ASD, considering multiple genetic variants within the same analysis can potentially increase the total explained phenotypic variance and thereby boost the power of genetic studies. In the current study we investigated in an ADHD case-only design, whether glutamatergic signalling pathways are candidate pathways for both ADHD and ASD, and would show association with ADHD symptoms and/or autism symptoms. Phenotypes included ADHD symptom severity (inattention and hyperactivity/impulsivity symptoms) measured with Conners' Parent Scales and autism symptoms measured with the social communication questionnaire (SCQ). Variants within glutamate pathway genes (selected from Ingenuity IPA, www.ingenuity.com) including a 25-kb flanking region were selected for SNP-by-SNP linear regression with our phenotypes of interest, with age and sex as covariate. By summing effects of common genetic variants within the pathway to create an observed summed statistic and comparing this with 10.000 permutations, we were able to compute a pathway-based empirical p-value. This was based on the number of times the summed permuted statistic was more extreme than the summed observed statistic. The selection of genes yielded a total of 66 glutamatergic genes. The pathway analysis for symptoms severity showed a significant association with autism symptoms (Pempircal =.0013) and hyperactivity/impulsivity symptoms (Pempirical = .0010), but not with inattention symptoms (Pempirical = .063). Single gene and single SNP analyses did not show any significant associations. This study is the first to show an association between glutamatergic signalling and autism and hyperactivity/impulsivity symptoms in ADHD using a hypothesis-based pathway association analysis in a case-only design. Further studies investigating a possible link between ADHD and autism based on altered glutamatergic signaling are warranted.

Title: Methylation of germ cell DNA as the basis for transgenerational transmission of nicotine-induced cognitive phenotypes

Authors: *T. J. MORGAN, JR, D. M. MCCARTHY, S. E. LOWE, P. G. BHIDE;
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Exposure to environmental chemicals is known to influence our germ cells and therefore future generations. A key area of concern in this regard has been maternal nicotine use and the consequent fetal nicotine exposure. Interestingly, smoking is more prevalent among men (21.6%) than women (16.5%; CDC), and the effects of paternal tobacco use on future generations are not well understood. We have developed a mouse model of paternal nicotine exposure (200 µg nicotine in drinking water for 12 consecutive weeks), in which offspring sired by the nicotine exposed males display significant deficits in cognitive behaviors, particularly working memory and attention (two key ADHD phenotypes). Based on these intriguing findings we hypothesized that the nicotine produces epigenetic changes in the fathers' germ cells and that these changes in the germ cell DNA are the basis for transmission of an ADHD-like phenotype to the offspring. To test this hypothesis, we performed molecular genetic analysis of sperm obtained from nicotine exposed male mice to identify potential nicotine-induced epigenetic modifications of the DNA. Initial findings suggest a 40% decrease in global methylation of the sperm DNA in the nicotine exposed males. To further characterize the epigenetic changes (e.g. methylation or de-methylation) in promoter regions of specific genes, we performed 5-mC immunoprecipitation and subsequent PCR validation of sperm DNA from nicotine-exposed and drug naive males. Parallel *in vitro* studies were conducted to test the influence of direct exposure of the sperm to nicotine and other chemicals. Collectively, our findings establish, for the first time that epigenetic modification of the germ cell DNA is the mechanism of heritability of cognitive and molecular phenotypes produced by paternal nicotine exposure.

Title: Speech-evoked brainstem responses relate to KIAA0319 variants and phonological skills in pre-reading children: a biomarker for dyslexia?

Authors: *E. N. NEEF[1], J. BRAUER[1], A. WILCKE[2], H. KIRSTEN[2], B. MÜLLER[2], M. A. SKEIDE[1], J. LIEBIG[1], I. KRAFT[1], G. SCHAADT[1], N. KRAUS[3], F. EMMRICH[2], A. D. FRIEDERICI[1];
[1]Max Planck Inst., Leipzig, Germany; [2]Fraunhofer Inst. for Cell Therapy and Immunol., Leipzig, Germany; [3]Northwestern Univ., Evanston, IL

Abstract: Developmental dyslexia is a disorder most often accompanied by deficits in phonological awareness, phonemic categorization and speech-in-noise perception. Very early signals of the auditory pathway indicate an abnormal encoding of speech stimuli in reading impaired children. Their speech-evoked brainstem responses are less consistent and distinctive. An insufficient signal-to-noise ratio at the brainstem level may be a generator of established behavioural and neural irregularities found in poor readers. However, dyslexia is familial and moderately heritable but very little is known about the function of identified candidate genes. Knockdown of the dyslexia associated gene Kiaa0319 impairs temporal responses to speech stimuli in rat auditory pathway. We studied, whether KIAA0319 polymorphisms relate to phonological skills, phoneme discrimination, speech-in-noise perception and speech-evoked brainstem responses in a group of pre-reading children at familiar risk of dyslexia and in aged-matched control children. KIAA0319 was associated with the consistency of speech-evoked brainstem responses as well as with pseudoword repetition. KIAA0319 was not associated with speech perceptual acuity, phonological awareness, or speech-in-noise perception in pre-reading children. It remains to be shown, to what extend reading outcome will be related to the pre-reading physiological measures and to the genotype.

Title: FEZ1 regulates autophagy and protects against neuropsychiatric manifestation

Authors: *A. SUMITOMO[1], K.-I. NAKAYAMA[2], A. SAWA[3], T. TOMODA[1];
[1]MIC, Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan; [2]Med. Inst. of Bioregulation, Kyushu Univ., Fukuoka, Japan; [3]Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Fasciculation and elongation protein zeta-1 (FEZ1) is a scaffolding protein that regulates neuronal development and vesicle transport. FEZ1 interacts with Disrupted-In-Schizophrenia 1 (DISC1), a susceptibility factor for major mental illnesses, such as depression and schizophrenia. Although mice deficient for Fez1 display neuropsychiatric phenotypes such as psychostimulant-induced hyperlocomotion, underlying cellular mechanisms that account for such behavioral abnormalities remain to be understood. Here we show that FEZ1 regulates autophagy by binding with LC3, an autophagic membrane protein. In response to autophagy induction, FEZ1_LC3 interaction was upregulated, as confirmed by co-immunoprecipitation and Förster resonance energy transfer (FRET) assays. This interaction was mediated in part by phosphorylation of FEZ1 by Ulk1 serine/threonine kinase, and attenuated by treatment with psychoactive substances. Consistently, neurons in prefrontal cortex of Fez1 knockout (KO) mice show elevated levels of sequestosome 1 (p62) expression, suggesting attenuated autophagy. In behavioral assays, Fez1-KO mice showed hyperlocomotion and impulsivity, which were normalized by chronic treatment with methylphenidate, a psychostimulant used to control symptoms of attention-deficit hyperactivity disorder (ADHD), or with guanfacine, an α2 adrenergic receptor agonist, which is also used to treat ADHD. These lines of evidence imply that Fez1-KO mice may serve as a new mouse model of ADHD. Moreover, lithium, a mood stabilizer with autophagy-inducing activity, significantly suppressed both hyperlocomotion and impulsivity phenotypes in Fez1-KO mice, suggesting that augmenting autophagy might serve as a novel therapeutic approach against ADHD. Additionally, HPLC analysis revealed hypo-dopaminergic status of nucleus accumbens in Fez1-KO mice, a phenotype frequently observed for ADHD patients. Effects of methylphenidate, guanfacine and lithium on dopamine contents are being evaluated after treating Fez1-KO mice with these drugs, in order to further establish the predictive validity of this mouse line as a novel model for ADHD, and also to validate the autophagy induction strategy as a novel ADHD treatment. Taken together, we propose that FEZ1 regulates autophagy and protects against neuropsychiatric manifestation.

Title: The role of dyslexia-susceptibility candidate genes Kiaa0319 and Kiaa0319-Like in brain development

Authors: *L. GUIDI[1], I. MARTINEZ-GARAY[1], Z. G. HOLLOWAY[1], M. BAILEY[1], T. SCHNEIDER[2], A. P. MONACO[1], A. VELAYOS-BAEZA[1], Z. MOLNAR[1];

Abstract: The capacity for language is a key innovation underlying the complexity of human cognition and its evolution but little is understood about the molecular and neurobiological mechanisms underlying normal or impaired linguistic ability. Developmental dyslexia is a specific impairment in reading ability despite normal intelligence, educational opportunity or major sensory defects, and it is the most common neurodevelopmental disability in school-aged children [1]. Molecular genetics studies have linked several genes to susceptibility to dyslexia and, amongst these, KIAA0319 emerges as a prime candidate based on consistently replicated associations [2], with some genetic overlap with other neurodevelopmental disorders [3]. Interestingly, the paralogous gene KIAA0319-Like is the only other member of this gene family and has also been linked to dyslexia [4]. ShRNA-mediated knockdown of the rat homologues Kiaa0319 or Kiaa0319-Like were shown to impair neuronal migration in the developing neocortex [5-8], similarly to other main dyslexia-susceptibility candidate genes [e.g. 9]. Combined with human histopathological and neuroimaging studies, these findings led to the hypothesis that dyslexia is a neuronal migration disorder [10]. We are conducting detailed analyses at the molecular, neurobiological and behavioural levels using transgenic mouse lines targeting the Kiaa0319 and/or Kiaa0319-Like loci. Neuroanatomical examination of constitutive knockouts have revealed no disruption in cortical lamination or neurogenesis. Acute knockout by *in utero* electroporation of Cre-expressing plasmids in floxed mice revealed similar results and no morphological abnormalities were detected in the hippocampus and cerebellum, other laminated brain regions. Behavioural characterisation of these mice are currently ongoing. This

data suggests these genes are not required for neuronal migration in mice, contrasting with previous findings using shRNA in rats [5-8]. This discrepancy may indicate potential methodological differences, possibly due to off target effect of shRNA [11], or be indicative of functional divergence across species. [1] Peterson, R. Sch., Seoul, Korea, Republic of

Abstract: Attention-deficit/hyperactivity disorder (ADHD) is the commonest neurobehavioral developmental disorder of childhood. It characterized by the three core symptoms of hyperactivity, impulsivity, and inattention. The exact cause of ADHD is still unknown, but substantial evidence has shown this disorder has a significant genetic component. Genetic animal

models have been remarkably valuable in the understanding of this disorder. Although it cannot accurately reflect the human condition, animal models can yield insight into the disorder that cannot be obtained from human studies because of numerous limitations. However, ADHD is a heterogeneous disorder, and a single model is unlikely to be able to mimic all of its symptoms. At the same time, a model that recapitulates key endophenotypes can be useful in understanding the biological basis of ADHD and in developing specific pharmacological therapies for the clinical subtypes of this disorder. Thus, the present study sought to develop an animal model of ADHD which would recapitulate the hyperactive phenotype of the disorder. To explore some of the potential genetic underpinnings of hyperactivity in ADHD, we examined common differentially expressed genes (DEGs) in the prefrontal cortex of SHR/Ncrl, the most validated animal model of ADHD. In contrast with Wistar and WKY rats, a strain representing the "normal" heterogeneous population, SHR shows hyperactivity in various behavioral tasks. In addition, these symptoms were attenuated by treatment of psychostimulants. The common DEGs in the PFC of SHR vs. WKY/NCrl and Wistar rats are those involved in transcription, circadian rhythm, and corticotropin secretion. We then made transgenic animal models in which these genes are over- or under-expressed. Here we report our initial finding that mice over-expressing one of the candidate gene indeed showed hyperactive behavior. Additional studies are underway to further characterize the behavior of this new transgenic animal model of this transgenic animal and to elucidate any underlying neurobiological changes.

Title: Altered regional homogeneity in children with ADHD: A surface-based analysis

Authors: *J. YOO[1], I. KIM[3], B.-N. KIM[4], B. JEONG[2];
[2]Grad. Sch. of Med. Sci. and Engin., [1]Korea Advanced Inst. of Sci. and Technol., Yu-sung-Gu, Daejeon, Korea, Republic of; [3]Dept. of Psychiatry, [4]Dept. of Psychiatry and Inst. of Human Behavioral, Seoul Natl. Univ. college of medicine, Seoul, Korea, Republic of

Abstract: Introduction Attention deficit hyperactivity disorder (ADHD) is one of the most common neurodevelopmental disorders of childhood. Previous studies have implicated that

dysfunctional modulation of the default mode network activity might be responsible for regulation deficits in children with ADHD. We hypothesized that spontaneous brain activity of ADHD can be affected by either disease state or developmental change with aging. For this aim, we tested functional measures reflects spontaneous brain activation such as amplitude of low frequency fluctuation (ALFF), fractional ALFF (fALFF), and regional homogeneity (ReHo) with resting state functional MRI (rs-fMRI). **Methods** A total of 181 subjects (120 ADHD, 61 Control), were included in this study. ALFF and fALFF were calculated using frequency band around 0.009-0.08 Hz and ReHo was measured from Kendal's coefficient of concordance from 27 surrounding voxels. For the accurate registration, those measures projected to spherical surface created by Freesurfer image analysis suite version 5.3 (http://surfer.nmr.mgh.harvard.edu/), then, the effect of diagnosis and interaction with age were estimated using general linear model after controlling effect of gender, IQ and intracranial volume. **Results** ADHD group showed reduced ReHo in the cluster located at the left postcentral ($z=-6.319$, $p=0.002$) and right superior temporal surface ($z=-7.3685$, $p=0.002$). In contrast, a cluster in precentral area had increased ReHo than healthy control group ($z=5.711$, $p=0.002$). Significant group effect was not found in ALFF and fALFF analysis, and none of the measures showed age by diagnosis interaction effect. **Discussion** We found alteration of ReHo in primary sensory and motor cortex in ADHD group, which suggests baseline spontaneous neuronal activity of these regions reflects underlying pathophysiology in children with ADHD.

Title: Goal-directed behavior is impaired in Spontaneously Hypertensive Rats and Methylphenidate remediates this deficit in a dose-dependent manner

Authors: *J. Y. NATSHEH[1,2], F. AL-SHAMMARY[3], A. KOSC[3], M. W. SHIFLETT[3];
[1]Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ;

[2]Palestinian Neurosci. Initiative, Al-Quds Univ. Med. Sch., Jerusalem, Palestinian Territory;
[3]Psychology, Rutgers, the State Univ. of New Jersey, Newark, NJ

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is a psychiatric disorder that is primarily characterized by symptoms of inattention. Attentional impairments are well described in ADHD; however, no studies have examined goal-directed control over behavior. In a previous study, using outcome devaluation paradigm, we examined goal-directed behavior and the effect of methylphenidate (MPH) on the pattern of this behavior in adult (P75-P105) Spontaneously Hypertensive Rat strain. SHR is the best validated animal model of ADHD as it mimics the fundamental behavioral, genetic and neurobiological correlates of ADHD in humans. We found that SHR has a deficit in goal-directed behavior as compared to Wistar Kyoto controls (WKY). Administration of 2.0 mg/kg of MPH remediated this deficit in SHR and impaired goal-directed behavior in WKY. To validate our findings, we performed three follow-up experiments: (1) we tested the same age group of SHR and WKY on a contingency degradation test, which provides an alternative assessment of goal-directed behavior; (2) we tested adolescent (P35-P60) SHR and WKY rats on outcome devaluation paradigm to characterize the pattern of goal-directed behavior in a different age group; (3) we investigated the effects of different doses of MPH (0.5, 1.0, and 4.0 mg/kg) on goal-directed behavior in adolescent SHR and WKY rats. In all experiments we trained the rats on an instrumental conditioning paradigm in which they separately acquired two distinct action-outcome contingencies. In Experiment 1, we degraded one of the acquired action-outcome contingencies by non-contingently delivering one of the instrumental outcomes. During an extinction test SHR showed no effect of contingency degradation on lever preference as compared to WKY that reduced responding on the degraded lever. In Experiment 2, we tested adolescent SHR and WKY rats on a choice test conducted in extinction following instrumental training. Prior to test one of the food outcomes was devalued through specific satiety and rats received a dose of either 2.0 mg/kg of MPH or normal saline. SHR showed no effect of outcome devaluation on choice behavior, in contrast to WKY. Furthermore, unlike adult SHR rats, a dose of 2.0 mg/kg did not restore this deficit. In Experiment 3, we used the same paradigm in experiment 2, but with different doses of MPH. We found that only a dose of 1.0 mg/kg of MPH is sufficient to restore outcome-sensitive behavior in this age group. These experiments strongly suggest that SHR has a fundamental deficit in goal-directed action control that can be remediated by MPH administration in a dose-dependent manner according to the animal's developmental stage.

Title: New EEG measures reveal infra-slow fluctuations in both attending and ignoring in adults with ADHD that provide high accuracy in discriminating ADHD from control

Authors: A. LENARTOWICZ[1], *G. V. SIMPSON[2], S. R. O'CONNELL[1,2], S. L. M. NOAH[2], A. L. HEAD[1], R. M. BILDER[1], J. T. MCCRACKEN[1], S. Y. BOOKHEIMER[1], R. REID[1], M. S. COHEN[1];
[1]Semel Inst. for Neurosci. and Human Behavior, UCLA, Los Angeles, CA; [2]Think Now, San Francisco, CA

Abstract: There is a great need for brain-based measures in the assessment of Attention Deficit/Hyperactivity Disorder (ADHD) for better diagnosis and treatment evaluation, and for development of brain-based models (in keeping with RDoC). Within-individual variability in performance is commonly cited as reflecting inconsistent control of attention in ADHD, and has been characterized as infra-slow fluctuations in performance (roughly 0.1 to 0.02Hz). We also know that attention control involves two separable functions (and possibly brain systems), attending and ignoring, suggesting that ADHD might involve deficits in consistent and purposeful maintenance of either attending or ignoring or both. We created and tested a new EEG-based method for characterizing the infra-slow fluctuations (ISFs) of steady-state visual evoked potentials (SSVEPs) reflecting attended target and ignored distractor processing during a sustained attention task. We studied 28 adults with ADHD and 28 matched controls with a battery of neuropsychological tests, questionnaires and cognitive tests as well as the new EEG measure - the Neurophysiological Attention Test (NAT). The NAT uses a sustained spatial attention task in which the stimuli on the left and right of fixation flicker at different frequencies providing SSVEPs corresponding to the attended and ignored stimuli. We analyzed the infra-slow fluctuations in the SSVEP magnitudes (256 channel recordings) for both attending and ignoring over time during the sustained attention task. Consistent with our hypothesis, the results revealed that adults with ADHD have much larger infra-slow fluctuations in both their attended and ignored SSVEP signals as well as their performance relative to control participants. Furthermore, the NAT indicators, both behavioral and EEG, successfully discriminated between individuals with ADHD from healthy comparison individuals (effect size = 0.75), and correlated with scores on rating scales widely used to characterize the inattentive and impulsive features of ADHD. Discriminant function analyses revealed the NAT to be superior to the Conners CPT and the Theta/Beta EEG measures: Sensitivity: 79%, 79% and 43% (respectively) and Specificity: 89%, 82%, 64% (respectively). We conclude that attention control in ADHD is associated with

instability in the sustaining of attending and ignoring processes, this instability can be measured using the newly developed NAT, which offers high accuracy in predicting diagnosis.

Title: Characterizing the effects of Tsc1 mutations on thalamic circuit function

Authors: R. MARTINEZ-GARCIA, J. M. SMITH, S. R. CRANDALL, B. VOELCKER, M. ZERVAS, *B. W. CONNORS;
Dept of Neurosci., Brown Univ., Providence, RI

Abstract: Tuberous Sclerosis (TSC) is a developmental genetic disorder caused by mutations in *TSC1* and/or *TSC2*. Neurocognitive signs in TSC patients include epilepsy, intellectual disability, and autism, but the altered cellular mechanisms underpinning TSC are poorly understood. One brain region implicated in the pathology of some TSC patients is the thalamus. Thalamic relay nuclei are functionally distinct clusters of excitatory neurons that project to the neocortex. Relay neurons also excite neurons of thalamic reticular nucleus (TRN), which in turn inhibit relay neurons. The laboratory previously generated a mouse model in which *Tsc1* was deleted in ~70% of relay neurons on E12.5 (Normand et al., *Neuron*, 78:895, 2013). This mosaic deletion was sufficient to disrupt thalamic circuits and caused aberrant repetitive grooming and seizures. An

unresolved question is how functional neural circuits are affected in this model. We tested whether mosaic *Tsc1* deletion alters the intrinsic properties, synaptic function, and synaptic architecture of thalamic relay neurons. We first replicated previous results (Normand et al., 2013), confirming that $Tsc1^{\Delta/\Delta(Thal)}$ relay neurons have lower input resistance and reduced excitability. Action potentials of $Tsc1^{\Delta/\Delta(Thal)}$ neurons have larger amplitudes and faster rates of depolarization and repolarization. When firing in tonic mode, $Tsc1^{\Delta/\Delta(Thal)}$ neurons have shallower frequency vs. stimulus current slopes than those of wild type relay neurons. When firing in bursting mode, $Tsc1^{\Delta/\Delta(Thal)}$ neurons have increased intra-burst frequency compared to wild type relay neurons. $Tsc1^{\Delta/\Delta(Thal)}$ neurons also have ectopic expression of the calcium binding protein parvalbumin, which may affect thalamic physiology (Normand et al., 2013). Interestingly, *Tsc1* deletion in relay neurons decreased the frequency of miniature excitatory postsynaptic currents and reduced the paired pulse depression of evoked synaptic responses in neurons of the TRN. Our results suggest that altered neurotransmission is likely caused by changes in presynaptic function, such as reduced release probability. Circuit dynamics can also be altered by changing the number and distribution of synapses. However, we observed no significant differences in excitatory or inhibitory synaptic markers in relay neurons or excitatory synaptic markers in TRN neurons. We are now testing how mosaic deletion of *Tsc1* in relay neurons affects synaptic strength, dynamics, and network functions of the relay neuron-TRN circuit.

Title: Acute prenatal exposure to valproic acid (VPA) alters social and anxiety-like behaviors in prairie voles

Authors: *L. L. ELVIR[1], H. WANG[2], F. DUCLOT[1], Y. LIU[2], Z. WANG[2], M. KABBAJ[1];

Abstract: Previous studies have shown that rats and mice prenatally treated with sodium valproate (valproic acid, VPA) exhibit deficits in social behaviors that resemble some aspects of autism spectrum disorders. In this study, the socially monogamous prairie vole *(Microtus ochrogaster)* was used as a novel animal model to examine social behaviors following prenatal VPA exposure. Male and female control and VPA-exposed subjects were assessed on a battery of social tests to evaluate the VPA-induced social deficits and anxiety-like behavior. VPA-pretreated voles engaged in fewer play behaviors and had reduced social interaction with novel conspecifics of the same age, compared to control animals. VPA-pretreated male, but not female, subjects showed enhanced anxiety-like behavior and did not develop partner preference when they became adults. We are now in the process of examining whether some of these VPA-induced social deficits in male subjects can be ameliorated by histone deacetylase (HDAC) inhibitors administered at different developmental periods.

Title: Functional connectivity impairments resulting from neurofibromin deficiency are linked to striatal dysfunction

Authors: *B. SHOFTY[1], E. BERGMANN[1], N. COHEN[1], A. KAVUSHINSKY[1], S. CONSTANTINI[2], I. KAHN[1];
[1]Kahn lab, Technion, Haifa, Israel; [2]Pediatric Neurosurg., Tel-Aviv Med. Ctr., Tel-Aviv, Israel

Abstract: Deletion of neurofibromin, results in several cellular and systemic defects. Children suffering from this syndrome (termed neurofibromatosis type 1 [NF1]) display a unique profile of attention, memory and various psychomotor impairments. A potential pivotal role for the basal ganglia in NF1 associated impairments was suggested. We used whole-brain intrinsic functional connectivity MRI to interrogate functional changes in NF1 mice. Three Nf1+/- mice were scanned awake in a 9.4 Tesla MRI, for a total of 116 scans (15.4 data hours), and 3 littermate Nf1+/+ (wild-type) mice serving as control animals were scanned a total of 120 scans (16 data hours). Coherent slow fluctuations in the fMRI signal across the entire brain were used to interrogate the pattern of functional connectivity of the cortical and subcortical structures between NF1 and wild-type mice and as compared to normal connectional anatomy in the mouse brain. While neurofibromin deficiency is estimated to be equivalent across cortical regions, measures of functional connectivity differed across brain systems. Specifically, primary motor cortex demonstrated reduced correlation with contralateral primary motor and secondary motor cortices, resulting in overall reduced motor cortical network correlations. Primary somatosensory cortex showed increased correlation with contralateral primary somatosensory, and secondary somatosensory cortices, resulting in overall increased somatosneosry cortical network correlations. Brain-wide analysis revealed a common source for this effect when comparing the projection fibers of these regions to subdivisions within the dorsal striatum. In both pathways increased corticostriatal connectivity was observed in the NF1 group. While maintaining spatial organization in relation to connectional anatomy, the NF1 group demonstrated increased corticostriatal connectivity with both motor and sensory cortices. Next we sought to test whether this pattern of functional connectivity was present in NF1 pediatric patients. We performed whole-brain intrinsic functional connectivity MRI in NF1 pediatric patients (n = 20; 6.2 ± 2.8 yo) and age-matched controls (n = 20; 7.7 ± 0.6, yo). Similar to the NF1 animals, we found that corticostriatal connectivity is increased in the patient group when compared to normal controls. The present results implicate the dorsal striatum as a source for altered cortical activity seen in NF1 patients. We would like to propose the striatum as a therapeutic target for alleviating the neurocognitive phenotype in neurofibromatosis type 1.

Title: Adolescent suppression of prefrontal nicotinic signaling shapes attention

Authors: *E. NABEL, M. DEMARS, J. SHORT, H. KOIKE, H. MORISHITA;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Attention, the cognitive function that selects task-relevant information, is pervasively impaired in neurodevelopmental disorders and psychiatric illnesses with developmental contributions. Despite this important link, the mechanisms driving development in neural systems mediating attention are poorly understood. Regulatory mechanisms of visual cortex development -the preeminent model for cortical maturation- have been identified in other brain regions and provide a conceptual framework for studying cortical development underlying other functions. Lynx1, a critical period regulator, spurs cortical maturation in the visual cortex by antagonizing nicotinic acetylcholine receptors (nAChRs). Furthermore, the nACh system is integral to attention processing. In light of this converging evidence, we tested the hypothesis that Lynx1 plays a key role in establishing frontal cortex-dependent attentional function. We coupled genetic, viral, pharmacological, and histological approaches to behavioral measures of attention using a translational automated touchscreen version of the 5 choice serial reaction time test. We first found that Lynx1 knock-out mice displayed attention deficits in adulthood. This functional deficit was associated with reduced task-dependent-activation of anterior cingulate cortex (ACC) neurons that increasingly express Lynx1 during the peri-adolescence period and throughout adulthood. Viral knockdown of Lynx1 in the ACC from adolescence into adulthood phenocopied the impairment. Strikingly, this attention deficit was rescued by a chronic 10 day pharmacologic nAChR blockade both during peri-adolescent and adult periods -but not by acute blockades during attention testing. These data suggest that, in the absence of Lynx1, excess nAChR signaling across adolescent development may “freeze” attentional circuit maturation, rendering immature cortical circuits that underlie aberrant frontal cortex activity and long-lasting impairment in attention. Developmental regulation of attentional function by Lynx1 may prove a novel mechanism and therapeutic target for a major cognitive function disturbed in psychiatric disorders with developmental contributions including autism, ADHD, and schizophrenia. *E.N., M.D., J.S. equal contribution

Abstract: Evidence supports that autism spectrum disorder (ASD) is associated with modifications in GABAergic and glutamatergic neurotransmission, effect that may be related to hiperexcitability observed in those patients. In fact, some epidemiological reports show higher prevalence of epilepsy (10-30%) in ASD patients than in the general population. The aim of this study was to determine brain tissue and plasma amino acid concentration in rats prenatally exposed to valproic acid (VPA), a well-accepted experimental model of autism. Pregnant females were injected with VPA (600 mg/Kg, i.p.) during the twelfth embryonic day (E12); control rats were injected with saline solution during E12. On the fourteen postnatal day, rats from both experimental groups were anesthetized with pentobarbital, euthanized by decapitation and their brain dissected out on frappe ice. Then, frontal cortex, hippocampus, amygdala, brain stem and cerebellum were dissected and homogenized in 0.1 M perchloric acid containing 4 mM sodium bisulfite. Homogenates were centrifuged and supernatant was used to quantify GABA, glutamate, glutamine, alanine and glycine tissue concentrations by HPLC coupled with fluorometric detection. Blood samples were obtained by cardiac puncture on anesthetized rats; plasma was separated and deproteinized with 0.5 M perchloric acid in order to quantify amino acids concentration by HPLC. Amino acid tissue levels were similar in control and VPA rats for all the brain areas analyzed. Plasma concentration of GABA was significant higher (53%) in VPA rats when compared with control rats ($t=4.04$, $p=0.0004$); however, no differences were detected between experimental groups for the other amino acids evaluated. Increased GABA concentration observed in the plasma from rats prenatally exposed to VPA could be related to brain immaturity and hiperexcitability due to an excitatory effect of GABA.

Title: Experience-dependent morphological changes in the indirect basal ganglia pathway mediate repetitive motor behaviors

Authors: A. BECHARD[1], N. CACODCAR[2], M. A. KING[3], A. MUEHLMANN[4], *M. H. LEWIS[4];
[1]Psychology, [3]Neurosci., [2]Univ. of Florida, Gainesville, FL; [4]Psychiatry, UF Col. of Med., Gainesville, FL

Abstract: Repetitive motor behaviors are observed in many neurodevelopmental and neurological disorders (e.g. autism, Tourette syndrome, fronto-temporal dementia). Despite their clinical importance, the neurobiology underlying these invariant, apparently functionless behaviors is poorly understood, and there are no effective pharmacological treatments. Identification of mechanisms that mediate the development of repetitive behaviors will aid in the discovery of new therapeutic targets and treatment development. Using a deer mouse model, we have shown that decreased indirect basal ganglia pathway activity is associated with high levels of repetitive behavior. We, and others, have shown that environmental enrichment (EE) markedly attenuates the development of such aberrant behaviors in mice, although mechanisms driving this effect are unknown. Thus, we hypothesized that EE would reduce repetitive behavior by increasing indirect basal ganglia pathway function. We tested the effects of EE on repetitive behavior of deer mice and basal ganglia dendritic morphology. Following Golgi-Cox histochemistry, we measured dendritic spine density and length in the dorsolateral striatum (DLS), substantia nigra pars reticulata (SNR), and subthalamic nucleus (STN) in adult mice reared in EE and standard housing. EE significantly increased dendritic spine density only in the STN and only for those mice that exhibited a marked EE-induced decrease in repetitive behavior. As the STN lies exclusively in the indirect pathway, these data suggest that EE-induced attenuation of repetitive behavior is associated with increased functional activation of the indirect

basal ganglia pathway. These results are consistent with our other findings highlighting the importance of the indirect pathway in mediating repetitive behaviors.

Abstract: Mutations in the creatine (Cr) transporter (CrT) gene lead to cerebral creatine deficiency syndrome-1 (CCDS1), an X-linked metabolic disorder characterized by cerebral Cr deficiency causing intellectual disability, seizures, movement and behavioral disturbances, language and speech impairment (OMIM #300352). CCSD1 is still an untreatable a pathology that can be very invalidating for patients and caregivers. Only two murine models of CCDS1, one of which is an ubiquitous knockout mouse, are currently available to study the possible mechanisms underlying the pathologic phenotype of CCSD1 and to develop therapeutic strategies. Given the importance of validating phenotypes and the efficacy of promising treatments in more than one mouse model we have generated a new murine model of CCSD1 obtained by ubiquitous deletion of 5-7 exons in the Slc6a8 gene. We showed a remarkable Cr depletion in the murine brain tissues and cognitive defects, thus resembling the key features of human CCSD1. These results confirm that CCDS1 can be well modeled in mice. This CrT−/y

murine model will provide a new tool for increasing the relevance of preclinical studies to the human disease.

Title: Generation and characterization of a CNS-specific Ikbkap/Elp1 mouse model of Familial Dysautonomia

Authors: ***M. A. MERGY**[1], M. CHAVERRA[1], L. GEORGE[1], N. PODGAJNY[1], H. WALLER[1], A. GRINDELAND[2], C. CUSICK[1], G. CARLSON[2], F. LEFCORT[1];
[1]Cell Biol. and Neurosci., Montana State Univ., Bozeman, MT; [2]McLaughlin Res. Inst., Great Falls, MT

Abstract: Familial Dysautonomia (FD), also known as Hereditary Sensory and Autonomic Neuropathy (HSAN) Type III, results from an intronic point mutation (IVS20 +6T → C) in the gene IKBKAP. Classic hallmarks of the disease include decreased pain and temperature sensation, orthostatic hypotension, scoliosis, reduced tear production, and dysautonomic "crises" marked by vomiting, hypertension, and tachycardia. In addition to substantial changes to the peripheral nervous system (PNS), the central nervous system (CNS) is also abnormal in FD patients. CNS signs of FD include high anxiety, learning and cognitive impairment, seizures, decreased motor nerve conduction, ataxia, and reductions in size in specific CNS nuclei. We have previously reported a mouse model in which Ikbkap is selectively deleted from neural crest cells (precursors for most of the PNS) and found that neural crest migration occurs normally, and that Ikbkap is required for survival of neural progenitors and post-mitotic neurons in the PNS (Hunnicutt et al., 2012; George et al., 2013; Jackson et al., 2014). We have subsequently generated a mouse model where Ikbkap is selectively deleted from the CNS (cKO). This mouse model recapitulates several characteristics of human FD, including small stature, kyphosis, and slow gait. Gross morphological analysis reveals that the brains of Ikbkap cKO mice are smaller

than control brains, and show enlarged lateral ventricles and hippocampi (Chaverra et al., in preparation). We have also examined behavioral alterations in our Ikbkap cKO mice and have found a non-significant increase in basal locomotor activity, a significant reduction in anxiety-like behavior, and apparent learning and memory deficits. Furthermore, our cKO mice display repetitive jumping behavior and abnormal social interactions with conspecific mice, traits commonly associated with autism spectrum disorders. Our CNS-specific Ikbkap knockout mouse displays many features of FD and will be a valuable tool for studying the role of the CNS in this disease.

Title: Chemogenetic inactivation of dorsal anterior cingulate cortex neurons disrupts attentional behavior in mouse

Authors: *H. KOIKE[1], M. DEMARS[1], J. SHORT[1], E. NABEL[1], S. AKBARIAN[1,2,3], M. BAXTER[1,2,3], H. MORISHITA[1,2,4,5,3];

Abstract: Attention, the process of selecting task-relevant information from incoming sensory stimuli, is disrupted commonly in psychiatric disorders. Dorsal anterior cingulate cortex (dACC) excitotoxic lesions and pharmacological disinhibition are associated with deficits in this cognitive ability, however, no causal link between dACC neuronal activity and attention performance has been established. Moreover, this association has been observed in humans, monkey, and rat, but has not yet been examined in a genetically tractable species such as mice. Here, we establish a causal role of the dACC neuronal activity in attention behavior by

combining a chemogenetic approach that allows reversible neural activity manipulations with a translational, touchscreen-based attention task. We virally expressed inhibitory hM4Di designer receptor exclusively activated by a designer drug (DREADD) in dACC neurons, and examined the effects of this inhibitory action with the attention-based 5-choice serial reaction time task. DREADD inactivation of the dACC neurons during the task significantly increased omission and correct response latencies, indicating that the neuronal activities of dACC contribute to attention and processing speed. Selective inactivation of excitatory neurons in the dACC not only increased omission, but also decreased accuracy. This finding suggests that dACC excitatory neurons play a principle role in modulating attention and further proposes that a physiologic balance between excitatory and inhibitory tone is pertinent to attention behavior. The effect of inactivating dACC neurons was selective to attention as response control, motivation and locomotion remain normal. Our findings demonstrate that dACC neuron inactivation produces attention deficits. This study establishes a foundational chemogenetic approach in a genetically tractable species to dissect specific cell-type and circuit mechanisms underlying attentional behaviors.

Title: Neural activation differences in prefrontal-striatal-cerebellar circuitry and striatal gene expression in a selectively bred hyperactive mouse line

Authors: ***P. MAJDAK**[1], B. PANOZZO[2], E. L. GROGAN[2], T. K. BHATTACHARYA[2], J. S. RHODES[2];
[2]Beckman Inst., [1]UIUC, Urbana, IL

Abstract: Attention deficit-hyperactivity disorder (ADHD) is a relatively common behavioral disorder characterized by developmentally inappropriate levels of hyperactivity, inattention and

impulsivity. It is highly heritable; however, the specific genes and neurobiological risk factors remain unknown, partly due to the fact that few animal models have been generated for the purpose of exploring the neurobiological changes underlying a hyperactive phenotype. The goal of this study was to continue our ongoing evaluation of a line of mice selectively bred for increased locomotor activity in the home cage for construct validity as an animal model for ADHD. Two lines of mice were maintained for over 18 generations. One line, referred to as High-Active, was subjected to within family selection each generation for increased total distance traveled in the home cage. The other line, referred to as unselected Control, was randomly bred each generation (except avoiding sibling mating). The purpose of the first experiment was to examine whether High-Active mice show differential activation of the prefrontal cortex, striatum, and cerebellum as compared to Control mice under baseline conditions. Reduced functionality of these regions is increasingly identified in clinical observations of individuals with ADHD. Neural activation in these lines was assessed by immunohistochemical detection of the protein product of the immediate early gene, c-fos. Furthermore, we were interested in determining whether therapeutic amphetamine administration would correct regional deficits in the High-Active mice. Therefore mice of each line were injected with either 0.25 mg/kg amphetamine or saline 90 minutes prior to sacrifice. The purpose of the second experiment was to determine via qPCR whether certain candidate genes identified as contributors to the pathophysiology of ADHD (dopamine- and serotonin-related) are differentially expressed in the striatum of our High-Active vs. Control mice. Preliminary data suggest that amphetamines differentially regulate prefrontal cortical activation of High-Active mice relative to Controls, which supports the construct validity of our High-Active line as a potential model for ADHD.

The Anesthesia Research Distinguished Trailblazer Award

Title: Enhanced ascending serotonergic system activity in the Timothy syndrome mouse model of autism spectrum disorder

Authors: *D. G. EHLINGER, C. M. PANZINI, K. G. COMMONS;
Dept. of Anesthesia, Boston Children's Hosp/Harvard Med. Sch., Boston, MA

Abstract: Accumulating evidence suggests that altered function of the ascending serotonergic system may underlie the development and/or behavioral impairments characteristic of autism spectrum disorder (ASD). However, dissecting the neural underpinnings of ASD has proven to be a unique challenge for neuroscience research, as animal models must accurately represent the pervasiveness of the disorder across a widespread variety of behaviors and incorporate a known environmental or genetic influence that has been found in the human condition. The TS2-neo mouse model of ASD contains a G406R mutation in exon 8 of the CaV1.2 L-type calcium channel locus (Cacna1c) associated with Timothy Syndrome. In heterozygous mice, a proportion of CaV1.2 channels display reduced channel inactivation, leading to behavioral abnormalities reminiscent of all components in the core triad of ASD symptomology: repetitive and perseverative behavior, deficits in communication ability, and impaired social behavior. Interestingly, human genetic variation in CaV1.2 channels has also been strongly associated with neuropsychiatric illness including bipolar disorder and schizophrenia. Here, we utilize the TS2-neo mouse model to assay abnormalities in serotonergic system structure and function that may be involved in the etiology of ASD and other disorders. In response to an acute stressor known to alter the activity state of the ascending serotonin system (forced-swim test), immunofluorescent co-labeling of Tph2 and c-Fos reveals that TS2-neo mice exhibit enhanced serotonin neuron activity and 5HT1A-dependent feedback inhibition across multiple subregions of the dorsal raphe nucleus, while coping behavior remains unimpaired. These changes in serotonin neuron activity are accompanied by increased serotonin concentration and altered serotonin turnover in forebrain structures, including the dorsal striatum and amygdala, that have been previously associated with behavioral impairments in ASD, bipolar disorder, and schizophrenia. Collectively, our results suggest the presence of abnormalities in the ascending serotonergic system of TS2-neo mice, and may reflect a common neural circuit that is disrupted in both ASD and neuropsychiatric illness.

Title: Ectopic sox2 cells and neuroglial heterotopia in the hindbrain of the frog model of fetal alcohol syndrome

Authors: *B. KATBAMNA[1], T. BEEBE[1], C. IDE[2];
[1]Speech Pathology & Audiol., [2]Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Previous work in our laboratory showed that developmental exposure to alcohol produced significant eye and craniofacial anomalies in the Xenopus model of fetal alcohol syndrome. The most notable abnormality associated with craniofacial malformations was ectopic positioning of ventricular zone connexin 43 (Cx43) cells in the hindbrain, with clusters in the lateral gray matter and neuropil. In the present study we examined Sox2 and BLBP expression in the proliferating cells of the ventricular zone and its relationship to Cx43 cells. Xenopus laevis embryos were exposed to 2% ethanol in spring water along with a control cohort with no ethanol, before neural tube closure at stages 10-12 for 24 hours. BrdU exposure was conducted on day 4 post-exposure for 24 hours and animals were fixed on day 5 post-exposure for assays. All animals in the control group showed BrdU and Sox2 or BLBP co-labeling at the ventricular zone, with Cx43 cells in mid-rhombomeric locations. Alcohol exposed animals showed normal overall organization of hindbrain rhombomeres, however, positioning of BrdU, Sox2 and Cx43, but not BLBP expressing cells was altered. Specifically, proliferating cells occurred at both the ventricular margin as well as in the subventricular zone. Some of these ectopic subventricular proliferating cells were also Sox2 and Cx43 positive, but not BLBP positive. Thus, alcohol exposure appears to cause abnormal movement of Sox2 and Cx43 positive proliferating cells away from the ventricular margin in the hindbrain, disrupting normal craniofacial development. Since Cx43 expressing cells have been shown to be involved in cell migration and axonal guidance during normal development, abnormal movement of Cx43 cells may explain ethanol induced neural and craniofacial abnormalities. Moreover, positional displacement of Sox2, a universal marker of neural stem cells known to promote cell division and differentiation, suggests that Sox2 may be the primary source of heterotopia related defects. In summary, the normal expression of BLBP, a stem cell marker associated with radial glial cells, but aberrant disposition of Cx43 and Sox2 in the lateral gray matter and neuropil, supports the idea that Cx43 and Sox2 may mediate heterotopia.

Abstract: Autism spectrum disorders (ASD) are a severe neurodevelopmental disorders, which typically emerge early in childhood. Animal models of ASD include various genetically modified strains as well as inbred strains of mice expressing traits relevant to autism and targeted mutations in candidate genes. One of the used models is a BTBR $T^{+tf/J}$ mouse model which reportedly exhibits several symptoms of ASD, including reduced social interactions, low exploratory behavior, unusual vocalizations, and high anxiety as compared to other inbred strains. Also, mouse brain anatomy in this model has previously revealed profound abnormalities in the mouse phenotype when compared to regular strains, such as C57Bl/6. Due to the reported ASD related features of this strain, our objective was to characterize BTBR $T^{+tf/J}$ (BTBR) model phenotype. We sought to evaluate behavioral phenotype but also brain abnormalities at different ages of the mice by using different imaging tools. BTBR and C57BL6/J mice were behaviorally tested for spontaneous locomotor activity in open field, anxiety like behavior in elevated plus maze, impairments in social behavior and interaction, cognitive functions in T-maze reversal learning and contextual fear conditioning, social transmission of food preference, as well as for stereotypic behavior at different ages. Brain anatomical and metabolic profile was assessed by using MRI and 1H-MRS, respectively. Furthermore, histological/immunohistochemical and biochemical tools were used to assess ASD related markers and to compliment MRI/1H-MRS data from the model.

Title: Diminished rates of protein synthesis in a mouse model of Tuberous Sclerosis Complex: an mTORC1-dependent phenomenon

Authors: *R. M. REITH, T. HUANG, T. BURLIN, C. BEEBE SMITH;
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Tuberous Sclerosis Complex (TSC) is an autosomal dominant neurogenetic disorder affecting about 1 in 6,000 people, leading to benign growths throughout the brain and other vital organs. TSC usually has effects on the central nervous system manifested by a high incidence of seizures, intellectual disability, and autism. TSC is caused by mutations in either TSC1 or TSC2, which encode for proteins that form a complex and interact with a small GTP-binding protein, RHEB, to inhibit mammalian target of rapamycin complex 1 (mTORC1). mTORC1 is a central regulator of ribosomal biogenesis and translation initiation, and loss of TSC1/2 function results in increased activity of mTORC1. Nevertheless, heterozygous loss of Tsc2 leads to diminished protein synthesis both *in vitro* and *in vivo*. Specifically, with the *in vivo* quantitative autoradiographic L-[1-14C]leucine method, we found reduced rates of cerebral protein synthesis (rCPS) in Tsc2+/- mice at 3 months of age, particularly in the parietal cortex, dorsal and ventral hippocampus, median raphe, and visual cortex. We treated mice with rapamycin to determine if we could reverse this phenotype. We performed both acute and chronic rapamycin studies. For acute studies, we injected 3mg/kg rapamycin or vehicle (about 5% ethanol) i.v., 30 min prior to tracer infusion. For chronic studies, we treated mice from P21 until P90-P105 with rapamycin-enriched chow to achieve a daily dose of approximately 2.2mg/kg. Preliminary results indicate that acute rapamycin treatment of Tsc2+/- mice (n=5) increased rCPS in many brain regions, including thalamus, hippocampus, and parietal cortex compared to vehicle-treated Tsc2+/- mice (n=4). Rapamycin treatment did not significantly alter rCPS in controls. In vehicle-treated animals, we confirm decreased protein synthesis in Tsc2+/- mice (n=4) compared to controls (n=3). Our preliminary results suggest a complex role of mTORC1 in the regulation of cerebral protein synthesis, a role that is sensitive to rapamycin treatment.

Title: Congenic and BAC transgenic manipulations of BTBR mice correct interhemispheric connectivity defects

Authors: *A. SNYDER-KELLER[1,2], K. MANLEY[1], K. KLUETZMAN[1], V. J. BOLIVAR[1,2]; [1]Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY; [2]Biomed. Sci., U Albany Sch. of Publ. Hlth., Albany, NY

Abstract: Investigations into the pathological basis of autism spectrum disorder (ASD) have benefitted from the study of mouse strains that model both behavioral and neuroanatomical characteristics. Inbred strains that exhibit reduced social behavior and increased repetitive behaviors, such as BTBR T+Itpr3tf/J (BTBR), also have decreased interhemispheric connectivity. Using a combination of congenic (FVB/NJ (FVB) donor DNA) and BAC transgenic (C57BL/6J (B6) source DNA) strains on a BTBR background, we have identified a locus on the distal end of Chromosome 4 that, when replaced/supplemented with DNA from a "normal" strain (FVB or B6), corrects the connectivity defect seen in BTBR mice. The corpus callosum is fully formed in the majority (over 70%) of our heterozygous congenics, and in 100% of those homozygous for FVB at this locus. The majority (60%) of BAC transgenics were also fully corrected. The remaining mice exhibited a "partial correction" phenotype that consisted of a normal corpus callosum appearance caudally, but a failure of fibers to cross in more rostral sections. Interestingly, a smaller percentage of females - both congenic and transgenic - were fully corrected compared to males. Here we present a comprehensive analysis of forebrain connectivity, using a non-suppressive silver stain for intact neural fibers (Lund & Westrum modification of the Nauta-Gygax technique). Semi-quantitative assessment of the rostral-caudal extent of crossing fibers will be related to behavioral performance in the congenic and transgenic mice. We also use DiI tracing of commissural projections in neonates and adults to demonstrate that cortical axons fail to cross in the absence of a copy of the wildtype locus, despite the presence of a truncated bridge of midline tissue in BTBR mice in place of a full corpus callosum and hippocampal commissure. In combination with immunostaining for neuronal and glial markers in perinatal brains, we are investigating the mechanisms involved in misrouting of callosal axons during development in BTBR mice. Elucidation of the genes responsible for corpus callosum defects in this mouse model of ASD may inform more complete anatomical analyses of neural connectivity defects that are at the core of developmental disorders.

Title: Foxp2 function in the adult brain

Authors: *C. A. FRENCH[1], M. CORREIA[1], S. E. FISHER[2], R. M. COSTA[1];
[1]Champalimaud Ctr. For the Unknown, Lisbon, Portugal; [2]Max Planck Inst. for Psycholinguistics, Nijmegen, Netherlands

Abstract: Disruptions of the FOXP2 gene cause a rare speech and language disorder. In the KE family a heterozygous FOXP2 mutation is dominantly inherited and affected individuals have difficulty producing the sequences of orofacial motor movements necessary for fluent speech. This is considered a core deficit of the disorder, although other expressive and receptive language problems also exist. The FOXP2 transcription factor is expressed in cortico-striatal/ -cerebellar circuits required for sensorimotor integration and motor-skill learning, and imaging studies have identified structural abnormalities in several of these regions in affected KE-family members. FOXP2 is also highly conserved in a number of other vertebrate species, where expression is seen during development and in adulthood. Mice carrying the KE-family mutation have motor-skill learning deficits and lack striatal long-term depression. They also have abnormally high striatal activity *in vivo* which is aberrantly modulated during the learning of a motor task. Juvenile zebra finches show increased FoxP2 expression during the song learning period in striatal nucleus Area X, and FoxP2 knockdown in this region results in inaccurate and incomplete song imitation. More recently, FoxP2 knockdown in Area X of mature birds was shown to render song more variable and abolished the mediation of song by social context, implicating FoxP2 in adult as well as developmental neural function. We used a conditional Foxp2 line and a tamoxifen-inducible Cre (CAGGS-CreER) to disrupt Foxp2 globally in adult mice. Tamoxifen was administered at 10 weeks of age and substantial Foxp2 deletion was seen 60 days thereafter. Around one third of Foxp2-flox/flox; CAGGS-Cre animals died, with the first

deaths occurring 6 weeks after tamoxifen administration. Surviving animals appeared healthy and their performance was indistinguishable from that of littermate controls on the accelerating rotarod. An operant lever-pressing task was used to examine motor-sequence learning in detail in the surviving group. In this task mice must complete 8 lever presses to trigger the release of a sucrose reinforcer. Initially the task is self-paced, but after 12 days of training a time constraint is added and the 8 presses must be completed at increasingly high speeds. Foxp2-flox/flox; CAGGS-Cre mice were able to learn the lever-pressing skill but rates of reinforcer delivery and lever pressing were reduced during both phases of training. Results are compared and contrasted with those from mice carrying aetiological and region-specific Foxp2 disruptions.

Title: Region-specific requirement for ERK/MAPK signaling in regulating GABAergic interneuron number and excitatory synaptic drive during development

Authors: J. S. MARTINEZ[1], J. D. NICHOLS[2,1], T. R. ANDERSON[2], *J. NEWBERN[1]; [1]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [2]Dept. of Basic Med. Sci., Univ. of Arizona - Col. of Med., Phoenix, AZ

Abstract: The precise function of ERK/MAPK signaling in distinct neuronal subtypes during normal and pathological brain development remains unclear. We conditionally inactivated ERK/MAPK in specific subsets of mouse embryonic GABAergic interneurons to define the functions of ERK/MAPK signaling in developing inhibitory interneuron circuits *in vivo*. Loss of ERK/MAPK signaling in the entire GABAergic population with VGAT/VIAAT:Cre led to neonatal growth delay and lethality by the second postnatal week. Interestingly, the total number of cortical GABAergic neurons was intact at neonatal stages. To circumvent early lethality, we employed an Nkx2.1:Cre line to delete ERK/MAPK in a restricted population of GABAergic neurons arising from the medial ganglionic eminence. Immunolabeling of mature recombined GABAergic neurons in adult mutants did not reveal significant changes in total cortical GABAergic neuron number. In striking contrast, we found a substantial decrease in somatostatin

(SST) expression in cortical GABAergic neurons as early as P14, while parvalbumin expression was relatively less effected. SST expression has been linked to changes in neuronal activity and CREB mediated transcription. Indeed, electrophysiological recordings of recombined P14 GABAergic neurons revealed a decrease in the frequency of spontaneous excitatory post-synaptic potentials in mutant sensory cortices. In contrast to the cortex, we found that loss of ERK/MAPK signaling significantly reduced the total number of GABAergic interneurons in the dentate gyrus in both VGAT/VIAAT:Cre and Nkx2.1:Cre expressing mutants. Our data reveal that in developing GABAergic circuits, ERK/MAPK is necessary for establishing appropriate number in the hippocampus, while in the cortex, ERK/MAPK signaling is required for excitatory synaptic drive and SST expression. These findings suggest that the pathogenesis of neurobehavioral changes in forms of RASopathies and schizophrenia linked to reduced ERK/MAPK signaling may involve region and subtype specific alterations in developing GABAergic circuits.

Title: Analysis of Gtf2i mutant mice exhibiting social behavioral abnormality

Authors: *S. UEDA[1], A. SAWA[2], T. SAKURAI[1];
[1]MIC, Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan; [2]Dept. of Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Rare genome copy number variations (CNVs) caused by micro-deletion/duplication of chromosome play significant roles in psychiatric disorders. Altered functions of genes inside/nearby CNVs contribute to phenotypes of the disorders. Developmental neuropsychiatric syndromes associated with 7q11.23 CNV have been identified, deletion being with Williams-Beuren syndrome (WBS) that shows hypersociability, opposite to behavioral characteristics of

autism. Interestingly, 7q11.23 duplication is associated with autism, suggesting that genes affected by the CNV may be crucial for development of social neurocircuitry. One of genes in the region, GTF2I, has been implicated in the hypersociability and visuospatial deficits of WBS by genotype-phenotype correlation studies of patients with atypical deletions. To assess whether and how general transcription factor II-I (Gtf2i) is involved in the social behaviors, we established two mouse lines; Gtf2i heterozygous knockout (Gtf2i-het) mice and Gtf2i BAC transgenic (Gtf2i-TG) mice mimicking deletion and duplication, respectively. Gtf2i-het mice displayed more social exploration, reminiscent of hypersocial behavior of WBS. On the other hand, Gtf2i-TG mice showed impaired sociability and enhanced repetitive behaviors relevant to autism. These results indicate that Gtf2i plays important roles in the circuitry governing social behaviors. To identify the substrates of Gtf2i responsible for social behavior, we are analyzing gene expression by using RNA-seq on Gtf2i-het and Gtf2i-TG mice. Furthermore, to clarify the circuitry activity changes of these mice, we are currently performing whole brain activity mapping after social interaction.

Title: Altered adult neurogenesis and enhanced seizure propensity in oligophrenin-1 knock-out mice, a murine model of X-linked intellectual disability

Authors: ***M. ALLEGRA**[1], C. SPALLETTI[2], B. VIGNOLI[3], S. AZZIMONDI[1], I. BUSTI[4], M. CANOSSA[3], M. CALEO[1];
[1]Inst. Di Neuroscienze CNR, Pisa, Italy; [2]Scuola Superiore Sant'Anna, Pisa, Italy; [3]Univ. di Bologna, Bologna, Italy; [4]Univ. degli Studi di Pisa, Pisa, Italy

Abstract: Oligophrenin-1 (OPHN1) gene is located on the X chromosome, whose mutations cause X-linked intellectual disability and epilepsy. OPHN1 encodes a RhoGTPase-activating protein (Rho-GAP) that regulates neuronal morphology, cell proliferation and migration, and participates in synaptic function. OPHN1 knock out (KO) mice exhibit impairments in spatial memory and social behavior, an immature phenotype of dendritic spines in CA1 pyramidal

neurons associated with altered synaptic plasticity. However, how mutations in OPHN1 affect circuit formation, with consequent cognitive impairment and network hyperexcitability remains still incompletely understood. A useful model to investigate neural network formation and function is adult hippocampal neurogenesis. Using labeling of newborn neurons with bromodeoxyuridine (BrdU) at different time point, doublecortin and retroviral vectors expressing GFP, we found significant impairments in differentiation, migration and integration of newborn neurons in the dentate gyrus of OPHN1 KO mice as compared to controls. We found an altered morphological maturation of newly generated cells, in particular a lack of axonal extension towards the CA3 area and reduced neuronal survival. Some of these pathological phenotypes could be rescued by systemic administration of fasudil, an inhibitor of the Rho kinase (ROCK) whose activity is potentially upregulated by loss of OPHN1. Moreover, since electrophysiological studies indicated an impairment of GABAergic synaptic transmission in hippocampal slices of OPHN1 KO mice, we investigated seizure propensity in KO and wild type (WT) animals. By *in vivo* recordings of hippocampal activity in freely moving animals (two months of age), we found significant epileptiform alterations in OPHN1 KO but not WT mice. We also studied seizure activity induced by administration of the glutamatergic agonist kainic acid, and we found higher susceptibility to seizures in OPHN1 KO mice. This was accompanied by neuropathological alterations such as GABAergic interneuronal death and neuropeptide Y (NPY) upregulation. Altogether, our results demonstrate that the loss of function of OPHN1 affects the adult hippocampal circuitry, causing alterations in neurogenesis and enhanced seizure susceptibility.

Title: Neonatal one-day binge-like ethanol exposure results in an acute loss of neurons in the anteroventral and anterodorsal thalamic nucleus in the rat: a stereological investigation

Authors: *R. M. NAPPER, G. GIBSON, J. MITTENDORFF-GOODALL;
Univ. of Otago, Dunedin, New Zealand

Abstract: Apoptotic cell death in the developing brain has been established as a key factor in alcohol induced developmental brain damage (Idrus and Napper, 2012). The thalamic nuclei have been shown to be susceptible to the toxic effects of ethanol during development in the mouse but this effect has not been quantified or the long-term effects assessed (Wozniak et al., 2004). The present study used stereological methods to quantify the magnitude of apoptotic cell death, phenotype of dying cells and long-term neural deficit following a single binge exposure to ethanol on postnatal day 7 (PN7) in the anterodorsal (AD) and anteroventral (AV) thalamic nuclei of the rat. On PN7 Long Evans rat pups, were randomly assigned to either an alcohol exposed (AE) group, 6g/kg/day in artificial milk solution given in two feeds two hours apart or a sham intubation (SI) group. Peak BEC was 335±76 in AE animals (mean ± sd). At either 12 hours after initial alcohol exposure, or on PN60 animals were anaesthetized and perfused. The brains removed, cryo-protected, frozen and serial 50μm thick sections cut through the thalamus. The optical fractionator method was used on a systematic random subset of cresyl violet stained sections to estimate total number of apoptotic cells (12 hours) or total cell number (PN60). A subset of sections, immunostained for NeuN and counterstained with Hoescht were used to phenotype apoptotic neurons. Ethanol treatment resulted in a significant increase in the total number of apoptotic cells in the AD (E12hrs: 1991 ± 434.8; IC: 90.5 ± 32.23; SC: 12.25 ± 12.25) (mean ± SEM) ($p<0.05$) and AV (E12hrs: 20111 ± 3429; IC: 182.7 ± 41.33; SC: 113.3 ± 42.93) ($p<0.01$) thalamic nuclei. Within the AV neurons were identified in the group of apoptotic cells. This study has shown that a single binge ethanol exposure is sufficient to induce significant apoptotic cell death in the AD and AV thalamic nuclei, within 12 hours of the initiation of ethanol exposure. The long-term effect on the thalamic nuclei is under investigation. This study provides further evidence that pregnant women should abstain from binge drinking at any stage during their pregnancy, particularly during the third trimester.

Title: Allopregnanolone mediates tics and sensorimotor gating in the D1CT-7 animal model of Tourette syndrome

Authors: *L. J. MOSHER[1], S. C. GODAR[1], G. PINNA[2], M. BORTOLATO[1];
[1]Pharmacol. and Toxicology, Kansas Univ., Lawrence, KS; [2]Psychiatry, Univ. of Illinois, Chicago, IL

Abstract: Tourette syndrome (TS) is a neurodevelopmental disorder characterized by repetitive motor and phonic tics. Tics are typically triggered by premonitory urges. These are highly intrusive feelings of hypersensitivity and discomfort, which have been posited to reflect deficits in sensorimotor gating, a core function aimed at filtering relevant information. TS patients exhibit disruptions in the prepulse inhibition of the startle reflex (PPI), an operational index of sensorimotor gating. Studies indicate that TS symptoms are underpinned by dysfunctions in dopaminergic signaling, leading to an imbalance in excitation/inhibition within cortico-striato-thalamocortical circuits. Dopamine receptor activation has been shown to elicit stereotyped behaviors and PPI deficits in rodents. The prototypical treatments for TS patients mainly consist of dopamine receptor antagonists; however, these compounds exhibit mixed effectiveness and are associated with extrapyramidal and metabolic side effects. Previous studies from our lab have investigated the therapeutic potential of targeting 5α-reductase, the main rate-limiting enzyme that catalyzes the synthesis of neurosteroids. Treatment with the 5α-reductase inhibitor finasteride (FIN) reduces tics in TS patients without the accompanying extrapyramidal symptoms, and ameliorates PPI deficits and stereotyped behaviors induced by dopamine receptor agonists in rodents. The neurosteroid(s) responsible for these actions have remained largely elusive. TS patients exhibit a hypersensitivity to stress and symptoms are exacerbated by stress. In line with these studies, we have explored the effects of a mild stress, space confinement, on the D1CT-7 mice, the only model of TS that exhibit spontaneous tic-like behaviors. We found that confinement exacerbates tic-like responses and elicits PPI deficits, both of which are attenuated by FIN. These findings led us to study the role of the 5α-reduced neurosteroid allopregnanolone (AP), a key neurosteroid in the stress cascade, on PPI deficits and tic-like behaviors in D1CT-7 mice. We found that AP did not further intensify the effects of confinement, but administration of AP to mice under normal conditions (home cage, no confinement) dose dependently increased tic-like behaviors and induced PPI deficits in D1CT-7, but not wild-type littermates. In addition, AP (15mg/kg, IP), reversed the effects of FIN (25mg/kg, IP) on PPI deficits in D1CT-7 mice. These data suggest not only that the therapeutic potential of FIN is possibly due to a reduction in AP synthesis, but also that AP may be a key neurosteroid in the mechanism whereby stress exacerbates TS symptoms.

Title: Development of Pten mutant neuronal cultures as an *in vitro* model of cortical dysplasia

Authors: *I. K. NIKOLAEVA[1], P. SWIATKOWSKI[1], T. KAZDOBA[2], B. CROWELL[2], G. MAESTRI[2], B. L. FIRESTEIN[2], G. D'ARCANGELO[2];

Abstract: Cortical dysplasia is a group of developmental brain disorders characterized by anatomical malformations of the cerebral cortex, cellular overgrowth, intellectual disability, and drug-resistant childhood epilepsy. In humans, this disorder has been associated with somatic mutations in the PI3K/Akt/mTOR signaling cascade, which is a major pathway that promotes cell growth and repair. To model the molecular abnormalities underlying cortical dysplasia, we previously generated a mutant mouse line in which the *Pten* gene is conditionally disrupted in excitatory neurons of the developing forebrain (NEX-*Pten*). Since the Pten phosphatase normally suppresses PI3K/Akt/mTOR signaling, this genetic manipulation results in the pathway's activation, specifically in these neurons. We then established forebrain neuronal cultures derived from mutant embryos as an *in vitro* model of the disorder to facilitate the identification of pharmacological treatments. We found that mutant neurons exhibited dramatic cellular hypertrophy, including increased soma size and dendrite complexity. In addition to these morphological abnormalities, Pten mutant cultures exhibited altered electrophysiological properties. We then tested compounds that are known to inhibit specific components of the PI3K/Akt/mTOR pathway to identify agents that effectively rescue the abnormalities of NEX-*Pten* mutant neurons without affecting neuronal viability. Here, we report on the beneficial effects of FDA-approved compounds, such as the Akt inhibitor MK2206 and the mTORC1 inhibitor RAD001 (a rapamycin analog). These findings will help to develop novel pharmacological treatments for children affected by cortical dysplasia. This work is supported in part by multiprogrammatic grant CBIR12MIG011 from the New Jersey Commission on Brain Injury Research (G.D. and B.L.F.), and by Exploration-Hypothesis Development Award #TS110033 from the Department of Defense - CDMRP - TSCRP (G.D.).

Title: Determining the role of gtf2i family transcription factors in social behavior and oxytocin regulation

Authors: ***N. D. KOPP**, J. DOUGHERTY;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: William's syndrome is a neurodevelopmental disorder with a prevalence of 1/7000 births. It is caused by a microdeletion of 1.8 Mbp on chromosome 7q11.23, which results in cardiovascular, craniofacial, visual-spatial, and social aberrations. Further, human studies of patients with William's syndrome have discovered that there is an increase in plasma oxytocin levels compared with typically developing controls. Two general transcription factor 2I genes, *GTF2I* and *GTF2IRD1*, are commonly deleted and are high priority candidates for mediating the hypersocial phenotype in humans and mouse models. However, it is not clear if they act independently or collaboratively to produce phenotype. We have used the CRISPR/Cas9 system to delete these transcription factors in various combinations in mice to investigate how the interaction of these genes affect the social phenotype and understand possible molecular intermediaries that manifest the hypersocial behavior. To characterize the lines, we employ a targeted sequencing technique, MDiGs, to observe large and small-scale genome editing events

within and between these genes, and perform extensive biochemical validation of the lines. Next, we have initiated longitudinal behavioral phenotyping beginning with pup ultrasonic vocalization to examine social and communication deficits in the mouse lines. Finally, to reconcile the human observation of increased oxytocin and previous mouse behavior data, we investigate the plasma oxytocin levels of *gtf2i*$^{+/-}$, *gtf2ird1*$^{+/-}$, and *gtf2i*$^{+/-}$/*gtf2ird1*$^{+/-}$ mice. We show that we have successfully knocked down *gtf2i* and *gtf2ird1* expression and report on the developmental communication behavior of ultrasonic vocalization. We show that haploinsuffiency of these two transcription factors alter the levels of oxytocin in the plasma of mice. These results suggest that oxytocin could play a salient role in the hypersocial phenotype seen in patients with William's syndrome. This observation can lead to a better understanding of the genetic contribution to the abnormal sociality seen in this syndrome and identify new mechanisms for the regulation of oxytocin.

Title: Transgenerational transmission and modification of behavioral deficits induced by prenatal immune activation

Authors: *U. WEBER-STADLBAUER, U. MEYER;
Univ. Zurich - Vetsuisse, Zurich, Switzerland

Abstract: Objective: It has been demonstrated that environmentally induced brain dysfunctions are not solely expressed by the individuals directly exposed, but can also be transmitted to the offspring, sometimes across multiple generations. Here we explored whether such transgenerational effects can be induced by prenatal infection, an established environmental risk factor of developmental neuropsychiatric disease. To do so, we used a well-established prenatal infection murine model, which has been shown to induce long-term deficits in numerous behavioral domains in the offspring. Methods: Pregnant mice (F0) were injected with the viral mimetic poly(I:C) (5 mg/kg, iv) or control solution (saline, iv) in early pregnancy (gestation day 9), and we examined behavioral effects in direct descendants (F1). To examine whether such

effects can be transmitted to subsequent generations, we generated F2 and F3 offspring by inter-crossing F1 and F2 offspring, respectively. Results: Behavioral analyses in F1, F2 and F3 offspring revealed that deficits in social interaction and cued fear conditioning, which emerge in F1 offspring, are also present in the F2 and F3 generation. Interestingly, deficits in sensorimotor gating, observed in the F1 generation, were not present in F2 and F3 offspring. We further observed reduced amphetamine sensitivity in F2 offspring, which in turn is typically increased in F1 animals. Conclusions: Our findings demonstrate that behavioral deficits induced by prenatal infection can be transmitted and modified across subsequent generations. Future experiments will examine the possibility that the behavioral abnormalities following prenatal immune activation are transmitted to subsequent generations via modifications in the epigenetic machinery.

Title: Neuroanatomical abnormalities in a PAX6 deficient mouse model

Authors: *A. M. BOBILEV[1], K. K. JOHNSON[2], C. J. BLATCHER[2], K. HEKMATYAR[2], J. D. LAUDERDALE[2];
[1]Neurosci., [2]The Univ. of Georgia, Athens, GA

Abstract: The PAX6 gene encodes a highly conserved transcription factor that is expressed in the developing eye, brain, spinal cord and pancreas, and is required for various aspects of anatomical and functional development. Heterozygous loss-of-function mutations of PAX6 are causal for aniridia in humans. While the effects of PAX6 mutations on ocular development have been well characterized in human and mouse, the implications of these mutations on brain structure remain poorly understood. Previous studies have identified structural abnormalities in fiber tracts and subcortical structures in the brain including corpus callosum, anterior and posterior commissures, pineal gland and Probst bundles in persons with aniridia using magnetic

resonance imaging (MRI). The current study sought to determine whether structural brain abnormalities observed in patient case studies are present in the *Small Eye*^{Neu} (PAX6$^{Sey\ Neu/+}$) mouse model of the disorder using MRI and histological measures of brain structure. This study employed high resolution MRI using a 7T Agilent system to acquire structural brain images using both 2D T1 MEMRI (manganese enhanced MRI), T2 and 3D T2 weighted fast spin echo sequences. Sixteen mice (8 PAX6$^{Sey\ Neu/+}$, 8 wild-type littermates, age 3-4 months, outbred background) were administered $MnCl_2$ contrast agent at a rate of 40mg/kg bodyweight for 3 consecutive days prior to T1-weighted image acquisition using T1-weighted spin echo imaging (TR/TE 500/12 msec, matrix 128 x 128, nt =8 with fov of 22 x 22). The 2D T2 and 3D T2 acquisition was performed on a separate day (2D: TR/TE 4600/35 msec, nt =16; 3D: TR/TE 400/44 msec, nt=4). Both manual ROI analysis of the specific regions in MEMRI images using inbuilt analysis functions in VNMRJ and SPM VBM analyses in 2D and 3D images were performed to detect differences. Statistics were performed on a voxel -by-voxel basis to identify significant differences in volume (FDR <.05) between genotype groups. Upon completion of *in vivo* imaging, animals were euthanized following approved protocols, and their brains examined for structural abnormalities. Preliminary analyses demonstrate significant differences in brain volume in regions where PAX6 is known to be expressed during neural development. Further, preliminary histological data suggests PAX6$^{Sey\ Neu/+}$ mice have larger lateral ventricles compared to wild-type littermates. These results provide evidence for neuroanatomical abnormalities in mice with haploinsufficient levels of PAX6, presenting new avenues for investigation with regard to regionalized PAX6 necessity during brain development as well as the neuroanatomical implications of PAX6 mutations in humans.

Title: Neuronal heterotopias affect the activities of distant brain areas and lead to behavioral deficits

Authors: *K. ISHII[1], K.-I. KUBO[2], T. ENDO[3], K. YOSHIDA[2], S. BENNER[3], Y. ITO[4], H. AIZAWA[4], M. ARAMAKI[2], A. YAMANAKA[5], K. TANAKA[4], N. TAKATA[2], K. F. TANAKA[2], M. MIMURA[2], C. TOHYAMA[3], M. KAKEYAMA[6], K. NAKAJIMA[2];

Univ., Tokyo, Japan; [5]Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan; [6]Waseda Univ. Fac. of Human Sci., Tokyo, Japan

Abstract: Neuronal heterotopia refers to brain malformations resulting from deficits of neuronal migration. Individuals with heterotopias show a high incidence of neurological impairments, such as epilepsy. More recently, it has come to be recognized that focal heterotopias may also show a variety of psychiatric symptoms, including cognitive and behavioral deficits. However, since focal heterotopias are not always located in the brain areas responsible for the symptoms, the causal relationship between the symptoms and heterotopias remains unclear. In this study, we showed that mice with focal heterotopias in the somatosensory cortex generated by *in utero* electroporation exhibited spatial working memory deficit and low competitive dominance behavior, which have been shown to be closely related to the activity of the medial prefrontal cortex (mPFC) in rodents. Analysis of the mPFC activity revealed that the immediate-early gene expression was decreased and the local field potentials (LFPs) of the mPFC were altered in the mice with heterotopias as compared to the control mice. This difference in the LFPs between the mice with heterotopia and the control mice disappeared after optogenetic activation of the ectopic neurons and their sister neurons in the overlying cortex. Moreover, activation of these ectopic and overlying sister neurons using the DREADD (designer receptor exclusively activated by designer drug) system also improved the spatial working memory deficits. These findings suggest that cortical regions containing focal heterotopias can affect distant brain regions and give rise to behavioral abnormalities, and provide mechanistic insight into the various symptoms associated with heterotopia.

Title: Hyperactivation of ERK1/2 signaling in developing GABAergic circuits reduces parvalbumin interneuron number and increases cortical excitability

Authors: *M. A. MORENO[1], L. T. HEWITT[1], G. R. BJORKLUND[1], C. W. DANIELS[2], M. F. OLIVE[2], F. SANABRIA[2], S. MARSH[3], D. M. TREIMAN[3], W. D. SNIDER[4], J. M. NEWBERN[1];

Abstract: The MAP (Mitogen-activated Protein) kinases, ERK1 and ERK2 (extracellular signal-regulated kinase) govern important aspects of nervous system development. Gain of function signaling through ERK1/2 is commonly observed in the Rasopathies, aka Ras/MAPK syndromes or NCFC syndromes, a family of syndromes with deficits in cardiac, cranial, ectodermal, and nervous system development. Previous studies have suggested that mature GABAergic inhibitory interneuron function is disrupted in Ras/MAPK syndromes. However, it remains unknown whether alterations in the initial development of GABAergic circuits is an important feature of disease pathogenesis. We investigated the effects of ERK1/2 signaling hyperactivation on the early development of cortical GABAergic interneurons by crossing VGAT:Cre expressing mice with a Cre-dependent constitutively activated MEK1S217/2221Q allele. Our results show that hyperactivation of ERK1/2 signaling in inhibitory interneurons during embryogenesis leads to a significant decrease in the total number of neocortical GABAergic interneurons. Interestingly, this decrease is primarily confined to a specific subset of inhibitory neurons that expresses parvalbumin. The reduction in the number of parvalbumin expressing neurons is detectable by P14 in sensory cortices. RNA immunoprecipitation and sequencing of cortical GABAergic neuron-specific mRNA identified broad changes in the gene expression profile during neonatal stages that indicate accelerated lineage progression in mutant mice. To better

understand the behavioral consequences of ERK1/2 hyperactivation in GABAergic circuits, mice were tested in the elevated plus maze, open field test, social approach task, and a fixed interval schedule of reinforcement. Though no significant differences were observed in these neurobehavioral tests in mutants, we detected a striking increase in freezing behavior during open field testing. Direct electroencephalography (EEG) recordings provided evidence of enhanced epileptiform-like brain activity in mutant mice. These data suggest that hyperactivation of ERK1/2 accelerates the trajectory of GABAergic neuron development, leading to a postnatal reduction in parvalbumin interneuron number and seizure-like activity in the neocortex. Defining the mechanisms regulated by ERK1/2 in GABAergic circuits may assist in our understanding of the pathogenesis of epilepsy and E/I imbalances in Ras/MAPK Syndromes.

Title: Mechanisms by which systemic administration of insulin-like growth factor ii reverses autism spectrum disorder phenotypes in mice

Authors: ***A. B. STEINMETZ**, S. A. STERN, A. S. KOHTZ, C. M. ALBERINI;
New York Univ., New York, NY

Abstract: Autism spectrum disorder (ASD) is a developmental disability characterized by altered social interaction and cognitive functions as well as increased repetitive behavior. Thus far, there is no efficacious therapy that can ameliorate most of the major ASD symptomatology, and the identification of potential novel targets and therapies is urgently needed. We used BTBR mice, a behaviorally well-characterized mouse model that reproduces behaviors typical of ASD, to test the effects of systemic administrations of insulin like growth factor II (IGF-II). Previous

results from our lab have shown that intrahippocampal or systemic administration of IGF-II in rats or mice results in enhanced short and long term memories in a variety of paradigms. Here we report that IGF-II rescues the three major behavioral deficits of ASD modeled in the BTBR mice. Specifically, IGF-II increased social interactions and memory, contextual memory, and decreased repetitive behaviors. The treatment did not affect locomotor or anxiety-like behaviors. Blocking the IGF-II but not the IGF-1 receptor within the hippocampus prevented the IGF-II rescuing of social and contextual memory. Furthermore, an increase of the AMP-activated protein kinase (AMPk)- mammalian target of rapamycin (mTOR) - p70 S6 kinase (S6k) pathway in BTBR synaptoneurosomal fractions as compared to control animals was found. The administration of systemic IGF-II along with contextual fear conditioning reduced the levels of AMPk, mTOR, and S6k to control levels. Thus, IGF-II treatment seems to act via regulation of the AMPk-mTOR-S6k pathway to rescue ASD phenotypes. Funding: R01-MH074736 and R37-MH065635 to C.M.A. and T32 MH019524 to A.B.S.

Title: Deficiency and haploinsufficiency of bridging integrator 1 (Bin1) causes abnormalities in the developing mouse brain

Authors: *K. D. ONOS[1], L. C. GRAHAM[1,2], C. J. ACKLIN[1], X. WANG[1], G. W. CARTER[1], G. R. HOWELL[1,2];
[1]The Jackson Lab., Bar Harbor, ME; [2]Tufts Univ., Boston, MA

Abstract: *Bin1* (also known as *Amphiphysin II*) belongs to the BAR (Bin/Amphyiphysin/Rvs) family of genes that support a diverse number of cellular processes such as endocytosis, endosome trafficking, actin dynamics, calcium signaling and stress signaling through neuroendocrine cells (Sarret et al., 2004). Variations in *Bin1* have been associated with Alzheimer's disease, autism and schizophrenia (Yang, et. al., 2008; Butler, et. al, 2015;Chauhan et. al, 2015) but the mechanisms are not known. *Bin1* has been shown to play a critical role in

development as homozygous knockout mice exhibit perinatal lethality due to severe ventricular cardiomyopathy (Muller et al., 2003), and this has impeded further work to fully understand the role of *Bin1* in the developing brain. Therefore, we are using genetic and genomic approaches using *Bin1* homozygote (*Bin1* deficient), heterozygote (haploinsufficient) and conditional knockout mice to elucidate the role of *Bin1* in the developing mouse brain. To determine the impact of *Bin1* deficiency on brain development we first examined brains of *Bin1* sufficient, deficient and haploinsufficient mice for structural and molecular changes at P0 (all genotypes) and P60 (sufficient and haploinsufficient only). Although there were no gross morphological changes between genotypes, using antibodies to PSD95, NEUN, phosphorylated neurofilament and myelin basic protein, differences were observed between genotypes to both synapses and axons of neurons in the amygdala, CA1 and CA3 regions of the hippocampus and the dentate gyrus. Secondly, we have performed gene profiling by RNA-seq on brains from *Bin1* haploinsufficient mice at 6 months of age compared to *Bin1* sufficient controls. A total of 221 genes were upregulated and a 117 genes downregulated (338 in total), including a 1.5 fold downregulation of *Bin1*. Gene set enrichment analysis identified genes associated with membrane-bounded organelles, in particular localized to the mitochondria, as enriched in this dataset. Finally, to fully understand the role of *Bin1* in development and aging we have obtained a floxed allele of *Bin1* and are employing a Cre/LoxP strategy to generate mice deficient in *Bin1* in neural progenitors. Taken together, these findings show that *Bin1* deficiency and haploinsufficiency impact critical process in the developing brain and highlight the importance of determining the mechanism(s) by which *Bin1* contributes to normal brain function and disease.

Title: The effects of *in utero* valproic acid exposure on placental transfer and brain development in autism: A T2 MR study

Authors: *L. S. TRUICA[1], S. RAZA[2], J. K. MCCREARY[2], I. Q. WHISHAW[2], R. GIBB[2]; [1]Neurosci., Canadian Ctr. For Behavioral Neurosci., Lethbridge, AB, Canada; [2]Canadian Ctr. for Behavioural Neurosci., Lethbridge, AB, Canada

Abstract: Neurobiological anomalies have been reported in autism spectrum disorders (ASD), although the mechanisms underlying these changes are not well known. Human neuroimaging studies have shown abnormal regulation of brain growth in ASD, where processes governing apoptosis and synaptic pruning are highly implicated. The aberrant cortical connectivity observed in ASD has been hypothesised to be correlated to accelerated early neuronal growth, followed by excessive synaptic pruning. The present study investigated brain tissue changes in the valproic acid (VPA) animal model of ASD using MRI, as well as placental transfer of the drug. Pregnant dams were exposed orally to VPA on gestational day (GD) 12.5. Brain and placental *in vivo* T2-relaxometry measurements were conducted on GD 16, 18 and 20 using a 4.7 T Oxford magnet (Oxford, UK). On postnatal (P) day 30, P35, P40, and P45, the offspring were also imaged. Parametric maps were constructed for both rat placentas and the pup brains. The offspring were also behaviourally tested in the pre-weaning period to assess changes in emotional regulation and sensorimotor development, two predominant symptoms of autism. MRI results showed differences between VPA and control groups in the prefrontal cortex, suggesting that prenatal exposure to VPA altered the expected neuronal density. This may reflect a delay in synaptic pruning, which is consistent with human ASD literature. The drug placental transfer was also evident in the T2 maps across gestational age, supporting the pharmacokinetics of the VPA in the investigated animal model. Alterations in early behavior were also exhibited, suggesting perturbations in the neurodevelopmental trajectories. Altogether, results from this study conclude that VPA impacts the offspring by crossing the placental barrier, and thereby influences neurodevelopment in early and later life. Moreover, this study indicates that T2 relaxometry is a valuable tool in detecting early life developmental abnormalities.

Title: Maternal influences on pup ultrasonic vocalizations in D2 and M5 deficient mice

Authors: *J. S. YEOMANS[1], D. I. WASSERMAN[3], T. CURRY[4], B. J. PEREIRA[2], P. TSELICHTCHEV[2], M. LAM[1];
[2]Psychology, [1]Univ. Toronto, Toronto, ON, Canada; [3]Psychology, Guelph Univ., Guelph, ON, Canada; [4]Med., McMaster Univ., Hamilton, ON, Canada

Abstract: Ultrasonic vocalizations (USVs) occur in 3-11 day old mouse pups isolated from their dams. Fewer USVs occur in pups deficient in genes for D2 dopamine or M5 muscarinic receptors, or the Gtf2i gene deficient in Williams' syndrome. We crossed heterozygous mice to quantify pup gene contributions, and made reciprocal crosses to quantify parental gene contributions to 8 day old pup USVs. In D2 deficient mice, both pups' and dams' genotype were important, with dams' genotype affecting the onset and pups' genotype affecting the gradual increase, of USVs over 4 minutes. Heterozygous D2 pup USVs increased plasma prolactin levels and maternal behaviors (nest building and pup retrieval) in wild-type, but not D2 knockout, dams. This suggests that USV activation of maternal prolactin is important for maternal behaviors in D2 mice. In M5 deficient mice, dams' genotypes were most important for pups' USVs, possibly due to M5 receptor expression in the medial hypothalamus of female mice. The roles of prolactin, oxytocin, endorphins, and other hormones associated with bonding, social and brain development, and autism are discussed.

Title: Can a poor sleep/wake cycle contribute to hippocampal malfunction in a mouse model of neurodevelopmental disabilities?

Authors: D. H. LOH[1], H.-B. WANG[1], F. Y. LEE[2], D. S. WHITTAKER[3], K. Y. CHENG[4], E. C. DELL'ANGELICA[2], C. S. COLWELL[1], *C. A. GHIANI[5,6];
[1]Psychiatry, [2]Human Genet., [3]MCIP Program, [4]Neurosci. IDP, [5]IDDRC, Semel Inst., [6]Pathology and Psychiatry, UCLA, Los Angeles, CA

Abstract: Major psychiatric diseases with a neurodevelopmental origin are triggered by a combination of genetic predisposition and environmental stressors. It has been proposed that exogenously disrupting the circadian system may account for increased susceptibility to neuropsychiatric symptoms. Hence, we have become interested in the possibility that circadian disruption may be a trigger that can push a vulnerable patient into disease state. To test this hypothesis, we have been using the pallid mouse, which carries a mutation in the gene that encodes pallidin (bloc1s6), a subunit of the dysbindin-containing complex BLOC1 (Biogenesis of Lysosome-related Organelles Complex 1). This complex is developmentally regulated and implicated in intracellular protein trafficking. Here, we show that lack of BLOC-1 altered gene expression in the developing central nervous system (CNS) of mutant mice, eliciting defective neural cell maturation and maldevelopment of relevant brain areas, such as the hippocampus. BLOC1-deficient mice exhibited reduced levels of activity, and their activity rhythms were significantly more fragmented and of lower precision than in age-matched WT. Whilst the pallid mutants slept for the same amount of time as WT, the quality of sleep was compromised by the highly fragmented nature of their sleeping pattern. In agreement with these results, the levels of Period2, a protein involved in the regulation of the intrinsic clock were altered in the pallid hippocampus. Our data suggest that lack of BLOC-1 negatively influences CNS development and functions, perhaps leading to faulty brain wiring, as well as circadian disruption.

Title: Spontaneous motor behavior of *Drosophila* fragile X mental retardation 1 (dfmr1) mutants reveals perseverative and excessive grooming

Authors: *D. R. ANDREW[1,4,2,3], M. E. MOE[2,3], R. L. DOSER[3,2], L. L. RESTIFO[3,2];
[2]Ctr. for Insect Sci., [3]Dept. of Neurol., [1]Univ. of Arizona, Tucson, AZ; [4]Dept. of Biol., Lycoming Col., Williamsport, PA

Abstract: Fragile X Syndrome (FXS), caused by loss of function mutations in the *fragile X mental retardation 1* gene (*FMR1*), is the leading monogenic cause of human intellectual disability (ID). In addition to the hallmark feature of ID, patients with FXS often manifest concomitant neurological disorders such as epilepsy, sleep disorders, anxiety, hyperactivity, attention deficits, autism, and decreased motor coordination. The fruit fly, *Drosophila melanogaster*, provides a well-established genetic model for FXS. Flies with null mutations in *dfmr1*, the sole ortholog of *FMR1*, show neuroanatomical and behavioral deficits, several of which resemble those in patients with FXS. Here, we present a quantitative analysis of spontaneous motor behaviors in *dfmr1* mutant flies toward the goal of a more nuanced understanding of behavioral perturbations caused by absence of dFMRP. We recorded and observed socially isolated, 1-day-old flies during a 15-minute observational period in a small circular arena and scored walking, standing, grooming, and falls. We found that the grooming index, the proportion of time spent grooming, was significantly increased in *dfmr1* mutants, and that the introduction of a wild-type $dfmr1^{+}$ transgene in a mutant background rescued this difference. We could attribute this excessive grooming to increases in both the number and mean duration of grooming bouts. We also found that mutants groomed significantly more body parts per grooming bout and showed a greater variety of grooming-site transitions compared to genetic controls. Mutant animals performed different patterns of grooming, with a marked increase in rear-body grooming transitions carried out by the middle and rear legs. We quantified repetitive grooming via two distinct pattern measures and found that mutants showed elevated numbers of these repetitions. Preliminary data indicate that the grooming phenotype is exacerbated by higher concentrations of glutamate in the food of developing larvae. Together, these attributes of excessive repetitive grooming in *dfmr1*-mutant flies are reminiscent of the perseverative behaviors observed in patients with FXS. These observations call into question the interpretation of other *dfmr1* behavioral phenotypes, notably “reduced courtship interest.”

Title: The impact of maternal diet on large scale network patterns and behavior in macaque offspring

Authors: *J. S. RAMIREZ[1], E. L. SULLIVAN[2], B. D. MILLS[1], J. VALLEAU[2], E. EARL[1], O. MIRANDA-DOMINGUEZ[1], D. A. FAIR[1];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Div. of Neurosci., Oregon Natl. Primate Res. Ctr., Beaverton, OR

Abstract: Resting state functional connectivity MRI (rs-fcMRI) is a tool used to investigate neurophysiology *in vivo*. This tool has identified unique connectivity in an array of different populations, as well as animal models. The current project aims to investigate rs-fcMRI in macaques in order to establish developmental associations in connectivity of offspring that occur secondary to a maternal high-fat diet (HFD) during pregnancy. Maternal HFD has been associated with complex neurodevelopmental disorders such as ADHD and Autism. Thus, the goal of this project is to examine how maternal diet affects large scale network patterns, as measured via rs-fcMRI, in the macaque previously shown as atypical in these populations (I.e. Nucleus accumbens (NAc) and amygdalae connectivity). Preliminary results suggest atypical connectivity with the NAc in offspring exposed to maternal HFD, which was associated with anxiety in female offspring, repetitive behaviors in male offspring and impairments in social behavior in both male and female offspring- component dimensions of both ADHD and Autism.

Title: The effects of creatine loss in adult creatine transporter conditional knockout mice

Authors: *K. C. UDOBI, M. R. SKELTON;
Dept. of Pediatrics, Neurol. Div., Cincinnati Children's Res. Fndn., Cincinnati, OH

Abstract: Creatine (Cr) transporter (CrT) deficiency (CTD) is a leading cause of X-linked intellectual disability. CTD is characterized by a lack of brain Cr, severe intellectual disability and aphasia. We generated conditional CrT knockout mice ($CrT^{flox/flox}$). Ubiquitous CrT knockout mice ($CrT^{-/y}$) and brain specific knockout mice (bKO) generated from this line exhibit

cognitive deficits, mimicking the human disorder. While it is clear that Cr is essential for proper neurologic function, it is still unknown if Cr is required for proper brain development. A better understanding of the role of Cr in brain development is essential for the development of treatments and treatment strategies for CTD. The purpose of this study is to determine if CTD is a developmental disorder or if the loss of Cr in itself is sufficient to induce learning deficits. To better understand if the cognitive deficits in $CrT^{-/y}$ mice are due to developmental changes in the brain, mice lacking the CrT only during adulthood were generated. $CrT^{flox/flox}$ mice were crossed with mice expressing a ubiquitous tamoxifen-inducible Cre recombinase (UBC-cre/ERT2) to create a temporally mediated CrT knockout mouse (cKO). Recombination was initiated by tamoxifen administration from postnatal day 60-65. Following the induction of Cre recombinase activity, cKO mice exhibit a significant reduction in body weight compared to wildtype (WT) mice. Brain CrT transcripts were undetectable 5 days following Cre recombinase induction. Following validation of the knockout, cognitive function was assessed based on deficits observed in the bKO and $CrT^{-/y}$ mice. In the visible platform testing, cKO mice show no significant difference in latency to the platform compared with WT mice. The cKO mice showed no significant difference in latency and path length during the acquisition and reversal phases of the Morris Water Maze (MWM). No reference memory deficits were present in both phases of testing. WT and cKO mice performed similarly in tasks of object recognition and fear memory. The absence of learning and memory deficits observed in the adult cKO mice suggest that the deficits seen in bKO and $CrT^{-/y}$ mice are likely due to a lack of Cr during brain development.

Title: Examination of cortizol receptor and endogenous opioid expression in a primate model of self injurious behavior

Authors: *B. FORET[1], M. JACKSON[1], J. A. FONTENOT[2], E. C. ROMERO[2], J. A. SMITH[2], D. L. HASSELSCHWERT[2], K. M. SMITH[1];

Abstract: Self Injurious Behavior (SIB) in humans is characterized by deliberate self-harm or mutilation outside the context of societal rituals or body modification practices, and may include

head banging, self biting, self cutting, picking at wounds, or intentional burns. SIB is expressed in various neuropsychiatric disorders, most prominently in Borderline Personality Disorder, Obsessive Compulsive Disorder, Tourette Syndrome, and Autism Spectrum Disorders. SIB can lead to suicidal ideations in adolescents and adults. SIB in captive Rhesus macaques is a spontaneously emerging animal model of self-injury in humans that may aid our understanding of the neurobiology of SIB. In both humans and monkeys, SIB can be triggered or exacerbated by stressful events. Given the recurring nature of the behaviors, a reduction of endogenous opioid signaling in affected individuals (and animals) has been hypothesized based on the known release of opioids by injury, the escalating nature of self-harm, the endorsement of addictive compulsions to self injure, the high rates of substance abuse in individuals with BPD, and the effectiveness of opioid blockers in reducing symptoms of self-injury in human and animal trials. We hypothesize that the expression of stress hormone receptor and endogenous opioid signaling genes may be altered in monkeys with SIB. However, the neurobiology of these changes is poorly understood. We will examine prefrontal cortex (orbital frontal), anterior cingulate cortex, hippocampus, amygdala, and caudate putamen and hypothalamus of control and SIB animals. We have initiated these studies by collecting brain tissue form 8 rhesus macaques with SIB (4 males and 4 females) and 8 age and sex matched controls. No differences in brain weight, or brain/body weight ratio were observed. Glucocorticoid (GR) and mineralocorticoid receptor (MR) mRNA levels in the hippocampus are currently being examined. No differences in GR levels in the hippocampus of male SIB (N=3) and control males (N=3) were observed. Preliminary evidence indicates that SIB animals may have lower expression levels of MR, but additional animals need to be examined. Future studies will extend these analyses to additional brain regions for GR and MR expression, as well as genes involved in endogenous opioid signaling.

Title: Involvement of Cadherin-13 in the regulation of the response to early-life stress and environmental enrichment

Authors: *O. RIVERO, S. POPP, D. KISER, S. SICH, K.-P. LESCH;
Univ. Clin. Wuerzburg, Wuerzburg, Germany

Abstract: Many evidences support the role of genetic risk factors for psychiatric disorders in the response to environmental changes. Genome-wide screening approaches have consistently identified cadherin-13 (*CDH13*), an atypical member of the cadherin family of cell adhesion molecules, as a risk gene for various psychiatric disorders including ADHD and autism spectrum disorders as well as substance use/dependence. The differential expression pattern of cadherin-13 within the brain suggests a functional role in different aspects of brain connectivity and plasticity (neurite outgrowth, axonal pathfinding and synapse formation). In this study, we aimed at understanding the role of Cadherin-13 in Gene x Environment interactions. For this purpose, we used a constitutive *Cdh13* knockout mouse to study the behavioral and molecular consequences of cadherin-13 deficiency in the response to early life stress (maternal separation from postnatal day P1 to P14) or environmental enrichment in early adulthood (voluntary exercise with running wheels). Our results show that maternal separation reduces anxiety-like behavior in wildtype male animals when tested in the light-dark box, whereas this effect is not observed in knockout ($Cdh13^{-/-}$) mice. This finding suggests that knockout animals respond less to MS. Furthermore, maternally separated $Cdh13^{-/-}$ animals also presented cognitive alterations during the performance of the Novel Object Recognition task and the Barnes maze. Further studies are being performed in order to elucidate the molecular mechanisms behind these behavioral alterations. On the other hand, voluntary exercise with running wheels (RW) induces, as expected, increased adult neurogenesis in all mice when compared to control, sedentary animals, although the distribution of newborn cells in the dentate gyrus (DG) suggests that $Cdh13^{-/-}$ mice are more sensitive to the effects of RW than wildtype animals, probably due to the involvement of Cadherin-13 in the migration of newborn neurons from the subgranular zone of the DG. In addition, at the behavioral level, voluntary exercise with RW induces, regardless of genotype, hyperactivity in a novel non-aversive environment, as well as impulsivity and attentional deficits in the 5 Choice Serial Reaction Time Task (5CSRTT), although the effects of GxE interactions are milder than under early-life stress conditions. In conclusion, our results support the view that cadherin-13 contributes to how the brain responds to different environmental experiences, likely via its role in structural and synaptic plasticity.

Title: Wdfy3 links defective cortical neurogenesis to autism spectrum disorders

Authors: *K. ZARBALIS[1], L. OROSCO[2], A. ROSS[2], S. CATES[2], S. SCOTT[2], D. WU[2], J. SOHN[2], D. PLEASURE[2], S. PLEASURE[3], I. ADAMOPOULOS[2];

Abstract: Autism spectrum disorders (ASDs) are complex and heterogeneous developmental disabilities affecting an ever-increasing number of children worldwide. The complexity of manifestations, etiologies, and comorbidities of ASDs pose major challenges to the identification of consistent neuropathological features. Nonetheless, in a subset of young children on the autism spectrum abnormal cerebral growth trajectories have been observed. Normal cerebral size at birth is followed by a period of excessive growth, apparently the consequence of increased neuron generation. Intriguingly, we observe a reminiscent pattern of regional overgrowth in mouse models carrying deleterious alleles of the Wdfy3 gene, recently recognized as causative in ASDs. In addition, Wdfy3 mutants display focal migration defects of cortical projection neurons, a recognized cause of epilepsy, which is highly comorbid with autism. Our analysis of affected mutants identified an important function for Wdfy3 in regulating neural progenitor proliferation and neural migration in the developing brain. Specifically, Wdfy3 governs the mitosis of radial glia cells by setting the balance between proliferative and differentiative mitoses. Loss-of-function leads to an increase in proliferative divisions, an expansion of the progenitor pool, more neurons, and a larger cerebrum. In summary, our study defines an essential role for the autism factor Wdfy3 in regulating the developmental expansion and functional organization of the cerebral cortex while its loss-of-function results in pathological changes characteristic of ASDs.

Title: Developing a ferret model of cortical dysmaturation following newborn brain injury

Authors: *F. F. GONZALEZ[1], A. MIKHAILOVA[2], P. S. MCQUILLEN[2], S. F. SORRELLS[3], J. K. ELLIS[4];

Abstract: Existing small animal models fail to reproduce permanent myelination failure that is the hallmark of brain injury in the preterm human newborn. Furthermore, it is unclear how closely these models recapitulate human developmental pathways because rodents have a lisencephalic cortex. Despite being a small animal (0.5-1kg), ferrets have gyrencephalic cortex with radial cortical organization and a well-developed outer subventricular zone. We aim to develop an improved translational small animal model that reproduces cerebral cortical dysmaturation that may contribute to adverse neurodevelopment following human newborn brain injury. Our specific focus is glial development in the outer subventricular zone and late cortical migratory pathways of neuronal precursors. Exposure to 10% oxygen from P10-20 in ferret has been shown to impair oligodendrocyte maturation and stimulate gliosis (Tao et al Pediatric Research (2012) 71, 192-198). We find that ten days exposure to 10% oxygen is well tolerated by the jill (N=2) and kits (N=3), with no mortality and no observable distress or morbidity. Maternal hematocrit increases (38 - 54%) during this relatively brief hypoxia exposure. Using these conditions for the model we are analyzing oligodendrocyte and astrocyte lineage progression in the outer subventricular zone and novel postnatal migratory streams of neuronal precursors using cell type specific markers and immunofluorescence. A Ferret model of human preterm brain injury may provide insight into important cerebral cortical developmental pathways that are perturbed with preterm birth, birth asphyxia and congenital heart disease in human newborns.

Title: Sex specific deficits in affective behavior in a rodent model of autism

Authors: *T. M. HENNESSEY[1], C. BARRETT[2], S. RYAN[2], L. WANG[1], D. RAINNIE[3]; [1]Neurosci., [2]Div. of Behavioral Neurosci. and Psychiatric Disorders, [3]Dept. of Psychiatry, Emory Univ., Atlanta, GA

Abstract: Development of a valid animal model of autism is a critical step in studying autism spectrum disorder (ASD). Valproic acid (VPA) exposure during the first trimester increases the risk of autism by 10 fold. By exposing developing rat embryos to VPA we can mimic the human condition with ethological and predictive validity. VPA exposed rats exhibit less social drive and increased anxiety-like behavior, as in ASD. However previous studies used intraperitoneal (IP) administration which has a high rate of fetal reabsorption. Here, we used gavage VPA administration, which markedly reduced reabsorption and is more clinically relevant. Our first aim was to recapitulate the phenotype seen when VPA is given IP. As autistic individuals are more stress sensitive, we then investigated the impact of unpredictable shock stress (USS) on social interaction and anxiety-like behavior in VPA rats. Finally, we used RNAseq to analyze gene expression changes in the basolateral amygdala (BLA) of VPA rats. Behavior was assessed in 2 pups per sex from each of 41 litters. Social drive was measured through tests of ultrasonic vocalizations (USVs), approach to maternal bedding, social preference (SP), and social novelty (SN). Anxiety-like behavior was measured in the open field (OF) and acoustic startle (AS) tests. After USS (4 days), we measured contextual freezing and OF, SP, SN and AS were retested. Notably, the effects of VPA on social interaction and anxiety were sex dependent. At P11 VPA exposed males produced significantly fewer USVs than control pups ($p=.002$), and fewer approached maternal bedding ($p=.041$). VPA exposed males also spent less time with the novel rat ($p=.033$) and more time isolated from any rat ($p=.015$) during SN. Conversely, VPA females spent less time in the center in the OF test ($p=.031$) but males showed no difference. After USS, only VPA exposed females tended to higher AS ($p=.055$). USS also tended to cause VPA males to spend less time in social context ($p=.097$). Parallel to this, the BLA of P14 and P21 rats were micropunched and sent to the Emory Genomics Core for RNAseq. There were substantial differences in genes expressed in the BLA particularly in peptide signaling, behavior, and fear

learning pathways. In sum, gavage administration of VPA to dams recapitulates the social and emotional deficits in pups seen after IP administration. We also saw sex-specific behavioral effects of VPA exposure that were exacerbated by USS. Finally, VPA exposure caused many changes in gene expression that may prove useful for finding new treatment targets to reduce anxiety and improve social function in ASD.

Title: Gestational ethanol exposure during the first trimester most dramatically decreases gaba activity in the dorsolateral striatum of mice

Authors: ***S. I. SHIN**[1], V. C. CUZON-CARLSON[2];
[2]Neurosci., [1]OHSU/ONPRC, Beaverton, OR

Abstract: Alcohol is the leading preventable cause of birth defects and developmental disabilities in the US. Fetal alcohol spectrum disorders (FASD) is an umbrella term that encompasses physical, mental, and behavioral deficits. Behavioral abnormalities such as impaired motor skills, decision-making, and learning suggest alterations in cortico-basal circuitry. Within the basal ganglia, the dorsal striatum has been heavily implicated in the behavioral changes involved with addictive substances, including alcohol. We have shown that gestational exposure to ethanol (GEE) throughout a time period in mice that mimics all three trimesters of human development leads to deficits in habit formation. In the dorsolateral striatum (DLS), GEE causes an increase in median spiny neuron (MSN) firing. The increase is possibly mediated by decreased GABA input to MSNs in the DLS, as observed through a decrease in mIPSC frequency and amplitude in DLS MSNs. This decrease in GABA activity may be associated to a complementary decrease in cannabinoid receptor type 1 (CB1) activity. However, these changes were found in mice exposed to ethanol from conception through the first postnatal week, mimicking the three trimesters of human pregnancy. As a majority of alcohol consumption during pregnancy occurs within the first trimester, the aim of this study was to determine if there

is a critical period of exposure responsible for the GEE effects in the DLS. Thus, using whole cell patch clamp electrophysiology we measured the changes in DLS activity in mice that were exposed to various lengths of ethanol during pregnancy. Mice were placed in ethanol vapor chambers to produce blood ethanol levels of approximately 84 mg/dl in dams and 74 mg/dl in new born pups. Mice in the presence of ethanol during only the first trimester (to embryonic day (e)9.5) showed the most dramatic decrease in mIPSC activity in the DLS compared to control animals. Exposures up to the second (to e21) and third trimester (to postnatal day (p)10) exhibited a less profound decrease. These findings provide evidence for a critical period during gestation in which the developmental disabilities of FASD may most aggressively be inflicted. Furthermore, to substantiate our findings of a critical period of gestational ethanol exposure, we will use whole cell patch clamp electrophysiology to study CB1 receptor activity and will also look to see if these changes translate to habit formation behavior through using an instrumental learning task that can delineate goal-directed and habitual actions.

Title: Behavioral deficits and cholinergic pathway abnormalities in male Sanfilippo B mice

Authors: *P. DICKSON[1], S. Q. LE[1], S.-H. KAN[1], B. BENEDICT[1], Q. BUI[1], J. CUSHMAN[2], M. S. SANDS[3];
[1]Harbor-Ucla, Torrance, CA; [2]UCLA, Los Angeles, CA; [3]Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Sanfilippo syndrome causes progressive neurological deterioration and reduced fear associated with volume loss in the amygdala. We studied 12 male Sanfilippo B mice and 12 littermate controls age 16-20 weeks to determine whether this model would be similarly affected. Affected mice showed reduced anxiety, with a decrease in the number of stretch-attend postures during the elevated plus maze ($p=0.01$, $F=13.7$), an increased tendency to approach a novel

mouse ($p=0.067$, $F=3.66$), and an increased tendency to linger in the center of an open field ($p=0.032$, $F=5.28$). Radial arm maze testing showed a longer latency to find reward during training ($p=0.025$, $F=5.96$). We stained sections of 2 affected and 2 control female mice aged 41-42 weeks for acetylcholinesterase (AChE) activity for stereology to measure volume of the amygdala. Upon staining, we noticed an overall reduction in AChE activity staining in affected animals. To verify our observation, we measured AChE and choline acetyltransferase (ChAT) activity via colorometric assays in whole brain homogenates of the mice that were used in the behavioral experiment. We found a 12.4% reduction in mean AChE activity ($p<0.001$) and no difference in ChAT activity in affected animals. However, as the amygdala may be specifically affected in Sanfilippo disease, we evaluated AChE and ChAT in 3 affected mice and 3 controls using a hemicoronal section (thickness 2 mm) that contained amygdala. AChE activity was 25% lower ($p=0.006$) and ChAT activity 14% lower ($p=0.002$) in affected animals in that section of the brain. The levels of AChE and ChAT in whole brain homogenates did not show correlation with the behavioral variables that showed intergroup differences in the mice. Cholinergic pathways are affected in adult-onset dementias, including Alzheimer disease. Our results suggest that male Sanfilippo B mice display neurobehavioral deficits at a relatively early age, and that as in adult dementias, they may display deficits in cholinergic pathways.

Title: Too much, too early: effects of sensory overstimulation in early life

Authors: ***S. RAVINDER**[1], J. S. B. RAMIREZ[2], D. CHRISTAKIS[1], J. M. RAMIREZ[1], S. FERGUSON[1];

[1]Seattle Children's Res. Inst., Seattle, WA; [2]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Attention deficit hyperactivity disorder (ADHD) is a common childhood neurodevelopmental disorder that has profound effects on individuals, their families and society. Most research has focused on understanding genetic causes, but there remains a large role for environmental factors in the etiology of this disease. In particular, early life experiences exert long-lasting effects on neural function, which can have a deep impact on behavior and vulnerability to developing neuropsychiatric illnesses such as ADHD. We have developed a rodent model of "excessive non-normative stimulation (ENS)" whereby mice are exposed to audio-visual stimuli for six hours per day, from P10-P52 (Christakis et al., Sci Rep., 2012). When subsequently tested, ENS mice demonstrate numerous behavioral outcomes that are reminiscent of the 3 core clinical dimensions of ADHD (inattentiveness, impulsivity, hyperactivity). Compared to controls, ENS mice show (i) poorer short-term memory, impaired learning and attention in the novel object recognition test and barnes maze; (ii) increased risk-taking and impulsivity in the elevated plus-maze, open field and light-dark box tests; and (iii) locomotor hyperactivity that develops over time but a blunted locomotor sensitization to cocaine. We are currently extending these results by examining the effects of ENS in the 5-choice serial reaction time test and the delay-discounting test, both of which are well-established for testing impulsivity and attention. ADHD is also highly comorbid with substance abuse. We found that ENS mice develop a stronger conditioned place preference for cocaine compared to controls, suggesting that they may have a higher addiction liability. Interestingly, our behavioral observations are specific to the developmental period as mice exposed to ENS as adults were not affected. At the cellular level, we found that ENS leads to a decrease in neurogenesis in the dentate gyrus of the hippocampus and an increase in miniature excitatory postsynaptic currents in the basal amygdala and nucleus accumbens shell. We are currently pursuing experiments to further characterize these cellular effects. In today's increasingly complex technological age, children face a tremendous amount of sensory stimulation that could interact with genetic predispositions to produce detrimental effects on behavior and brain function. Indeed, observational studies have shown an association between excessive stimulation in young children and subsequent memory and attentional problems. Thus, ENS may serve as a useful model to study the influence of environmental factors on vulnerability to ADHD and its underlying etiology.

Title: Dynamics of Inositol 1,4,5-triphosphate receptor type 1 (IP3R1) in neonatal anoxia

Authors: *J. M. IKEBARA, M. V. DAMICO, D. S. CARDOSO, F. A. DOS SANTOS, G. S. V. HIGA, S. H. TAKADA, A. H. KIHARA;
Univ. Federal Do ABC, São Bernardo do Campo, Brazil

Abstract: The neonatal anoxia is one of the most common causes of morbidity and mortality in neonates. The longlasting sequelae include motor deficits, behavioral and sensory and /or cognitive impairments. The oxygen deprivation causes loss of ionic homeostasis resulting in calcium overloading and changes of calcium waves patterns, which are responsible for initiating the cell death in neuronal tissue. Inositol 1,4,5-triphosphate receptors (IP3Rs) are important calcium channels which regulate cellular calcium homeostasis and dynamics at the level of the endoplasmic reticulum (ER). Furthermore, the IP3Rs can be present in clusters or individually and this property alters of the way that calcium is released. Into a IP3R1 cluster, the released calcium forms puffs, and when IP3R is isolated, the released calcium forms blips. The IP3R1 is widely expressed in brain and spinal tissue and plays a pivotal role in these processes by mediating calcium flux from the ER into the cytosol and mitochondria. The aim of this study was to identify possible changes in the expression and dynamic of IP3R1 in endoplasmic reticulum caused by anoxic insult in neonatal rat hippocampus. In this work were used Wistar rats (Rattus norvegicus) for anoxia and sham groups. Anoxia was performed in P1/P2 neonates according to described system of neonatal anoxia, composed by 25 minutes of 100% nitrogen gas exposure at 37°C (Takada et al., 2011). We measured genic expression 24 hours after neonatal anoxia (by real-time PCR) and analysis showed a decreased genic expression of IP3R1 in anoxia treated animals. It suggests that probably there is a compensatory mechanism after an intracellular calcium overload in order to restore the calcium homeostasis and prevent the cell death. Interestingly, it was observed differences in subcellular location of immunolabeled hippocampal cells in CA1 area in anoxia animals. Nucleus was labelled in anoxia group while in sham group the labelling was distributed throughout the cytoplasm. These results showed that neonatal anoxia altered the distribution and genic expression of IP3R1 and probably may interfere in calcium release patterns, providing bases for future therapeutic approaches aiming the normalization of IP3R1-mediated calcium release.

Title: Identification of brain morphology defects in *Drosophila* CASK mutants

Authors: *J. TELLO, W. GRONENBERG, L. RESTIFO;
Univ. of Arizona, Tucson, AZ

Abstract: CASK encodes a highly conserved multi-domain scaffolding protein with major roles in brain development and function. CASK contains a guanylate kinase and selective protein-binding domains (PDZ and SH3) that define the MAGUK family; the amino-terminal CaM kinase-like domain has no enzymatic activity. CASK is primarily found in neurons, localized to both pre- and post-synaptic zones, as well as to the nucleus. Mutations in human CASK cause three distinct X-linked intellectual disability disorders, the most severe of which causes microcephaly with pontine-cerebellar hypoplasia and ataxia. To study the role of CASK in brain development, we used the recessive *Drosophila* CASK mutation, Δ18, a small deletion that eliminates all full-length CASK protein, compared with its specific genetic control, Ex33. Like the human patients, CASK-mutant *Drosophila* have impaired motor coordination that resembles ataxia. We analyzed brain morphology of Δ18 homozygous flies by histology of serial plastic-embedded sections. Estimated brain volume was reduced by 25% in Δ18 homozygotes, with the volume of different brain structures appearing to be reduced proportionately. Higher-resolution analysis of individual brain regions, such as the mushroom bodies and central complex, is underway. To investigate the cellular basis of the "small-brain" phenotype, we used primary cultures prepared from the CNS of *Drosophila* larvae to examine neuronal morphogenesis *in vitro*. Although the CNS of CASK mutants was visibly smaller than that of control larvae, neuronal cell recovery after dissociation was comparable. Neurite-arbor size and shape were quantified using NeuronMetricsTM software for semi-automated image analysis. CASK-mutant CNS neurons extended smaller arbors, with significant reductions in length, higher-order branch number, and territory, whereas branch density was increased. This "mini-arbor" defect suggests that the CASK-mutation-associated phenotypes, "small-brain" in flies and microcephaly in children, are due to impaired extension of dendritic arbors and axonal projections, rather than to

a reduction of neuronal numbers. These findings support the use of the *Drosophila* genetics system to model human brain disorders, in particular to study the functional consequences of specific human CASK mutations.

Title: Impaired plasticity in adult visual cortex following neonatal hypoxia

Authors: E. W. ATKINSON, H. ZHANG, *J. E. COLEMAN;
Pediatrics, Univ. of Florida, Gainesville, FL

Abstract: Premature infants are susceptible to diffuse white matter injury (DWMI), reductions in cortical and thalamic gray matter volume, and axonal injury. Consequently, children born premature are at an increased risk for long-term cognitive and behavioral deficits. Chronic hypoxia is a major risk factor for preterm brain injury and causes DWMI, ventriculomegaly, and behavioral deficits in rodents exposed to chronic sublethal hypoxia (CSH) as neonates. Although neuroimaging studies in children born premature suggest a link between anatomical abnormalities and the cognitive, learning and sensory processing deficits observed later in life, relatively little is known about the underlying pathophysiological mechanisms. We hypothesize that neonatal hypoxic brain injury disrupts the formation of microcircuitry in the cerebral cortex, which in turn impairs experience-dependent plasticity throughout life. To test our hypothesis, we characterized a robust form of adult experience-dependent plasticity in mouse primary visual cortex (V1), called stimulus-selective response potentiation (SRP), after exposure to CSH (10% O2, hypoxic, Hx) or room air (20% O2, normoxic, Nx) from postnatal day (P) 3 to P12. We used visually evoked potentials (VEPs) to assess basic visual function and SRP in adult (P40-60) Nx and Hx mice. We found that the intrinsic contralateral bias, visual acuity, and contrast sensitivity were normal in Hx mice. Following SRP induction, both Nx and Hx showed a significant potentiation of VEP amplitude to familiar (X deg) stimuli relative to novel (X + 90 deg) stimuli after 5 days, but the rate and overall magnitude was significantly reduced in Hx mice. Examination of the distribution of familiar and novel VEP amplitudes measured on day 5 in Hx

mice showed a scaled reduction in familiar, but not novel, VEP amplitudes. Furthermore, while VEPs elicited by familiar stimuli showed reduced variability in peak latencies when compared to VEPs elicited by novel stimuli, there was no difference between peak latencies measured in VEPs elicited by familiar and novel stimuli in Hx mice. These data provide support for our hypothesis by showing that cortical plasticity is impaired in adult Hx mice. Together, our findings warrant further investigation into the integrity of V1 microcircuitry in Hx mice and the behavioral consequences of reduced plasticity.

Title: Structural basis underlying therapeutic sensitive period for autistic behaviors in cerebellar mouse model of TSC

Authors: *P. TSAI[1], J. ELLEGOOD[2], J. LERCH[2], W. REGEHR[3], M. SAHIN[4];
[1]Neurol., UT Southwestern, Dallas, TX; [2]Toronto Sick Kids Children's Hosp., Toronto, ON, Canada; [3]Harvard Med. Sch., Boston, MA; [4]Boston Children's Hosp., Boston, MA

Abstract: Autism spectrum disorders are highly prevalent neurodevelopmental disorders that present a significant health care challenge. Despite the heightened prevalence, the underlying pathogenesis of autism spectrum disorders remains poorly understood. Clinically, cerebellar dysfunction has been implicated in autistic behaviors. Using a mouse model of tuberous sclerosis complex, we have demonstrated that cerebellar dysfunction is sufficient to generate autistic-like behaviors in mice and that early treatment with the mtor specific inhibitor rapamycin can prevent these abnormal behaviors. Here, we demonstrate that rapamycin treatment at a time corresponding to young adulthood can rescue abnormal autistic-like behaviors. Moreover, using voxel based morphometry and diffusion tensor imaging to investigate circuit based mechanisms underlying dysfunction and rescue, we also demonstrate underlying anatomic changes in mutant mice that - similar to behavioral disruption - can be rescued with adult onset rapamycin therapy.

Title: Chronic intranasal oxytocin administration in the 16p11.2 mouse model has a marginal effect on behaviour and no effect on neuroanatomy

Authors: ***Z. BUCHWALD**[1], J. ELLEGOOD[1], E. ANAGNOSTOU[2], J. LERCH[1];
[1]Mouse Imaging Ctr., Toronto, ON, Canada; [2]Pediatrics, Bloorview Res. Inst., Toronto, ON, Canada

Abstract: Introduction: Autism is a neurodevelopmental disorder characterized by social/communication deficits and repetitive behaviors. Oxytocin is a neuromodulator known for its ability to promote social behaviours and therefore, may be a promising therapeutic for autism. However, as autism is heterogenous, the treatment will likely only help with a subset of patients. To determine what might contribute to response susceptibility, we treated the 16p11.2 mouse model, representing one of the most common copy number variants found in autism, with oxytocin. Methods: To assess the efficacy of treatment, intranasal oxytocin (~6ul) was administered once a day, for 28 days, starting at 5 weeks of age to 17 male 16p11.2 mutant mice and 19 male littermate controls. On the third week of treatment, the mice were assessed for repetitive behaviours (as assessed by grooming), sociability (three chamber sociability task), anxiety and hyperactivity (open field), memory (novel object recognition), and learning and motor coordination (rotarod). Prior to the oxytocin treatment, and before and after behavioural testing, the mice underwent *in vivo* neuroimaging using MRI to gather information about any neuroanatomical changes. An additional *ex vivo* MRI was acquired at the end of the study. Results: Oxytocin treatment normalized ($p< 8.8e-5$) the repetitive behaviour deficits of the 16p11.2 mutant mouse and increased ($p<0.034$) their object recognition (memory), but had no effect on sociability, anxiety, or hyperactivity. Treated mutant mice fell off the rod quicker ($p<0.005$) than untreated mutants, indicating that oxytocin might exacerbate motor deficits. Treatment also had no significant effect on neuroanatomy. Discussion: Oxytocin is expected to increase social behaviours and memory, and decrease repetitive behaviours. Treatment had no

significant effect on neuroanatomy and, for the most part, did not enhance the behaviours of the 16p11.2 mouse, though it normalized a deficit in grooming and increased memory. Results indicate that oxytocin may not be a good treatment option for 16p11.2 mutant mice, and therefore, humans with the 16p11.2 mutation also may not respond positively to oxytocin treatment. Future directions involve looking at the response of multiple strains of autism-related mouse models, including 16p11.2, to several promising therapeutics used in human patients with autism, yielding the ability to establish a translational paradigm for predicting responders from non-responders.

Title: Impairment in spatial memory and alteration in excitatory synaptic transmission in Myosin9a heterozygous mice

Authors: ***E. VEZZOLI**[1,2], A. FOLCI[3], L. MURRU[3], S. BASSANI[3], L. PONZONI[1], F. LONGO[3], E. MORETTO[3], L. GEROSA[3], J. ZAPATA[3], D. BRAIDA[1], M. BÄHLER[4], M. SALA[1], M. FRANCOLINI[1,3], M. PASSAFARO[3];

Abstract: Unconventional myosins are a superfamily of actin-based motors; among these, Myosins9, belong to a class formed by two members: Myosin9a (Myo9a) and Myosin9b (Myo9b). Myo9a was first identified and cloned in 1998 and it was demonstrated that it was enriched in rat brain (cerebellum, cortex and hippocampus) where its high level of expression suggested that it had a prominent role in the central nervous system functions (Chieregatti et al., 1998), a role that is however still elusive. In humans, mutations in Myosin9a gene were shown to be correlated to the Bardet-Biedl Syndrome, an autosomal recessive disorder characterized by a number of pathological features including intellectual disability. In mice, loss of Myo9a induced severe hydrocephalus; brains from early postnatal mice were characterized by stenosis of the ventral caudal third ventricle and the aqueduct. It was recently shown that hydrocephalus was

caused by a persistent activation of RhoA proteins as treatment with a specific inhibitor was able to reduce its formation new-born mice (Chieregatti et al., 2009). Here, we investigated the role of Myo9a in the hippocampal excitatory synapses, in Myo9a heterozygous male mice (C57BL/6) at four/six weeks of age. Ultrastructural analyses of the CA1 region of hippocampus showed that synapses of Myo9a+/- mice were characterized by an increase in the thickness of postsynaptic density (PSD). On the other hand, no differences were observed in the architecture of presynaptic terminals. In agreement with these results biochemical assay on Myo9a-/+ hippocampus homogenates showed increased levels of postsynaptic (PSD-95 and GluA2) but not presynaptic markers. We also found that Myo9a was enriched in the PSD, where it colocalized with postsynaptic markers and directly bind the C-terminus of the GluA2 AMPA receptor subunits. This last result suggested a possible involvement of Myo9 in AMPA receptor trafficking; a role in glutamate receptors dynamics that was further confirmed by electrophysiological recordings indicating that hippocampal neurons from Myo9a+/- mice showed an altered basal excitatory pattern characterized by increased amplitude and frequency of mEPSCs. Moreover in the CA3-CA1 synapses from acute slices from Myo9a+/- mice, the induction of Long Term Potentiation (LTP) was severely impaired and this impairment of LTP in *ex vivo* recordings was paralleled by a strong deficit in spatial learning and memory. From these data, we could conclude that the partial deletion of Myo9a, impaired spatial memory and altered excitatory transmission interacting with the AMPA receptors trafficking in the hippocampus.

Title: Long-term cognitive impairment in a murine model of intraventricular hemorrhage in the preterm infant

Authors: A. SEGADO-ARENAS[1], C. INFANTE-GARCIA[2], J. RAMOS-RODRIGUEZ[2], S. LUBIAN-LOPEZ[1], *M. GARCIA ALLOZA[2];
[1]Hosp. Universitario Puerta del Mar, Cadiz, Spain; [2]Div. of Physiology, Sch. of Med., Cadiz, Spain

Abstract: Preterm birth (PTB) is defined as birth prior to 37 weeks of gestational age and affects over 10% of births worldwide. Also, the increase in the survival of the tiniest premature infants, has also raised the incidence of preterm-related pathologies. One of the most feared complications in PTB is the germinal matrix-intraventricular hemorrhage (IVH), affecting up to 30% of babies with extremely low birth weight (<1000 g) and 15% of those under 1500 g. We have developed a murine model of IVH by intracerebroventricular injection of 0.1U or 0.3 U of proteolytic enzyme collagenase to p7 CD1 mice. As soon as 24 h after the injections we observed dose-dependent intraventricular bleeding. We hypothesized that induced IVH had deleterious effects on cortical and hippocampal development. In order to further explore this possibility, mice were analyzed postmortem at p14 and at p70. Whereas brain weight was similar in all groups under study at p14, an slight reduction was observed in p70 mice treated with highest dose of collagenase. Brain morphology and atrophy were further assessed using cresyl violet staining. Bleeding was measured by Prussian blue staining and inflammatory processes were quantified by microglia immunostaining with anti-iba 1 antibody, both in the close proximity of ventricular hemorrhages, as well as in hemorrhage free areas. By p70, when behavioural assessment can be performed, we observed a dose-dependent cognition impairment in collagenase treated mice. Spatial memory was significantly impaired in the Morris water maze test, both in 0.1 U and 0.3 U treated mice. Episodic memory was also significantly impaired in collagenase injected mice in a dose-dependent manner. Altogether, our data suggest that our model of induced IVH in PTB might be useful in the study of the related pathology and prognosis. Our results may guide us to better understand the physiopathology involving IVH and help us in the search for new therapeutic targets. Title: Developmental exposure to fluoxetine alters social behavior and arginine vasopressin receptor binding in prairie voles (Microtus ochragaster) associated with Autism Spectrum Disorder

Authors: *M. C. PALUMBO[1,2], R. H. LARKE[1,2], S. M. FREEMAN[2], K. L. BALES[2,1]; [1]Univ. of California, Davis, Davis, CA; [2]California Natl. Primate Res. Ctr., Davis, CA

Abstract: The neuropeptide hormone arginine vasopressin (AVP) is involved in social behavior, pair bonding, and stress responses in the socially monogamous prairie vole (Microtus ochrogaster). Exposure to a developmental selective serotonin reuptake inhibitor (SSRI) *in utero* may be linked to the prevalence of Autism Spectrum Disorder (ASD). As a translational model of developmental pre-and postnatal SSRI exposure, twenty female prairie voles were treated with 5mg/kg subcutaneous fluoxetine or saline solution daily throughout pregnancy to weaning. The SSRI-exposed pups were behaviorally assessed to examine anxiety-like and attachment behaviors using the partner preference (PPT), elevated plus maze, open field, and alloparental care tests. Brains were collected 24 hours after behavioral testing. Quantitative receptor autoradiography was used to measure vasopressin 1a receptor (V1aR) binding density in the medial amygdala, lateral septum, and ventral pallidum. Analyses (N=69) indicate developmental fluoxetine exposure decreases V1aR density in the medial amygdala ($F_{1,47}=4.2$, $p<.05$) and voles with lowered V1aR density in the medial amygdala spent a longer duration in the empty testing chamber ($F_{1,2}=39.82$, $p=.02$) in the PPT. Females with decreased V1aR density in the medial amygdala ($F_{1,2}=70.51$, $p=.01$) spent the most amount of time in the empty testing chamber during the PPT. These results suggest changes to V1aR density in the medial amygdala alter sociality and may mediate the increased risk of ASD. This research may help to explain the relationship between SSRI exposure during pregnancy and neural and behavioral alterations associated with ASD.

Title: A bidirectional threshold of ERK/MAPK signaling regulates axonal outgrowth in developing corticospinal neurons

Authors: *L. XING[1], G. R. BJORKLUND[2], X. LI[1], Y. WU[1], W. D. SNIDER[1], J. M. NEWBERN[2];
[1]Neurosci. Ctr., UNC Chapel Hill, Chapel Hill, NC; [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: RASopathies represent a large family of human neurodevelopmental disorders caused by aberrant ERK/MAPK signaling due to germline mutations in regulators and components of the canonical Ras/Raf/MEK/ERK signaling pathway. However, the cellular and molecular mechanisms underlying the pathogenesis of RASopathies are largely unclear. Here, using a mouse genetic approach, we have delineated the specific effects of both loss and gain of function of ERK/MAPK signaling in the development of long-range cortical projection neurons. We found that inactivation of ERK/MAPK signaling in developing cortical excitatory neurons resulted in a marked loss of Ctip2 expressing, subcerebrally-projecting neurons in sensorimotor layer V and a dramatic reduction in the size of the corticospinal tract (CST) by P14. ERK/MAPK signaling is not required for initial neuronal specification as, at P0, Ctip2-expressing layer V neurons were present in normal numbers. However, the entry and extension of CST axons into the cervical spinal cord was markedly reduced at P2. Subsequently, many layer V neurons underwent apoptosis as evidenced by the presence of activated Caspase-3 labeled cells and the association of microglia with degenerating neurons. We hypothesize that CST axon growth failure may be due to reduced ability to respond to IGF1 which we have found is intensely expressed in the ventral medulla from E18-P14. Surprisingly, hyperactivation of ERK/MAPK also resulted in diminished CST size in the spinal cord dorsal funiculus in adult mice, but the number of Ctip2 expressing layer V neurons was not altered. A striking decrease in the initial extension of corticospinal afferents into the cervical spinal cord was evident at P3-4. Viral tracing of layer V neuronal projections provided further support for reduced spinal cord

innervation in adults. Interestingly, reduced extension the spinal cord was associated with enhanced CST axon targeting and branching in the medulla. In contrast, neither loss nor gain of function of ERK/MAPK signaling had an overt effect on the survival and axonal growth of callosal projection neurons in layer II/III in early postnatal developmental stage. Collectively, our data reveal that a bidirectional threshold of ERK/MAPK signaling is critical to the regulation of elongation and branching of corticospinal axons. Abnormalities in axonal connectivity of layer V neurons might contribute to the pathogenesis of neurodevelopmental syndromes associated with pathological ERK/MAPK activity.

Title: Electron microscopic evaluation of myelination in the sensorymotor cortex in a neonatal hypoxic-ischemia model that has hindlimb motor dysfunction without neuronal loss

Authors: *Y. UEDA[1,1], H. TAKASE[2], S. MISUMI[3], A. ISHIDA[3], C.-G. JUNG[3], H. HIDA[3]; [1]Neurophysiol & Brain Sci., [2]Core Lab., [3]Neurophysiol and Brain Sci., Nagoya City Univ. Grad Sch. Med. Sci., Nagoya, Japan

Abstract: Developing white matter injury (DWMI) caused by perinatal hypoxia-ischemia (H-I) in preterm infants is associated with permanent neurodevelopmental disabilities such as paralysis and cognitive dysfunction. We established a DWMI model rat that received H-I (right common carotid artery occlusion and 6% hypoxia for 1 hour) at P3. Our DWMI model showed less hindlimb motor coordination and altered motor mapping in the sensorymotor cortex. Less neuronal damage was observed in the cortex and white matter: few apoptotic neuronal cell death, few degenerating cells in Argyrophil-III silver staining, comparable number of cortical projecting neurons and pyramidal neurons, and comparable number of GABAergic cells. We also revealed that the intensity of MBP staining was lower in the layer II-III of the sensorymotor

cortex. To clarify the reason for hindlimb dysfunction and the mechanism of mapping change in our DWMI model, we investigated myelination in the motor cortex (M1) and the sensory cortex (S1) using electron microscopy (EM). DWMI rats were perfused with the fixative, and ultrathin sections of each hindlimb area were observed under EM (x 5,000). The number of myelinated axons and their g-ratio was evaluated in the layer II-III, the layer V and corpus callosum (CC). In frontal section assessment, No significant difference in the number of myelinated axons in M1 and S1 was detected in the layer II-III where the intensity of MBP was less. In addition, no significant difference in g-ratio of myelinated axons was there in M1 and S1. However, evaluation from the horizontal section of the layer II in M1 showed increased myelinated axons on the DWMI side. Data suggest that myelination in the layer II is altered in our DWMI model, which could explain the reason for the hindlimb dysfunction and the mechanism of mapping change in the cortex.

Title: Crosstalk between paternal Pax6 mutation and aging accelerates vocal communication

Authors: ***R. KIMURA**, K. YOSHIZAKI, K. KOIKE, H. INADA, N. OSUMI;
Tohoku Univ. Grad. Sch. of Med., Miyagi, Japan

Abstract: In rodent, advanced paternal age induces some abnormal behaviors, and how paternal aging affects phenotypes of their offspring is an intriguing issue. We previously demonstrated that the offspring derived from old sires showed significant decrease in average number of ultrasonic vocalization (USV) that is known as communicative call of mice. Histological analysis suggested that this trans-generational effect of advanced paternal age had its molecular basis on epigenetic changes during spermatogenesis. Here, we report that paternal Pax6 mutation accelerates the decrease in USV calls caused by advanced paternal age. To examine the influence of paternal Pax6 mutation and paternal aging to their offspring, spontaneous Pax6 mutant (Sey) sire mice at each stage of young (3-month-old), middle-aged (6-8-month-old), and old (>12-

month-old) were mated with young (3-month-old) wiled-type (WT) females. Their offspring were separated from the dams at postnatal-day 6 and the number of USV calls was measured during 5 minutes separation. Although the number of USV calls was comparable between Sey offspring and WT litter when their Sey sire was young, Sey offspring derived from middle-age Sey sire showed significant decrease in the number of USV calls compared to WT litter. The number of USV calls was decreased in both genotypes of offspring when their Sey sire was old. We also found the expression of Pax6 in spermatocyte, suggesting that Pax6 haploinsufficiency accelerates epigenetic changes in spermatocyte caused by advanced paternal age. Semiquantitative analysis demonstrated that histone H3 K9 di-methylation and K79 di-and tri-metylation level in spermatocyte were up regulated in Sey spermatocytes. This increase of H3K79 tri-methylation was also observed in mature sperm. Since there was a significant association between the level of H3K79 tri-methylation in sperm and the number of USV in their offspring in WT, it is possible that paternal Pax6 mutation accelerates vocal communication deficit in offspring caused by paternal aging through the transgenerational mechanism including H3K79 tri-methylation in spermatocytes.

Title: The effects of prenatal exposure to valproic acid on the development of juvenile-typical social play in rats

Authors: *S. RAZA, B. T. HIMMLER, S. M. HIMMLER, A. HARKER, B. KOLB, S. M. PELLIS, R. GIBB;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Autism is a severe neurodevelopmental disorder characterized by qualitative impairments in social behavior, communication, and aberrant repetitive behaviors. A major focus

of animal models of autism has been to mimic the social deficits of the disorder. The present study assessed whether rats exposed prenatally to valproic acid (VPA) exhibit deficits in social play as juveniles that are consistent with the social deficits seen in autism. Dams were exposed to an acute dose of VPA on gestational day 12.5. Later, the playful interactions and associated ultrasonic vocalizations (USVs) of the juveniles were examined. It was predicted that VPA-treated rats should play less than the controls. Characteristic of neurobehavioral insult at this early age, the VPA-treated juveniles exhibited significant increases in the frequency of body shakes and sexual mounting, but played at the same frequency as the controls. However, when playing, they were less likely to use tactics that facilitated bodily contact and vocalized less. These data suggest that prenatal VPA exposure disrupts some aspects of being able to communicate effectively and engage partners in dynamic interactions - deficits that are consistent with those seen in autism.

Title: Complex behavioral and functional phenotype in a rat prenatal valproate model of autism

Authors: ***G. LEVAY**[1], C. CSOLLE[2], R. KEDVES[2], K. SAGHY[2], K. KORDAS[2], A. VARGA[2], T. SPISAK[3], D. GAJARI[3], V. ROMAN[2];
[2]Lab. of Neurodevelopmental Biol., [1]Gedeon Richter Plc., Budapest, Hungary; [3]Preclinical Imaging Ctr., Gedeon Richter Plc, Budapest, Hungary

Abstract: Autism spectrum disorder is a highly prevalent developmental disorder that is characterized by deficits in socio-communication, increased stereotyped behaviors and compromised cognitive processes. Human fetal exposure to valproate (VPA), a widely-used anti-epileptic drug has been shown to increase the risk of developmental disorders including autism spectrum disorder. Literature data indicate that VPA administration to pregnant rodents may also lead to autistic-like behavioral elements in the offspring and is used as an animal model of autism. In the present study, Sprague-Dawley rat dams were treated with 400 mg/kg sodium

VPA (sc.) or the same volume of saline vehicle (given the same route) on gestational day 12.5 and behavior of the offspring was investigated in a battery of tests. In accordance with an autistic-like phenotype, ultrasonic vocalization after maternal deprivation was reduced in the VPA-treated pups and adult offspring showed a major defect in social memory measured in the social discrimination set-up of the 3-chamber apparatus. Social preference in the 3-chamber assay, juvenile social play, spontaneous locomotor activity and full circadian activity in adulthood were mildly affected or unaltered in the *in utero* VPA-exposed rats. Animals were also investigated in a rodent-dedicated magnetic resonance imageing (MRI) apparatus to reveal potential underlying anatomical, resting state and/or functional alterations. MRI done in an anatomical mode indicated a reduction in both white and grey matter in the VPA group. Resting state MRI did not show a difference between *in utero* VPA and saline treated offspring. In a functional MRI set-up air-puff stimulation of the whisker pad induced a hyperactivation of the somatosensory cortex in the prenatally VPA-treated offspring compared to controls, supporting the excitatory/inhibitory imbalance theory of autism spectrum disorder. In conclusion, our results suggest that VPA treatment in Sprague-Dawley rats results in a complex phenotype with a number of behavioral and functional alterations that are compatible with the notion of prenatal VPA administration as a pharmacological model of ASD. This work was partially supported by a Hungarian Governmental Grant ("Ernyő" 2013-2016).

Title: Live group B Streptococcus-induced maternal immune activation: gender dichotomic chorioamnionitis and autistic-like traits in male offspring

Authors: *M.-J. ALLARD[1], J. BERGERON[1], M. DESCOTEAUX[1], L. TREMBLAY[1], M. LEPAGE[1], L.-C. FORTIER[1], C. POYART[2], G. SÉBIRE[1,3];
[1]Univ. de Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. Paris Descartes, Paris, France; [3]McGill Univ., Montreal, QC, Canada

Abstract: Background Group B *Streptococcus* (GBS) is a commensal bacterium colonizing 15 to 30% of healthy pregnant women. GBS is one of the major causes of chorioamnionitis, associated to preterm delivery and cerebral injuries in the newborn. Our hypothesis is that GBS-induced maternal immune activation has a deleterious neurodevelopmental impact on the offspring. Using a new preclinical rat model, our goal is to study the impacts of GBS-induced gestational inflammation on the developing brain and its behavioral outcomes. **Methods** Dams were inoculated at gestational day (G) 19 with live serotype Ia GBS (10^8 CFU). Caesarian sections were performed at G21 and G22 to collect maternal and fetal blood, placentas and fetal brains. The maternofetal inflammatory response was studied by ELISA and immunohistochemistry. Brains were collected at postnatal (P) 40 for histological studies. Magnetic resonance imaging (MRI) and diffusion tensor imaging were executed on 69 to 83 days old anesthetized rats. Behavioral tests were performed from P7 to P40 to assess communication, sociability, sensory integration and exploratory abilities. **Results** GBS-exposed dams displayed gender dichotomic chorioamnionitis characterized by a higher infiltration of polymorphonuclear cells in male, compared to female fetuses. Increased titers of interleukine-1β were detected in the maternal blood and in male fetuses' blood following GBS inoculation. At P40, GBS-exposed males showed a reduced thickness of frontal cortex and of periventricular white matter, and an enlargement of lateral ventricles, which was also visible on MRI. Trend toward a decreased mean fractional anisotropy, reflecting dysconnectivity of white matter fibers, was observed in the genu and body of corpus callosum in GBS-exposed *vs* control male rats. GBS-exposed males, but not females, showed autistic-like behavior: defective communication, social behavior impairments, impaired sensory integration, and hyperactivity, as compared to male controls. **Conclusions** Exposure to live GBS induces maternal immune activation resulting in neurodevelopmental and behavioral abnormalities recapitulating those of human autism spectrum disorders, including gender dichotomy and neurobehavioral phenotype. White matter dysconnectivity will be further characterized by ongoing studies. Further neurobehavioral characterization and inflammatory mechanistic studies of this new preclinical animal model will help to target future neuroprotective strategies.

Title: Effects of perinatal administration of antidepressants on behavior of the adult offspring in Sprague-Dawley rats

Authors: *J. NELMS SPROWLES[1,2], J. R. HUFGARD[1,3], A. GUTIERREZ[1,3], R. A. BAILEY[1,3], S. A. JABLONSKI[1,2], M. T. WILLIAMS[1,2,3], C. V. VORHEES[1,2,3];

Abstract: During fetal life, the brain rapidly develops and undergoes numerous processes such as cell fate determination, neurogenesis, migration, synaptogenesis, apoptosis, and pruning. Throughout this critical period, the brain is susceptible to insult from exposure to exogenous factors, including drugs, which may negatively impact brain development. Antidepressants (ADs) modify neurotransmitter reuptake and interact with receptors in the brains of adults; however, the effects of such activity on early brain development are not well understood. A recent study suggested an increase in autism spectrum disorder (ASD) in children whose mothers took selective serotonin reuptake inhibitors (SSRIs) while pregnant (Croen et al., 2011). Another study reported deficits in learning and memory after exposure to an SSRI from P11-20 in rats (Schaefer et al., 2013). The present study investigated whether perinatal exposure to antidepressants affects long-term behavioral outcomes. Sprague-Dawley dams were randomly assigned to one of six treatment groups: Citalopram (10 mg/kg or 5 mg/kg; SSRI), Fluoxetine (5 mg/kg; SSRI), Buproprion (15 mg/kg; NDRI), Valproic Acid (500 mg/kg - given once on E12 as a positive control for ASD-like behavior), or Saline. Dams were treated by subcutaneous injection twice daily (6 h apart) from E6-21, and pups were dosed directly from P1-20. Behavioral testing began on approximately P60. One male/female pair from each litter was tested in the Cincinnati water maze for egocentric learning. Another pair received the Morris water

maze to assess allocentric learning and memory. A third pair received a series of tests: elevated zero maze, open-field, marble burying, acoustic startle response with prepulse inhibition, sociability/social preference, radial water maze, and forced swim. Rats underwent testing in a straight water channel prior to maze testing to assess motor function, motivation to escape, and to teach them how to escape on a hidden platform. A fourth pair was sacrificed for immunohistochemistry and HPLC analyses. Preliminary data analyses show significant treatment effects in open-field (Cit-10 group was hypoactive compared with Sal, $p<0.05$) and marble burying (Cit-10 rats buried more marbles than Sal rats, $p<0.05$, suggesting increased compulsive behavior). Early results suggest that AD exposure during early development results in altered adult behavior in the offspring with possible implications for the safety of these drugs when used during pregnancy.

Title: Human-Mouse:Disease Connection, utilizing mouse models to gain insights on autism

Authors: *M. TOMCZUK, S. M. BELLO, C. L. SMITH, J. A. KADIN, J. E. RICHARDSON, J. T. EPPIG, &. THE MOUSE GENOME INFORMATICS GROUP;
Mouse Genome Informatics, The Jackson Lab., Bar Harbor, ME

Abstract: The Human-Mouse: Disease Connection (HMDC, www.diseasemodel.org) is a translational tool developed by the Mouse Genome Informatics resource (MGI, www.informatics.jax.org) to aid researchers in identifying candidate disease genes and finding mouse models of diseases and disorders such as autism. Autism spectrum disorder encompasses a group of neurodevelopmental disorders with a strong genetic basis, characterized by social interaction and communication difficulties, repetitive behaviors, and other health issues. The use of mouse models is key for gaining insights on the etiology, molecular and cellular mechanisms, behavioral phenotypes, and environmental factors that contribute to autism. In addition, well-defined mouse models showing core autism phenotypes can help discover new therapies and be

used to test potential treatments. The HMDC integrates mouse and human genomic, phenotypic, and disease information, including over 1,300 OMIM-derived human diseases with one or more mouse models, phenotypes from more than 54,800 mouse genotypes, and high-throughput phenotyping data of mouse knockout mutations from the International Mouse Phenotype Consortium (IMPC), in easy to navigate and interactive grids and tables. Investigators can identify experimental mouse models of autism based on OMIM disease associations by searching for disease terms. The results of a search on "autism" (as of May 2015) show 32 mutant mouse genes described to produce autism phenotypes. Of these, three orthologs are identified in humans as autism genes. These mouse mutants are robust models that can be used for testing therapeutic agents. An additional 23 of the mutant mouse genes have human orthologs and are potential autism candidate genes that researchers may want to explore further in patients. The results also show 7 human genes implicated in autism for which mouse orthologs are known, but no data exists to determine if mutants in these mice will display autism phenotypes. For example, mutations in *Slc9a9* or *Rpl10* are candidates for mouse autism models, but as these mutants exist only in ES cell lines, no phenotypic data are available. Phenotyping mice created from these mutant ES cell lines may yield new models. In HMDC, investigators can also prioritize candidate variants from whole genome sequencing of autistic patients and candidates within a genomic region based on reported phenotypes and disease associations. The HMDC portal eases the translation between human and mouse data. We will illustrate how users can exploit the wealth of mouse data to further research on complex neurodevelopmental diseases such as autism and to build better mouse models of disease.

Title: Weaker myelin expression in layer II-III of the sensorymotor cortex in a neonatal hypoxic-ischemia model that has hindlimb motor dysfunction without neuronal loss

Authors: R. NISHIGAKI, *S. MISUMI, M. SUZUKI, Y. UEDA, S. OGAWA, C.-G. JUNG, H. HIDA;
Nagoya City Univ. Grad Sch., Nagoya, Japan

Abstract: Developing white matter injury (DWMI) caused by perinatal hypoxia-ischemia (H-I) in preterm infants is associated with permanent neurodevelopmental disabilities such as paralysis and cognitive dysfunction. We reported a DWMI model rat that received H-I (right common carotid artery occlusion and 6% hypoxia for 1 hour) at P3. Our DWMI model showed less hindlimb motor coordination and altered motor mapping in the sensorymotor cortex. Less neuronal damage was observed in the cortex and white matter: few apoptotic cell death in NeuN positive cells, few degenerating cells in Argyrophil-III silver staining, comparable number of SATBII and Ctip2 positive cortical projecting neurons and Fluoro-gold positive pyramidal neurons, and comparable number of GABAergis cells after H-I. To clarify the reason for hindlimb dysfunction in our DWMI model, we challenged to know the myelination in the motor cortex (M1) and the sensory cortex (S1) using myelin basic protein (MBP) staining. Weaker MBP staining was apparently shown in both M1 and S1 in H-I side. Quantitative assessment in a selected area of layer II-III and layer IV-V that was defined by STABII staining was performed using Image J software: the intensity was digitalized at 16 bit, appropriate threshold was set, and the pixel above the threshold was quantified. It found that the intensity of MBP staining was lower in the layer II-III both M1 and S1 although it was same level in the layer V-VI in both areas. Data suggest that less MBP in the layer II-III in our DWMI model rat might explain hindlimb motor dysfunction without neuronal loss in the sensory-motor cortex.

Abstract: Recent studies have implicated immune dysregulation or inflammation, oxidative stress, mitochondrial dysfunction and environmental toxicant exposures in ASD. Among then, strong evidences suggest neuroinflammatory and immunological dysregulation is important in the pathogenesis of ASD Prominent microglia activation in certain brain regions has been discovered in ASD patients. Previously, we have demonstrated that amygdala dysfunction may play a key role in the pathogenesis of ASD by using the valproic acid (VPA)-induced ASD rat model. In the current study, we treated the model with minocycline to study the effects on neuroinflammation, emotion brain activity and social phenotypes. The results showed, minocycline (50mg/kg) treatments for 14 days could increase social interaction and improved fear memory extinction in these VPA-exposed offspring. The results suggested the possible role of emotion brain neuroinflammation in the pathogenesis and the intervention of ASD. This work may shed light on our understanding of ASD and ultimately pave the way for developing safe and effective therapeutic strategies.

Title: Mechanisms and rescue strategy for complex neuropsychiatric disorders in inborn error of peptide metabolism

Authors: *M.-H. KIM, Y.-S. BAE, S. YOON, W. SONG, S. LEE;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Inborn errors of metabolism (IEMs) are commonly accompanied by neurodevelopmental disorders. However, pathological mechanisms and pharmacological treatments for neurological symptoms in most IEMs are still unknown. Here we report that restoration of NMDAR (N-methyl-D-aspartate receptor) activity rescues neurodevelopmental disorders in mice lacking aminopeptidase p1 (Xpnpep1-/-). Mice deficient for aminopeptidase p1, a proline-specific endopeptidase encoded by Xpnpep1 gene, display hyperactivity, epileptic EEG rhythms, and impaired learning. These behavioral impairments were associated with

abnormal NMDAR signaling in the hippocampus. Restoration of NMDAR signaling by pharmacological intervention ameliorated behavioral and cognitive impairments caused by aminopeptidase p1-deficiency. These results indicate that metabolic dysfunction in Xpnpep1-/- neurons results in perturbation of NMDAR homeostasis and provide a potential therapeutic strategy to alleviate neurodevelopmental disorders in IEM caused by aminopeptidase P1-deficiency.

Abstract: Epidemiological and experimental evidences indicates that insults during fetal and neonatal developmental period can increases the risk in the offspring to develop several chronic diseases including cardiovascular diseases and hypertension. In association, low-protein diet induces disruption in biochemical milieu in many tissues also increasing the risk of several diseases. Previous studies have shown that the estrogen has an important role on brain protection and its presence may be related to the decrease in the occurrence of diseases. Our hypothesis is that female offsprings are more protected than male that received low-protein diet during critical period of brain develop regards to the oxidative stress. Wistar offsprings (male, n=17 and female n= 15) were divided into two groups according mothers' diets: control (NP, 17 % of casein) and low-protein (LP, 8 % of casein) groups. There was no difference in lipid peroxidation in both a groups. We found a decrease in protein oxidation in females-LP group when compared to males-LP group (approximately 100%). The superoxide dismutase-SOD activity showed no difference

between groups. Related to catalase-CAT activity we observe an increase in in females-LP compared to males-LP (approximately 60%). The levels of reduced glutathione-GSH increased and decreased of levels of oxidized glutathione-GSSG in females-LP compared to males-LP group (20% and 45% approximately, respectively). Our results show that females are less susceptible to oxidative stress than males when submitted to protein malnutrition early in life.

Title: The role of Slitrk-1 gene in striatal cholinergic interneurons in behavioral manifestations mimicking Tourrette syndrome

Authors: ***J.-C. DU**[1,2], H.-J. LEE[2], L.-C. CHIOU[2,3];
[1]Taipei City Hosp., Taipei City, Taiwan; [2]Grad. Inst. of Pharmacology, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [3]Grad. Inst. of Brain and Mind Sciences, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The Slitrk-1 (Slit and NTrk-like family 1) gene is one of vulnerable risk genes in Tourette syndrome (TS), a chronic neuropsychiatric disorder with multiple motor and phonic tics regarded as stereotyped behaviors. In the striatum of mammals, Slitrk-1 is highly expressed in early childhood but gradually disappeared in adulthood except cholinergic interneurons, which are the only striatal neurons with persistent expression of Slitrk-1 into adult stage. A postmortem study had shown that adult TS patients had less cholinergic interneurons in the striatum than normal subjects, suggesting the contribution of Slitrk-1 in maintaining normal function of striatal cholinergic interneurons in adults. We, therefore, hypothesized that silencing Slitrk-1 in the striatum of adult mice can be an animal model of TS by impairing the function of striatal cholinergic interneurons specifically, leading to certain stereotyped behaviors. Slitrk-1 siRNA or non-targeting scramble siRNA (Accell siRNA) was bilaterally injected (0.5 μg in 0.5 μl) into the dorso-medial striatum (A:-0.74mm, L:±1.6 mm, D: 3.5 mm) of C57Bl/ 6J mice (8-10 weeks). A serial analysis of mice behaviors and prepulse inhibition (PPI), a TS endophenotype, was performed after injection of siRNA for 72 hours. Mice with Slitrk-1 siRNA injection (Slitrk-1-KD, n=4) showed significantly more stereotyped behaviors, compared to those with scramble

siRNA (n=4), and these stereotyped behaviors were suppressed significantly by haloperidol (0.3mg/kg, i.p.), an effective anti-tic agent by blocking D2 receptors (n=4). Both groups (n=6) displayed similar spontaneous locomotor activities and rearing numbers. The Slitrk-1-KD group had more apomorphine-induced climbing behaviors (n=6) and impaired PPI (n=3), as compared with the scramble group (n=3). Western blot analysis shows 69.4% decrease of the Slitrk-1 protein in the bilateral striatum of Slitrk-1-KD mice (n=4), as compared to wild type mice, but no change in the scramble group. Immunofluorescence study of brain slices in Slitrk-1 group (n=8) also revealed 69.6% decrease in the number of striatal neurons co-expressing Slitrk-1 and choline acetyltransferase, compared with scramble group. These results support Slitrk-1 deficit plays a role in the pathogenesis of TS and selective knockdown Slitrk-1 gene in the striatal cholinergic neurons of adult mice, inducing haloperidol-sensitive excessive stereotypy behaviors and impaired PPI, can be an animal model of TS.

Abstract: Phosphoinositide 3-kinases (PI3Ks) are an essential family of enzymes involved in cell signaling, regulating fundamental processes such as cell growth, proliferation, differentiation, motility, survival and intracellular trafficking; and are long studied for their roles in cancer. Mutations in the catalytic subunit of phosphoinositide 3-kinase (*PIK3CA*) have recently been associated with a wide spectrum of brain and body overgrowth phenotypes. In the brain, the phenotypic spectrum of *PIK3CA*-related segmental cortical dysplasia includes bilateral dysplastic megalencephaly, hemimegalencephaly and focal cortical dysplasia, the most common cause of intractable pediatric epilepsy. The role of these mutations in these developmental disorders, however, is not understood. Megalencephaly or "large brain" is a developmental brain overgrowth disorder, associated with intellectual disability, autism, epilepsy, hydrocephalus, cerebellar tonsillar ectopia and a host of other developmental and functional anomalies. We generated mouse models expressing the most common activating *Pik3ca* mutations (*H1047R* and *E545K*) in developing neural progenitors. These accurately recapitulate all the key pathological features including enlarged brain size, cortical malformation, hydrocephalus and epilepsy, with phenotypic severity dependent on the mutant allele and its time of activation. Underlying mechanisms include altered rate of proliferation, cell size and white matter dysplasia. Notably, we demonstrate that acute suppression of PI3K signaling in adult mice, despite the presence of dysplasia, has dramatic anti-seizure benefit. Thus PI3K inhibitors offer a promising new avenue for effective anti-epileptic therapy for intractable pediatric epilepsy patients.

Title: The iron deficiency diet during development induces oxidative stress in relation to age and gender

Authors: *P. VIEYRA-REYES[1], C. JIMENEZ-GARCES[2], M. HERNANDEZ-GONZALEZ[2], D. MILLA-ALDACO[3];
[1]Depto Neurofisiologia De La Conducta. Facultad De, Toluca, Mexico; [2]Depto Neurofisiologia De La Conducta. Facultad De Medicina. Uaemex, Toluca, Mexico; [3]Dept. de Neuropatología Molecular, Inst. de Fisiología Celular, Univ. Nacional Autónoma de México, México, Mexico

Abstract: Iron is a trace element and structural part of antioxidant enzymes, its requirements vary according to age and gender. We hypothesized that iron deficiency (ID) leads to an increase in free radicals which mainly affect the brain, and the severity of damage would therefore be dependent on age and gender. Two groups of Wistar rats were evaluated evolutionarily: 100 rats (50 male; 50 female) with ID diet, and 100 rats (50 male; 50 female) with standard diet. Both groups were offspring from mothers who were previously under the same dietary intervention. The ages studied roughly correspond to stages of human development: birth (0 postnatal day "PND" in rats); childhood (21-PND), early-adolescence (42-PND), late-adolescence (56-PND) and adulthood (70-PND). The following biomarkers in brain, blood and liver were analyzed: lipid peroxidation products (LPO); protein carbonyl content and activity of the antioxidant enzymes; superoxide dismutase; catalase and glutathione peroxidase. It was demonstrated that ID-subjects are born with high levels of LPO in brain and low antioxidant activity, the damage being more severe in males. After birth, antioxidant defense focuses on central level (brain) in ID-females and on peripheral level (blood and liver) in ID-males. In two critical stages of development, birth and late-adolescence, antioxidant protection is insufficient to counteract oxidative damage in ID-subjects. Moreover, we observed that the variability of results in literature on oxidative stress and ID comes from gender and age of subjects under study. With this, we can establish patterns and exact moments to carry out studies or treatments.

Abstract: Ciliopathies are a genetic disorder of the cellular cilia that manifest as a spectrum of pathologies including respiratory, renal, cochlear, retinal, and brain aberrations. Primary cilia function as mechano- or chemo-receptors and stimulate intracellular signaling that preserve homeostatic ion and water transport such as those involved in cerebrospinal fluid production and resorption. Hydrocephalus has been described in both animal models and humans suffering from ciliopathies. The Wistar polycystic kidney (Wpk) rat is orthologous to the human Meckel-Gruber Syndrome and exhibits many of the characteristics of pediatric hydrocephalus. A point mutation in trans-membrane protein 67 (TMEM67) leads to elongated cilia on the choroid plexus, and increased fluid accumulation in the ventricles. Based on this, the purpose of this work is to characterize the anatomical and functional consequences of this point mutation in developing rats. Genotyping has discerned that littermates displaying severe hydrocephalus are homozygous recessive (TMEM67-/-) while those possessing TMEM67+/- heterozygosity display mild hydrocephalus from early postnatal periods through adulthood. Head dimensions of the TMEM67-/- animals were significantly increased over the control animals when measured in vertical ($p=0.006$) or horizontal orientation ($p=0.007$). T2 weighted MRI scans of ventricular volumes confirmed the individual genotypes were statistically different ($p<0.001$), where lateral ventricle volumes for wild type, TMEM67+/- and TMEM67-/- were 1.5±0.6, 6.7±1.8, and 71.9±9.2µl at P7-8, and 2.6±0.3, 16.7±5.4, and 491.2±61.9µl at P17-18, respectively. To determine potential alteration in histo-architecture, and using the pineal gland as reference, we found changes in TMEM67+/- and TMEM67-/- that had significant alteration of visual cortex and midbrain reticular formation. To confirm the histo-architecture effect of hydrocephalus on cerebral glucose utilization, 2-deoxyglucose uptake was examined in P17-18 rats, where isotope concentrations were normalized to cerebellar cortex in order to allow for comparisons between wild type and hydrocephalic (TMEM67+/-, TMEM67-/-) groups. By this method, glucose uptake values were statistically lower with brain region ($p<0.0001$) and genotype ($p<0.0001$), and are in agreement with previous reports of hydrocephalus models. Based on these findings, the Wpk rat model provides a unique platform to study the development of both severe and mild hydrocephalus. Moreover, this rodent model provides an opportunity to screen for potential drug candidates that may be useful in treating human forms of hydrocephalus.

Abstract: Objective: Epidemiological and experimental evidences demonstrate that maternal exposure to infection during gestation is an environmental risk factor for a variety neurodevelopmental disorders, such as schizophrenia and autism. Moreover, the precise timing of the prenatal infection seems to be critical, as it can determine specific clusters of behavioral and morphological phenotypes in the offspring. Thus, we used a specific animal model of prenatal immune challenge to investigate the possible molecular mechanisms underlying differences and similarities in specific clusters of behavioral abnormalities brought on by infection at two different time points in pregnancy. First of all, we compared adult behavioral features in offspring born to mothers subjected to infection early or late during gestation. Secondly, we investigated the possible molecular mechanisms underlying such abnormalities, focusing our attention on how prenatal infection could affect DNA methylation patterns in the prefrontal cortex. Methods: C57BL/6 mice were treated with the synthetic viral mimetic poly(I:C) (5 mg/kg, i.v.) or control (saline, i.v.) solution on gestation day 9 or on gestation day 17. Offspring were subjected to cognitive and behavioral testing in adulthood, and then capture-sequencing DNA methylation analysis and subsequent q-PCR validation were performed on the

prefrontal cortex. Results: Prenatal exposure to Poly(I:C) led to a variety of behavioral abnormalities, some of which were common to both time points, while others, as for example prepulse inhibition, were specific to one time point. Specific and overlapping changes were also observed when considering the DNA methylation analysis in the prefrontal cortex. In particular, both early and late exposure to prenatal infection led to extensive changes in DNA methylation, and a significant portion of these differentially methylated regions is common to both time points of infection. Different genes, such as Mid1, Ntm and Nrxn2, stood out as top candidates for deeper investigation based on their involvement in neurodevelopment and psychiatric disorders. Conclusions: Our results provide new insight into the molecular mechanisms mediating the association between prenatal infection and adult vulnerability to psychiatric disorders, and, more specifically, provide further knowledge regarding the impact of the precise timing of the infection. Moreover, our results uncover possible targets of future studies and point to a possible role of DNA methylation in mediating the detrimental effects of prenatal immune challenge, consistent with similar reports in human studies.

Title: Decreased performance in an active avoidance task in the valproic acid rat model of autism

Authors: ***J. R. HOLLERMAN**[1], T. J. BARR[2], W. Z. PADEN[1], J. D. CROSS[1];
[1]Psychology/Neuroscience, [2]Psychology, Allegheny Col., Meadville, PA

Abstract: The initial proposal for the use of prenatal exposure of rats to valproic acid (VPA) as an animal model of autism (Rodier et al., 1997) is supported by observations of co-incidence of autistic symptoms and fetal Valproate Syndrome in humans (e.g., Christianson et al., 1994; Williams and Hersch, 1997), as well as behavioral studies using the model (e.g., Schneider and Przewlocki, 2005; Schneider et al., 2008). Anatomically, the amygdala has received a great deal of attention both in human studies (e.g., Bechevalier and Loveland, 2006) and in the VPA model, where electrophysiological effects have also been characterized (Markram et al., 2008). The further functional implications of the effects of prenatal VPA on the amygdala are not clear. In

order to help further elucidate this, VPA-exposed rats were tested for preference for familiarity to verify the "autistic" phenotype, as well as performance on an active avoidance task. VPA exposure consisted of administration of VPA (470mg/kg, i.p.) to dams at gestational day 12.5. Rats were raised by their dams and allowed to grow to adulthood (8 weeks). Male VPA-exposed (n = 12) and control (n= 8) rats were then tested for relative preference for interacting with a novel versus a familiar object and trained on a shuttle box, active avoidance task using a 5sec 2.4kHz tone as CS and 0.1mA electric foot shock (max 5sec duration) as the aversive stimulus. Rats were trained on 50 trials per day over 5 days with performance assessed in terms of escape and avoidance responses (individually and combined). Object preference was calculated as (time spent with a novel object - time spent with familiar object)/ (time spent with a novel object + time spent with familiar object), producing negative values for novelty preference and positive values for familiarity preference. While controls expressed an expected preference for novelty (M = -0.28, SEM = 0.06), VPA-exposed rats differed significantly, displaying a preference for familiarity (M = +0.25, SEM = 0.05). In the acquisition of the shuttle box avoidance task, performance of the VPA-exposed rats differed significantly from that of control rats. VPA rats made fewer escapes, avoidances, and total responses than Controls across all 5 days. However, the two groups showed similar rates of acquisition, with both groups displaying an increase in avoidance responses (and total responses) across the 5 days. While it is not yet clear whether this difference reflects a specific learning deficit or is due to a deficit in nociceptive processing, it does indicate a behavioral effect on a putatively amygdala-dependent learning task in the VPA model.

Title: Behavioral and transcriptomic alterations in 15q13.3 homozygous knockout mice

Authors: ***A. FORSINGDAL**[1,2], M. BERTALAN[2], K. FEJGIN[1], V. NIELSEN[1], T. WERGE[2], J. NIELSEN[1];

[1]H. Lundbeck A/S, Valby, Denmark; [2]Inst. of Biol. Psychiatry, Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Genome wide association studies have revealed that certain copy number variants (CNVs) strongly increase the risk of schizophrenia and other psychiatric diseases. One such CNV is a 1.5 MB long hemizygous deletion located in the 15q13.3 region that covers 6 genes (FAN1, MTMR10, TRPM1, KLF13, OTUD7A, and CHRNA7). The 15q13.3 microdeletion increases the risk of schizophrenia, epilepsy and autism (Malhotra and Sebat, 2012). A mouse model of the human 15q13.3 hemizygous microdeletion syndrome has been generated. Characterization of the model identified disease-related phenotypes (Fejgin et al., 2013). However, the mechanisms underlying increased disease risk in the 15q13.3 microdeletion syndromes remains unknown. Human cases of homozygous microdeletion carriers have also been reported, all with severe impairments (Hoppman-Chaney et al., 2013). We hypothesized that 15q13.3 homozygous knockout mice would display stronger phenotypes than 15q13.3 hemizygous mice and thereby facilitate mechanistic studies. 15q13.3 knockout mice were characterized by basic physiological and behavioral tests as well as disease related behavioral tests. Indeed, 15q13.3 knockout mice display stronger disease-related phenotypes than the 15q13.3 hemizygous deletion mice. In order to elucidate the underlying biological mechanisms of these disease-related phenotypes, we have initiated transcriptomic studies of the 15q13.3 homozygous knockout mice. A number of genes are differentially expressed in 15q13.3 homozygous knockout mice compared to wildtype mice. The expression profile of these mice provides cues to which biological mechanisms that predispose 15q13.3 deletion carriers to psychiatric diseases and guides future mechanistic exploration.

Title: Effect of cocaine on striatal dopamine clearance in an animal model of developmental stress and attention-deficit/hyperactivity disorder

Authors: *V. A. RUSSELL[1], J. S. WOMERSLEY[2], L. A. KELLAWAY[2], D. J. STEIN[3], G. A. GERHARDT[4];
[2]Human Biol., [3]Dept. of Psychiatry and Mental Hlth., [1]Univ. Cape Town, Cape Town, South Africa; [4]Anat. and Neurobio., Univ. of Kentucky, Lexington, KY

Abstract: Attention-deficit/hyperactivity disorder (ADHD) and developmental stress are considered risk factors for the development of drug abuse and all 3 processes share underlying disturbances in dopamine neurotransmission. The dopamine transporter (DAT) is responsible for the rapid reuptake of dopamine and thereby carefully controls the extra-synaptic concentration of dopamine. Inhibition of DAT by psychostimulants (e.g. cocaine) increases the extracellular concentration of dopamine and is responsible for the rewarding properties of drugs. Though research has indicated that a history of developmental stress and a diagnosis of ADHD increase the likelihood of developing drug abuse, the physiological mechanism underlying this relationship is not fully understood. In the current study, the effect of maternal separation (MS), a model of developmental stress, on striatal dopamine clearance before and after cocaine administration was investigated using the spontaneously hypertensive rat (SHR), a well-validated model of ADHD. *In vivo* chronoamperometric recordings revealed that there was no difference between SHR and the control Wistar-Kyoto (WKY) strain in the cocaine-induced elevation of dopamine levels. However, the cocaine-induced increase in time to clear 50% of exogenously applied dopamine was elevated in maternally separated SHR compared to non-separated SHR but had no effect in WKY. These findings suggest that a strain x environment interaction altered DAT function, prolonging elevated levels of dopamine and thereby potentially increasing the rewarding properties of this drug in SHR.

Title: Social isolation during the critical period affects excitatory neuronal activity in mouse medial prefrntal cortex

Authors: *K. YAMAMURO[1], H. YOSHINO[1], Y. OGAWA[2], K. OKAMURA[1], Y. NISHIHATA[1], Y. SAITO[2], T. KISHIMOTO[1];

Abstract: Social experience is crucial for the development of forebrain function and the maturation of medial prefrontal cortex (mPFC). Rearing mice in post-weaning social isolation produces prefrontal dysfunction and poor social interaction with hypomyelination in mPFC (Makinodan et al. Science 2012). However it isn't well-known about the alteration in neural circuits of mPFC induced by social isolation. In the present study, we examined the change of excitatory synaptic inputs and membrane properties of layer 5 pyramidal cells in mouse mPFC induced by social isolation, with whole-cell patch clamp recording in the brain slices. After weaning at P21, the 4 male littermates were randomly divided into one isolate-housing mouse and three group-housing mice. After the isolation period (from P21 to P35), the isolated mouse was again reared together with his three grouped littermates. We also examined the change induced by isolate-housing during the later period (from P35 to P49). The recording from each mouse was done at P63-69. We found that the spontaneous excitatory postsynaptic current (sEPSC) frequency and miniature excitatory postsynaptic current (mEPSC) frequency were significantly lower in P21-P35 isolated mice than in grouped mice. On the other hand, membrane properties of layer 5 pyramidal cells were not changed in P21-P35 isolated mice. And there was no significant difference in sEPSC and mEPSC frequency between P35-P49 isolate-housing mice and group-housing mice. Moreover, in somatosensory cortex, there was no significant difference in sEPSC and mEPSC frequency between P21-P35 isolated mice and grouped mice. These results show that only 2 weeks social isolation (from P21 to 35) exclusively reduces excitatory synaptic inputs on layer 5 pyramidal cells of mouse mPFC and suggest that social experience during the critical period is pivotal in the development of mPFC excitatory neural circuit.

Title: Docosahexaenoic acid (DHA) rescued autistic symptoms accompanied by dopaminergic change on a gene/prenatal stress mouse model

Authors: *F. MATSUI[1,2], K. YOSHIMOTO[3], P. HECHT[2], K. FRITSCHE[2], M. WILL[2], D. BEVERSDORF[2];

Abstract: Autism Spectrum Disorder (ASD) is characterized by impairments in social interaction and social communication, and repetitive and stereotyped behaviors. While genetics is thought to play a large role in the disorder, environmental factors, such as prenatal stress are also thought to contribute to it. We previously reported that prenatal stress exposure in stress-susceptible heterozygous serotonin transporter (SERT) KO pregnant dams in a mouse model altered social interaction and repetitive behavior in the male offspring (SERT/stress mice), and additionally found that docosahexaenoic acid (DHA) rescued the autism associated symptoms. DHA plays an important role in the functioning and development of the central nervous system, but the mechanism how DHA may impact the development of autism in this setting is unknown. In the present study, we measured monoamine levels in selected brain regions in the SERT/stress mouse model. Then, we measured monoamine levels in three treatment groups; DHA rich diet continuously from breeding, DHA rich diet only after weaning, and control diet only. The dopamine (DA) content in the striatum was significantly increased in the SERT/stress mice compared with wild type (WT) mice. Noradrenaline and serotonin content were not changed between the SERT/stress and WT mice in the selected brain regions. Moreover, DA content in the striatum was significantly reduced in the SERT/stress mice with the DHA rich diet provided continuously from breeding. The results indicate that autism-associated behavior in this setting can be reversed with DHA accompanied by changes in the dopaminergic system. Future research will be necessary to explore whether DHA treatment during pregnancy may be important for rescuing the symptoms associated with some etiologies of ASD in the clinical setting.

Title: Novel usefulness of cylinder test for assessing long-term dysfunction in mouse model of mild ischemic stroke

Authors: *L. LIU[1], M. WEIDER[1], Y. DWEIK[1], S. DORE[1,2];
[1]Anesthesiology, Ctr. for Translational Res. in Neurodegenerative Dis., [2]Departments of Neurology, Psychiatry, Pharmaceutics, Psychology, and Neurosci., Univ. of Florida, Col. of Med., Gainesville, FL

Abstract: Stroke is a debilitating neurological disorder, which is more disabling than it is fatal-remains one of the leading causes of disability. Permanent focal middle cerebral artery occlusion (pMCAO) C57BL/6 mouse model is believed to be one of the most predictable and potentially useful stroke translational models. Long-term sensorimotor function evaluation is a key component for testing the efficacy of potential therapeutics. However, till now few behavior tests provide reliable functional outcome evaluation after stroke. Therefore, there is an important need to develop sensitive and reliable behavior tests. In this study, we investigated the sensorimotor functional deficit and recovery in pMCAO model mice over 4 weeks by using a behavior test battery including locomotor activity, cylinder test and corner test. In comparison to the only parameter-total rate of forelimb use in traditional cylinder test, we first used multiple parameters to characterize the sensorimotor asymmetry, including the rates of first use of forelimb (single and both) in rearing instances with contacting the cylinder wall. The novel use and analytic approach in cylinder test provide more sensitive and reliable assessment to detect the sensorimotor deficit. Thus, this novel use of cylinder test will be most instrumental and promising in investigating therapy strategy of stroke.

Title: Effects of transient ischemia and D-cycloserine on aromatase expression in the rat brain

Authors: *J. DHAWAN, A. BIEGON;
Stony Brook Univ., Stony Brook, NY

Abstract: Estrogen is thought to be neuroprotective in animal models of stroke and in this context, transient increases in the levels of the estrogen synthesizing enzyme aromatase were considered to represent activation of an endogenous neuroprotective mechanism. We have used quantitative immunohistochemistry to explore the long term effects of stroke and the partial NMDA receptor agonist D-Cycloserine (DCS) on aromatase expression in cortex and striatum of rats subjected to transient (90 min) focal ischemia through occlusion of the middle cerebral artery (MCAO). Rats were given i.p injections of DCS (10 mg/kg, N=14) or vehicle (PBS, N=14) 24 hours post reperfusion. Eight rats subjected to sham surgery served as controls. Animals were killed more than 4 weeks after MCAO, following repeated evaluations for neurological deficits and memory. Brains were quickly frozen and coronal sections at the level of the infarct were incubated with a polyclonal antibody to aromatase and stain developed with 3,3-diaminobenzidine (DAB). Sections were then counterstained with hematoxylin. Staining density was analyzed in striatum and cortex using ImageJ (NIH) software at low magnification. The number of aromatase positive neuronal cells in layers II to VI of the frontal were counted with ImageJ using stereological principles at 200x magnification. Increased expression of aromatase relative to controls was still evident in MCAO rats more than 4 weeks after occlusion, in the peri infarct zone but also in the cortex; however aromatase density in DCS treated rats was significantly lower than in vehicle treated animals. Analysis of aromatase positive neurons in the frontal cortex revealed layer- and treatment related effects. MCAO animals had a significantly larger number of aromatase positive neurons in layers II ,IV and VI relative to controls. However, the effects were significantly smaller in DCS treated animals. These results show that DCS, previously shown to improve neurological outcome, memory function and BDNF expression in rat models of brain injury and stroke; can also reverse, at least in part, a persistent increase in aromatase expression in cortical neurons induced by transient focal ischemia.

Title: Neuronal remodelling following cerebral photothrombotic infarcts in mice

Authors: *N. GORLAMANDALA[1], J. PARMAR[1], A. J. CRAIG[1], J. M. POWER[1], A. V. KRISHNAN[2], G. D. HOUSLEY[1];
[1]Translational Neurosci. Facility & Dept. of Physiology, Sch. of Med. Sci., UNSW Australia, Sydney, Australia; [2]Prince of Wales Hosp. & UNSW Australia, Inst. of Neurolog. Sci., Sydney, Australia

Abstract: Rodent models of stroke typically employ middle cerebral artery occlusion to induce ischemic brain injury. This method produces lesion volumes that have considerable variation and typically encompass a large portion of the forebrain, resulting in a high mortality rate. These factors make study of neuroprotection problematic. An alternative model for focal ischaemic brain injury utilizes photothrombotic lesions. Despite the emerging prominence of this stroke model, there is a paucity of information on the spatiotemporal injury sequelae in mice that we address here. Platelet aggregation was triggered by photosensitising the brain microvessel endothelium, via a tail vein injection of rose bengal dye, followed immediately by irradiation of the target brain surface (midline; 2 mm rostral to lambda) with green light (2 mm diameter, 532 nm, ~ 3 mW, 6 min) under isoflurane anaesthesia. Mice were euthanized and their brains removed 2 hours, 1, 4, 7 or 14 days post injury (DPI; n = 3 for each time point). Brains were initially stained with 2, 3, 5- triphenyltetrazolium chloride to visualize viable tissue. The tissue was then fixed in 4% paraformaldehyde and cryosectioned (50 µm). The infarct volume and ischemic tissue remodelling were assayed using dark field imaging and haematoxylin and eosin (H & E) staining. Under dark field imaging injury-associated oedema and tissue structure changes manifest as increased tissue opacity. The infarct volume, calculated from the dark field images, increased up to 4 DPI. H&E assessment showed systematic transition of histopathology over time. At 2 hours post injury, neuronal loss was observed with microglial infiltration at the site of lesion. By 1 DPI there was a complete loss of neurons in the infarct core. Consistent with the dark field images, there was extensive lateral expansion of the lesion observed 4 DPI, along with loss of neuronal cytoplasm and evidence of extravasation. Sections prepared from mice 7 DPI displayed less extravasation and greater microglial infiltration than those prepared 4 DPI. Further microglial invasion into the site of lesion was observed 14 DPI, delineating the infarct boundary distinctly. The spatiotemporal changes in cell composition within the ischemic core and surrounding penumbra suggest the remodelling of cerebral tissue, with darkfield imaging confirming the reduction in oedema at 7 DPI onwards. The 100 % survival rate, consistency in lesion volume and cell response profile over time in this study validate this preclinical stoke model as a neuroprotective treatment assay. The protocol was approved by the UNSW Australia Animal Care and Ethics Committee.

Title: Laropiprant, a clinically tested prostaglandin D2 DP1 receptor antagonist, minimizes brain injury following intracerebral hemorrhage

Authors: M. MENDES[1,2], S. DORE[1,2,3], *A. S. AHMAD[1,2];
[1]Dept. of Anesthesiol., [2]Ctr. for Translational Res. in Neurodegenerative Dis., [3]Departments of Neurology, Psychiatry, Pharmaceutics, Psychiatry, and Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Laropiprant, a clinically tested prostaglandin D_2 DP1 receptor antagonist, minimizes brain injury following intracerebral hemorrhage Monique Mendes[1,2], Sylvain Dore[1,2,3], Abdullah Shafique Ahmad[1,2] [1]Department of Anesthesiology, [2]Center for Translational Research in Neurodegenerative Disease, [3]Departments of Neurology, Psychiatry, Pharmaceutics, Psychiatry, and Neuroscience, University of Florida, Gainesville, FL The respective importance of PGD2 and its receptor DP1 in the vasculature, the blood, and the brain warrants further examination of their role in intracerebral hemorrhage. In this study, we tested whether deletion of DP1 receptor or its blockade by the selective antagonist Laropiprant improves functional and anatomical outcomes following ICH by limiting intracranial bleeding. Wildtype (WT) and DP1-/- C57BL/6 mice were subjected to ICH by giving a single dose of collagenase in the striatum. Neurologic deficits, brain injury volume, and edema volume were calculated at 72h. In another set of cohorts, WT mice were subjected to ICH followed by single i.p. injection of Laropiprant. To test whether the beneficial effects of DP1 receptor inhibition could be through reduced intracranial bleeding, non-ICH WT and DP1-/- mice were tested for tail bleeding time following the Laropiprant treatment. To further test the effect of Laropiprant on *ex-vivo* coagulation, mouse blood was mixed with vehicle or Laropiprant and the uncoagulated content was quantified. Finally, the role of DP1 inhibition in modulation gliosis was also tested by performing immunoreactivity for Iba1 and GFAP on the brain sections of WT and DP1-/- mice. A significant decrease in the injury volume (4.8±1.7 vs 14.1±4.5mm3; $p<0.001$) and edema volume (4.5±1.8 vs 13.2±4.1mm3; $p<0.001$) in DP1-/- was observed. Furthermore, WT mice treated with Laropiprant also exhibited significantly lower brain damage as compared with the vehicle treated group (6.2±2.2 vs 12.7±5.1mm3; $p<0.01$). Interestingly, the tail bleeding time was also

significantly lower in Laropiprant group (219.4±75.2sec; $p<0.001$) as compared with the vehicle group (345.2±45.6sec), and similarly the uncoagulated content was also lower in Laropiprant group (356.2±53.6µL; $p<0.001$) as compared with the vehicle group (486.4±26.7µL). Interestingly, a significant decrease in Iba1 immunoreactivity and increase in GFAP immunoreactivity was observed in DP1-/-. Together, the data suggests that inhibition of the DP1 receptor after ICH attenuates functional and anatomical deficits partially by minimizing intracranial bleeding and neuroinflammation. Title: Intermittent surge of brain-heart coupling prior to sudden death in ischemic rats

Authors: ***F. TIAN**[1], D. LI[1], T. LIU[1], M. WANG[1,2], J. BORJIGIN[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Veterans Admin. Ann Arbor Healthcare Syst., Ann Arbor, MI

Abstract: Sudden death is an important but under-recognized consequence of stroke. Acute stroke can disturb central control of autonomic function, result in cardiac dysfunction, and ultimately lead to sudden death. Previous study showed that bilateral common carotid artery (BCCA) ligation in spontaneously hypertensive stroke-prone rats (SHRSP) could lead to sudden death. However, the underlying mechanism by which cerebral ischemia induces cardiac dysfunction and sudden death is not well understood. The objective of this study is to investigate the functional interactions between the brain and the heart during this process using advanced signal processing techniques. ECoG (from 6 cortical loci) and ECG signals were simultaneously collected from SHRSP and control Wistar Kyoto (WKY) rats before and following BCCA ligation. Consistent with published studies, BCCA ligation resulted in 100% mortality in SHRSP rats within 24 hours, whereas no mortality was observed in WKY rats. In contrast to WKY rats, SHRSP rats exhibited intermittent and elevated cardiac event-related potentials in the cortex and increased brain-heart coherence following the onset of ischemia. SHRSP rats also exhibited reduced heart-rate variability prior to sudden death. Further studies are aimed at investigating the effective connectivity between the brain and the heart during ischemia. This study is expected to improve our understanding of the mechanism of stroke-induced cardiovascular abnormalities and

sudden death, and may provide important information for future treatment of cardiac dysfunction and prevention of sudden death after ischemic stroke.

Title: Post-stroke spontaneous hypothermia predicts stroke severity and is correlated with mitochondrial impairment

Authors: ***X. REN**[1], H. HU[1], D. DOLL[2], J. SUN[1], J. WIMSATT[3], M. KESSLER[4], J. SIMPKINS[1];
[1]Ctr. for Basic and Translational Stroke Research, Physiol. & Pharmacol. PO, [2]Neurobio. and Anat., [3]Med., [4]Office of Lab. Animal Resources, West Virginia Univesity Robert C. Byrd Healthe Sci. Ctr., Morgantown, WV

Abstract: Stroke is the second leading cause of death and the leading cause of disability worldwide. Animal models of ischemic stroke are indispensable tools to investigate the pathophysiological mechanisms involved in ischemic brain injury and to develop novel therapies for stroke. Controlled-hypothermia is known to protect ischemic outcomes in human subjects and experimental animal studies in stroke. However, spontaneous hypothermia has confounded experimental results and pharmacological studies in stroke, and the mechanisms are poorly understood. In this study, we performed a correlation and regression analysis of the pooled data (n=311) using mouse models of transient and permanent occlusion of the middle cerebral artery and determined a relationship between post-stroke body temperature and stroke severity in experimental stroke. We found that stroke mice had lower body temperature compared to sham mice within 6 hours post-surgery. Rectal temperature within 6 hours post-stroke was

significantly negatively correlated with stroke outcomes. Linear regression with neurological deficits as the dependent variable showed that low body temperature was significantly associated with high neurological score at 6-, 24-, and 48-hour end points ($P<0.0001$), and larger infarct volumes in cortex ($P<0.0001$), striatum ($P=0.0013$) and total hemisphere ($P<0.0001$). Lipopolysaccharide (LPS) has been recently reported to inhibit mitochondria in cerebrovascular endothelial cells, and the LPS-cohort analysis indicated rectal temperature at 6 hours post-stroke had strong negative correlations with neurological deficits ($r=-0.6564$, $P<0.0001$), infarct volumes in cortex ($r=-0.6976$, $P=0.0055$), and total hemisphere ($r=-0.5992$, $P=0.0235$). Rotenone (mitochondrial respiratory chain complex I inhibitor) cohort analysis indicated rectal temperature at 6 hours post-stroke had very strong negative associations with neurological deficits ($r=-0.7452$, $P<0.0001$), infarct volumes in cortex ($r=-0.7368$, $P=0.0011$) and total hemisphere ($r=-0.8231$, $P<0.0001$), and strong negative association with stratum infarction ($r=-0.6633$, $P=0.0051$). We concluded that post-stroke spontaneous hypothermia predicts stroke severity and mitochondria may play a pivotal role in this hypothermic response in acute stroke.

Title: An examination of sex differences in neocortical excitatory synapse number in the aged rat

Authors: ***V. BORKOWSKI**[1,2,4], S.-Y. TSAI[4], J. L. MARTIN[5], H. HIOKI[6], A. E. MARINOPOULOS[4], K. S. HSU[4], C. M. PAPADAPOULOS[4], G. L. KARTJE[4,3];

Physiol., Loyola University Chicago, IL; [6]Dept. of Morphological Brain Science, Grad. Sch. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: Sex-based differences in recovery from stroke are an area of research not yet fully explored, especially with regard to aged rats performing sensorimotor tasks, which model human post-stroke functional recovery. In the human clinical population, post-menopausal females have been shown to recover from stroke less successfully than age-matched males, and therefore studying sex differences in rat models of stroke recovery is clinically relevant. We therefore set out to determine if differences in excitatory synaptic number were evident in different sexes, which may influence recovery from stroke. 18 month-old Fischer 344 male and female aged rats were used for these studies. Rats were divided into three groups: ovariectomized (OVX) females, intact females, and age-matched males. Rats were trained in the skilled forelimb reaching task, then received adeno-associated virus (AAV8.cmv.myrGFP-LDLRct) injections to the motor cortex to pre-label cortico-efferent pyramidal neurons in layer V. At the end of three or eight weeks of behavioral testing, rats were sacrificed for immunohistochemistry to quantify excitatory synapses in pyramidal layer V forelimb motor cortex. Neurons that were GFP-positive with a typical pyramidal shape and good dendritic labeling were identified via confocal microscopy. Using 63x oil magnification, basilar dendrites were examined for presynaptic (vGlut1 or vGlut2) markers and co-localization with the postsynaptic marker NMDAR-NR1. The number of co-localized synapses was quantified using an orthogonal Z-stack (Z step .89um, 16 Z-steps) on basilar dendrites for a 40um length starting at the cell soma. Our preliminary results showed that after 3 weeks of behavioral testing, no differences were found between groups in the number of excitatory synapses on layer V pyramidal neurons. However, after 8 weeks of testing, the number of excitatory synapses in the aged OVX female group was significantly less than the intact females and age matched males. These results indicate a possible long-term effect of estradiol depletion on neocortical synaptic number in aged females. Further work is in progress to correlate these findings with post-stroke recovery in the aged rat.

Title: Classification of the lateral cerebellar nucleus neuronal activity during skilled reaching tasks

Authors: *H.-J. PARK[1], J. COOPERRIDER[1], H. H. CHAN[1], C. WATHEN[1], J. T. GALE[1], M. D. JOHNSON[2], K. B. BAKER[2], A. G. MACHADO[1];

Abstract: Stimulation of the lateral cerebellar nucleus (LCN) has been shown to be effective for post-stroke rehabilitation in a model of rodent focal ischemia, likely through activation of broad motor cortical areas, including the perilesional cortex, via the excitatory di-synaptic dentato-thalamo-cortical (DTC) pathway. In our previous studies, deep brain stimulation (DBS) of the LCN was conducted in a pre-programmed, open-loop fashion. In contrast to open-loop stimulation, closed-loop stimulation may improve post-stroke rehabilitation by selectively stimulating or adaptively changing the stimulation parameters of LCN DBS based on the brain state. Electrophysiological recordings of the LCN during a behavioral task may assist in estimating the brain states to be utilized for closed-loop stimulation. For selective stimulation with stimulation parameter adaptation, estimation and classification of the brain states using machine learning algorithms are required with respect to the important event markers in a skilled reaching behavioral task. In order to record event related modulation of brain activity, multiple contact microelectrode arrays was placed in the deep cerebellum of the rats. The rats were trained on a skilled pellet-reaching task with the paw ipsilateral to the implanted electrode. The performance of the reaching task was videotaped to classify trials into successful or unsuccessful, and electrophysiological recordings were synchronized with the behavioral data using an infrared beam, which detected the reaching motion. The electrophysiological recordings were wirelessly transmitted from the headstage to the receiver, and the data were analyzed offline. Time-frequency analysis on the filtered local field potentials (LFP) and/or neuronal spike activity analysis generated features for the classification. Different classifiers were tested in order to build an optimal classifier, including a generalized linear model and support vector machine.

Title: Granulocyte-colony stimulating factor enhances the angiogenetic effect of indirect bypass surgery for chronic cerebral hypoperfusion in a rat model

Authors: *K. ORITO, M. MORIOKA;
Kurume Med. Univ., Kurume-Shi, Japan

Abstract: OBJECTIVE - Granulocyte-colony stimulating factor (G-CSF) mobilizes hematopoietic bone marrow cells into systemic circulation and has been used clinically to treat chemotherapy-induced neutropenia. Recently, G-CSF has been shown to have neuroprotective and angiogenetic effects in acute cerebral infarction. We hypothesized that G-CSF could act as an enhancer of angiogenesis after indirect bypass surgery. METHODS - Chronic cerebral hypoperfusions were induced in male Wistar rats by permanent bilateral internal carotid artery occlusion (BICAO). After BICAO, unilateral indirect bypass and encephalo-galeo-synangiosis (EGS) were performed and human recombinant G-CSF (10 μg/kg) or saline was injected intramuscularly for 5 consecutive days. We measured regional cerebral blood flow (rCBF) by laser Doppler flowmetry and performed immunohistochemical analysis 21 days after BICAO. RESULTS - BICAO decreased rCBF to 62.52% ± 5.8% of control ($P < 0.01$). The rCBF increased significantly 21 days after BICAO in all treatment groups ($n = 10$; $P < 0.05$) except in the G-E- group. The rCBF increase observed in the G+E+ group was significantly higher than that observed in other groups. Both G-CSF and EGS treatments significantly increased the number of small vessels ($P < 0.01$), and G-CSF and EGS showed additive effect in increasing the number of small vessels. CONCLUSION - Combined use of G-CSF and indirect bypass surgery induces an increase in rCBF and angiogenesis under cerebral chronic hypoperfusion conditions. This is the first report to demonstrate that G-CSF can enhance angiogenesis induced by indirect bypass surgery, and this combined therapy is safe and easy method of treatment.

Title: An eye-opener for stroke: pathological consequences of reduced blood flow in the ipsilateral eye following transient middle cerebral artery occlusion in adult rats

Authors: *C. BORLONGAN[1], J.-Y. LEE[2], N. TAJIRI[3], S. ACOSTA[2], H. NGUYEN[2]; [2]Neurosurg. and Brain Repair, [3]Sch. of Physical Therapy, [1]Univ. of South Florida, Tampa, FL

Abstract: Middle cerebral artery occlusion (MCAO) in rodent remains a widely used model of ischemic stroke. Recently, many studies have reported the occurrence of retinal ischemia in animals subjected to MCAO, owing in part to the circulatory juxtaposition of the ophthalmic artery to the MCA. In this study, we employed the laser Doppler to evaluate the hemodynamic in the eye of MCAO-induced stroke rats. Brain and retinal perfusion was evaluated by laser Doppler at baseline (prior to MCAO), during MCAO, and after MCAO. Retinal function-relevant behavioral and histological outcomes were performed at 3 days post-MCAO. We also studied changing density of retinal ganglion cell and measure of optic nerve depth. Laser Doppler revealed typical reduction in brain perfusion in the ipsilateral front parietal cortical area of at least 80% reduction during MCAO compared to baseline, which returned to near baseline levels after MCAO. A significant defect in the retinal perfusion in the ipsilateral eye was detected with at least 30% reduction in perfusion during MCAO compared to baseline, which was restored to near baseline levels after MCAO. Behavioral performance in light stimulus-mediated place preference was significantly impaired in MCAO rats compared to control animals. Moreover, retinal ganglion cell density and optic nerve depth were significantly decreased in ipsilateral eye. Retinal perfusion defects closely parallel the timing of cerebral blood flow alterations in the acute stages of MCAO in adult rats. Behavioral and histological impairments further reveal the contribution of retinal dysfunction in stroke outcomes. In view of some stroke patients presenting with visual deficits, closely monitoring of brain and retinal perfusion via laser Doppler measurements may facilitate the diagnosis of stroke onset and progression, as well as treatment of stroke patients with retinal dysfunctions.

Title: High throughput identification and quantification of peri-infarct depolarization in mouse cortex with optical intrinsic signal imaging

Authors: *J. BUMSTEAD[1], A. KRAFT[2], X. YANG[2], A. BAUER[3], J. CULVER[3], J. LEE[2], J. LU[4];

Abstract: Objective: Focal brain ischemia results in repetitive waves of electrophysiological hyperactivity followed by silence in surrounding cortex, a phenomenon known as peri-infarct depolarization (PID). Despite the potential role that PIDs play in ischemic injury, their propagation over the entire mouse cortex has not been well studied. We developed an optical intrinsic signal (OIS) imaging system and image processing algorithms that enable high throughput identification of PIDs over the mouse cortex. Automated and robust algorithms, such as the one developed, are essential for analyzing the large datasets involved in studies that compare PIDs between different groups of mice. Methods: Ten mice (male C57Bl6/J, 12-14 weeks old) were anesthetized with 0.75% isoflurane and imaged up to 6 hours during middle cerebral artery occlusion (MCAO). A light emitting diode operating at 478nm illuminated the skull, and diffuse reflected light was detected by a CCD camera, at a frame rate of 30 Hz (Fig 1A). The diffuse reflectance was corrected for baseline by mean-subtraction. Results: PIDs were detected by applying several criteria to create an image mask over the trial (Fig 1B). In addition to detecting PIDs, the algorithm also calculated the duration, average velocity, and spatial trace of the PID. After the automated identification of PIDs, the user can inspect the intensity trace (Fig 1C), the spatial location of the mask over the trial (Fig 1D), and the trace of the PID (Fig 1D) to identify potential false positives and false negatives at around five times faster than manually watching all trials. Conclusion: Our algorithm automatically detected PIDs that occurred after MCAO in mice. During the 50 hours of data analyzed, there was a total of 208 PIDs. The sensitivity and specificity of the algorithm was 0.93 and 0.97 respectively, and there was a false positive and false negative rate of 0.11 and 0.07. Our imaging system and processing algorithm efficiently identify PIDs over mouse cortex, and provide quantitative information about the propagation of PIDs that cannot be calculated by manual inspection.

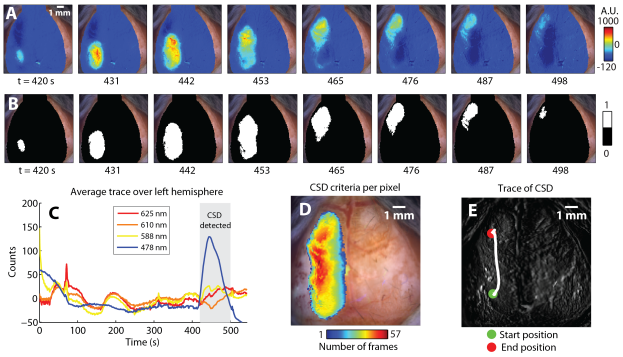

Figure 1. PID detection in mouse cortex after MCAO. **A.** Image sequence of PID in mouse after MCAO. The PID propagates at an average velocity of 3.5 mm/min from posterior to anterior. **B.** Image sequence of mask generated after passing all criteria of the detection algorithm. **C.** Average light intensity over the left hemisphere over time. Time traces of four different color LEDs are shown. In gray is the time epoch in which the algorithm detected the PID shown in A & B. **D.** The number of frames that each pixel satisfied the PID detection criteria. **E.** Trace of the PID over the mouse cortex. The start position is in green and the end position is in red.

Title: The spatial and temporal distribution of immature, proliferating and mature oligodendrocytes in a rat intracerebral hemorrhage model

Authors: *M. J. JOSEPH[1,2], J. CALIAPERUMAL[1], L. C. SCHLICHTER[1,2];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Following intracerebral hemorrhage (ICH), many brain cells die and many surviving neurons are damaged. Several aspects of the damage to grey and white matter have been characterized in animal models of ICH, and it appears that neurons in the peri-hematoma region can survive. However, little is known about re-myelination, which will be important for potential functional recovery after ICH. Re-myelination will require healthy, fully differentiated

oligodendrocytes, which are the myelin-producing cells. Our lab has previously investigated white-matter damage and inflammation during the first week after experimental ICH, but it is not known how ICH affects oligodendrocytes. Here, we analyzed the spatial and temporal changes in oligodendrocyte numbers and differentiation state at 1, 3, 7, 14 and 28 days after inducing ICH by stereotaxically injecting type IV collagenase into the rat striatum. The total number of oligodendrocytes (Olig2+ cells, identified using immunohistochemistry) in the peri-hematoma region increased after ICH and peaked at 7 days, at which time they formed a distinct band around the lesion. Closer examination of this band of oligodendrocytes showed that their numbers increased specifically inside white-matter bundles. Oligodendrocyte numbers declined by 14 days; and to determine whether this decrease was due to cell death, they were co-stained for TUNEL and cleaved caspase-3. To further characterize the oligodendrocyte population, we analyzed numbers of oligodendrocyte precursor cells (OPCs, identified as NG2+Olig2+ cells) and mature oligodendrocytes (identified as CC-1+Olig2+ cells). Numbers of OPCs and mature oligodendrocytes both peaked at 7 days. We then compared the spatial distribution of OPCs and mature oligodendrocytes inside white-matter bundles with those in the surrounding neuropil of the peri-hematoma. Interestingly, oligodendrocyte proliferation (identified as Olig2+Ki67+ cells) was elevated in the peri-hematoma at 3 days post-ICH. In contrast, there was no change in oligodendrocyte proliferation in the subventricular zone, a major site of normal oligodendrogenesis. Taken together, our findings suggest that local proliferation near the hematoma helps replenish the oligodendrocyte population after ICH.

Title: Caffeine and/or hypothermia intervention for neonatal hypoxic-ischemic injury: effects on behavioral outcomes in a rat model

Authors: ***H. M. CONTRERAS**[1], A. L. SMITH[1], A. R. RENDALL[1], T. S. ROSENKRANTZ[2], R. H. FITCH[1];
[1]Psychology, Univ. of Connecticut, Storrs, CT; [2]Pediatrics/Neonatology, Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: One of the most common injuries among term and preterm/very low birth weight (VLBW) infants is hypoxia-ischemia (HI; reduced blood oxygenation and/or flow to the brain). Following an HI insult, an array of deficits are often seen, including motor impairments (e.g., cerebral palsy), and cognitive deficits including learning/memory, attention, sensory processing and language impairments. Caffeine and hypothermia have each been individually proposed as possible treatments for neonatal HI, and hypothermia is routinely used to treat term infants at risk for hypoxic-ischemic encephalopathy. Although magnitude of benefit varies depending on severity of insult, method (head vs whole body hypothermia), core temperature, post-injury delay, and other variables, there is substantial evidence showing improvements in overall outcome. However, cooling has not been trialed in preterm infants, due to concerns regarding co-morbid health issues. In preterm/VLBW infants, caffeine therapy has been effective for treating apnea of prematurity, and has secondarily been found to improve rate of survival. Potential benefits from the use of caffeine and hypothermia together in preterm infants remain largely unknown. Previous studies in our laboratory using Rice-Vannucci rodent HI model have revealed significant deficits in rapid auditory processing and spatial learning in male rats with postnatal day 1 (P1), P7, or P10 HI injury. Moreover, these deficits have been found to be attenuated by caffeine treatment when administered immediately following the induction of HI. The current study sought to investigate the potential therapeutic effects of caffeine citrate and hypothermia -- both alone, and in combination -- in a preterm rodent HI model. On (P) 6, HI injury was induced (cauterization of the right common carotid artery, followed by two hours of 8% oxygen). Male sham animals received only a midline incision with no manipulation of the artery, followed by room air exposure for two hours. Subsets of HI and sham animals then received either an intraperitoneal injection of 10 mg/kg of caffeine citrate, or saline immediately following hypoxia, 24 and 48 hours after. Following the first administration of caffeine citrate or vehicle, animals were assigned to hypothermic or normothermic conditions for 3 hours. All animals later underwent a battery of behavioral test that included rotarod, rapid auditory processing, Morris Water Maze (spatial and non-spatial), novel object recognition, and five choice serial reaction time task. Putative behavioral outcome benefits from intervention with caffeine, hypothermia, and caffeine + hypothermia in a late preterm HI model will be reported.

Title: Is infarct location a predictor of the degree of post-stroke motor recovery?

Authors: *S. KARTHIKEYAN[1,2], M. JEFFERS[2], A. CARTER[2,3], D. CORBETT[2,3];
[1]Neurosci., [2]Univ. of Ottawa, Ottawa, ON, Canada; [3]Canadian Partnership for Stroke Recovery, Ottawa, ON, Canada

Abstract: Stroke is a leading cause of neurological disability and a majority of patients have long-term motor impairments, often as a result of damage to the motor cortex and/or striatum. While both humans and animals show spontaneous recovery following stroke, little is known about how injury location affects the recovery process. This information is essential in order to develop new therapies to enhance recovery. In this study we used endothelin-1 (ET-1), a potent vasoconstrictor, to produce focal infarcts in the forelimb motor cortex, the dorsolateral striatum or both the cortex and striatum in male Sprague-Dawley rats. The spontaneous recovery profile of the animals was followed over an 8-week period using four behavioural tasks assessing motor function and limb preference to identify how recovery varies depending on injury location. Infarct volumes were derived from MRI 72 hours post-stroke. All three models resulted in functional deficits on the Montoya staircase ($p < 0.002$), beam ($p < 0.017$), and cylinder ($p < 0.001$) tasks but no significant impairments were seen in the adhesive removal task. The three groups demonstrated distinct patterns of recovery on the behavioural tasks with the combined cortical plus striatal group having the largest and most persistent impairments overall. There were no significant differences between groups for total hemispheric infarct volume. These results suggest that damage to the striatum is an important predictor of the level of post-stroke motor impairment. Moreover, the pattern of recovery is not simply dependent on lesion volume but on lesion location and the behavioural test employed. All three models produce sustained motor impairments that will be valuable in assessing novel, adjunctive post-stroke therapies.

Title: Evaluation of compensatory re-organization and damage to the contralateral hemisphere following experimentally induced neonatal hypoxic ischemic brain injury in rats

Authors: *A. L. SMITH[1], T. S. ROSENKRANTZ[2], R. H. FITCH[1];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Dept. of Pediatrics/Neonatology, Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: The most common cause of neurological morbidity and infant mortality in the preterm/term infant is hypoxia ischemia (HI; a lack of blood and/or oxygen to the brain). In the preterm, HI may occur through intra-cranial bleeding or deficiencies in circulatory regulation, while in the term infant HI often results from prolonged labor, placental dysfunction, or other adverse birth events. Despite different etiologies, HI in either population can lead to gray and/or white matter brain damage, and subsequent cognitive/behavioral deficits. Most notably, cortical and hippocampal damage frequently underlie subsequent impairments in speech and language, motor abilities, attention, memory, and spatial orientation. However, when damage occurs early in development, the plasticity of the neonatal brain appears to allow for re-organization and/or compensation that may minimize later deficits. In fact, brain injury during this time is typically subtle, and associated behavioral deficits can often be ameliorated. This stands in contrast to the adult brain, where localized brain injury typically leads to very robust behavioral deficits (aphasia, hemiplegia, etc.), and the brain is less likely to elicit compensatory mechanisms following injury. To assess possible compensatory mechanisms following a neonatal HI insult, the current study used morphometry to measure brain tissue from rats with experimentally induced unilateral hypoxia ischemia on postnatal day (P) 7 (roughly equating to injury in the late preterm infant). Numerous studies using the Rice-Vannucci HI model have reported cortical and hippocampal damage, predominantly on the side ipsilateral to insult. The contralateral (left) hemisphere often reveals no measurable damage, despite being exposed to hypoxia (a component of the HI injury protocol). Also, though neonatal HI subjects consistently exhibit reduced right hemisphere volumes, studies have shown that these same animals are able to perform behavioral tasks with surprising levels of competency. Based on this convergent data, we sought to assess compensatory mechanisms in the contralateral hemisphere by measuring the size of various cortical and hippocampal regions in the "unaffected" hemisphere of P7 HI injured rats. Our intent was to determine whether the contralateral hemisphere sustains subtle HI damage similar to the ipsilateral hemisphere, or alternately, displays an increase in connectivity/thickness reflecting compensation in the injured neonatal rodent brain.

Title: Crossed cerebellar atrophy of the lateral cerebellar nucleus following endothelin-1 induced stroke

Authors: *H. H. CHAN[1,2], J. COOPERRIDER[2], A. LIU[2], H. PARK[2], J. T. GALE[2], A. G. MACHADO[2];
[2]Neurosci., [1]Cleveland Clin., Cleveland, OH

Abstract: Crossed cerebellar diaschisis (CCD) is a functional deficit of the cerebellar hemisphere contralateral to a lesioned cerebral hemisphere. This deficit results from the reduction of afferent input from the injured cerebral region through the corticopontocerebellar pathway. Clinically, CCD manifests as a reduction of blood flow and metabolism at the contralateral cerebellar hemisphere. Furthermore, there are also anatomical defects detected in the cerebella, termed as crossed cerebellar atrophy (CCA). In this study, we demonstrate that there was CCA, specifically in the lateral cerebellar nucleus (LCN), following an ischemic stroke in rats. Six intracortical injections of endothelin 1 (ET-1) were applied to the motor cortex of eight male Long Evans rats for induction of ischemic stroke, while another eight served as uninjected controls. Experimental rats were sacrificed six weeks after stroke induction. Cerebral sections with the motor cortex and cerebellar sections with the LCN were prepared for analyses, including Nissl staining, TUNEL assay and immunohistochemistry. Focally injected ET-1 induced a significant stroke lesion at the motor cortex, accompanied by a reduction of volume of the contralesional LCN. Apoptosis (TUNEL) was observed at the perilesional motor cortex and LCN, both ipsilesionally and contralesionally. Immunohistochemically, the densities of glutamatergic (VGluT-1) and GABAergic (GAD) neurons of the contralesional LCN were lower than those of the ipsilesional LCN. Moreover, there was a higher density of astrocytes (GFAP) at the ipsilesional motor cortex and contralesional LCN than the opposite sides. These findings suggest that cortical ischemia induced bilateral atrophy of the LCN. The higher severity of atrophy of the contralesional LCN compared to the ipsilesional LCN confirmed that the CCA of the LCN was induced by the unilateral stroke lesion at the motor cortex. This atrophy was associated with astrogliosis, implying an inflammatory mechanism.

Title: Docosahexanoic acid improves mitochondrial funcionality and integrity in neonatal brain after hipoxia-ischemia

Authors: *E. HILARIORODRIGUEZ, M. REVUELTA, L. URIGÜEN, A. ALVAREZ, O. ARTEAGA;
Univ. of the Basque Country, Leioa, Spain

Abstract: One of the most common causes of mortality and morbidity in children is perinatal hypoxia-ischemia, so new and more effective neuroprotective strategies are urgently required, in order to minimize as much as possible the neurological consequences of this encephalopathy. In this sense, interest has grown in the neuroprotective possibilities of docosahexanoic acid (DHA), which is a long-chain omega-3 fatty acid, commonly found in fish such as tuna and salmon. The aim of the present work was to evaluate the protective effects of the docosahexanoic acid when administered before HI brain injury in neonatal rats using the Rice-Vannucci model. Hypoxic-ischemic brain injury was provoked by permanent ligature of the left common carotid artery and then by asphyxia for 135 minutes with 8% O2 when rats was P7. Then they were randomly assigned to: control, hypoxia-ischemia (HI) and HI animals that received a single dose of 1 mg/kg of DHA 10 minutes before hypoxia (HI+DHA). P14 brains were stained with Nissl and immunolabelled with MBP and mitochondrial state were evaluated by flow cytometry. Mitochondrial integrity was determined by using the fluorocrome Nonyl Acridine Orange (NAO) and mitochondrial transmembrane potential was analyzed by Rhodamine 123 (Rh 123). HI animals showed swollen and deformed neurons especially in the ipsilateral CA 1 and CTX areas, while only mild cell loss and a few damaged neurons were observed in slices from animals pretreated with DHA. A substantial loss of ipsilateral MBP immunostaining was observed in external capsule and striatum areas of animals that underwent hypoxia-ischemia respect to controls, but DHA pretreatment avoided is loss. Regarding mitochondrial integrity, at 12 h, HI group underwent a diminishment with statistical differences with respect to the Control group in the percentage of NAO positive cells, while animals pretreated with DHA maintained

mitochondrial integrity. In regards to mitochondrial transmembrane potential, animals subjected to the HI event underwent an important diminishment in the percentage of Rh 123 positive cells, but rats pretreated with the antioxidant showed similar values to those of the controls. Our results suggest that docosahexanoic acid led to neuroprottective effects by ameliorating cell damage, preserving myeling and by maintaining mitochondrial integrity and functionality.

Title: New animal model for brain edema

Authors: *N. MATSUKI[1], T. KITAGAWA[1], Y. HOSHI[1], Y. IKEDA-MATSUO[2], R. KOYAMA[1], Y. IKEGAYA[1];
[1]Univ. Tokyo, Tokyo, Japan; [2]Pharmacol., Kitazato Univ., Tokyo, Japan

Abstract: Brain edema is characterized by an excess fluid accumulation within the brain tissue generally caused by ischemia. In spite of its high mortality of patients with edema in the cerebellum and brain stem, the mechanism is poorly understood, and no effective treatment has been established. One of the reasons is a lack of proper animal model corresponding to the early stage of the edema. Therefore, we have established an *in vitro* brain edema model and analyzed its mechanism. Acute brain slices of young adult mice were exposed to oxygen-glucose deprivation condition (OGD) for 10 min. The cross-sectional area of the slice was measured for 150 min with a macro-microscope. Water content of slices was also measured after the experiment. After OGD treatment, the cross-sectional area of slices increased to 120% at 150 min. This increase was dependent on temperature and inhibited by an NMDA receptor antagonist or hyperosmolar treatment. Water content was also increased. These facts suggest that the model adequately replicates some features of brain edema. OGD-induced edema was significantly reduced in aquaporin4-deficient mice. Hyponatremic treatment was also preventive. A Na+/K+ ATPase inhibitor alone induced edema without OGD. These results suggest that accumulation of

intracellular sodium is involved in an early stae of the formation of brain edema. The model can contribute to elucidate the nature of brain edema and to develop effective treatments.

Title: Vulnerable vasculature and inflammation contribute to the exacerbation of transient focal ischemia in a genetic mouse model of type 1 diabetes

Authors: *A. C. LO[1,2], A. K. W. LAI[1];
[1]Dept. of Ophthalmology, The Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Res. Ctr. of Heart, Brain, Hormone and Healthy Aging, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: PURPOSE: Epidemiological studies showed that type 1 diabetic patients are much more prone to cerebrovascular mortality from stroke and the median survival is only half when compared with those in the general population. It has been suggested that type 1 diabetes is a risk factor for stroke; however, the underlying mechanisms are still unclear. In the current study, we aim to elucidate the potential mechanisms contributing to the exacerbation. METHOD: $Ins2^{Akita/+}$ mice, a type 1 diabetic murine model, and their wildtype ($Ins2^{+/+}$) littermates at 12 weeks of age were challenged with experimental stroke by middle cerebral artery occlusion (MCAO) for 2h followed by 2h of reperfusion. Survival rate and neurological deficits were accessed at the end of reperfusion. Brain slices were prepared and stained with 2, 3, 5-triphenyltetrazolium chloride for estimating the infarction, hemispheric swelling, and hemorrhagic area. Blood vessel integrity (ZO-1) and inflammatory response (VEGF and pErk) were compared between $Ins2^{Akita/+}$ and $Ins2^{+/+}$ ipsilateral brains using Western blot analysis. ER-stress (ATF6, BiP, CHOP, PERK and IRE-1α) and autophagy (Atg12, Bcn1, LC3-a, LC3-b and p62) response were also compared using real-time PCR. RESULTS: $Ins2^{Akita/+}$ mice showed a decreased survival rate and increased neurological deficits after MCAO, together with a significant increase in infarction and

hemorrhage size. Down-regulation of ZO-1 protein and remarkable up-regulation of VEGF and pErk protein were observed in $Ins2^{Akita/+}$ mice when compared with $Ins2^{+/+}$ mice. mRNA expression of CHOP was significantly increased in both mice after MCAO challenge and was further augmented in $Ins2^{Aktia/+}$ mice. Atg12, Bcn1 and LC3-b mRNA expressions were significantly lower in the $Ins2^{+/+}$ mice after MCAO when compared with the sham-operated controls but there was no difference between the post-MCAO $Ins2^{Akita/+}$ and $Ins2^{+/+}$ groups. CONCLUSION: We showed that induction of MCAO in $Ins2^{Akita/+}$ mice could mimic the clinical observations of high mortality in type 1 diabetic patients upon stroke. Decrease in ZO-1 expression and augmented hemorrhage indicated that blood vessel integrity was more vulnerable in the $Ins2^{Akita/+}$ mice. Provoked inflammatory response and ER-stress may play important roles in the exacerbation of the ischemic brain, which was evidenced in increased infarction in $Ins2^{Akita/+}$ mice.

Title: Resveratrol improves long-term memory impairments and neuronal conexions in hypoxia-ischemic brain injury in neonatal rats

Authors: O. ARTEAGA, M. REVUELTA, L. MARTINEZ-MILLAN, L. URIGÜEN, A. ALVAREZ, A. MARTINEZ-IBARGÜEN, *J. PINEDA, E. HILARIO;
Univ. of the Basque Country-UPV/EHU, Leioa (Bizkaia), Spain

Abstract: Neonatal hypoxic-ischemic brain injuries involve primary destructive events, but also secondary maturational disturbances, which lead to subsequent abnormal development and altered functions, such as severe neurological handicap, and behavioral and learning deficits. Resveratrol (RVT) is a natural pythoalexin present in grapes and red wine with anti-oxidant and anti-inflammatory properties. The aim of the present work was to investigate if short-term protective effects of reveratrol against HI brain injury in neonatal rats were also persisted in

adulthood. To this end we performed long-term behavioral tests related with memory impairments and we evaluated axonal anterograde conexions. Hypoxic-ischemic brain injury was induced by permanent ligature of the left common carotid artery and then by asphyxia for two hours and a 15 minutes with 8% O2 when rats were 7 days old (P7), and then, they were randomly assigned to three experimental groups: control, hypoxia-ischemia (HI) and HI animals that received a single dose of 20 mg/kg of resveratrol 10 minutes before the hypoxic event (HI+RVT). On P90 we evaluated the long-lasting behavioral alterations related with memory, through T-maze and novel object recognition tests. For anterograde tracing experiments, when P100 animals, biotinylated dextran amines (BDA) injections were made in left lateral of the cortex, under anesthesia. Animals pretreated with resveratrol made a similar number of correct choices in the T-maze at 40 second delay to the control ones, while HI animals made significantly fewer correct choices. In a novel object recognition test, HI rats displayed a decrease in discrimination index when compared to control animals that was fully reversed by acute resveratrol administration. Changes in the axonal connections of corticofugal neurons following neonatal hypoxic-ischemic injury were detected in HI rats in the talamun and corpus callosum, but these changes were reverted with RVT, showing similar patterns to control animals. Our results suggest that the pretreatment with resveratrol was able to improve the long-lasting cognitive deficits related with memory and the changes in the axonal connections of corticofugal neurons in the talamun and corpus callosum induced by hypoxia-ischemia.

Title: Effects of forced exercise on changes in expression of milk fat globule-EGF factor 8 and brain-derived neurotrophic factor in cortical infarct area after focal cerebral ischemia in rats

Authors: Y.-W. CHOI[1,2], S.-G. KANG[3], *K.-Y. KAM[4,2];

Abstract: After cerebral ischemia, the two major zones of injury appear in the lesion: the core and the penumbra. In the core, reduction of blood flow induces a catastrophic event due to rapid depletion of energy. However, in the penumbra, neural cells are still alive but subjected to a wave of deleterious events propagated from the core, leading to delayed cell death. According to recent studies, delayed death of stressed-but-viable neurons is executed by phagocytic microglia in ischemic region after focal cerebral ischemia. Milk fat globule-EGF factor 8 (MFG-E8) plays a role as opsonin in the phagocytosis. The neuroprotective effects of exercise are well known in recovery of damaged tissue and functions after cerebral ischemia through the mediation of brain-derived neurotrophic factor (BDNF), but its effect on MFG-E8 is still not understood. In this study, we examined the effect of forced exercise on MFG-E8 and BDNF-positive cells in the injured area after cerebral ischemia. Transient focal cerebral ischemia was induced by middle cerebral artery occlusion (MCAO) on male Sprague-Dawley rats weighing 280-300g. Three days after MCAO, animals were subjected to forced treadmill exercise (20 m/min, 30 min, 1 session/day) for 14 consecutive days. The modified neurological severity score was used to evaluate neurological function at day 1, 3, 10, 17 after MCAO. The infarct size was determined by the Nissl staining. The immunohistochemical analysis was performed with antibodies against NeuN (neuronal marker), MFG-E8, and BDNF. Compared to sedentary group, exercise group showed significant improvement of neurological function and smaller infarct size. Based on the distribution of $NeuN^+$ cells, virtual borderline could be drawn to distinguish infarct core. In the peri-infarct of exercise group, the number of $MFG\text{-}E8^+\text{-}NeuN^+$ cells was significantly less than those of subacute ischemia group (3 days after MCAO) and sedentary group, while the number of $BDNF^+\text{-}NeuN^+$ cells was more than that of sedentary group. But the number of $NeuN^+$ cells in the same area was not significantly different between groups. This study suggests that the effects of forced exercise on recovery after cerebral ischemia may be mediated by alterations in actions of MFG-E8 and BDNF in the ischemic region.

Title: Antioxidant treatments recover the alteration of auditory evoked potentials and reduce morphological damage in the inferior colliculus after perinatal asphyxia in rat

Authors: *A. MARTINEZIBARGUEN[1], O. ARTEAGA[2], A. ALVAREZ[2], E. HILARIO[2], M. REVUELTA[2];
[1]Dermatol. Ophtalmology and Otorhinolaryngology, Univ. of Basque Country Med. Sch., Getxo, Spain; [2]Cell Biol., UPV/EHU, Leioa, Spain

Abstract: Despite improvements in neonatology, perinatal hypoxic-ischemic (HI) encephalopathy remains one of the main causes of disabilities in term-born infants. This pathology underlies many neurological disorders such as learning difficulties, language and attention deficit, hyperactivity disorders and cerebral palsy. Moreover, it is a notable risk factor for hearing impairments which affect neonates. The aim of the present work was to evaluate morphologically and electrophysiologically the effect of a panel of antioxidants on HI-induced auditory deficits. To this end, we studied the effects of nicotine, melatonin, resveratrol and DHA on the neonatal auditory system via measurement of auditory evoked potentials and characterization of the morphological integrity of the Inferior Colliculus (IC). The hypoxic ischemic event was induced in perinatal rat, by the Rice-Vannucci method. Rats were randomly assigned to six experimental groups (n=8): control, HI and four HI groups administered with the different drugs. We measured the Auditory Brainstem Responses (ABR) and after ABR recordings, animals were weighed and sacrificed for the histological and cellular studies. Astrogliosis and white matter injury were evaluated by GFAP (glial fibrillary acidic protein) and MBP (myelin basic protein) staining and membrane integrity, potential and intracellular ROS were analyzed with a flow cytometer. We found that the integrity of the auditory pathway in the brainstem was altered as consequence of the HI insult. Thus, the auditory brainstem response showed increased I-V interval and latencies III, V waves. At a histological level, hypoxia-ischemia altered the morphology of the inferior colliculus: neurons had altered axonal prolongations and condensed cytoplasm; astrocytes were reactive with increased glial fibrillary acidic protein expression, and oligodendrocytes exhibited reduced myelin basic protein expression. Following antioxidant treatment, ABR intervals were restored and the body and brain weight was recovered as well as the morphology of the inferior colliculus that was similar to the control group. Our results support the hypothesis that antioxidant treatments have a protective effect on the functional changes of the auditory pathway and on the morphological damage which occurs after hypoxic ischemic insult. Title: Modulation of the lateral cerebellar nucleus during motor learning

Authors: *J. COOPERRIDER, J. T. GALE, R. GOPALAKRISHNAN, H.-J. PARK, C. WATHEN, H. H. CHAN, A. G. MACHADO;
Cleveland Clin., Cleveland, OH

Abstract: Our group has previously investigated the local field modulation of the rat lateral cerebellar nucleus (LCN) during a skilled reaching task, identifying differences between successful and unsuccessful reaching attempts. Because there is evidence of motor learning-dependent modulation in the cerebellum, we wished to examine the activity of the LCN while animals learned this skilled reaching task. Local field potential and multi-unit spiking activity was acquired from a five-microelectrode array in the LCN of seven animals. Analysis of neurophysiological data revealed that there were significant modulatory changes during successful and unsuccessful trials over the course of learning a skilled reaching task.

Title: Intrauterine ischemia and systemic inflammation: a model of encephalopathy of prematurity

Authors: *B. CARUSILLO, V. GERZANICH, J. SIMARD;
Univ. of Maryland-Baltimore, Baltimore, MD

Abstract: Complications preceding premature birth are complex and multifactorial. These complications, including maternal infection and hypoxia-ischemia, can lead to several neurological pathologies in newborns such as Periventricular Leukomalacia and Intraventricular hemorrhage and other non-hemorrhagic brain lesions, collectively referred to as "Encephalopathy of Prematurity." Currently, this multifaceted perinatal injury is not adequately replicated in animal models. Here, we propose a novel model of encephalopathy of prematurity in which insults are induced *in utero*. Intrauterine ischemia (IUI) was induced at E19 in pregnant dams. Following IUI, an osmotic pump was implanted to deliver 600ng/hr Lipopolysaccharide (LPS) for 24 hours into the maternal circulation to mimic systemic bacterial infection. After 2-3 days, birth occurred naturally. Pups were studied from P1-P50 for histological and behavioral phenotypes. At Post-natal day 1 (P1), H&E stains showed cortical and intraventricular hemorrhages in injured pups. Additionally, these pups showed marked microglial activation in periventricular areas as evidenced by increased ED1 and IBA1 immunohistochemical labeling in those areas. Behaviorally, injured pups showed motor deficits including delayed righting reflex and negative geotropism from P1-P14 and worse performance on beam balance, rearing, and grip test at P24-P31. In the Morris Water Maze, injured pups spent significantly less time in the correct quadrant during the memory probe. Additionally, these pups displayed heightened anxiety in the Elevated Plus Maze and Open Field tests. The present rat model of transient *in utero* ischemia and maternal systemic inflammation accurately reflects the clinical events that often precede prematurity and the development of later neurological deficits. Pups from injured mothers showed marked inflammation and intracerebral hemorrhage in early post-natal life and displayed persistent motor and cognitive deficits throughout development.

Title: Neuroprotective effects of (-)-Phenserine against ischemia/reperfusion injury through the ERK-1/2 signaling pathway *in vitro* and *in vivo*

Authors: *J.-H. LAI, ESQ;
Taipei Med. Univ., Taipei, Taiwan

Abstract: **Background:** It is well known that stroke mainly leads to adult disability and death in global. The acetylcholinesteras (AChE) are upregulated and connected with inflammation and apoptosis after stroke. Recent studies have suggested that the inhibition of AChE ameliorates the ischemia-reperfusion injury and has neuroprotection. (-)-Phenserine, a selective AChE inhibitor has be demonstrated the nuroprotective properties. However, the protective effects and detail mechanisms of (-)-Phenserine on rat middle cerebral artery occlusion (MCAO) model is still unclear. This study focusses on the therapeutic effects of (-)-Phenserine for stroke in rodent focal cerebral ischemia model and oxygen-glucose deprivation/reperfusion (OGD/RP) damage on SH-SY5Y cells. **Methods:** SH-SY5Y cells which were cultured under OGD/RP and treated with (-)-Phenserine, were analyzed by MTT assay, Western blotting. Moreover, to investigated the therapeutic effects of (-)-Phenserine in rat used the MCAO model and was determined by TTC staining, TUNEL staining, immunohistochemical staining and Western blotting. **Results:** The viability and MMP-9 expression in SH-SY5Y cells was reduced by (-)-Phenserine under the OGD/RP condition. (-)-Phenserine increased the BDNF and Bcl-2 expression, but decreased activated-caspase 3 level, APP and GFAP expression through ERK-1/2 signaling pathway *in vitro* and *in vivo*. (-)-Phenserine also attenuated the infraction volume, apoptosis and improved the body asymmetry. **Conclusions:** These results were shown that (-)-Phenserine could enhance the Bcl-2 and BDNF expression for inhibiting neuronal apoptosis, GFAP, and MMP-9 expression via the ERK-1/2 signaling pathway. Furthermore, (-)-Phenserine could mitigate the injury of nerve cells to against ischemia/reperfusion injury in rat models of middle cerebral artery (MCA) ligation. Key words: Ischemia/reperfusion, MCAO, (-)-Phenserine, AChE

Title: ERV, an analgesic drug, suppresses the development of brain edema after focal ischemia: Analysis using 7-T MRI

Authors: *Y. NAKAJO[1,2], Q. ZHAO[1,3], K. YAMATO[1], J. ENMI[4], H. IIDA[4], H. KATAOKA[3], J. C. TAKAHASHI[3], H. YANAMOTO[1,5];

[1]Lab. of Neurol. and Neurosurg., NCVC, Suita, Japan; [2]Res. Lab., Rakuwa-kai Otowa Hosp, Kyoto, Japan; [3]Dept. of Neurosurg., Natl. Cerebral and Cardiovasc. Ctr., Suita, Japan; [4]Dept. of Invest. Radiol., Natl. Cerebral and Cardiovasc. Ctr. Res. Inst., Suita, Japan; [5]Dept. of Cardiovasc. Science, Div. of Surgical Med., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: "An extract derived from the inflamed cutaneous tissue of rabbits inoculated with vaccinia virus (ERV)" is a mixture of multiple, non-protein, inflammation-related biological molecules and is used an anti-allergic and analgesic drug in humans. Since ERV is known to inhibit the kallikrein-kinin system, which increases vascular permeability and causes vasogenic edema (breakdown of the blood-brain barrier [BBB]), we investigated the effect of prophylactic ERV treatment on the development of cerebral edema after focal ischemia. C57BL/6J mice were treated with vehicle (water) (n = 6) or ERV (0.27 U $\bullet kg^{-1} \bullet day^{-1}$ [the clinical dose for chronic pain in humans]; n = 6) for 21 consecutive days. At the end of the treatment, temporary focal ischemia was induced in the cortex using the three vessel occlusion (3VO) technique. Using 7-T MRI, T2-weighted image and apparent diffusion coefficient (ADC) values were measured at 5 and 24 h after reperfusion. On the basis of the findings of 2,3,5-triphenyltetrazolium chloride (TTC) staining performed at 24 h after reperfusion, regions of interest (ROIs) were set at the ischemic core, medial border area (penumbra), lateral border area (surviving area), and an area with no ischemic injury. T2 signal amplitudes at the ischemic core and penumbra in the ERV-treated mice were significantly reduced at 5 h and 24 h of reperfusion ($P < 0.01$), whereas ADC values at the ischemic core and penumbra were significantly increased only at 5 h ($P < 0.01$), compared to the vehicle-treated mice, respectively. Further, 24 h after induction of reperfusion, the infarcted lesion volume was significantly reduced in the ERV group than in the vehicle group ($P < 0.05$). Increased T2 signal amplitudes and reduced ADC values indicate vasogenic and cytotoxic edema, respectively. Prophylactic treatment with ERV significantly reduced vasogenic as well as cytotoxic edema at the ischemic core and penumbra in the ultra-acute phase (5 h) after focal ischemia and reperfusion. At 24 h, vasogenic edema was still significantly reduced at the ischemic core and the penumbra, in the ERV group.

Title: Defining an alternative murine model of cerebral ischemia: focal vasoconstriction via endothelin-1

Authors: *C. DOJO SOEANDY, F. SALMASI, J. HENDERSON;
Univ. of Toronto, Toronto, ON, Canada

Abstract: Stroke represents one of the leading causes of long-term disability and death in North America. The failure of a number of recent human clinical trials aimed at enhancing stroke therapy have highlighted the importance of developing clearly defined, reproducible models of stroke. Many current animal models of stroke depend upon anatomical impedance of local arterial sources resulting in very large cortical infarct volumes compared with that typically seen in humans, and in substantial injury to sub-cortical structures. These injuries lie in contrast to the presentation of the vast majority of human clinical strokes. Additionally, many of these models exhibit considerable variability in infarct representation due to the stochastic nature of the parent vascular bed even within genetically identical animals. In order to understand the *in vivo* mechanisms regulating programmed cell death within cortical strokes, and to effectively evaluate potential therapeutic strategies, we must strive to first develop accurate and appropriate *in vivo* models. To this end, we have examined controlled stereotactic infusion of endothelin-1 into the adult mouse cortex as a means to generate transient focal ischemia/reperfusion injury within predefined cortical regions. Use of this approach results in discreet, well-defined infarcts which are limited to the cortex. Analysis of cellular ultrastructure in these infarct regions using electron microscopy together with molecular markers demonstrate features of programmed cell death that are consistent with apoptosis. Infarct regions were indeed confined to cortical layers and consistent with diffusion-based modelling. Analysis at increasing times after injury demonstrate the progressive nature of these cortical injuries with associated functional impairment. Stereotactic endothelin-1-mediated cortical injury thus exhibits reduced variability and morbidity compared to traditional models of rodent stroke while retaining key features seen in the majority of human clinical stroke. This system is in turn currently being utilized to decipher PCD signaling interactions in control and genetically modified murine mutants.

Title: Specific and local overexpression of haptoglobin improves anatomical and functional outcomes in the autologous blood intracerebral hemorrhage model

Authors: *T. ESFANDIARY[1,2], J. L. LECLERC[1,2,3], A. DANG[1,2], J. SANTIAGO-MORENO[1,2], S. DORE[1,3,2,4];
[1]Anesthesiol., [2]Ctr. for Translational Res. in Neurodegenerative Dis., [3]Neurosci., [4]Neurology, Psychiatry, Psychology, and Pharmaceutics, Univ. of Florida, Gainesville, FL

Abstract: Intracerebral hemorrhage (ICH) is a stroke subtype associated with high morbidity and mortality. With breakdown of the blood-brain barrier and entry of toxic blood components and metabolites within the brain, a highly oxidative environment ensues and leads to a toxic neuroinflammatory cascade. A major cause of the debilitation following brain hemorrhage is due to the direct toxicity of blood components, namely hemoglobin (Hb), the most upstream precipitating factor in the cascade. The acute phase plasma protein haptoglobin (Hp) binds Hb and inhibits its cytotoxic, pro-oxidative, and pro-inflammatory properties. In this study, we investigated whether the local and specific overexpression of Hp would aid in the safe detoxification and clearance of free Hb, thereby protecting the neuropil from Hb-mediated oxidative stress and improving ICH outcomes. Hp was overexpressed locally within the brain using uniquely designed adeno-associated viral vectors and ICH was induced using the intrastriatal autologous whole blood injection model. Functional outcomes were assessed daily by a 24-point neurological deficit score. At 72h post-hemorrhage, mice were sacrificed and brains collected for histological staining. Hp-overexpressing mice demonstrated smaller lesion volumes ($p<0.05$) with less blood accumulation ($p<0.05$) and improved neurologic status at 24h, 48h, and 72h post-hemorrhage ($p<0.05$) when compared to an identically treated control group (n=7-11/group). Histological staining for Iba1, GFAP, heme oxygenase-1, 4-hydroxynonenal, ferric iron, and myeloperoxidase was performed and revealed: i) significantly less heme oxygenase-1 expression and lipid peroxidation, ii) a trend towards reduced peripheral neutrophil infiltration, iii) significantly increased cortical microgliosis and cortical and striatal astrogliosis, and iv) no changes in ferric iron content or striatal microgliosis. In conclusion, Hp overexpression in the brain reduces ICH-induced brain injury and improves functional outcomes. Locally modulating brain Hp levels could represent an important clinically relevant strategy for the treatment of ICH.

Title: Blocking gsk-3beta increase post tbi prevents memory impairment

Authors: *S. A. FARR[1], M. L. NIEHOFF[2], V. B. KUMAR[1], J. E. MORLEY[3];
[1]St Louis Univ/VA Med. Ctr., Saint Louis, MO; [2]Div. of Geriatrics, [3]Div. of Geriatrics/Div of Endocrinol., St. Louis Univ., St. Louis, MO

Abstract: Traumatic brain injury (TBI) is a serious problem. Veterans and individuals involved in accidents often have injuries that result in learning and memory disorders. There is a great need for treatment of TBI. Here we used an animal model of TBI which produces no visible outward signs of injury, but results in learning and memory deficits. One of the chemical reactions that occur in the brain after TBI is an increase of glycogen synthase kinase-3β (GSK-3β). Elevation GSK-3β leads to the phosphorylation of Tau and increase beta amyloid production. Both of these factors are involved in memory disorders. We have developed an antisense which blocks the activity of GSK-3β. In our first study, we developed a model of closed head concussive TBI which produces no visible outward signs of injury, but results in learning and memory deficits. Mice are subjected to 30 gram weight drop from a height of 80cm. Post-injury mice are subjected to an acute neurological evaluation to verify that the TBI did not produce any neurological damage. One week post-injury mice were tested in object recognition with 24 hour delay. At 4 weeks post injury mice were tested in T-maze foot shock avoidance memory test and another object recognition test with 24 hour delay. The objects in the second object recognition test were different shapes and made of different materials from the first to ensure there was no carry over from the first test. In the first study, we established that our mice that received the TBI were impaired on learning and memory. Memory was impaired in the TBI mice at both 1 and 4 weeks post TBI in object recognition. T-maze memory was impaired at 4 weeks post-injury. In the second study, we examined the effect of GSK-3β administration 15 minutes post injury on memory at 1 and 4 weeks. Mice which received GSK-3β antisense show improved memory in both object recognition and T-maze compared to random antisense treated mice that were subjected to TBI. The current finding suggest that inhibiting the GSK-3β spike with an antisense directed at GSK-3β after TBI prevents the learning and memory impairments associated with TBI.

Title: Re-expression of developmental thrombospondins after experimental diffuse traumatic brain injury coincides with injury-induced temporal profile of synaptic markers

Authors: ***S. OGLE**[1,3,4], H. MAY[1,3], R. K. ROWE[1,3,5], B. RUMNEY[1,3,6], S. JOHNSON[2,4], P. ADELSON[1,3], J. LIFSCHITZ[1,3,5], T. CURRIER THOMAS[1,3,5];

Abstract: Annually, 20-50% of patients with a traumatic brain injury (TBI) develop persistent neurological deficits (e.g. sensory sensitivity) over months to years post-injury. No prophylactic treatments are available to negate the onset of these deficits. In rodents, late-onset sensory sensitivity following TBI is expressed as reduced tolerance to whisker stimulation with evidence of circuit reorganization in the somatosensory thalamocortical tracts. For circuit reorganization to result in neurological deficits, synaptogenesis is necessary. During development, thrombospondin-1 and thrombospondin-2 (TSPs), predominantly astrocyte-secreted proteins, mediate synaptogenesis through the α2δ-1 subunit of the voltage-dependent calcium channel receptor (α2δ-1). However, after neurological insult in the adult CNS, re-expression of TSPs have been implicated in mediating synaptogenesis and is thought to be the source of circuit reorganization during recovery. We hypothesize that re-expression of TSPs coincides with a

distinct temporal profile of synaptogenic molecules in the thalamus that supports circuit reorganization. For this study, adult male Sprague-Dawley rats underwent sham or moderate midline fluid percussion brain injury. At eight/ten time points over 2-months post-injury, gene and protein expression of TSPs and synaptic markers were quantified from thalamic biopsies using qPCR and automated capillary westerns, respectively. Gene expression demonstrated significant changes over time for TSP-1, TSP-2, α2δ-1, and post-synaptic density-95 (PSD-95; $p<0.05$). Protein expression demonstrated a significant increase in TSP-1 that coincided with changes in the temporal profile of synaptophysin and PSD-95 protein. Analysis of protein expression of TSP-2, α2δ-1, GAP-43, and PICK-1 are ongoing. These experiments provide a temporal profile of TSPs and synaptic markers after TBI in the thalamus. Future studies aim to mitigate injury-induced synaptogenesis as an approach to alleviate chronic neurological deficits. Success of this treatment would support a paradigm shift towards prevention of late-onset morbidity, rather than treatment of the symptoms, thereby improving quality of life for countless survivors of TBI.

Title: Noise-induced maladaptive anxiety-like and risk assessment behaviors were reverted by rearing periadolescent rats in an environmental enrichment

Authors: S. J. MOLINA[1], M. MICELI[1], F. CAPANI[2], *L. R. GUELMAN[1];
[1]Fac Med, UBA-CEFYBO-CONICET, Buenos Aires, Argentina; [2]Inst. de Investigaciones Cardiológicas "Prof. Dr. Alberto C. Taquini" (ININCA), UBA-CONICET, Buenos Aires, Argentina

Abstract: It is known that noise exposure can induce hearing loss. However, few data are available regarding its effects on extra-auditory structures such as developing Central Nervous

System. Previous studies of our laboratory showed that exposure of immature rats to moderate noise can induce anxiety-like behaviour alterations. Interestingly, rearing these animals in an enriched environment (EE) has shown to be an effective protective tool which can prevent some noise-induced behavioral changes. Risk assessment (RA) can be defined as the acts and postures serving as defensive behaviors against threatening dangers, which rodents use to cope with potentially unsafe situations, closely related to fear and anxiety behaviors. Nevertheless, no data on noise-induced RA effects have been obtained yet. Therefore, the aim of the present work was to test the effects of different schedules of noise exposure in 7-days-old rats on anxiety-like and RA behaviours as well as the potential preventive effect of EE rearing. Rats of 7 days were exposed during 2 hours to white noise (95-97 dBA), for one day (acute noise exposure, ANE) or five consecutive days (sub-acute noise exposure, SANE), using an “ad-hoc” sound camera. After weaning, groups of 3-4 rats were transferred to an enriched cage, consisting of toys, a wheel, tunnels and ramps, while other groups were placed in standard cages. One week later, rats were subjected to elevated plus maze (EPM) and open field (OF) tasks. Results showed an increase in both anxiety-like and RA behaviors in ANE rats. In contrast, a decrease in most anxiety-like behaviors was found in SANE animals, whereas an increase in RA behaviors was observed. EE rearing was fully effective in reverting RA changes in both schedules. Interestingly, while a partial reversion was observed in anxiety-like behaviors in ANE rats, the decreased anxiety-like levels observed in SANE rats were normalized when animals were reared in EE. These findings suggest that rats exposed at an early developmental age to different noise exposure schedules might be differentially affected in emotion-related behavioral performances that EE rearing was able to reverse. It seems that the rearing of young rats in an EE tend to normalize anxiety-like behaviors, in particular in SANE animals. Conversely, the maladaptive RA behavior observed in noise-exposed animals was reestablished when animals were reared in an EE. Therefore, it could be concluded that visual, social and physical stimulation during the peri-adolescence period could interact with behavioral abnormalities induced by an earlier exposure to a physical agent such as noise, generating normalized emotional and behavioral parameters.

Title: Chronic impairment of cerebral blood flow in a mouse model of repetitive mild traumatic brain injury

Authors: ***C. E. LYNCH**[1,2,3], B. MOUZON[1,3,2], C. BACHMEIER[1,2,3], F. CRAWFORD[1,2,3]; [1]Neurosci., The Roskamp Inst., Sarasota, FL; [2]The Open Univ., Milton Keynes, United Kingdom; [3]James A. Haley Veteran's, Tampa, FL

Abstract: Repeated exposure to mild traumatic brain injury (mTBI), as seen in contact sports injuries, is known to predispose individuals to development of neurodegenerative diseases such as Alzheimers Disease and Chronic Traumatic Encephalopathy (CTE). CTE is characterized by deposition and hyper-phosphorylation of the microtubule-associated protein tau throughout the brain. In addition to aberrant proteinopathy, neurodegenerative diseases are often associated with cerebrovascular abnormalities, including changes in cerebral blood flow (CBF), and loss of Blood Brain Barrier (BBB) integrity. Owing to the prevalence of mTBI, there is an urgent requirement for animal models recapitulating the pathological hallmarks, cognitive deficits, and cerebrovascular components of neurodegeneration following repetitive mild head trauma. We used heterozygous transgenic hTau mice expressing all 6 isoforms of human tau on a null murine tau background, allowing for a clinically relevant investigation of the effects of repetitive mTBI (r-mTBI) on cerebrovascular mechanics in the presence of human tau. The closed-head mTBI was administered to mice under isofluorane anesthetic using a 5mm blunt metal impactor tip at a velocity of 5m/s and a strike depth of 1mm, positioned midway to the sagittal suture. We administered 2 hits every week for 3 months to replicate the incidence of mTBI that can occur over the course of a career in contact sports. We measured CBF in both hTau and wild-type mice 3 months and 7 months post-injury, respectively, using laser Doppler imaging. We observed a significant decrease in CBF in wild-type mice (10.66% ± 1.44% compared to sham) and hTau mice (8.92% ± 1.39% compared to sham) This effect of r-mTBI on CBF may provide rationale for the link between head trauma and the development of neurodegenerative disorders like CTE. We will continue to evaluate the impact of r-mTBI on the cerebrovasculature by assessing BBB integrity and examining specific vascular markers at various time-points post-injury in upcoming studies

Title: Time dependent changes in the brain stem of rats exposed to blast-induced neurotrauma

Authors: *F. GHODDOUSSI[1], S. V. SAJJA[2], E. L. ETNYRE[3], P. VANDEVORD[5], M. P. GALLOWAY[4];

Engin. and Sciences, Virginia Polytechnic and State Univ., Blacksburg, VA

Abstract: Introduction: Traumatic brain injury (TBI) induced by blast overpressure waves (bTBI) is a significant clinical problem in soldiers returning from combat. Psychiatric illnesses such as depression, anxiety, sleep disturbances, memory impairment, and PTSD have a delayed expression after the bTBI event. Reliable biomarkers are non-existent for bTBI and bTBI is under diagnosed partly due to the absence of diagnostic criteria in morphology based neuroimaging modalities (e.g. CT and MRI). Therefore, using other neuroimaging modalities such as MRS and DTI may provide insight into the development of diagnostic biomarkers for bTBIof the pathology. Brain stem (BS) is particularly vulnerable to bTBI because of the proximity of the BS to the bony protrusions of the skull, when brain bounces against the skull as a result of the blast. BS nuclei regulate arousal and autonomic functions, as well as attention and short-term memory. Trauma to this area can lead to disorientation, increased sense of frustration and anger, problems with balance and movement and sleeping difficulties. Clinically BS is one of the most commonly studied anatomic structures for prognosis after TBI. Methods: We used proton magnetic resonance spectroscopy (1H-MRS) and high-performance liquid chromatography (HPLC), both *ex vivo*, to assess the neurochemical profiles in the brain stem of male rats 3 hours, 1, 2, 3 and 7 days after exposure to a calibrated blast overpressure (117kPa). Short-term and working memory impairment as well as anxiety-like behaviors was assessed by novel object recognition and light/dark box respectively. Results: In the bTBI group, anxiety-like behavior was evident from 2 d thru 3 mo and impaired memory tasks evident at 7 d thru 3 mo post insult. MRS analysis showed that GABA, myo-Inositol (INS) and Cholines [and their ratio to creatine (CRE)] were increased significantly in the BS 1d after the blast. HPLC analysis showed significant decrease in 5HIAA/5HT ratio 3Hr after the blast. Discussion: Decreased

5HIAA/5HT 3Hr after the blast suggests attenuated 5HT input to BS nuclei as an early consequence of overpressure insult. Increase in INS, choline and GABA (or their ratio to creatine) 1d after the blast respectively may represent glial activation (including membrane turnover) and a potential compensatory response (neuronal or metabolic) to glutamate excitotoxicity. Increased GABA in this region may also be associated with the diminished 5HIAA/5HT ratio. The results highlight the utility of 1H-MRS for assessment of the neurochemical status of the brain after bTBI.

Title: The effects of mild TBI on spatial memory: impaired discrimination of novel spatial locations rooted in altered *in vivo* hippocampal activity

Authors: *R. PATERNO[1], H. METHENY[1], B. JOHNSON[1], C. SMITH[2,1], G. XIONG[1], A. COHEN[1,2];
[1]Children Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Traumatic brain injury (TBI) can lead to significant cognitive impairment, however the underlying neurological basis for TBI-induced cognitive dysfunction remains unknown. Many lines of research have implicated the hippocampus in the pathophysiology of traumatic brain injury. Furthermore, it has been demonstrated that the hippocampus consistently plays an important role during novelty exploration. That is, where an initially presented object is moved to a new location. However, specific impairments of spatial memory after TBI have yet to be shown. To test the association of TBI and spatial memory dysfunction, we used the Lateral Fluid Percussion Injury mouse model of TBI together with a spontaneous novelty exploration task. The task used both a transient (1 h) and protracted (1 day) retention interval between the

familiarization and test phases of the task. We found that TBI animals exhibited significantly impaired discrimination of old versus new spatial locations compared to Sham control animals. *In vivo* area CA1 local field potential recording in brain injured animals demonstrated a significant decrease in broadband activity during exploratory behavior in the home cage. To further investigate how brain injury alters spatial memory, *in vivo* electrophysiological activity in hippocampal areas CA1 and CA3 was performed. These hippocampal recordings were undertaken in TBI and Sham animals during the novelty spatial navigation task to correlate the hippocampal-associated behavior to neural oscillations. These findings indicate that TBI impairs spatial memory after a protracted compared to a transient delay interval, and further explores the neural basis underlying this cognitive dysfunction.

Title: Characterizing the role of hif-1α as a mediator of blood-brain barrier dysfunction in blast neurotrauma

Authors: W. HUBBARD[1], M. LASHOF-SULLIVAN[2], J. ECK[1], E. LAVIK[2], *P. J. VANDEVORD[1];
[1]Biomed. Engin., Virginia Tech. Univ., Blacksburg, VA; [2]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Although hypoxia inducible factor-1α (HIF-1α) is known to contribute to TBI pathology, it has not been studied in relation to blast-induced neurotrauma (BINT). Hypoxia is thought to play a key role in injury progression after blast due to impaired pulmonary gas exchange in the lung and secondary effects on cerebral vasculature (Kirkman 2011; DeWitt 2009). HIF-1α is a mediator of blood-brain barrier (BBB) disruption which is linked to detrimental effects on brain pathology (Ogunshola, 2012). This injury pathway, specifically in the amygdala, can potentially lead to neurologic impairment, such as anxiety (Sajja, 2014). Understanding the mechanism of how HIF-1α contributes to BINT could provide evidence of

BBB dysfunction following blast. Sprague Dawley rats were exposed to peak overpressure of 28 psi in a side-thorax orientation for 2.5 ms duration. Anesthetized animals were exposed to a blast from an Advanced Blast Simulator. Sham animals underwent similar procedures with the exception of the exposure to blast. One week post-blast, animals were given a behavioral task to explore an open field box (anxiety assessment) for five minutes. After the behavioral assay, animals were euthanized, brains were collected and processing. Sections from the amygdala were obtained for immunohistochemistry using HIF-1α (hypoxia indicator) and SMI-71 (BBB integrity marker). Images were taken at 20x under fluorescent filters and analyzed using ImageJ. Statistical analyzes were performed using JMP Pro 11, $p < 0.05$ considered statistically significant. Anxiety-like behavior, which was measure by the fraction of time spent at the walls of the open field box, was significantly increased in the blast group ($p<0.02$) when compared to sham. Changes in anxiety have been previously reported following blast and could be the neurological manifestation of amygdala injury pathology. Histological results showed that HIF-1α expression was increased around the major vessels in the amygdala at seven days post-blast as compared to sham. In addition, the presence of SMI-71 was decreased in the blast group compared to the sham. These results are indicative of compromised BBB integrity. Characterizing the role of HIF-1α as a systemic responder and secondary mediator after polytrauma is important in understanding injury pathways and how they can contribute to behavioral deficits. The presence of HIF-1α in blast injury modes can direct therapeutic interventions for BINT. Elucidating the temporal response of HIF-1α after BINT and subsequent inflammatory pathways will provide more understanding of injury progression.

Title: Longitudinal characterization of gait disturbances following repeated mild traumatic brain injury in rats

Authors: *A. MOUNTNEY, J. FLERLAGE, C. RHO, W. YANG, F. TORTELLA, D. SHEAR; Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Concussion management represents a significant clinical challenge, particularly in soldiers and professional athletes who are at increased risk of sustaining repeated concussions. The current study is part of a larger series of studies designed to evaluate the critical time-frame during which the injured brain remains most vulnerable to a second concussion. This study assessed effects of multiple concussions occurring at different intervals on sensorimotor function. Rats were exposed to a single projectile concussive impact (sPCI) injury followed by a second PCI injury at 24h ($rPCI_{24H}$) or 7 days post ($rPCI_{7D}$). Sensorimotor abnormalities were assessed using the CatWalk gait analysis system, the neurological severity score-revised (NSS-R) and rotarod. Single PCI injury produced subtle, yet significant differences in fine sensorimotor parameters such as stance, swing speed, and step cycle with no overt changes in coordination (regularity index). All PCI-injured animals showed decreased cadence, increased stance, and decreased swing-speeds. Deficits were equally distributed between the four limbs and appeared acutely, with progressive resolution over 2-7 days post-injury. Regardless of injury interval, the majority of changes were detected at 2h post-injury. By 24h post-injury, sPCI, $rPCI_{24H}$ and $rPCI_{7D}$ showed 80%, 63%, and 100% reductions in abnormal gait parameters, respectively. Critically, all PCI-injured animals exhibited a bi-phasic profile showing delayed reemergence of gait abnormalities. Specifically, at 28d the $rPCI_{24H}$ group showed the greatest number of gait alterations (19) compared to sPCI (6) and $rPCI_{7D}$ (12). Animals subjected to repeated concussion at 24h intervals displayed significant changes in interlimb support, adopting an overly reliant tri-limb walking pattern. Additionally these $rPCI_{24H}$ rats exhibited significant deficits in motor learning capacity (rotarod task) and highest NSSR scores, indicative of chronic neurologic damage compared to all other groups. Overall, we found that repeated concussion significantly altered sensorimotor function with the greatest decrements evident with two concussions occurring within 24h. Additional studies are ongoing to evaluate effects of different intervals between hits (i.e. 48 to 72h) and to identify potential correlations between sensorimotor and molecular changes. However, these initial results provide further validation for usefulness of the PCI model as a research tool to better understand the time frame during which the injured brain is more vulnerable to repeat concussions and, ultimately, to evaluate the therapeutic efficacy of promising treatment strategies.

Title: Language impairments in traumatic brain injury: A case series

Authors: *M. HALL, L. CLOUTMAN, A. WOOLLAMS;
Sch. of Psychological Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: Cognitive deficits and cortical lesions are common following traumatic brain injury (TBI). Research into language deficits resulting from TBI is scarce. As there are many aspects of language controlled by various regions and language is also underpinned by executive control, it can be expected that language impairments would occur following TBI. We aim to determine if language deficits occur in this group and if they can be attributed to common cortical lesions. Four TBI patients (P1-4; age range 29-48), recruited from community groups, completed neuropsychological tasks designed to examine general cognition and various aspects of language functioning. Reaction times (RT) were also recorded. Using automated lesion identification software, participants' T1 weighted MRI images were segmented into grey/white matter images, smoothed, and compared with control data (18 healthy controls aged 18-30) to identify abnormal voxels. Lesions were grouped, defined and lesion overlay maps generated which were then compared to behavioural data. P1 and P2 had overlapping right frontal and callosal lesions. Performance was worse in general cognition, reasoning, visuospatial abilities, semantics and orthographics. P1 had increased RT globally and P2 showed increased RT for semantics. P3 also showed overlapping abnormal voxels in the corpus callosum and a small lesion in the left cerebellar lobe. Performance was impaired on executive functioning and orthographics. P4 had no lesions. However, executive performance was impaired. The results suggest that right frontal regions and the corpus callosum may play a role in semantics and orthographic processing as well as visuospatial and executive functioning. These areas may also play a role in speed of functioning. However, given the small sample size this needs to be explored further. The absence of cortical lesions in P4, despite impaired performance on executive tasks, highlights the need for more complex imaging such as diffusion tensor imaging and anatomical connectivity mapping as white matter injury may account for impaired performance.

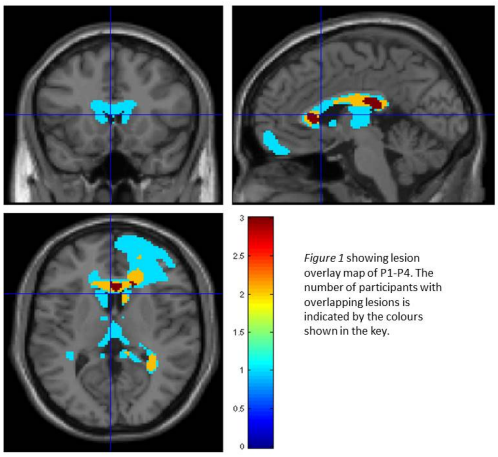

Figure 1 showing lesion overlay map of P1-P4. The number of participants with overlapping lesions is indicated by the colours shown in the key.

Abstract: The mechanisms by which head injury induces acute concussion and chronic sequelae are not known. We examined postmortem brains from young athletes after concussive head injury and found parenchymal contusion, myelinated axonopathy, microvasculopathy, neuroinflammation, neurodegeneration, and phosphorylated tauopathy consistent with early chronic traumatic encephalopathy (CTE). We developed a biofidelic mouse model of impact concussion that induces non-skull deforming head acceleration, acute concussion, and traumatic brain injury (TBI) in non-anesthetized C57BL/6 mice. Impacted mice exhibited contralateral circling, limb weakness, locomotor abnormalities, and impaired balance that recapitulates human concussion. Neurological function rapidly returned to baseline, but markers of early CTE persisted long after recovery. Impact concussion induced blood-brain barrier disruption, neuroinflammation, impaired hippocampal axonal conduction, and defective long-term potentiation (LTP) of synaptic transmission in prefrontal cortex. Kinematic analysis revealed head acceleration sufficient to induce concussion, TBI, and CTE-linked pathology. Notably, concussion did not correlate with CTE markers or chronic sequelae. Concussion was observed following impact injury but not blast exposure under conditions of comparable head kinematics. Dynamic modeling revealed greater brain shear stress during impact compared to blast neurotrauma. These results indicate that while acute concussion and chronic sequelae may be triggered by the same insult, the pathophysiological responses underpinning these effects engage distinct mechanisms and time domains. Concussion per se is neither necessary nor sufficient to trigger acute brain injury and chronic sequelae, including CTE. These results suggest that the critical variable of clinical relevance is neurotrauma exposure (hits).

Title: Visual dysfunction screening in mice after TBI using an optomotor assessment of the optokinetic response

Authors: *S. FERGUSON[1,2], B. MOUZON[1,2], D. APONTE[1], G. CRYNEN[1], V. MATHURA[1], M. MULLAN[1], F. CRAWFORD[1,2];
[1]Roskamp Inst., Sarasota, FL; [2]James A Haley Veterans' Hosp., Tampa, FL

Abstract: Introduction: Our mouse model of repetitive mild TBI (r-mTBI) produces chronic optic nerve pathology and retinal degeneration. In order to assess the visual function of the mice, we have optimized a mechanical optomotor assay to assess the optokinetic response. Methods: The optomotor apparatus consisted of a rotating drum containing black and white stripes at varying angular resolutions. Mice were acclimated to the apparatus for a period of 5 minutes in phototopic lighting. Optomotor testing at each resolution consisted of pairs of 2 minute trials with 1 trial in a clockwise rotation followed by 1 trial in a counter-clockwise rotation with an inter-trial time of 30 seconds. Following the completion of the first pair of trials in photopic conditions, lighting was dimmed to scotopic conditions and the mice were allowed to acclimate for a period of 5 minutes followed by another pair of trials. After the completion of all 4 trials the mouse was returned to the home cage and the next mouse was tested. On subsequent days this testing was repeated with the rotation of the drum increased in a range from 2 to 5 rpm. All trials were recorded with Noldus Ethovision XT. Results: Optomotor testing and optimization revealed a non-random, quantifiable optokinetic response of the mice which was found by excluding the portions of the trial where the mouse was in motion and by quantifying the angular rate of rotation of the head of each mouse. Conclusions: By varying the resolution of the stripes we were able to increase the difficulty of the task and determine the optimal conditions for eliciting an optokinetic response in healthy mice capable of discriminating subtle vision deficits. Varying the rotation rate of the optomotor drum also allowed us to determine the optimal speed for eliciting the optokinetic response. The optimized assay will allow us to accurately assess the functional outcome of potential therapeutics for the treatment of TBI-induced visual dysfunction.

Title: Effect of age and APOE isoform on traumatic brain injury in mice

Authors: *E. L. CASTRANIO[1], A. MOUNIER[1], J. SCHUG[2,3], N. F. FITZ[1], R. KOLDAMOVA[1], I. LEFTEROV[1];
[1]Envrn. and Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA; [2]Functional Genomics Core, Dept. of Genet., [3]Inst. for Diabetes, Obesity and Metabolism, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) is a leading cause of death and disability in army personnel and general population. Recent studies demonstrate that inheritance of the APOEε4 allele may lead to worse outcome following TBI. It is unknown, however, how the deficiency in ATP-binding cassette transporter A1 (ABCA1), which impacts both APOE lipidation and stability, affects outcome after TBI. This study uses mice with targeted replacement of endogenous ApoE by human cDNA for expression of APOEε3 (E3) and APOEε4 (E4), and E3 and E4 mice with only one functional copy of ABCA1 gene. The goal was to determine if age, expression of APOE isoform and ABCA1 deficiency affect cognition and gene expression following TBI. Young adult and aged mice received either a controlled cortical impact (CCI) brain injury or a craniotomy in the left hemisphere. Following three days of recovery, mice underwent multiple motor coordination and cognitive behavior tests. We found that injury causes significant differences in anxiety as tested by elevated plus maze in both young adult ($p < 0.05$) and aged ($p < 0.05$) mice regardless of APOE isoform. Injury also affected performance in Morris Water Maze ($p < 0.05$) in aged mice. In contextual fear conditioning paradigm, expression of APOE isoform had a significant effect ($p < 0.05$) in aged mice. We also found an

effect of Abca1 deficiency in some tests. At the end of the tests, mice were anesthetized and perfused, during which ipsilateral and contralateral cortical and hippocampal tissues were harvested. These tissues were used to perform gene expression analysis through RT-QPCR and RNA-Seq. The outcome of all these tests revealed differences in response to injury in both behavior and RNA gene expression dependent on genotype and age.

Title: Choice impulsivity is increased following frontal traumatic brain injury in rats

Authors: *K. M. MARTENS, C. L. WELLINGTON, C. A. WINSTANLEY, C. VONDER HAAR;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Intro Traumatic brain injury (TBI) is associated with numerous consequences, including chronic changes in cognitive function. Persons with brain injury frequently show sub-optimal or even deleterious choice behavior, resulting in considerable financial, social and work-related strain. Despite the obvious problems for human patients, many animal studies have neglected the study of decision-making following TBI. Methods The current study aimed to explore shifts in impulsive choice behavior following a brain injury using the delay discounting paradigm in rats. Rats were trained on the delay discounting task for 35 sessions. Once choice behavior had stabilized, they were given either a severe (depth: 2.5 mm @ 3 m/s) or mild (depth: 0.8 mm @ 1 m/s) bilateral controlled cortical impact injury centered over the frontal cortex or given either an intact or craniotomy sham procedure to account for effects of surgery. After a week of recovery, they were re-tested on the delay discounting task. Results Both sham groups showed no change from pre-surgery choice behavior and there was no difference between craniotomy and intact shams. Severe TBI caused a large shift towards more impulsive choices, and even mild TBI produced an increase in impulsive choice, although it was less pronounced. Severe injury initially caused a high level of omitted trials which resolved to pre-injury levels by

session 5. Discussion In the current study, we show that choice impulsivity is increased in rats following a frontal TBI. This resembles reports in the clinical literature regarding impulse control problems in human patients. By examining decision-making in animals following a TBI, we are able to more closely mimic the human condition, which could lead to novel and/or improved treatments for brain injury.

Title: Increased cocaine self-administration is associated with changes in neuroinflammatory markers following frontal traumatic brain injury

Authors: *C. VONDER HAAR[1], J.-M. N. FERLAND[1], L.-K. RIPARIP[2], S. ROSI[2], C. A. WINSTANLEY[1];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Physical Therapy and Rehabil. Sci., Univ. of California-San Francisco, San Francisco, CA

Abstract: Intro Clinically, increased risk for drug addiction is becoming a large concern following traumatic brain injury (TBI). Recent reports have suggested that even milder injuries may lead to an increased likelihood of developing drug addiction. However, these concerns have not been evaluated in an animal model of TBI. Methods In the current study, rats were assessed on a cocaine self-administration paradigm following a mild or severe TBI. Rats received either severe (depth: 2.5 mm @ 3 m/s) or mild (depth: 0.8 mm @ 1 m/s) bilateral controlled cortical impact centered over the frontal cortex or sham procedures. After one week of recovery, rats underwent surgery to implant a catheter in the jugular vein. Following another week of recovery, they began the cocaine (or saline as control) self-administration procedure. Rats were placed in an operant chamber for six hours daily for ten days with access to cocaine infusions (0.5 mg/kg/infusion) contingent upon a lever press with a minimum of 40 seconds between infusions and a maximum of 30 infusions per hour. Following self-administration, rats were euthanized the next day and brains collected for analyses. Brains were analyzed in a multiplex ELISA to

determine the levels of various cytokines. Results Both mild and severe brain injury increased the number of presses for and total infusions of cocaine compared to sham animals. Cocaine increased the levels of all measurable cytokines in sham animals compared to saline shams. Brain injury also increased the levels of all cytokines compared to saline shams. However, cocaine in brain-injured animals actually reduced the levels of multiple cytokines relative to their saline controls. Discussion This study demonstrates a novel finding in rats that cocaine intake is increased following a brain injury and that this intake may mediate neuroinflammatory status. This provides experimental evidence for the clinical observations that risk for addiction is increased in brain injury cohorts and identifies a potential mechanism by which this may occur. Further studies will be required to investigate this outcome more fully and determine if therapeutics may be able to reduce the likelihood of addiction in patients with brain injury.

Title: Development and validation of a novel experimental animal model of post-traumatic stress disorder (PTSD)

Authors: ***N. SINGH**, D. GARABADU, S. KRISHNAMURTHY;
Indian Inst. of Technol. (BHU), Varanasi, India

Abstract: Post-traumatic stress disorder (PTSD) develops following exposure to life-threatening trauma. The high prevalence, chronicity, and resistance to treatment underscore the importance of the development of effective therapeutic strategies for PTSD. The establishment of an appropriate animal model of PTSD can elucidate the pathophysiology of PTSD which may help to identify novel and more effective therapeutic strategies. Thus, an optimal animal model would mimic the pathophysiological abnormalities and behavioral characteristics of PTSD and involve exposure to trauma-like events. No single widely accepted animal model of PTSD has been established to date. Recently, we have developed a chronic modified stress re-stress model of PTSD for the evaluation of drugs in its pharmacotherapy which exhibits most of the PTSD-like behavioral and neuroendocrinological abnormalities in rats. Further, to make the model more simpler than the earlier we have hypothesized to replace the force-swim paradigm with foot-

shock as re-stress cue in the previous experimental protocol. In the present study, two different sets of variable stressors (2 hr restraint followed by 20 min forced-swim and halothane anaesthesia (VS+FST); 2hr restraint followed by 2.0 mA shock for 10 sec and halothane anaesthesia (VS+FS)) were subjected to the animals on day-2 of the experimental animals. The re-stress paradigms for VS+FST and VS+FS were forced-swim and foot-shock respectively. Paroxetine (10.0 mg/kg, p.o.) was administered from day-8 to the day-32 of the experimental schedule. PTSD-like symptoms such as anxiety (decrease in percentage in open arm entries and time spent into open arm) during elevated plus maze test, depression (increase in immobility period) during forced-swim test and cognitive deficits (loss in spatial recognition memory) during Y-maze test induced by foot-shock as the re-stressor was higher compared to forced-swim as re-stress cue. The stress subjected rats showed lower plasma cortisone levels, a cardinal feature of PTSD. Moreover, the freezing behavior by foot-shock was elevated on day-8 of the experimental protocol and was found to be consistent throughout the experimental schedule. Paroxetine was able to ameliorate the behavioral and neuroendocrine function in the modified and novel model of PTSD. These observations emphasize the fact that foot-shock-induced PTSD-like symptoms are more precarious than forced-swim-induced PTSD-like manifestations in rats. Hence, this new animal model of PTSD could be more appropriate to evaluate the efficacy of therapeutic agents for PTSD.

Title: Establishment and characterization of a rodent model of repetitive subconcussive traumatic brain injury

Authors: ***M. LONG**[1,2], A. M. FITZSIMMONS[1], K. C. H. PANG[3], V. SANTHAKUMAR[4], B. J. PFISTER[1];

Abstract: Repetitive mild traumatic brain injury (rmTBI) and concussions are major risk factors for long-term cognitive and behavioral impairments. In animal studies rmTBI increases adverse outcomes of subsequent concussive insult. Cumulative head injuries over extended periods are implicated dementia and chronic traumatic encephalopathy (CTE). Curiously, the lack of correlation between clinical history of concussion and histological hallmarks of CTE (McKee et al., 2009) suggest that subconcussive insults may contribute to long-term damage. The paucity of information on cumulative subconcussive insults has led to little guidance in the management of repetitive scTBI within single day, a common occurrence among young adults in sports and combat. We present a model of repetitive scTBI defined by the absence of acute behavioral measures and neuronal degeneration. Wistar rats (21-25 day old) were subjected to lateral fluid percussion injury (FPI) at peak pressures 14±1.0 psi (Group 1) or 10±1.0p psi (Group 2) using a digitally controlled FPI (DcFPI) or received sham injury. Behavioral measures including apnea, righting time, toe-pinch reflex and seizures were assessed immediately after injury. Righting times pressure did not differ between groups with different injury peak pressure (one-way ANOVA, $F(2,37) = 0.550$, $p = 0.582$) Group 1: 148.4±24.65, Group 2: 122.1±25.95, n=13 each, Sham: 117.3±16.4 n=14 each. Seven of 13 group 1 rats exhibited apnea (3.75±0.46s, n=7), but none of group 2 or sham rats (n=5 each) did. Based on the presence of apnea Group 1, scTBI was modeled using FPI at peak pressure of 10 psi. To determine effects on repetitive scTBI, rats received 1, 2 or 3 subconcussive injuries at 5 min intervals. Although there was no hemorrhage or dentate hilar neuronal degeneration after single injury, rats with repetitive insults showed evidence of hemorrhage in the hippocampal fissure despite the absence of acute behavioral signs or hilar neuronal degeneration. Thus, we have a model of scTBI in young rats and demonstrated that repetitive scTBI can lead to the brain hemorrhage that could result in subsequent pathology. The repetitive scTBI model presented here is a valuable tool to assess long-term histological and behavioral deficits following multiple scTBI that occur in athletes and soldiers. Abstract: A novel mouse model of chronic PTSD and repetitive mild TBI with translation to a human clinical population Moustafa Algamal[1,3], Joseph O Ojo[1,2,3], Benoit Mouzon[1, 2, 3,5], Michael Mullan[1, 3] , David Diamond[2, 4], Fiona Crawford[1,2,3,5] Author Affiliation: 1 Roskamp Institute, Sarasota, Florida; 2 James A. Haley Veterans' Hospital, Tampa, Florida; 3 The Open University, Milton Keynes, United Kingdom; 4 University of South Florida (USF). 5 Chronic Effects of Neurotrauma Consortium, Richmond, VA Posttraumatic stress disorder (PTSD) is estimated to affect 20% of returning active duty soldiers engaged in recent conflicts in Iraq/Afghanistan. Very often these population are exposed to a previous history of mild traumatic brain injury (mTBI), which can double the risk for PTSD. Comorbid mTBI and PTSD can be clinically challenging to diagnose in humans, due primarily to the overlap in both conditions, and the heterogeneous nature of some clinical symptoms. This underscores the need to develop a relevant animal model that explores the effects of mTBI and PTSD. We previously developed a novel mouse model of combat related PTSD, involving exposures to predator odor, physical trauma and social instability. This model shows behavioral phenotypes at acute timepoints that are analogous to the first four criteria of the DSMV, namely: recall of traumatic memories, anxiety, and avoidance behavior. In this current study, we have modified our paradigm, including a more chronic repetitive exposure to aversive stimuli, and a new re-exposure paradigm that mimics the aspect of multiple deployments in our model. Additionally, we have included a repetitive concussive injury model into this paradigm, to explore the association between PTSD and repetitive mTBI. In this study, we perform a novel prospective analysis of our animal model on a longitudinal timescale, examining: neurobehavioral, neuroendocrine and neuroimmune phenotypes, metabolite profiles and histological outcomes, at a level that has not been previously employed, and compare these with profiles from human patients. Using multiple extended time points (2weeks, 3 and 6 months post-exposure), we address this major and often underexplored area in the field of PTSD research that has focused primarily on acute consequences of trauma. Generation of these data is currently ongoing. We anticipate that our model will be a good platform to explore targeted biomarkers and treatment strategies in PTSD and repetitive mTBI.
Key words: repetitive mild traumatic brain injury, posttraumatic stress disorder, animal models, neurobehavior, and biochemistry. This study is funded by the Roskamp Foundation.

Title: Transcriptomics of antiepileptogenic targets after traumatic brain injury

Authors: ***A. LIPPONEN**, M. HILTUNEN, J. PAANANEN, N. PUHAKKA, A. PITKÄNEN; Univ. of Eastern Finland, Kuopio, Finland

Abstract: Traumatic brain injury (TBI) is estimated to cause about 10-20% of acquired epilepsies. We hypothesized that transcriptional changes after experimental TBI can be used to screen potential targets for antiepileptogenic (AEG) treatments. TBI was induced with lateral fluid-percussion injury in adult rats. At 3 months post-TBI coronal slices were sectioned to sample the perilesional cortex, thalamus and hippocampus for transcriptome sequencing (RNA-Seq). In the cortex, we found differential expression in 4964, in the thalamus in 1966, and in the hippocampus in 1 gene as compared to controls (adj. $p<0.05$). Biological processes assessed with Gene Set Enrichment Analysis (GSEA) indicated down-regulation of neuronal and ion transport related gene sets and up-regulation of immunity related gene set both in the cortex and thalamus. In the hippocampus, we found a down-regulation in 1 axon guidance gene set. Expression of targets which have previously shown a disease-modifying effect on epileptogenesis in experimental models (n=52) were compared to differentially expressed genes. In the cortex 24 (16 down-regulated, 8 up-regulated) and in the thalamus 9 (5 down-regulated, 4 up-regulated) of the candidate AEG targets had altered expression after TBI. These data show a long-lasting downregulation of genes encoding ion channels and upregulation of genes involved in immune response after TBI. Moreover, majority of the candidate AEG targets were down-regulated at 3 months post-TBI.

Title: Traumatic brain injury elicits hemisphere-dependent motor and memory deficits in C57BL6/J mice

Authors: ***L. D. O'BRIEN**[1], T. M. REEVES[2], A. J. MORALES[1], A. H. LICHTMAN[3]; [2]Anat. and Neurobio., [3]Pharmacol. and Toxicology, [1]Virginia Commonwealth Univ., Richmond, VA

Abstract: Traumatic brain injury (TBI) represents a significant public health problem characterized by clinical cognitive impairments, such as learning and memory deficits. Left-right hippocampal asymmetry has been described in humans, which allows for functional specialization of memory. Murine left-right asymmetries have also been previously noted in hippocampal receptor morphology in mice, showing glutamate receptor content differences from afferents originating in the left or right CA3. Also, hemispheric asymmetries have been reported in long term potentiation of the CA3-to-CA1 system. Here, we examined whether lateral fluid percussion injury over the left or right parietal cortex of C57BL6/J mice produces hippocampal asymmetry of memory function. To address this question, we subjected mice to a moderate/severe (1.92-1.94 atm) injury, and measured impairments in hippocampal-dependent spatial memory tasks of the Morris water maze: 1) acquisition in the Fixed Platform task, and 2) cognitive flexibility in a Reversal task. The expression of spatial memory was assessed in both tasks using a Probe Trial, in which spatial preferences within the maze were measured without access to an escape platform. We also assessed post-injury righting time (a reliable correlate of injury severity), and neurological motor impairments using the Neurological Severity Score (NSS) and the Rotarod task. Left and right lateral injuries produced respective righting times of 391.8±54.3 and 415.0±81.3 s (mean±SEM), significantly greater in magnitude than respective sham control groups, 73.1±6.4 and 76.6±7.9 s (mean±SEM). In the Morris water maze, both injury groups showed similar acquisition rates in the Fixed Platform task as compared to sham controls, but displayed impaired search strategies during the probe trial. Unexpectedly, a left

lateral injury produced impairments compared to sham controls in both acquisition and expression of memory in the Reversal task. In contrast, the right lateral injury did not differ from sham controls in either measure in this task. Motor behavior was also differentially affected by left and right hemisphere injury, with right lateral injury mice displaying neurological motor deficits for 7 days post-injury in the NSS, and up to 14 days in the Rotarod, compared with a left lateral injury of only 1 day in both assays. In conclusion, differences in Morris water maze task-related demands revealed lateralization of TBI-induced cognitive deficits in mice. The results of the present study suggest that TBI may induce hemisphere dependent functional deficits in mice, consistent with CA3 cellular asymmetries previously noted by others.

Title: Lesion-induced brain plasticity: massive increase in neuron number in the monkey amygdala following early or late hippocampal lesion

Authors: *L. J. CHAREYRON[1], D. G. AMARAL[2], P. LAVENEX[1,3];
[1]Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland; [2]M.I.N.D. Inst., UC Davis, Davis, CA; [3]Inst. of Psychology, Univ. of Lausanne, Lausanne, Switzerland

Abstract: Focal brain lesions have been shown to trigger adaptive neuronal plasticity in other, sometimes distant, brain areas. Here, we investigated the effects of early and late hippocampal lesions on the fate of a population of Bcl-2-positive, immature neurons found in the ventral part

of the primate amygdala, mainly in the paralaminar nucleus. Four groups of adult rhesus monkeys were studied: 7 unoperated controls, 8 early-lesioned monkeys that received complete bilateral hippocampal lesion soon after birth, 6 late-lesioned monkeys that received complete bilateral hippocampal lesion in adulthood, and 2 lesioned monkeys with limited bilateral hippocampal damage that occurred naturally. First, confocal analyses confirmed that the immature neurons present in the ventral amygdala express both the neuron-specific marker NeuN and the anti-apoptotic marker Bcl-2. Second, using Nissl-stained sections, we performed stereological analyses of the numbers of mature and immature neurons in the paralaminar nucleus, and the adjacent lateral and basal nuclei of the amygdala. Compared to controls, we found that: (1) the number of mature neurons was larger in the paralaminar nucleus of early-, late- and naturally-lesioned monkeys; (2) the number of mature neurons was larger in the lateral nucleus of early- and naturally-lesioned monkeys; (3) the number of mature neurons was larger in the basal nucleus of early-lesioned monkeys. In controls, these three nuclei combined contained 3.7 million mature neurons; we found 5.3 million neurons in early-lesioned monkeys (+43%), 4.0 million neurons in late-lesioned monkeys (+8%) and 5.0 million neurons in naturally-lesioned monkeys (+35%). Interestingly, compared to controls, the number of immature neurons contained in the paralaminar nucleus was higher in early-lesioned monkeys (+38%) and lower in late-lesioned monkeys (-27%). These observations suggest that early hippocampal lesion is followed by (1) the maturation of immature neurons present in the paralaminar nucleus and their integration in the lateral, basal and paralaminar nuclei of the amygdala; and (2) the replacement of a large number of these immature neurons by new cells that possibly migrate from the ventricular zone. In contrast, late hippocampal lesion is followed by the maturation of immature neurons and their integration in the paralaminar nucleus; but it is not accompanied by a replacement of this population of immature neurons. These findings reveal a new mechanism of lesion-induced brain plasticity, characterized by the maturation of immature neurons and their integration in a brain structure interconnected with, yet clearly distinct from the lesioned area.

Title: Head-down tilt as a model for intracranial hypertension during spaceflight

Authors: *C. A. FULLER, H. GOMPF, E. L. ROBINSON, T. M. HOBAN-HIGGINS;
Dept of Neurobiology, Physiol. & Behavior, Univ. of California, Davis, CA

Abstract: Introduction: One of the responses to exposure to the microgravity spaceflight environment is a pronounced cephalic fluid shift. Recent evidence documents ocular changes in astronauts following long-duration missions including optic disc edema, globe flattening, choroidal folds and hyperopic shifts. These changes are hypothesized to result from this cephalic fluid shift, as these ocular effects are similar to those seen in terrestrial Idiopathic Intracranial Hypertension (IIH). Long duration missions are currently being undertaken on the International Space Station (ISS) and planning for manned missions to Mars has begun. This project aims to simulate the long-term microgravity cephalic fluid shift using a well-established terrestrial rat model with the objective of establishing a ground-based model for studying CNS changes observed in space. Methods: We are using the rat hindlimb suspension (HLS) model, functionally equivalent to human head-down bedrest (a human terrestrial model of cephalic fluid shift), to examine the relationship between cephalic fluid shifts and the regulation of intracranial pressure (ICP) as well as visual system structure and function. Rats are suspended for 90 days, which is roughly equivalent to the proportion of the lifespan astronauts would dedicate to an exploration class mission, followed by 90 days of observation during recovery in a vivarium cage. All HLS subjects have age-matched cage controls. All animals have ad lib access to food and water. A 12:12 LD cycle is present. Finally, we are also investigating the role of gender and age in these responses. Data collected include ICP, electroencephalogram (EEG) and body temperature (by telemetry) and repeated MRI during HLS and recovery. Brains will be collected for histology from a subset of animals after 90 days of HLS. The study includes three cohorts: young adult male, young adult female, and older middle-age adult males, roughly equivalent in age to most mission-ready astronauts. Results and Conclusions: Results to date indicate a pronounced and sustained increase in ICP during early HLS. This will form the basis for examining anatomical and indications of functional changes found in the MRI images and histology.

Title: A mouse model of blast-induced mild traumatic brain injury that yields behavioral deficits and neuron injury is associated with neuroinflammation in the forebrain

Authors: *B. T. WRIGHT, Y. GAO, S. A. HELDT, W. BU, Y. DENG, N. DEL MAR, M. G. HONIG, A. J. REINER;
Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Mild traumatic brain injury (mTBI) is a common occurrence in combat as well as sports and vehicular accidents. Many mTBI sufferers display persistent neuropsychiatric symptoms that overlap with post-traumatic stress disorder (PTSD), including heightened fearfulness and anxiety - functions normally ascribed to the amygdala. Using a closed-head, high pressure air blast model of mTBI in mice (Heldt et al, Frontiers Neurol, 2014), we have demonstrated the presence of diffuse axonal injury (DAI) in brain, a signature pathology in mild TBI, as well as more recent evidence of neuron loss (Bu et al., SFN 2015). Furthermore, blasted mice showed neuropsychiatric deficits including fearfulness and anxiety (Heldt et al, Frontiers Neurol, 2014). In the present study, we examined neurochemical changes in the brain after mTBI caused by left side focal cranial blast. As a microglial inflammatory response is thought to occur after brain trauma and to worsen the outcome, we assessed the expression of inflammatory markers, using quantitative RT-PCR in forebrain tissue samples taken from mice exposed to blast mTBI versus non-blasted sham controls. Our results indicate that microglial and inflammatory markers are increased in the left forebrain in blasted mice. For example, cannabinoid receptor type-2 (CB2) message appeared to be elevated at 6 hours post blast. As CB2 expression in brain is largely limited to microglia, the elevated CB2 is suggestive of post-blast microglial activation. Immunolabeling for IBA1 showed that microglia are activated in many brain regions, particularly in fiber tracts in which axonal damage was observed, such as the optic tract, pyramidal tract, lateral lemniscus, and medial lemniscus. In forebrain, quantitative RT-PCR showed that interleukin1-beta, tumor necrosis factor-alpha and interleukin-10 expression were elevated at 6 - 24 hours after blast, and tumor necrosis factor-alpha remained elevated at 48 hours. The increase in expression of cytokines we observed indicates a brain inflammatory response in our TBI model. This inflammatory response could play a role in worsening the severity of the outcome after blast. Consistent with this, we have found that a CB2

receptor inverse agonist that mitigates the microglial inflammatory response reduces deficits and brain pathology in our mTBI model (Reiner et al, Int J Molec Sci 2015).

Title: Radial water tread maze distinguishes cognitive deficits in mice with traumatic brain injury and Alzheimer's disease

Authors: *M. M. CLINE[1], J. YUMUL[2], L. HYSA[2], D. MURRA[2], E. BRIM[2], G. GARWIN[1], W. C. LADIGES[3], S. MINOSHIMA[4], D. J. CROSS[1];

Abstract: Introduction: Interspecies differences create challenges when using cognition tests designed for rats to assess mouse models. The most common such test, the Morris water maze, capitalizes on rat swimming ability by employing a forced-swim paradigm: a task aversive and difficult for mice. Mouse models of traumatic brain injury (TBI) and Alzheimer's disease (AD) are susceptible to compounding factors such as impaired motor function and stress-induced non-compliance during forced-swim testing. We evaluated the ability of a Radial Water Tread (RWT) maze, designed specifically for mice and requiring no swimming, to distinguish between Sham and TBI, as well as AD and wild type (WT) models. Methods: Male C57BL/6J mice 10-weeks old (n=29) were randomly assigned to receive craniotomy (Sham, n=14) or craniotomy plus controlled-cortical impact (Impact One, Leica Biosystems) surgery (TBI, n=15). RWT maze was acquired on a subset of mice at 11 days (early time point; Sham=8, TBI=9) and 35 days (late time point; Sham=6, TBI=6) post-injury. For our AD model, male 3xTg-AD mice (n=4) aged 56.7 weeks were tested and compared with age matched WT controls (n=5). Briefly, the testing

apparatus consisted of a 32-inch tub with one escape and nine decoy holes spaced evenly around the device, and filled with roughly 1½ inch of 12-16 °C water. Five unique visual cues lined the apparatus. RWT testing consisted of 3 trials/day for 4 days, short-term memory test at day 5, and long-term memory at day 12. Results: RWT maze successfully distinguished between Sham and TBI 11 days post-injury on both short and long-term testing days (day 5; 20.80±14.68s vs. 48.58±37.65s & day 12; 10.85±8.09s vs. 70.54±57.78s for Sham and TBI respectively), and long-term testing 35 days post-injury (19.88±20.11s vs. 61.06±31.96s; $p<0.05$). In our AD model, RWT maze successfully distinguished between AD and WT at both short and long-term memory tests (day 5; 143.83±43.02s vs. 64.2±59.84s & day 12; 138.33±52.05s vs. 33.4±49.11s), as well as 3 out of the 4 training days. Conclusion: The RWT maze was designed to capitalize on mouse instinctual behavior and presents a novel alternative to rat-biased cognition tests. Our results lend validation to the use of this apparatus in both TBI and AD mouse models.

Title: The role of tau and other pathologies in an animal model of repetitive mild traumatic brain injury

Authors: ***B. C. MOUZON**[1,2,3], C. BACHMEIER[1,3], J. OLUBUNMI[1,3], S. FERGUSON[1,2], V. MATHURA[1,3], C. LYNCH[1,3], R. WILLIAMS[4], E. MUFSON[5], F. CRAWFORD[1,3,2];
[1]The Roskamp Inst., Sarasota, FL; [2]James A. Haley Veterans' Hosp., Tampa, FL; [3]The Open Univ., Milton Keynes, United Kingdom; [4]RTI Intl., Research Triangle Park, NC; [5]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The Chronic Effects of Neurotrauma Consortium or CENC is dedicated to understanding the chronic sequelae associated with neurotrauma, primarily focused on mild TBI (mTBI)/concussion incurred by U.S. service personnel. However, little is known about the

timeline and sequence in which tau is processed following TBI, nor about the relationship with other TBI-dependent neuropathologies such as neuroinflammation and cerebrovascular changes. This study is evaluating tau alterations and accompanying neuropathologies over time after r-mTBI in hTau transgenic mice. hTau mice aged either 8-12 weeks will receive either r-mTBI or r-sham in order to control for effects of repeated anesthesia. Mice will be euthanized for neuropathological, genomic and biochemical analyses at 24hrs, 5, 10 and 15 days, 3, 6 and 12 months after last mTBI/anesthesia. For the 15 day and 3, 6 and 12 month time points post injury mice will undergo a battery of neurobehavioral test in the 2 weeks immediately prior to euthanasia. The entire paradigm is being replicated in hTau mice aged 12 months at the time of injury, to study the effects of age at time of injury. r-mTBI in the young cohort shows learning impairment post injury that progressively worsens from 2 weeks to 12 months. To date, Tau IHC and ELISA results suggest that r-mTBI is associated with a transient injury dependent increase in p-tau accumulation with greater dendritic and membranous staining in the cerebral cortex beneath the impact site without neurofibrillary tangles. While a trend for an increase in aggregated tau at 12 months post injury was observed, r-mTBI was not associated with elevated brain levels of abnormal soluble tau phosphorylation. This study is ongoing and will take several years to complete; our previous data suggest that neuroinflammatory pathology is key in this model and that TBI-dependent tau pathology will be evident in the older mouse models where tau pathology already exists.

Title: Impaired fatty acid oxidation after traumatic brain injury exaggerates the glial response and promotes cell death

Authors: *J. N. JERNBERG[1], C. BOWMAN[2], M. WOLFGANG[2], J. LEE[2], S. SCAFIDI[1]; [1]Anesthesiol. and Critical Care Med., [2]Biol. Chem., Johns Hopkins, Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a leading cause of permanent life-long disability and is characterized by deficits in cognition, attention and sensory-motor integration. Impaired oxidative glucose metabolism following TBI further contributes to cell death. The role of fatty acid (FA) oxidation after TBI, however, is unknown. Mitochondrial β-oxidation of fatty acids supports energy production and metabolic homeostasis, especially during the periods of fasting and stress. To be oxidized in mitochondria, fatty acids must be converted to acyl-carnitine esters by transfer of acyl groups to l-carnitine. This reaction is catalyzed by Carnitine Palmitoyl Transferases (CPT1a and CPT2), which are located on the outer and inner mitochondrial membranes respectively. Only then are acyl-carnitines transported into mitochondria to support oxidative metabolism. This study is the first to explore the role of fatty acid oxidation after TBI. To determine the requirement of mitochondrial fatty acid β-oxidation after TBI, Cpt2 floxed mice to Nestin-Cre mice (Cpt2N-/-), which cannot oxidize fatty acids within the brain, were generated. TBI was administered using a controlled cortical impact to the left parietal cortex and tissue was collected for histology 7 days post-injury. Using immunofluorescence, we determined that astrocytes are the only cells expressing CPT1a and CPT2 in WT mice, thus the only cells able to use fatty acids for energy and metabolism. CPT1a also colocalizes with the astrocytic marker GFAP in CPT2 KO mice. Iba1 expression was increased and microglia demonstrated a more activated M1 phenotype in CPT2 KO mice relative to WT, particularly within the hippocampus. GFAP was also increased in KO relative to WT after TBI. Lesion size was greater in CPT2 KO than WT. Fatty acid oxidation in the cortex and hippocampus was measured using [1-14C] oleic acid, and oxidation was increased after TBI in the ipsilateral hippocampus but not in the cortex. This study provides strong evidence that 1) astrocytes selectively oxidize fatty acids for energy and metabolism 2) brain-specific knockout mice unable to utilize long chain fatty acids exhibit increased astrocytic and microglial activation after TBI, as well as 3) increased lesion size relative to wild-type controls. These results indicate that fatty acid oxidative metabolism may be beneficial in promoting neuronal survival and reducing TBI-induced glial activation.

Title: Human chorionic gonadotropin treatment improves cognitive and motor performance following focal penetrating traumatic brain injury in adult male rats

Authors: *R. I. GEDDES, K. HAYASHI, M. WEHBER, R. A. RAUH, S. V. MEETHAL, C. S. ATWOOD;
Emergency Med., Univ. of Wisconsin at Madison, Madison, WI

Abstract: Traumatic brain injury (TBI) is a major US public health issue with ~270,000 people experiencing a moderate or severe TBI each year that results in chronic deficits to cognitive and motor function. Unfortunately, to date there is no satisfactory therapeutic intervention for TBI. The spontaneous, although often incomplete, cognitive recovery that occurs following TBI is thought to involve neuroregeneration that includes neurogenesis. Neurogenesis during embryogenesis and adulthood is driven by the key neurohormones gonadotropins and sex steroids. However, the stress from a TBI has been shown to markedly suppress circulating gonadotropin and sex steroid concentrations. In this study, we tested whether chronic administration of human chorionic gonadotropin (hCG), a neurodevelopmental gonadotropin, would promote neurogenesis in the adult brain thereby acting to enhance functional recovery. Male Sprague Dawley rats at 5 months of age were subjected to sham surgery (craniectomy) or a focal penetrating TBI using a controlled cortical impact (CCI) device (Hatterras, Inc.), n = 5-7 rats per group. hCG (200 mIU/kg) was administered intramuscularly at 1 h post-surgery and every 48 h thereafter for 28 d. Behavioral analyses were performed and plasma sampled before and 24 h post-CCI and weekly thereafter for assessment of cognitive and motor function, and circulating sex hormones, respectively. When compared to CCI-injured vehicle-treated rats, hCG-treatment (1) significantly increased the latency to fall off the rotarod in CCI-injured male rats by ~30 seconds or 20% (170 seconds vs. 135 seconds) over repeated testing, $F(25,135) = 3.994$, $p < .0001$) and (2) reduced the latency to reach the hidden Morris water maze platform by ~12 seconds or 34% (23 seconds vs. 35 seconds), $F(35,189) = 3.722$, $p < .0001$), while having (3) no effect on CCI-induced decrease in the distance travelled in an open field tasks (p's $> .05$) or (4) the surface area of the cortical contusion site ($p > .05$). A more in-depth analysis of lesion volume, as well as plasma hormones, cell death, inflammation and hCG-induced neurogenesis are currently underway. Importantly, non-surgical control (NSC) and sham-injured animals given hCG did not perform different from vehicle-treated NSC and sham-injured animals on any measures. We speculate that hCG mediates improvement in functional performance via decreasing inflammation and edema while promoting neurogenesis. hCG, a readily available neurohormone, may provide a physiological means of promoting functional improvement in the recovery from TBI.

Title: Neuropathological alterations in the hilus after diffuse brain injury

Authors: M. R. GROVOLA[1,2], J. P. HARRIS[1,2], D. CULLEN[1,2], *J. A. WOLF[2,1]; [1]Neurosurg., Philadelphia Veterans Affairs Med. Ctr., Philadelphia, PA; [2]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Each year in the United States, over 1.5 million people experience mild traumatic brain injury (mTBI) and recent studies suggest that mTBI is associated with long term physical and mental health problems. Functional and structural changes induced by mTBI may occur in the hippocampus, with the hilar region showing particular vulnerability in other models. Mossy cells, one of the predominant cells in the hilar region, have been a focus of attention due to their potential role in post-TBI hyperexcitability. The objective of the current study was to assess mossy cell pathology and microglial changes after a range of mTBI injuries. 5-month-old Yucatan swine were induced with mTBI using a coronal rotational head injury model of diffuse brain injury. Swine were subjected to sham conditions or coronal plane rotations at peak velocities of 180, 220, or 260 rad/sec. Neuropathological changes in the hilar region of the hippocampus were assessed at 6 hour, 7 day, and 14 day time points. Whole coronal sections of tissue were labeled with antibodies for MAP2, a microtubule associated protein, Synapsin, a pre-synaptic protein, and IBA1, a calcium binding protein used as a microglia marker. Using confocal microscopy, we measured the mossy cell somal area using MAP2, and visualized synaptic and microglial locations using Synapsin and IBA1 respectively. We observed the prevalence of microglia migrating within the synaptic clouds and their processes engulfing mossy cells in injured specimens, suggesting that microglia are recruited post-injury to remove disrupted synaptic components around mossy cells. Additionally, quantitative analysis of mossy cell somal area has demonstrated an increase in somal area at 7 day and 14 day time points post-

injury compared to sham and 6 hour time points. This alteration of mossy cell area paired with the increase of microglia processes around the cell demonstrates the vulnerability of hilar mossy cells after time points post-mTBI. Moreover, mTBI-induced hilar mossy cell pathology may lead to aberrant activity. This activity may effect dentate granule cells along the entire dorsoventral axis and enhance perforant path inputs.

Title: Diffuse traumatic brain injury affects chronic corticosterone levels and alters neuron morphology in the paraventricular nucleus

Authors: ***T. C. THOMAS**[1,3,4], R. K. ROWE[1,3,4], B. M. RUMNEY[5,3,2], H. G. MAY[5,3,2], C. D. CONRAD[6], S. M. HARMAN[4], P. A. PERMANA[4], P. D. ADELSON[3,2,6], J. LIFSHITZ[2,3,4,6]; [1]Dept. of Child Hlth., [2]Univ. of Arizona; Col. of Med. - Phoenix, Phoenix, AZ; [3]BARROW Neurolog. Inst. at Phoenix Children's Hosp., Phoenix, AZ; [4]Phoenix VA Hlth. Care Syst., Phoenix, AZ; [5]Univ. of Bath, Bath, United Kingdom; [6]Arizona State Univ., Phoenix, AZ

Abstract: As many as 20-55% of patients with a history of traumatic brain injury (TBI) experience chronic endocrine dysfunction, leading to impaired quality of life, impeded rehabilitation efforts, and lowered life expectancy. Endocrine dysfunction after TBI is thought to result from acceleration-deceleration forces to the brain within the skull, creating enduring hypothalamic and pituitary neuropathology, and subsequent hypothalamic-pituitary (HP)-axis

dysfunction. These experiments were designed to test the hypothesis that a single diffuse TBI results in chronic dysfunction of corticosterone (CORT), a glucocorticoid released in response to stress, with evidence of structural damage to the HP-axis. We used a rodent model (adult, male Sprague-Dawley rats) of diffuse TBI induced by midline fluid percussion (mFP). At 2 months post-injury, circulating levels of CORT were evaluated at rest, under restraint stress and in response to dexamethasone, a synthetic glucocorticoid commonly used to test HP-axis regulation. Further, we assessed changes in injury-induced neuron morphology (Golgi stain) and neuropathology (silver stain) in the paraventricular nucleus (PVN) of the hypothalamus. Resting plasma CORT levels were decreased by ~60% at 2 months post-injury and the dynamic release of CORT in response to restraint stress was significantly reduced in injured animals. TBI also altered complexity of neuron processes in the PVN over time. In order to determine when changes in CORT dysfunction were first detectable, a second cohort of animals containing sham, mild and moderate injured animals had repeated blood draws and restraint stress over two months. Resting CORT levels were significantly decreased in all test groups compared to baseline levels by 14 days post-injury ($p<0.05$), indicating that repeated exposure to stress masks the injury effect. Results provide evidence that a single moderate diffuse TBI leads to hormonal and structural changes, as it pertains to the HP-adrenal axis, which can contribute to the persistence of endocrine dysfunction.

Title: The effect of prolonged sleep deprivation on cognitive and behavioral outcomes following mild traumatic brain injury

Authors: R. CHIARIELLO[1], A. SHAH[1], N. WILKINS[1], M. BUDDE[1], C. OLSEN[2], F. A. PINTAR[1,3], D. THOMAS[4], *B. D. STEMPER[1,3];
[1]Dept. of Neurosurgery, Med. Col. of Wisconsin, Milwaukee, WI; [2]Dept. of Pharmacol. and Toxicology, Med. Col. of Wisconsin, Milwaukee, WI; [3]Veterans Affairs Med. Ctr., Milwaukee, WI; [4]Dept. of Pediatric Emergency Med. Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Mild traumatic brain injury has become an increasing concern in military personnel and athletes. There may be clinical uncertainty regarding whether or not to allow individuals to rest immediately following an exposure. In some cases, sleep may be interrupted for extended periods during deployment. The objective of this study was to delineate the confounding effects of sleep deprivation and TBI. Anesthetized female Sprague-Dawley rats were exposed to head rotational acceleration at a peak magnitude of 334 krad/s2 and pulse duration of 3.7 ms. Sleep-deprived control rats were exposed to a sham procedure that was identical to the injury protocol without head rotational acceleration. Immediately following exposure, animals (n=9 injured (SDTBI) and n=8 controls (SDC)) were placed on an analog orbital shaker for 48 hours. Repetitive on/off cycling of the shaker, which was set at 100 rpm, was controlled by a timer on a 120 second cycle (30s on, 90s off). An injured group of non-sleep-deprived animals (n=8, NSDTBI) was used for comparison. Cognitive and behavioral assessments including Morris Water Maze (MWM) and Elevated Plus Maze (EPM) were conducted on days 3-7 post injury. The SDTBI and SDC groups spent more time in the open arms of the EPM than the NSDTBI group (+29% and +33%, respectively), indicating decreased inhibition for rats receiving the sleep deprivation protocol. The total distance traveled was also greater for the SDTBI (+17%) and SDC (+16%) groups than for the NSDTBI group. The SDTBI group demonstrated an increased number of unsuccessful trials in the MWM (23% and 51% greater than the NSDTBI and SDC groups, respectively). A trend approaching significance (p=0.057) was seen in the latency to find the platform in the MWM. The SDTBI group took longer to reach the platform (24 seconds) than both the SDC (19 seconds) and NSDTBI (20 seconds) groups. These findings demonstrate a complex relationship between prolonged sleep deprivation and TBI, with sleep deprivation dominating acute changes in emotionality and coupled sleep deprivation with TBI leading to a dramatic acute increase in cognitive deficit. This finding is significant as our prior work highlighted significantly increased acute changes in emotionality for NSDTBI compared to controls that did not receive TBI or SD. However, cognitive testing demonstrated a different trend with SD plus TBI producing significant deficits compared to SD or TBI alone. Assessment of the chronic effects of sleep deprivation and TBI is an ongoing focus of these studies.

Title: Gamma-decanolactone effects on pilocarpine-mediated seizure in mice and oxidative stress parameters in N9 Cells

Authors: *P. PEREIRA[1], P. PFLÜGER[1], V. COELHO[1], L. DA SILVA[1], C. VIEIRA[1], N. BERWIG[2], R. STAUB[2], C. VIAU[2], J. SAFFI[2];
[1]Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil; [2]Univ. Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, Brazil

Abstract: Gamma-decanolactone (GD) is a monoterpenic compound that has demonstrated dose-dependent hypnotic, anticonvulsant, and hypothermic activities. In previous studies, *in vivo* and *ex vivo*, it has shown a protective effect on seizures induced by pentylenetetrazol and it has been able to inhibit the glutamate binding in cortex homogenate. The goal of this study was to evaluate the effect of GD on pilocarpine-induced seizures in mice and on oxidative stress parameters in N9 cell. To evaluate the effect of GD on pilocarpine-induced seizures, mice received the controls or GD (100 and 300 mg/kg), 30 min before the pilocarpine injection (250 mg/kg, i.p.). The latency to the first seizure and the occurrence of clonic seizure ≥ 3 seconds were observed during 1 h. The murine N9 microglial cell line was obtained by immortalization of embryonic brain cultures with 3RV retrovirus carrying an activated v-myc oncogene and was grown in RPMI. Cells (1 × 104 cells/mL) were seeded on 6-well tissue culture plates and grown for 1 day up to 70-80% confluence before treatment with the test compound. In all tests, N9 microglial cells were pretreated with GD (10, 50 and 100μM) for 20 hours and exposed to LPS (1μ/mL) for 4 h. Cell viability was measured by Trypan blue exclusion assay (TB). Reactive oxygen species (ROS) detection and quantification of cleaved caspase-9 were performed by flow cytometric analysis. After the treatment, the total protein was obtained using RIPA buffer and Western blot analysis was performed using anti-iNOS antibodies. Antigens were detected using the chemiluminescence technique. Image analysis was performed using an analysis software. The effect of GD on DNA was evaluated by Comet Assay. Data were analyzed by Fisher Test or ANOVA followed by Tukey or Student-Newman-Keuls. The highest dose of GD significantly increased the latency to onset of first seizure; however, the percentage of seizure was not significantly reduced. GD was not cytotoxic at the doses tested in N9 cells. At 50 and 100 μM doses GD inhibited the formation of ROS (DCF). It reduced DNA damage and the expression of caspase 9, an important pathway which regulates apoptosis. Moreover, GD decreased the expression of iNOS protein, one of the factors involved in inflammation processes. To conclude, the results indicated the highest GD dose (300 mg/kg) was able to alter parameters associated with pilocarpine-mediated seizures in mice. The results also suggested that GD at 50 and 100 μM

had a protective effect against the harmful consequences caused by LPS-induced oxidative stress, inflammation, and cell damage.

Title: An animal model of brain reversible vasogenic edema

Authors: *S. KIMURA[1], Y. YANG[2], J. THOMPSON[2], Y. YANG[3], L. SILLERUD[2], G. ROSENBERG[2];

Abstract: [Introduction] Brain vasogenic edema, defined by the disruption of the blood-brain barrier, is a fundamental and clinically common pathological condition in several neurological diseases. Posterior Reversible Encephalopathy Syndrome (PRES) is unique in that it is one of the few diseases which presents only with vasogenic edema and whose clinical course is usually reversible. Although vasogenic edema is heterogeneous in prognosis, the present paradigm could not determine the reversibility. [Methods] SHR-SP rats were treated with high-dose cyclosporine A to induce encephalopathy mimicking PRES. The recovery from the encephalopathy was achieved by the cessation of cyclosporine A. The extent and recovery of neurological symptoms and brain lesion were monitored by neurological score, behavioral tests, and MRI. Blood-brain barrier leakage was histologically confirmed. [Results] Rodent PRES model showed neurological symptoms and worsening scores in behavior tests, whose manifestations disappeared after the recovery. Brain lesions of PRES model revealed IgG leakage, suggesting the presence of vasogenic edema. This PRES model presented some characteristic changes in FA and ADC signals. [Conclusion] These results suggest that our PRES model represents reversible vasogenic edema. Fluid leakage in vasogenic edema may be the cause of FA change in PRES model.

Title: Differential effects of seed extracts of citrus fruits against hydrogen peroxide-induced toxicity in SH-SY5Y cells

Authors: *K. SUEN[1], W. TANG[1], P. HAU[1], H. MA[1], P. CHOW[1], Y. HUNG[1], P. SHI[1], W. CHAU[1], W. CHAN[1], C. CHANG[2];
[1]Po Leung Kuk Laws Fndn. Col., Hong Kong, China; [2]Anat., The Univ. of Hong Kong, Hong Kong, China

Abstract: Some plant seed extracts have been reported to offer neuroprotection (Okada and Okada 2013; Yang et. al. 2012). The neuroprotective effects of seed extracts from *Citrus limon* (Common name: Lemon) and *Citrus margarita* (Common name: Kumquat) have not yet been studied. It is believed that oxidative stress is most likely to act in some neurodegenerative processes. Agents that have antioxidant effects may possess neuroprotective functions. In the present study, the neuroprotective effects of seed extracts from two types of citrus fruits which are *Citrus limon* and *Citrus margarita* are examined. The extracts were prepared by dissolving the powder of ground fresh seeds in DMSO or ethanol and insolubles were filtered out by 0.22 μm membrane filter. Non-differentiated SH-SY5Y cells were pre-treated with either *Citrus limon* or *Citrus margarita*'s seed extract for 24 hours in DMEM supplemented with 2% fetal bovine serum. Following the removal of the seed extract, SH-SY5Y cells were treated with 500 μM of hydrogen peroxide for 24 hours in DMEM with 2% fetal bovine serum. Results indicated that the seed extract of *Citrus margarita* can significantly reduce toxicity induced by hydrogen peroxide. Yet, *Citrus limon*'s seed extract did not show attenuation of hydrogen peroxide-induced cytotoxicity. This implicates that seed extracts from different types of citrus fruits may have different effects against toxicity induced by hydrogen peroxide. The present findings suggest that *Citrus margarita*'s seed extract may offer neuroprotection.

Title: Activation of glp-1 receptors up-regulates apurinic/apyrimidinic endonuclease 1 protects neurons against oxidative dna damage

Authors: *J.-L. YANG, Y.-T. LIN, P.-C. CHUANG, S.-D. CHEN;
Kaohsiung Chang Gung Mem. Hosp., Kaohsiung, Taiwan

Abstract: Neurons are terminally-differentiated non- proliferating cells with a high risk for DNA damage because of their highly metabolic activity. Therefore, DNA repair is important for maintaining DNA integrity and neuronal survival. However, the impaired DNA repair capacity is suggested to play roles in normal aging and aging-associated neurodegenerative disorders. Base excision repair (BER) is commonly suggested being the major mechanism that repairs oxidative lesions, alkylated DNA bases, single-strand breaks, and abasic sites in nuclear and mitochondrial DNA. Therefore, elevating BER efficiency may be one of important mechanisms maintaining neuronal function and survival. Results of the present study has shown that activation of Glucagon-like peptide-1(GLP-1) receptors up-regulates expression of apurinic/apyrimidinic endonuclease 1 (APE1), an important enzyme of BER, via PI3K-Akt signaling pathway in rat primary cortical neurons. We also have observed that treatment of GLP-1 and its analogue rescuing cortical neurons against menadione induced oxidative insults, but the inhibitor of APE1compromised the neuron protective function of GLP-1. Many recent studies suggested that function of GLP-1 is not only decreasing blood sugar, but also acts as a neurotrophic factor and plays a role in neuronal survival, neurite outgrowth, and protecting synaptic plasticity and memory formation from effects of β-amyloid. Our study suggested that GLP-1 up-regulated APE1 enhances neuronal viability via increasing efficiency of BER. Therefore, enhancement of DNA repair efficiency is a potential strategy for prevention or therapeutic intervention in ischemic stroke and neurodegenerative diseases.

Title: Social isolation alters the toxic effects of ethanol in planarians

Authors: T. MCCHARLES, B. LOVELL, N. LANDRY, A. STILLAR, A. WEEKS, *M. J. SAARI;
Nipissing Univ., North Bay, ON, Canada

Abstract: In order to examine the potential interaction between low doses of alcohol and social isolation, planarians (Dugesia dorotocephala), were placed into isolation and exposed to ethanol (EtOH) while motor behaviours were examined. Control, non-isolated planarians were held in groups of ten. The planarians were placed in one of four conditions of EtOH: vehicle (30ml dechlorinated H2O), 1.0%, 1.5%, or 2.0%. These concentrations were chosen based on a pilot study to confirm EtOH thresholds that cause complete immobility of the planarians. Behavioural testing was carried out in a glass dish (10 cm diameter) which was placed on a 1cm x 1cm grid with a 5.35cm diameter interior circle drawn to designate a central field. Each subject was placed into dechlorinated H2O for five minutes, before being transferred to their EtOH condition. After the five minute exposure to the EtOH solution, the planarians were transferred back into the water bath. Motor behaviours, such as grid crossings, environmental surveys (raising the anterior portion of the body), and time spent in the peripheral or central regions of the Open Field were recorded, minute by minute, for each planarian. The results indicated that exposure to EtOH appeared to reduce motor behaviour in a dose dependent manner. A significant interaction was found between social condition and EtOH concentration, with the isolated group showing differences in activity between the highest concentrations of EtOH and the vehicle. Comparable effects were noted for the environmental survey measure. We suggest that social effects may ameliorate the behavioural sensitivity of planaria to toxins, such as EtOH. Title: Development and utilisation of a high content assay to identify putative small molecule modulators of expression and trafficking of the neuronal survival factor NMNAT2

Authors: J. FRANCIS[1], *D. F. FISCHER[2], G. SMITH[1], G. MCALLISTER[1], W. J. RAY[3], M. GECK DO[3], D. VENKITARAMANI[3];
[1]Biol., BioFocus, Charles River, Cambridge, United Kingdom; [2]Biofocus, Charles River, Leiden, Netherlands; [3]Neurobio., Inst. for Applied Cancer Science, MD Anderson Cancer Ctr., Houston, TX

Abstract: The NAD-synthetic enzyme NMNAT2 was recently identified as an endogenous neuronal survival factor acting as a chaperone for neuronal maintenance and protection (1,6). Depletion of NMNAT2 is reported to result in neuronal degeneration in the absence of injury (2), whilst overexpression *in vitro* has been demonstrated to have a protective effect on Wallerian degeneration that is dependent on NMNAT2 enzymatic activity (3). Overexpression of NMNAT2 has also been shown to have beneficial effects on axonal loss *in vivo* in the P301L mouse model of human tauopathy (4). These data suggest that a small molecule able to increase relative levels of cytosolic NMNAT2, for example by increasing the stability/half-life of the enzyme, could have therapeutic potential in a number of neurodegenerative diseases. Here we describe the development of a high content assay for the identification of small molecule modulators of NMNAT2 stability. Using a stable cell line expressing Flag tagged NMNAT2 the half-life of the enzyme was found to be ~ 100 minutes, suggesting this enzyme is fairly labile. Therefor in a pilot screen using a subset of 2000 SoftFocus® kinase targeting compounds were screened for three hours after which the NMNAT2 protein level and subcellular localization was assessed using automated high content imaging. Interestingly, a number of compounds appeared to up-regulate NMNAT2 levels with a 1 % hit rate. Co-localization studies revealed accumulation of NMNAT2 within the trans-golgi network in cells treated with DMSO alone over this time course. However, after compound treatment, modulators of NMNAT2 expression fell into two distinct phenotypic classes; those that up-regulated expression of NMNAT2 in the Golgi and those that appear to promote trafficking of NMNAT2 from the Golgi resulting in an increase of cytosolic NMNAT2 levels. The latter group represent an interesting class of compounds for validation of the role of NMNAT2 localization in its regulation and turnover; this is of particular interest as it has recently been postulated that the cytosolic form of NMNAT2 has an increased half life and is a key determinant in its role in the prevention of neurite degeneration (4). On the basis of this pilot screen, a larger unbiased HTS campaign has been initiated. 1. Zhai.R, Bellen.H. *et. al.* 452, 887-91, Nature. (2008) 2. Gilly.j and M.Coleman PLoS Biol. e1000300 (2010) 3. Title: Insulin receptor substrate -1 protects against neonatal hypoxic-ischemic encephalopathy

Authors: ***Y.-F. TU**[1], H.-I. SHIH[2], C.-C. HUANG[3];
[1]Dept. of Pediatrics, Natl. Cheng Kung Univ. Hospital,, Tainan, Taiwan; [2]Dept. of Emergency Med., [3]Dept. of Pediatrics,, Natl. Cheng Kung Univ. Hospital, Tainan, Taiwan, Tainan, Taiwan

Abstract: Background Neonatal hypoxic-ischemic (HI) encephalopathy is a major cause of neonatal mortality and of subsequent neurological disabilities among infants who survive it. Insulin receptor substrate -1 (IRS-1) is a ducking protein, which binds to phosphotyrosine residues on insulin-like growth factor-I or insulin receptors, and involves in activation of phosphoinositide3-kinase (PI3K) / Protein kinase B (Akt) pathways. Based on our previous study, we hypothesized that IRS-1 could protect against neonatal HI brain injury. Methods We used *in vivo* HI animal model and *in vitro* oxygen-glucose deprivation (OGD) model to test the effect of IRS-1 after HI injury on neonatal rat brain and cells. IRS-1 was modulated by either adenovirus or anti-sense oligonucleotide/shRNA. The treatment of proposed IRS-1 activator, metformin, was also conducted in both HI models. Results IRS-1 down-regulation reduced p-Akt, increasedp53, worsened blood brain-barrier (BBB) damage, and increased brain infarct volume, whereas IRS-1 over-expression up-regulated p-Akt, decreasedp53, attenuated BBB

damage, and decreased brain injury. *In vitro*, IRS-1 down-regulation aggravated cell death in neurons and endothelial cells, and is associated with decreased p-Akt and increased p53. In contrast, IRS-1 over-expression reduced cell death in endothelial cells with increased p-Akt and decreased p53. For clinical application, we found that metformin can increase IRS-1 in neuronal and endothelial cells. It increased cell viability after OGD, and the metformin-treated rats apparently reduced HI-induced cell death, BBB damage and infarct brain volume. Conclusion IRS-1 can protect against neonatal HI brain injury and is a therapeutic target for developing neuroprotective treatment.

Title: Orchestrated activation of the glutamatergic and cannabinoid systems can promote neuroprotection in primary cultured corticostriatal neurons

Authors: *F. M. RIBEIRO, E. M. L. BATISTA, T. H. FERREIRA-VIEIRA, F. A. MOREIRA; Univ. Federal De Minas Gerais, Belo Horizonte, Brazil

Abstract: Endocannabinoids are retrograde lipid regulators that bind and activate CB1 and CB2 receptors, which are linked to the Gi/0 protein. Cannabinoid receptors are present at the pre-synaptic site and their activation can reduce neurotransmitters release. Endocannabinoids can also regulate kinases, including extracellular regulated kinase (ERK), phosphatidylinositol-3-kinase (PI3K) and AKT, as well as transcription factors and ionic channels, having a role in cell survivor, differentiation and plasticity. It has been shown that the activation of the endocannabinoid system can induce neuroprotective effects both in animal models of neurodegenerative diseases and cell cultures. Despite of this, the molecular mechanisms and the signaling pathways involved in endocannabinoid-mediated neuroprotection are still poorly known. Moreover, data published by our research group and others have shown that activation of the metabotropic glutamate receptor 5 (mGluR5) by positive allosteric modulators (PAMs),

including CDPPB, can protect against glutamate-induced excitotoxicity. Since there is a close relationship between the glutamatergic and cannabinoid systems, we decided to investigate a possible link between CB1 and mGluR5 activation in the induction of neuroprotection using primary cultured corticostriatal neurons. To test that, neuronal cell death was assessed in neurons that were incubated with glutamate in the presence or absence of the endocannabinoid potentiating drugs, URB597 and JZL184, and the mGluR5 positive allosteric modulator, CDPPB. URB597, JZL184 or CDPPB led to neuroprotection against glutamate induced neuronal cell death. Surprisingly, the CB1 antagonist, AM251, reversed neuroprotection induced not only by URB597 and JZL184, but also by CDPPB. On the other hand, MPEP, which is an mGluR5 negative allosteric modulator, was also capable of ablating neuroprotection induced by CDPPB, URB597 or JZL184. These data indicate that there is a functional interaction between these two neurotransmitter systems to promote neuroprotection. Interestingly, stimulation of neuronal cultures with CDPPB, URB597 or JZL184, in the presence or absence of glutamate, promoted activation of ERK1/2 and AKT above basal levels. In addition, CDPPB, URB597 or JZL184 decreased intracellular Ca2+ levels induced by glutamate stimulation. Thus, mGluR5 and CB1 receptors seem to activate similar cell signaling pathways leading to neuroprotection.

Abstract: Parkinson's disease (PD) induces severe disability in victims and so far no suitable strategies have been developed. Thus, there is an urgent need to explore novel therapeutic strategies to treat PD for the benefit of the mankind. Recently, nanodrug delivery of therapeutic compounds has been shown to induce superior neuroprotective effects than the parent compounds in central nervous system (CNS) diseases. However, there are evidences that mode of nanodelivery e.g., using Poly Lactic-co-Glycolic Acid (PLGA), or TiO2 nanowires have slightly but significantly different effects on their neuroprotective ability in CNS diseases. Thus, there is an urgent need to find our suitable mode of nanodrug delivery to induce maximum neuroprotection in various neurodegenerative diseases e.g., PD, Alzheimer's disease (AD) or Huntington's disease (HD) in model experiments. Previous studies from our laboratory showed that intraperitoneal injections of or 1-metyl-4-fenyl-1,2,3,6-tetrahydropyridin (MPTP, 20 mg/kg) daily within 2-h intervals for 5 days in mice induces PD like symptoms on the 8th day. Thus, in this model, there is a significant decrease in dopamine (DA) and its metabolites 3,4-Dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). Also immunohistochemical studies showed marked decrease in the number of tyrosine hydroxylase (TH) positive cells in the Substantia Nigra Pars Compacta (SNpc) and striatum (STr). These observations indicate that our model can be used for drug treatment studies in PD. Interestingly, these MPTP treated animals exhibited marked behavioral dysfunctions on the 8th day as evaluated on Rota-Rod performances, walking on an inclined mesh grid as well as their gait analyses. Cerebrolysin (CBL) is a well-balanced composition of several neurotrophic factors and active peptide fragments. Thus, this multimodal drug may have an added value on therapeutic strategies in PD. In present investigations we examined timed release of CBL using titanate nanospheres (TiNS) in treating PD in our mouse model. Our observations show that TiNS-CBL (in a dose of 3 ml/kg, i.v.) given after 2-days of MPTP administration for 5 days resulted in a marked increase in TH-positive cells in the SNpc and STr as compared to normal CBL. Also TiNS-CBL resulted in significantly higher levels of DA, DOPAC and HVA in SNpc and STr on the 8th day as compared to normal CBL. The behavioral functions were also improved significantly in MPTP treated animals that received TiNS-CBL. Tehse observations are the first

to point out that timed release of TiNS-CBL has far more superior neuroprotective effects in PD than normal CBL, not reported earlier.

Title: Nanowired delivery of Bradykinin BK2 receptor antagonist HOE-140 induces neuroprotection in heat stroke through nitric oxide synthase and dynorphin downregulation

Authors: *L. FENG[1], A. SHARMA[2], D. F. MURESANU[3], J. V. LAFUENTE[4], A. OZKIZILCIK[5], Z. R. TIAN[5], H. S. SHARMA[2];
[1]Bethune Intl. Peace Hosp., Hebi Province, China; [2]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Hosp., Uppsala, Sweden; [3]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [4]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [5]Chem. & Biochem., Univ. of Arkansas, Fayetteville, AR

Abstract: Heat stroke (HS) affects millions of civilians and military personnel Worldwide during summer months when the ambient temperature reaches beyond 38°C. HS induces breakdown of the blood-brain barrier (BBB) in several areas e.g., cerebral cortex, hippocampus, hypothalamus, cerebellum, thalamus and brain stem leading to profound brain edema formation

and neuronal, glial and cellular injuries when exposed at 38°C for 4 h in a biological oxygen demand (BOD) incubator (relative humidity 45-47 %; wind velocity 20-25 cm/sec). Previous reports from our laboratory showed massive upregulation of dynorphin A (1-17) and neuronal nitric oxide synthase (nNOS) in the above brain areas that correlated well with brain pathology. Since bradykinin is potent mediator of brain edema and interacts with NOS, it is possible that this effect of the peptide is mediated through bradykinin receptors. In a model of spinal cord injury (SCI) we have shown that bradykinin B2 receptor antagonist HOE-140 is able to thwart nNOS upregulation and cord pathology. Thus, a possibility exists that HOE-140 may also have neuroprotective effects in HS via suppression of nNOS. Our previous study demonstrated a close interaction between NOS and dynorphin A (1-17) upregulation in SCI. Thus, it appears that in HS both bradykinin and NOS may interact synergistically in HS to induce brain pathology. In present investigation, we examined TiO2 nanodelivery of HOE-140 in HS induced brain pathology and NOS and dynorphin expression in the brain. Our observations showed that HS resulted in significant increase in nNOS and Dynorphin immunoreactivity in almost identical brain areas that showed neuronal, glial and axonal injuries. This indicates that HS is capable to induce both nNOS and Dynorphin A upregulation that is responsible for brain pathology. In separate groups of rats when HOE-140 was administered (1 or 2 mg/kg, s.c.) either 30 min before or 1 h after HS resulted in mild to moderate reduction in nNOS and dynorphin expression. In these rats BBB permeability, brain edema and neuronal injuries were reduced slightly but significantly. However, when TiO2 nanowired HOE-140 was given 60 to 90 min after HS, marked reduction in nNOS and dynorphin immunoreactivity was seen. In these groups of rats BBB breakdown, edema formation and cellular injury were markedly inhibited. These observations are the first to show that blockade of bradykinin B2 receptors effectively using nanodelivery of HOE-140 is capable to induce profound neuroprotection and this effect of well correlated with reduction in nNOS and dynorphin A expression in the neurons, glial cells and endothelial cells, not reported earlier.

Hopsital, Uppsala, Sweden

Abstract: The success of nanomedicine as new strategy for drug delivery and targeting prompted the interest to develop approaches toward basic and clinical neuroscience [1]. Despite enormous advances in brain research, central nervous system (CNS) disorders remain the world's leading cause of disability in part due to the inability of the majority of drugs to reach the brain parenchyma. Many attempts to use nanomedicines as CNS drug delivery systems (DDS) were performed; among the various non-invasive approaches, nanoparticulate carriers and particularly polymeric nanoparticles (NPs) seem to be the most interesting strategies [2,3]. In particular, the ability of poly-lactide-co-glycolide NPs (PLGA-NPs) specifically engineered with a glycopeptide (g7), conferring to NPs ability to cross the blood brain barrier (BBB) in rodents at a concentration of up to 10% of the injected dose, was demonstrated in previous studies after different routes of administrations. Most of the evidence on NP uptake mechanisms reported in the literature about intracellular pathways and processes of cell entry is based on *in vitro* studies. Therefore, beside a particular attention devoted to increase the knowledge of the rate of *in vivo* BBB crossing of nanocarriers, the subsequent exocytosis in the brain compartments, their fate and trafficking in the brain surely represent main topics in this field. Hopsital, Uppsala, Sweden

Abstract: Sleep deprivation (SD) is a serious problem in military as they have only quick nap for few hours under severe stressful conditions leading to profound mental and cognitive dysfunctions. We have previously shown that SD of 12 to 48 h causes blood-brain barrier (BBB) disruption, brain edema formation and neuronal damages. In this investigation we examined a

combination of emotional stress with SD on brain pathology and behavioral dysfunction in a rat model. We also measured regional distribution of brain derived neurotrophic facto (BDNF) in SD. Finally, we used a multimodal drug Cerebrolysin that is a balanced composition of several neurotrophic factors and active peptide fragments to reduce SD induced brain pathology and behavioral dysfunction. Male Wistar rats were subjected to 1 h partial immobilization in plastic tube for 2 weeks to simulate emotional depression. These rats were placed on an inverted flowerpot (7 cm diameter) kept in a pool (30±1°C) for SD where the water level was just below 6 cm from the surface. Control group of rats was placed directly on the flowerpot without any prior stress. In these normal or stressed rats after 48 h SD BBB, brain water content and neuronal damages were examined. Regional BDNF levels were measured using ELISA in cerebral cortex, hippocampus, thalamus, hypothalamus, cerebellum and brain stem. About 70 to 120 % increase in the BBB permeability to Evans blue albumin and radioiodine in the above brain regions was seen in stressed rats after SD as compared to normal rats. The brain water content rose by more than 2 % than in normal animals after identical period of SD. Neuronal injuries were 50 to 90 % more in than normal animals after identical SD. Measurement of BDNF showed 50 to 60 % decline in different brain areas in stressed animals than SD alone. The most marked decrease was seen in hippocampus (normal control 5. 41±0.02 to 2.1±0.08 normal SD; Stress+SD 1.12±0.02 pg/g) and hypothalamus (control 4.23±0.21 to 2.11±0.12 normal SD; Stress+SD 0.84±0.02 pg/g) followed by cortex and cerebellum. Cerebrolysin (2.5 ml/kg, i.v.) given in rats 4 to 6 h after the onset of SD significantly reduced brain pathology and enhanced regional BDNF levels after 48 h SD. However, this effect was not seen in stressed rats after SD. TiO2 nanodelivered cerebrolysin given after the onset of SD in stressed rats significantly enhanced the regional BDNF level and induced neuroprotection at 48 h. Cerebrolsyin treated animals also did not show behavioral dysfunction. These results are the first to show that stress aggravates SD induced behavioral dysfunction and brain pathology and nanodelivery of cerebrolysin has profound neuroprotective effects, not reported earlier.

Title: Repeated forced swim stress exacerbates methamphetamine-induced neurotoxicity. Neuroprotective effects of nanowired delivery of a 5-HT3-receptor antagonist ondansetron

Authors: *J. V. LAFUENTE[1], A. SHARMA[2], E. A. KIYATKIN[3], D. F. MURESANU[4], R. PATNAIK[5], H. S. SHARMA[2];
[1]Univ. of Basque Country, Bilbao, Spain; [2]Anesthesiol. & Intensive Care Med., Uppsala Univ. Hopsital, Uppsala, Sweden; [3]In-Vivo Electrorophysiology Unit, Behavioral Neurosci. Br., Natl. Abstract: Stress induced depression is associated with a part of human life. However, sometimes to cope with emotional stress or depression people across the Globe use psychostimulants for temporary pleasure or to get rid of stress induced effects momentarily. However, during this process gradually they are addicted to psychostimulants abuse. One of the most abused drugs is methamphetamine (METH) that leads to often neurotoxicity depending on the dose and duration of drug exposure. Furthermore, METH induced effects could be aggravated at both hot and cold environment. One of the key reasons for METH induced neurotoxicity is the breakdown of the blood-brain barrier (BBB) leading to development of edema and cellular injuries. Since strenuous stress by itself leads to BBB breakdown and cellular injuries, a possibility exists that combinations of stress and METH use could exacerbate brain damage. Forced swim (FS) stress and concomitant immobility is considered to be a model of depression. Pretreatment with drugs modifying serotonin metabolism reduces depressive episodes indication a role of serotonin in depressive illness. Administration of METH also known to alter serotonin metabolism. Thus, it would be interesting to find out whether repealed forced swim and concomitant depressive episodes could aggravate METH induced neurotoxicity in a rat model. Male Wistar rats (age 20 to 24 weeks) were subjected to FS in a pool (30°C) for 15 min daily for 8 days. Control rats kept at room temperature (21±1°C) for comparison. In these control and FS rats METH was administered (9 mg/kg, s.c.) and allowed to survive 4 h after drug

injection. METH treatment in FS rats induced a profound increase in the BBB breakdown to Evans blue albumin (EBA) by 150 to 220 % and [131]-Iodine by 250 to 380 % from the naive rats received identical dose of METH. The BBB leakage was most pronounced in the cerebrla cortex followed by hippocampus, cerebellum, thalamus and hypothalamus in both FS and naïve rats after METH intoxication. Development of brain edema was also 2 to 4 % higher in FS rats after METH than in naive animals. Neuronal and glial cell injuries were also aggravated by 3- to 5-fold in FS rats after METH. Pretreatment with ondansetron (1 mg/kg, i.p.) 30 min before METH injection in naïve rats reduced the brain pathology. However, TiO2-nanowired delivery of ondansetron (1 mg/kg, I,p,) was needed to reduce brain damage, BBB leakage and edema formation in FS rats after METH administration. Taken together these results are the first to show that METH exacerbates neurotoxicity in depressive animals and this effects is mediated though 5-HT3 receptors, not reported earlier.

Title: SiO2-nanoparticles associated with hypertension exacerbates blood-brain barrier breakdown, edema formation and cellular injuries following traumatic brain injury

Authors: *A. NOZARI[1], A. SHARMA[2], J. V. LAFUENTE[3], D. F. MURESANU[4], R. PATNAIK[5], H. MOESSLER[6], H. S. SHARMA[2];
[1]Anesthesia and Critical Care, Massachusetts Gen. Hosp., Boston, MA; [2]Anesthesiol. & Intensive Care Med., Uppsala Univ. Hopsital, Uppsala, Sweden; [3]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [4]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [5]Biomaterials, Indian Inst. of Technology, Banaras Hindu Univ., Varanasi, India; [6]Drug Discovery & Develop., Ever NeuroPharma, Oberburgau, Austria

Abstract: Military personnel during combat operation are often exposed to long-term chronic stress leading to mild to moderate work-related hypertension. In addition, in desert areas additional exposure of silica dust (SiO2 nanoparticles, SiO2NPs) could make their situation even worse. Under such circumstances, if combat related trauma to the central nervous system (CNS) will occur, the pathophysiological outcome may be more worse than similar trauma occurring in the absence of SiO2 NPs and/or hypertension. Thus, there is an urgent need to explore the possibility of hypertension and SiO2NPs exposure modulating the pathophysiology of traumatic brain injuries (TBI) in model experiments to find out suitable therapeutic strategies. Male Wistar rats (250-300 g) were made renal hypertensive by 2kidney 1clip (2K1C) procedure allowing mean arterial blood pressure (MABP) reaching 180±8 torr over 6 weeks. These hypertensive rats were exposed to SiO2NPs (40-50 nm) once daily (50 mg/kg, i.p.) for 8 days. On the 9th day these hypertensive and SiO2NPs intoxicated animals were subjected to TBI under anesthesia by making an incision (3 mm long and 2.5 mm deep) on the right parietal cerebral cortex after opening the skull (4mm OD) on both sides. The animas were allowed to survive 24 and 48 h after TBI. A focal TBI in hypertensive and SiO2NPs rats resulted a progressive increase in BBB breakdown to Evans blue albumin (EBA) and [131]-Iodine by 4-to 6- fold from the normal saline treated rats after 24 and 48 h TBI respectively. These animals also showed pronounced exacerbation of edema development in the injured hemisphere by 4- to 8 % and in the uninjured hemisphere by 2- to 3 % at 48 h TBI as compared to saline treated healthy animals. Marked neuronal, glial and myelin damage is seen in hypertensive rats with SiO2NPs exposure after TBI as compared to saline treated normal rats. The behavioral dysfunctions as seen using Rota-Rod apparatus, walking on an inclined mesh-grid and gait analysis also showed marked exacerbation in these hypertensive rats with SiO2NPs exposure at 48 h TBI. Treatment with a multimodal drug Cerebrolysin-a balanced composition of several neurotrophic factors and active peptide fragments in a dose of 10 ml/kg, i.v. started after 8 h TBI and continued every 8 h intervals (5 injections) markedly reduced brain pathologies in hypertensive and SiO2 intoxicated rats. Whereas only 5 ml/kg of the drug is needed to achieve identical neuroprotection in saline treated normal rats after TBI. These observations are the first to show that a combination of hypertension and SiO2NPs worsens brain pathology in TBI and require double dose of drugs to induce neuroprotection, not reported earlier.

Title: Nanodelivery of Mesenchymal Stem Cells with Cerebrolysin potentiates neprilysin level and decreases brain pathology and amyloid-beta peptide in Alzheimer's disease

Authors: *H. S. SHARMA[1], D. F. MURESANU[2], J. V. LAFUENTE[3], Z. TIAN[4], A. OZKIZILCIK[4], H. MOESSLER[5], R. PATNAIK[6], A. SHARMA[7];

Abstract: Neprilysin (NPL) is an endogenous enzyme that functions as rate-limiting step in amyloid-beta peptide (AβP) degradation. It is widely believed that an imbalance between production and clearance of AβP results in its accumulation leading to development of Alzheimer's Disease (AD). In several cases of AD the metalloprotease NPL brain concentration is decreased. Also NPL knocked out mice exhibited AD like brain pathology and behavioural dysfunctions. This suggests that enhancing the NPL concentartions by therapeutic means may reduce brain pathology in AD. Few studies indicated that mesenchymal stem cells (MSCs) administration into the brain fluid compartment resulted in enhanced NPL concentration and a

reduced AβP accumulation that correlates well with the behavioural and pathological deficit in a mouse model of AD. Thus, it would be interesting to examine whether nanodelivery of MSCs may further potentiate NPL enhancement and reduction in the AβP levels in the brain in an animal model of AD. Our previous studies have shown that TiO2-nanowired cerebrolysin (CBL), a balanced composition of several neurotrophic factors and active peptide fragments is able to thwart AD pathology following AβP infusion model in rats. However, role of CBL on NPL concentration are not well known. Thus, in present investigation we explored the combined effects of of nanowired MSCs and CBL on NPL and AβP levels in our rat model of AD. AD like symptoms was produced in rats by administering AβP (1-40) intraventricularly (i.c.v.) in the left lateral ventricle in a dose of 250 ng/10 µl once daily for 4 weeks. After 30 days of the 1st AβP infusion, the rats were examined for NPL and AβP concentrations in their brain by ELISA and brain pathology using histopathological techniques. Our observations showed that co-administration of TiO2 nanowired MSCs (106 cells) with 2.5 ml/kg CBL (i.v.) once daily for 1 week starting from 2 weeks after AβP infusion resulted in a significant increase of NPL in hippocampus (400 pg/g) from AβP group (120 pg/g; Control 420±8 pg/g brain). Also the combined treatment resulted in significant decrease of hippocampal AβP in treated group (45 pg/g) as compared to AβP group alone (75 pg/g; control 40±4 pg/g). Interestingly these changes were 30 to 45 % less by MSCs or CBL treated alone. The brain pathology in terms of neuronal damage, gliosis and myelin vesiculation was also most protected in combined treatment with TiO2 MSCs and CBL in our AD model. These observations are the first to show that a combination of CBL and MSCs has superior neuroprotective effects in AD by increasing the NPL level effectively, not reported earlier.

Title: Cerebrolysin improves memory and learning of the spontaneously hypertensive rats

Authors: *V. CABRERA PEDRAZA[1], C. SOLIS[2], R. VAZQUEZ-ROQUE[2], F. DE LA CRUZ[1], S. ZAMUDIO[1], M. GOMEZ-VILLALOBOS[2], G. FLORES[2];
[1]Escuela Nacional De Ciencias Biologicas, IPN, Ciudad de México, D.F., Mexico; [2]Inst. de Fisiologia, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: Hypertension (HT) is a disease characterized by a sustained increase in blood pressure. This condition is a major risk factor for suffering cerebrovascular disease, such as ischemic or hemorrhagic stroke, microvascular injury, cognitive impairment and vascular dementia. Experimentally, the model of spontaneously hypertensive (SH) rats has been widely used to study alterations at the anatomical, physiological and behavioral level, which develop by the progression of HT. The SH animals shown an increase in the blood pressure after second month affecting brain areas such as hippocampus and prefrontal cortex. The pyramidal neurons of these areas exhibited retraction of the dendritic arborization and reduced number of the dendritic spines. In the present report we analyzed the effect of chronic administration (6 month) of the Cerebrolysin (CBL), a polypeptide preparation with neurotrophic effects similar to those of endogenous neurotrophic factors, on the memory and learning and neural morphology of the pyramidal neurons of CA1 and dentate gyrus (DG) of the dorsal hippocampus and, layers III and V of prefrontal cortex by using Golgi-Cox stain. Wistar Kyoto rats were used as control animal groups and all animals used in this study were female rats. CBL improved learning and memory in the SH rats but not in WKY, measured by Water-Morris test. In addition, pyramidal neurons of layers III and V of the PFC and, CA1 and DG of dorsal hippocampus of the SH rats which received CBL, shown more arborization with increased number of dendritic spines. WKY rats shown more number of dendritic spines only in neurons of the DG of the hippocampus. Our results suggest that CBL is a potential drug in the treatment of the cognitive impairment caused by HT.

Title: L-Lactate as a neuroprotective agent against excitotoxicity: implication of an energy-dependent process

Authors: *P. JOURDAIN[1,2], I. ALLAMAN[1], P. MARQUET[2], P. J. MAGISTRETTI[3,1,2]; [1]EPFL, Lausanne, Switzerland; [2]CNP-CHUV, Prilly, Switzerland; [3]KAUST, Thuwal, Saudi Arabia

Abstract: There are several reports indicating a neuro-protective action of L-Lactate (Ros et al., 2001; Berthet et al., 2009, 2012). We have recently undertaken an analysis of this neuro-protective effect by using Digital Holographic Microscopy (DHM), a new imaging technique able to detect early signs of cell death in culture (Jourdain et al., 2011). Neuronal death elicited by application of glutamate (100μM; 2min) was detected in 65% of studied cells. This process is mainly linked to the activation of NMDA receptors since it was blocked by APV and MK801. In the presence of L-Lactate, the percentage of neuronal death induced by glutamate was significantly decreased to 32%. The neuro-protective action of L-Lactate was mimicked by L-pyruvate (but not by D-Lactate). UK5099, a specific blocker of mitochondrial pyruvate carrier, fully prevented the L-lactate-mediated neuroprotection, suggesting that the neuro-protective effects induced by L-Lactate required the synthesis of ATP. In addition, L-Lactate was not able to neuroprotect in presence of specific blockers of ATP channels pannexins (probenicid and carbenoxolone), nor in the presence of apyrase, an enzyme degrading ATP. However, ATPγS (10μM) in the extracellular medium was sufficient to rescue a neuroprotective effect even in presence of apyrase. These results indicate that ATP (and not its metabolites like adenosine) produced by the L-Lactate/Pyruvate pathway could be released to act on purinergic receptors. Using specific agonists and antagonists, we demonstrated that P2Y2 was the main purinergic receptor involved in neuroprotection. Finally, LY294002, a specific blocker of the PI3K pathway, blocked also the neuro-protective effect of L-Lactate. Interestingly, this intracellular pathway is activated by P2Y2. Altogether these data demonstrate that L-lactate confers neuroprotection from excitotoxic insults through complex intracellular pathways relying on an increase neuronal energy substrates availability, a release of ATP acting on purinergic receptors, which results in the mobilization of the PI3K intracellular pathway.

Title: Neuroprotection with androgens following partial motoneuron depletion: A role for microglia

Authors: B. J. KILEY, *D. R. SENGELAUB;
Indiana Univ., Bloomington, IN

Abstract: Neurodegenerative disease or nerve injury results in the loss of spinal motoneurons, and remaining motoneurons show a variety of morphological and functional changes. We have previously demonstrated that partial depletion of motoneurons innervating the quadriceps muscles induces dendritic atrophy in remaining motoneurons, with 70% decreases in dendritic length. Treatment with testosterone is neuroprotective, and dendritic atrophy following partial motoneuron depletion is attenuated. In the present study, we explored a potential mechanism for this induced atrophy and the protection by androgen treatment, examining the response of microglia to the partial depletion of motoneurons with and without testosterone treatment. Microglia are activated locally and recruited from other sites in response to injury. Microglia are involved in the removal of synapses and dendrites after injury, and there is evidence that their activation is influenced by steroid hormones. Motoneurons innervating the vastus medialis muscle in adult male rats were selectively killed by intramuscular injection of cholera toxin-conjugated saporin. Simultaneously, saporin-injected rats were given systemic treatments via interscapular implants containing testosterone or left blank. One or three weeks later, microglia were visualized after immunohistochemical staining for Iba1. Microglia surrounding the injured motoneurons were classified as monitoring or activated (primed, reactive, or ameboid) based on morphology and counted stereologically. Compared with intact males, partial motoneuron depletion resulted in increases in the total number of microglia (78% and 24% at 1 and 3 weeks post-saporin, respectively) in the quadriceps motor pool. These changes were driven by increases in the number of activated microglia compared to levels found in intact animals; the number of activated microglia increased by 144% at 1 week post-saporin, and remained elevated at 3 weeks (51%). The increases in the number of activated microglia were attenuated with testosterone treatment; the number of activated forms increased only 34% and 17% at 1 and 3 weeks post-saporin, respectively. These findings suggest that the dendritic atrophy observed in remaining motoneurons after partial motoneuron depletion could be a result of increased microglial activation in the injury site, resulting in collateral damage through synaptic stripping and dendritic loss. The attenuation of both dendritic atrophy and microglial activation with testosterone treatment supports this potential causal effect, and further supports a role for hormones as neurotherapeutic agents in the injured nervous system.

Title: AhR null mice are protected against neurotoxic insult

Authors: *L. G. GARCIA[1], F. PEREZ-SEVERIANO[2], D. GONZALEZ-ESQUIVEL[2], G. ELIZONDO[1], J. SEGOVIA-VILA[1];
[1]CINVESTAV, D.F., Mexico, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico City, Mexico

Abstract: L-kynurenine (Kyn) is a key element of the tryptophan metabolism; it is enzymatically converted by kynurenine aminotransferase II (KAT II) to kynurenic acid (KYNA), which acts as an antagonist to the NMDA receptor-glycine site. Kyn is also an endogenous ligand of the aryl hydrocarbon receptor (AhR), a transcription factor that regulates the expression of a diverse set of genes. Interestingly, KYNA levels are reduced in several regions of the brain of Huntington's disease (HD) patients. In the present work we used an AhR-null mouse and age-matched wild type mice to determine the effect of the absence of AhR on KYNA bioavailability. Moreover, we induced an excitotoxic insult by the intrastriatal administration of quinolinic acid, which is a biochemical model of HD, in both AhR-null and wild type mice in order to evaluate the neurological damage as well as the oxidative stress caused by the lesion. We found that in AhR-null mice there is an increase of KYNA levels in specific brain areas which are associated with higher expression of KAT II and this induces a neuroprotective effect against the neurotoxic insult. We also observed a decreased expression of the NR1 subunit of the NMDA glutamate receptor, which could be related to a decreased excitatory neurotransmission. Additionally, AhR-null mice also show improved motor performance in the rotarod test, indicating a constitutive protection of striatal tissue.

Title: The effects of low and high doses of 17β-estradiol on focal cerebral ischemia in rats

Authors: *E. INGBERG, E. THEODORSSON, A. THEODORSSON, J. O. STRÖM; Linköping University/Ike, Linköping, Sweden

Abstract: Although the majority of the studies of the effects of estrogens on focal cerebral ischemia in rodents have shown neuroprotection, there are also some contradicting studies in which increased damage have been observed. Differences in hormone administration methods, resulting in different serum 17β-estradiol concentrations has been suggested to account for this dichotomy. To test this hypothesis, female wistar rats were ovariectomized and randomized into three groups differing in administered dose of 17β-estradiol and subsequently subjected to transient middle cerebral artery occlusion using the filament method. After 24 h, sensorimotor function was evaluated with the tape test before the animals were sacrificed for infarct size measurement. No differences were found between the groups regarding either infarct size or behavioral performance and hence no support was found for the hypothesis of administered dose as the crucial factor determining the effects of 17β-estradiol.

Title: The effects of hemoxygenase-1 on lipopolysaccharide-induced neuroinflammation in astrocyte cultures

Authors: *J.-Y. WANG[1], C.-L. CHEN[2], S.-Y. CHEN[3];
[1]Dept Nursing (Basic Med. Sci), Hungkuang Univ., Taichung, Taiwan; [2]Li-Shin Hosp., Taoyuan, Taiwan; [3]Dept. of Nursing (Basic Med. Science), Taichung, Taiwan

Abstract: Heme oxygenase-1, a stress protein, may play a cytoprotective role in various neuronal injury. The induction of HO-1 is a sensitive marker of tissue oxidative stress. Furthermore, the changes in brain HO-1 expression patterns were associated with aging processes. In AD temporal cortex and hippocampus revealed more intense HO-1 band than in normal. *In vivo* and *in vitro* studies indicated that enhanced HO-1 activity may either ameliorate or exacerbate neuronal injury. Brain-derived neurotrophic factor (BDNF) exerts a neuroprotective effect against ischemic brain injury. Evidence revealed that the neuroprotective mechanisms of HO-1 may be related to the activation of the BDNF/TrkB/PI3K/Akt signaling pathway. However, the role of HO-1 in neuronal injury is still not clear. Alzheimer's disease (AD) is the most common neurodegenerative disorder. It is associated with relevant neuroinflammatory response. Astrocytes, a kind of glial cell, can produce mediators that involve in neuroinflammation. The processes accompany with inflammatory response are increasing in the expression of transcription factor NFκB, inducible nitric oxide synthase (iNOS) and the release of inflammatory mediators (ex. nitric oxide (NO) and cytokines). Ultimately, these events may create a vicious cycle to induce neuronal injury. In this study we want to estimate the effects of hemoxygenase-1 (HO-1) and BDNF on LPS-induced inflammation and oxidative stress in astrocytes (SVGp12). Cells cultures will be subjected to (1) control; (2) LPS treated with 1, 10, 100, 1000 ng/ml; (3) CoPP (HO-1 inducer) treated alone with 1, 2, 4, 10 μM; (4) pretreatment of CoPP following LPS treatment for 1, 3 or 5 days. Cell injury will be assessed by 3-(4, 5-Dimethyl thianol-2-yl) 2, 5 di-phenyltetrazolium bromide (MTT) reduction. The activation of astrocytes will visualize using anti-GFAP by immunocytochemistry. The production of MDA and NO will be measured to estimate the oxidative stress and inflammation. The expression of HO-1 and BDNF protein will be quantified by western blot analysis. Our data indicated that the NO production was increasing and the MTT reduction was decreasing in primary rat mixed glial cultures exposure to LPS. However, there was no significant difference in same condition of astrocyte cultures. The expression of HO-1 and BDNF protein were no significant change, too. BSO (will deplete glutathione in cells) 1000 μM induced cell injury, the percentage of MTT reduction decreasing to below 50 %. About the effects of HO-1 on neuroinflammation, we need more investigation.

Title: Differential targeting of HSPA (HSP70) heat shock protein family members in human neuronal cells following cellular stress

Authors: C. A. DEANE, *I. R. BROWN;
Ctr. for the Neurobio. of Stress, Univ. of Toronto Scarborough, Scarborough, ON, Canada

Abstract: HSPA6 (Hsp70B`) is a little studied member of the HSPA (HSP70) family of heat shock proteins that is present in the human genome but not rat and mouse and is therefore missing in current animal models of neurodegenerative diseases. HSPA6 shares 84% sequence homology with the more widely studied HSPA family member, HSPA1A (Hsp70-1). It is not known whether HSPA6 exhibits similar or divergent functions compared to HSPA1A. Hsps are highly conserved proteins that play roles in cellular repair and protective mechanisms. Co-application of celastrol and arimoclomol to differentiated human neuronal SH-SY5Y cells at dosages that do not affect viability or neuronal process morphology results in synergistic induction of a set of Hsps, including HSPA6. The induced proteins are diffusely distributed in the neuronal cytoplasm. Subsequent application of thermal stress triggers a transient, mass movement of HSPA6 and HSPA1A into the nucleus and targeting to discrete nuclear substructures. HSPA1A localizes to nuclear speckles rich in RNA splicing factors and to the nucleolus that is involved in ribosome biogenesis. HSPA6 translocates to the periphery of nuclear speckles that are sites of RNA transcription during recovery from thermal stress. The observed differences in nuclear targeting of endogenously induced HSPA6 compared to HSPA1A suggest divergent functions of these components of the cellular stress response.

Title: Inhibition of the IL-1 and TNF signaling pathways for neuroprotection is additive following acute soman-induced seizure in mice

Authors: *E. A. JOHNSON, J. IRWIN, K. LAITIPAYA, J. CHANDLER, L. SHUMWAY, T. FERRARA-BOWENS, M. WEGNER;
Pharmacol., US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Exposure to organophosphorus compounds such as soman (GD) can initiate status epilepticus (SE) that can lead to progressive brain damage and behavioral impairment. GD, a potent acetylcholinesterase inhibitor and chemical warfare nerve agent, causes prolonged SE activity and cell death in the hippocampus, thalamus and piriform cortex. Current treatments can ameliorate GD-induced SE, though treatment effectiveness diminishes rapidly following exposure. Therefore, neuroprotective strategies that can be used at later time points are needed to reduce neurodegeneration and improve cognitive outcomes. One strategy involves modulation of the neuroinflammatory response, a prominent feature in GD-induced brain injury. Previous studies have shown that both the tumor necrosis factor (TNF) and interleukin (IL)-1 signaling systems play a role in neuroprotection though the brain regions protected are specific to each pathway. This study focused on whether inhibition of both signaling pathways was a viable neuroprotective strategy that could confer greater neuroprotection in more regions than either pathway alone. A background-matched IL-1 receptor 1 (IL-1R1)/TNF receptor 1A (TNFR1A) double knockout (KO) mouse strain was exposed to GD and showed significant improvements in neuropathology, mortality, seizure onset and other relevant physiological responses compared to wild type, IL-1R1 KO and TNFR1A KO mice. These results suggest that a multi-pathway approach may be necessary to greatly improve brain injury outcomes following seizurogenic exposure to CWNA. Also, the use of multiple KO strains can help guide the selection of pathway-specific drugs for neuroprotection testing. These studies describe a rational and relatively rapid therapeutic strategy for the development of effective neuroprotectants and show that neuroprotection is possible with a longer therapeutic window after GD exposure than is provided by conventional treatments.

Title: Control of neuronal ryanodine receptor mediated calcium signaling by steroid hormone receptors

Authors: *P. KOULEN;
Basic Med. Sci. & Ophthalmology, Univ. of MO - Kansas City, Kansas City, MO

Abstract: Controlling the cytoplasmic concentration of free calcium ions (Ca^{2+}) is essential for the physiological activity of neurons and for neuronal survival under disease conditions. At the same time, the steroid hormones progesterone and the estrogen 17β-estradiol have been identified as neuroprotective and critical for proper neuronal viability. The present study determined novel mechanisms of action how signaling mediated by the interaction of ryanodine receptors with steroid hormone receptors controls the intracellular Ca^{2+} concentration in neurons. Specifically, it was identified how direct binding of cytoplasmic estrogen receptors to ryanodine receptors affects the activity of this major type of ligand-gated intracellular Ca^{2+} release channels in neurons. Using immunochemistry, optical imaging and electrophysiology, as well as immunochemical assays for determining protein-protein binding, changes in the activity of ryanodine receptors after binding of steroid hormone receptors were determined. Binding of steroid hormone receptors to the intracellular Ca^{2+} release channel resulted in distinct changes in both channel open frequency as well as the number of channel openings at the single channel level and preservation of key biophysical parameters of the channels such as single channel conductance. These molecular changes in channel open probability were mirrored at the cellular level by altered release of Ca^{2+} from intracellular stores and altered susceptibility of neurons to disease stimuli. The work indicates that neuronal Ca^{2+} signaling mediated by ryanodine receptors as Ca^{2+} dependent intracellular Ca^{2+} release channels is critically modulated by steroid hormone receptor binding. Such signaling controlled by protein-protein interactions in the central nervous system potentially provides a novel mechanism for drug development in the area of neurodegeneration.

Title: Glycyrrhizin suppresses oxidative stress in the hippocampus and olfactory bulb on status epilepticus in a lithium-pilocarpine seizure model

Authors: *S. GONZÁLEZ-REYES[1], J. J. SANTILLÁN-CIGALES[2], J. PEDRAZA-CHAVERRI[3], R. GUEVARA-GUZMÁN[2];
[2]Fisiología, [3]Biología, [1]UNAM, Mexico, Mexico

Abstract: Glycyrrhizin (GL), a triterpene, is considered the primary active compound present in the roots and rhizomes of licorice (Glycyrrhiza glabra). Extensive studies documented that GL has diverse biological activities as anti-inflammatory, antiviral and antioxidant, among others. This work was designed to determinate the potential protective effect of GL in the hippocampus and olfactory bulb on status epilepticus in a rat model. Male Wistar rats (220-250 g) were kept under controlled environmental conditions with free access to standard laboratory chow and tap water. Rats were randomly divided into four groups: 1) control of vehicle (CV); 2) status epilepticus (SE); 3) GL before SE (GL+SE); and, 4) only GL. Rats in groups 2 and 3 were injected with lithium chloride (3 meq/kg) 18 hours before pilocarpine (30 mg/Kg i.p.). Rats in group 3 were treated with GL (50 mg/kg i.p.) 30 minutes before pilocarpine injection. To minimize the peripheral cholinergic effects of pilocarpine, scopolamine methyl nitrate (1 mg/kg v.sc) was injected 30 min prior. Tissues were obtained 3 or 24 h after SE was interrupted with diazepam (2 mg/kg i.m). Oxidative stress (OS) was evaluated with glutathione (GSH) levels, malondialdehyde (MDA) content and the enzymatic activities of glutathione-S-transferase (GST), glutathione reductase (GR), glutathione peroxidase (GPx) and superoxide dismutase (SOD). The results showed increases of MDA content after the time of SE in hippocampus and olfactory bulb. GL was able to avoid OS, significantly in both tissues. The content of reduced glutathione (GSH) was maintained with the pretreatment of GL since 3 until 24 h. Also, MDA content was diminished with GL prior SE. Phase II enzymes were decreased with the injury. However, pre-treatment with GL prevented depletion of activities. This work suggested that GL

has a protective role against oxidative stress after SE in hippocampus and olfactory bulb of rats, on early hours (3 and 24h). GL prevents loss of activities of enzymes involved in GSH redox cycle and also in GSH levels and MDA content.

Title: X-irradiation-induced decrease in drebrin clusters within dendritic spines of cultured hippocampal neurons: Association with NMDA receptor and histone deacetylase activities

Authors: S. MIAO, N. KOGANEZAWA, T. HIRUMA, K. HANAMURA, A. PUSPITASARI, R. T. ROPPONGI, *T. SHIRAO;
Gunma Univ. Grad Sch. Med., Maebashi, Gunma, Japan

Abstract: Therapeutic X-irradiation of the brain possibly causes cognitive impairment, which is associated with synaptic dysfunction. We have shown that the acute effects of X-irradiation on contextual fear memory of adult mice and the immunostaining intensity of a postsynaptic F-actin-binding protein, drebrin in molecular layer of dentate gyrus *in vivo*. Although the decrease in drebrin-immunostaining intensity seems to be associated with fear memory, the mechanism regulating this decrease is unknown. We have shown that glutamate-induced decrease in drebrin clusters within dendritic spines of cultured neurons is mediated by NMDA receptor activity. To examine whether NMDA receptor activity is associated with X-irradiation-induced decrease in drebrin-immunostaining intensity in postsynaptic sites, we used primary hippocampal neuronal culture and analyzed the effect of X-irradiation on drebrin accumulation at dendritic spines *in vitro*. The neurons were treated with 50 μM Amino-5-phosphonovaleric acid (APV; an NMDA receptor antagonist) 1 hour before 10 Gy of X-irradiation at 21 days *in vitro*. The neurons were fixed 8 hours after X-irradiation. Immunocytochemical analysis showed that drebrin cluster density along dendrites significantly decreased 8 hours after X-irradiation ($p < 0.05$). This decrease was blocked by pretreatment with APV, suggesting that NMDA receptor activity is involved in X-irradiation-induced decrease in drebrin clusters within dendritic spines. We have also shown that amyloid beta oligomers-induced decrease in drebrin clusters within dendritic spines of cultured hippocampal neurons is mediated by histone deacetylase (HDAC). Moreover,

it is known that some HDAC inhibitors protect normal cells from radiation-induced damage. Then we are examining the effects of suberoylanilide hydroxamic acid (SAHA, a histone deacetylase inhibitor) on X-irradiation-induced decrease in drebrin clusters. These data suggest that NMDA receptor antagonists and histone deacetylase inhibitors may provide a new avenue toward therapeutic tools to mitigate X-irradiation-induced synaptic dysfunction.

Title: Protective effects of PACAP against alcohol-induced toxicity in SH-SY5Y cells

Authors: ***S. MANAVALAN**[1], D. BROWN[2], L. AKINFIRESOYE[2], S. TADESSE[2], K. MANAYE[3], A. TAMAS[1], D. REGLODI[1], Y. TIZABI[2];

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) is an endogenous 38 amino acid containing neuropeptide with various cytoprotective functions including neuroprotection. Thus, in-vitro and in-vivo studies have provided substantial evidence of PACAP protection against neuronal injury related to ischemia, trauma and various endogenous and exogenous toxic agents. We have earlier reported that exposure of neuroblastoma-derived SH-SY5Y cells to salsolinol, an endogenous toxicant formed through condensation of dopamine and acetaldehyde results in significant cell loss and that pre-exposure to PACAP can protect against this toxicity. In this study, we sought to determine whether PACAP might also protect against alcohol-induced toxicity in these cells and elucidate possible underlying mechanism(s). Ethanol treatment of SH-SY5Y cells resulted in a concentration-dependent toxicity where maximal effect (approximately 42% cell loss) was achieved with 500 mM ethanol. Pretreatment with PACAP resulted in a dose-dependent reduction in ethanol-induced toxicity where at 200 nM, PACAP completely blocked ethanol's maximal effect. The effects of PACAP in turn, were inhibited by PACAP antagonist (PACAP 6-38) where full block was achieved with 2 uM

antagonist. Cell flow cytometry indicated that the major toxicity by ethanol was apoptotically mediated and that PACAP could block this process. Taken together, these data indicate that PACAP or PAC1 receptor agonist, a major site of PACAP action, could be of therapeutic potential in alcohol-induced neurotoxicity. Title: Intranasal CNS delivery of catalytic bio-scavengers to protect against organophosphate threat agents: Preliminary studies

Authors: *A. P. APPU, A. PEETHAMBARAN, J. K. S. KRISHNAN, J. R. MOFFETT, A. M. A. NAMBOODIRI;
C-2069, Anatomy, Physiol. and Genet., Uniformed Services Univ. of Hlth. Sci., Bethesda, MD

Abstract: Organophosphate poisoning is a complex international health issue encompassing risks as diverse as insecticide poisoning and chemical threat agent (CTA) exposure. An emerging countermeasure approach is the use of catalytic bioscavengers such as organophosphate hydrolase (OPH) to detoxify the CTAs enzymatically. In recent studies, recombinant variants of OPH and paraoxonase 1 were found to afford protection against paraoxon intoxication in animal models. However, delivery of the active enzyme to the brain to prevent central nervous system (CNS) toxicity remains a challenge due to the blood brain barrier (BBB). We have been developing a method of nose-to-brain delivery for enzymes that bypasses the BBB to deliver these CTA treatments to the CNS. In the present study, we have demonstrated quick delivery of a model enzyme- chloramphenicol acetyltransferase (CAT) alone as well as in combination with matrix metaloproteinase-9 (MMP-9) into different areas of brain using an intranasal brain delivery system (ImpelNeurophrma, Seattle, WA). The enzyme activity in the different brain region was determined using a specific radiometric assay. The results showed that active enzyme

reached all region of the brain within 15 min, with approximately 15-31% of the total enzyme activity reaching the brain under this condition. Based on the results, it appears that both olfactory and trigeminal pathways are involved in the transport of CAT into the brain. Intranasal delivery of enzymes in combination with MMP-9 is a novel strategy to counter CTA toxicity in the CNS. The aim of this study was to provide an effective model for the rapid delivery of active enzymes into the brain in order to treat CTA exposure and various neurological disorders. Our immediate goals are to optimize the current intranasal brain delivery method for OPH in a model system of paraoxon toxicity in the rat with the enzyme delivered alone and in combination with oximes.

Title: Developmental regulation of stress-inducible neuroprotective protein pDING in human fetal brain with maternal alcohol and SSRI exposure

Authors: *N. DARBINIAN[1], N. MERABOVA[1], G. TATEVOSIAN[1], M. ALAMGIR[1], E. CHABRIERE[2,3], L. GOETZL[1,4];
[1]Shriners Hosp. Pediatric Res. Ctr., Temple Univ. Sch. of Med., Philadelphia, PA; [2]Faculte de Medecine, Aix-Marseille Univ., Marseille, France; [3]Biocristallographie Biotechnologie et Enzymologie Structurale, Univ. de France, Marseille, France; [4]Dept. of Obstetrics & Gynecology, Temple Univ., Philadelphia, PA

Abstract: Introduction: Maternal alcohol exposure can lead to significant neuronal loss, synaptic dysfunction and fetal alcohol syndrome (FAS). We have reported a neuroprotective role for stress-inducible DING phosphatase (pDING) in animal models and in-vitro human models. We hypothesized that pDING has a key protective role in normal human fetal neurodevelopment and that this protective effect may be disrupted in pregnancies exposed to EtOH and/or selective serotonin reuptake inhibitors (SSRIs). Methods: Fetal brain and placental tissue was collected with IRB approval following elective pregnancy termination between 8 and 20 weeks' gestation.

Placental tissue was also collected following term delivery >37 weeks Exposure was classified based on detailed SSRI/EtOH questionnaires. Endogenous pDING levels were assessed in total brain, synaptic extracts, total placenta and placental membrane vesicles in exposed cases vs. gestational age matched controls. Developmental expression of DING protein levels were quantified by western blot assay using the Odyssey® CLx Imaging System. Transcriptomic microarrays in human cells induced by human DING protein were performed. Results: pDING was developmentally expressed in brain and placenta tissues. Membrane fractions (placental vesicles and synaptic extracts) contained only the low molecular 37 kDa pDING isoform. Multiple DING isoforms were detected in total placenta and brain lysates. EtOH exposure was associated with increased placental pDING protein levels levels in the 1st trimester (Tri, ↑2.6 fold), and decreased pDING in the 2nd and 3rd TRI (↓2.6 and 4.0 fold). SSRI exposure with or without EtOH was associated with reduced placenta vesicle pDING (↓1.5 folds). In synaptic extracts, both EtOH and SSRI exposure were associated with reduced pDING (↓5.2; ↓1.1 fold respectively). Transcriptomics profiles for human DING revealed activation of several signaling pathways including cell survival, cell viability (↑5.4 fold) and inflammatory response, and identified several upstream regulators, including NUPR1, that empowers cells with resistance to the stress induced by a change in their microenvironment (↑5.6 fold). Conclusions: The 37kDa isoform of pDING, a key neuroprotective protein, is developmentally expressed in membrane extracts from human placenta and human fetal brain. Maternal EtOH and/or SSRI exposure is associated with decreased pDING levels, especially in the 2nd and 3rd trimesters, key periods of human cortical development. Our work supports a potential therapeutic/neuroprotective role of drug targets that result in increased pDING expression or in exogenous pDING in pregnancies at risk for FAS.

Title: Hyperhomocysteinemia increases ER stress and Impairs autophagic flux in murine therapy brain that is reversible with vitamin therapy

Authors: *M. TRIPATHI[1], C. ZHANG[1], B. K. SINGH[2], R. A. SINHA[2], K. MOE[3], D. DE SILVA[1], P. M. YEN[2];
[1]Neurol., Natl. Neurosci. Inst., Singapore, Singapore; [2]Duke-NUS Grad. medical Sch., Singapore, Singapore; [3]Med., Newcastle Univ. Med., Johor bahru, Malaysia

Abstract: Introduction: Elevated serum level of Hcy, hyperhomocysteinemia (HHcy), is a strong independent risk factor for ischemic stroke. Several vitamin intervention studies have shown their efficacy in lowering HHcy. Epidemiological studies have that increased dietary intake of antioxidants/vitamins prevented and decreased the extent of ischemic brain injury. However the causal mechanism remains elusive. Methodology: We used a diet-induced model (32 mice; C57BL6) and HHcy was confirmed in the serum. After 12 weeks, 16 mice were sacrificed (8 control and 8 HHcy) and remaining 16 mice were put on diet enriched in vitamin B12 and folate and were also sacrificed after 12 weeks. Brain tissue samples were collected from both the sacrifice points and were used for protein and RNA analysis. For *in vitro* studies, SH-SY5Y neuroblastoma and astrocytes were taken and were treated with varying concentrations of Hcy as well as vitamin therapy. Results: We observed that HHcy led to in an increase in ER stress, as evidenced by increase in CHOP, ATF-6, p-eIF2α and p-ERK. Also we observed that HHcy caused a significant increase in ubiquitination. We also examined expression of autophagic markers LC3B-II and p62 and found significant inhibition of autophagy in HHCy brain samples. In contrast, in samples from vitamin-supplemented HHCy mice, autophagy induction was observed along with restoration in ER stress markers to normal levels (CHOP, ATF-6 p-eIF2α and p-ERK). In addition phosphorylation of AKT and target of rapamycin (mTOR) and were found to be significantly increased in HHcy brain as well as SH-SY5Y cells consistent with decreased autophagy. Vitamin therapy also reversed these changes in AKT and mTOR. Conclusion: Results from this study suggest that HHcy increased ER stress in murine brain, SH-SY5Yand astrocytes. We also found that increased ER stress was associated with down-regulation of autophagic flux. Interestingly, vitamin (B12 and Folate) therapy not only rescued the block in autophagy induced by HHcy but also prevented ER-stress. Collectively, these results show for the first time that HHcy induces ER stress in the brain that was reversed by vitamin therapy. They also suggest that vitamin therapy might reduce the extent of brain injury during a stroke.

Title: Inhibition of quinolinate neosynthesis causes a rapid increase in extracellular kynurenic acid levels in the rat brain

Authors: *H.-Q. WU[1], G. COSTANTINO[2], F. M. NOTARANGELO[1], R. SCHWARCZ[1]; [1]Maryland Psych Res. Ctr, Univ. Maryland Sch. Med., Baltimore, MD; [2]Dept. di Farmacia, Universitaì degli Studi di Parma, Parma, Italy

Abstract: Quinolinic acid (QUIN), an excitotoxic NMDA receptor agonist and metabolite of the kynurenine pathway (KP) of tryptophan degradation, is present in the mammalian brain and may be causally involved in the pathophysiology of major neurodegenerative and psychiatric diseases. In the brain as elsewhere, QUIN is formed from its immediate bioprecursor 3-hydroxyanthranilic acid (3-HANA) by 3-hydroxyanthranilic acid 3,4-dioxygenase (3-HAO), and newly formed QUIN can be readily recovered from the extracellular compartment using *in vivo* microdialysis (Brain Res. Bull., 33: 513-516, 1994). The present study used this methodology to examine possible biochemical relationships between QUIN and kynurenic acid (KYNA), a neuroprotective tryptophan metabolite, which is synthesized by irreversible transamination of kynurenine by kynurenine aminotransferases (KATs) in a competing arm of the KP (Nat. Rev. Neurosci., 13: 465-477, 2012). Interestingly, applied by reverse dialysis to the medial prefrontal cortex of adult rats, 3-HANA (30 μM) resulted in a 201 ± 9% increase in extracellular KYNA levels (to 4.8 ± 0.3 nM) after 2 h (n=6). This KYNA elevation was totally abolished when the new, selective 3-HAO inhibitor 2-aminonicotinic acid 1-oxide (UPAR-12; J. Med. Chem., 56: 9482-9495, 2013) (100 μM) was co-infused with 3-HANA (30 μM) (n=6). To assess the possible role of NMDA receptor stimulation, and thus early, QUIN-induced excitotoxic events, 3-HANA (30 μM) was co-infused with the selective receptor antagonist (-)-2-amino-7-phosphonoheptanoic acid (50 μM). This co-treatment dramatically reduced the elevation of extracellular KYNA (to 115 ± 13% of baseline values; n=4). Co-infusion of 3-HANA (30 μM) with the non-specific KAT inhibitor aminooxyacetic acid (300 μM; n=3) or with the specific KAT II inhibitor (S)-(4-ethylsulfonyl)benzoylalanine (3 mM; n=4) also attenuated the 3-HANA-induced KYNA elevation (to 93 ± 10% and 121 ± 12% of baseline, respectively), indicating that enzymatic de novo formation from kynurenine plays a major role in the increases seen in extracellular KYNA. Finally, because the possibility that non-enzymatic oxidation of kynurenine to KYNA may be involved, the antioxidant glutathione (10 mM) was co-infused with 3-HANA (30 μM) (n=5). This treatment also attenuated the elevation in KYNA (to 151 ± 17% of

baseline). Taken together, these results reveal a heretofore unknown rapid stimulatory effect of relatively moderate increases in QUIN production on extracellular KYNA in the brain. Regardless of its underlying mechanism, this effect may have significant ramifications for brain physiology and pathology.

Title: Effect of kynurenines on copper toxicity in primary cultured astrocites

Authors: *D. RAMÍREZ ORTEGA[1], B. PINEDA[2], D. GONZÁLEZ ESQUIVEL[3], C. RÍOS[3], V. PÉREZ DE LA CRUZ[3];

Abstract: Copper is a heavy metal and an integral component of various enzymes. It is necessary for mitochondrial respiration and other biological functions; however, excess copper is neurotoxic and has been implicated with neurodegenerative diseases as Alzheimer. This metal is able to modify the cellular redox environment, which can influence various cellular functions. On another hand, tryptophan degradation through kynurenine pathway is also modulated by the redox environment and produces some metabolites with redox properties as L-kynurenine (L-KYN), kynurenic acid, 3-hydroxykynurenine (3-HK) and 3-hydroxyantrhanilic acid (3-HANA). The imbalance on the production of these kynurenines is related with some pathologies. The aim of this study was to evaluate the effect of these kynurenines on the cupper toxicity through MTT reduction, ROS production and mitochondrial membrane potential on primary cultured astrocytes. First, we evaluated the CuSO4 (0-500 μM) effect on mitochondrial function by MTT assay. Then was evaluated the effect of the co-incubation of CuSO4 whit L-KYN (10 μM), 3-HK and 3-HANA (100 μM) on mitochondrial membrane potential, cellular function (MTT

reduction) and cell death by propidium iodide assay. Our results showed that CuSO4 decreased MTT reduction in a concentration-dependent manner and the co-incubation with 3-HK and 3-HANA potentiated this effect. CuSO4 decrease mitochondrial membrane potential and the co-incubation with 3-HK and 3-HANA potentiated this parameter as well as the cell death. While the co-incubation CuSO4 with L-KYN attenuated partially the decrease on mitochondrial membrane potential but also increased the cell death. Data suggest that these kynurenines increased the cell vulnerability induced by CuSO4.

Title: Kynurenine pathway metabolites modulate neurodegeneration and related phenotypes in *Drosophila*

Authors: C. BREDA[1], *K. V. SATHYASAIKUMAR[2], F. M. NOTARANGELO[2], S. S. IDRISSI[1], J. G. ESTRAINERO[1], G. G. L. MOORE[1], E. W. GREEN[1], C. P. KYRIACOU[1], R. SCHWARCZ[2], F. GIORGINI[1];
[1]Dept. of Genet., Univ. of Leicester, Leicester, United Kingdom; [2]Maryland Psychiatric Res. Center, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Metabolites of the kynurenine pathway (KP) of tryptophan (TRP) degradation have been implicated in the pathophysiology of Huntington's (HD), Parkinson's (PD) and Alzheimer's (AD) diseases. In a *Drosophila* model of HD, genetic inhibition of two pivotal KP enzymes, kynurenine 3-monooxygenase (KMO) and tryptophan 2,3-dioxygenase (TDO), normalizes KP imbalances and rescues neurodegeneration (Campesan et al., 2011). In support of these findings, van der Goot et al. (2012) showed that genetic down-regulation of TDO decreases toxicity in a worm model of PD. Here we sought to characterize the neuroprotection conferred by TRP treatment and TDO inhibition in HD flies, and to extend our analyses of the neuroprotective potential of KP manipulation to fly models of PD and AD. To this end, we analyzed rhabdomere neurodegeneration, climbing performance and longevity in PD and AD flies. HD flies fed with

TRP showed a dose-dependent reduction of neurodegeneration compared to controls ($p<0.001$). Further, an increased kynurenic acid/3-hydroxykynurenine (KYNA/3-HK) ratio was observed in these flies ($p<0.001$), suggesting that neuroprotection is due at least in part to increased levels of KYNA. Notably, 3-HK feeding abrogated neuroprotection in TDO-deficient HD flies, which normally exhibit reduced levels of 3-HK ($p<0.01$). Flies were also humanized to investigate whether quinolinic acid (QUIN), which is not present in flies, could cause toxicity in this model. QUIN feeding enhanced neurodegeneration in HD flies and significantly abolished the neuroprotection conferred by KMO inhibition, indicating that QUIN can cause toxicity independently of 3-HK. Moreover, a *Drosophila* line carrying a transgene encoding for human kynurenine aminotransferase (hKAT), the biosynthetic enzyme of KYNA, reduced neurodegeneration in HD flies ($p<0.001$), indicating that increasing KYNA levels, and an increase in the ratio of KYNA/3-HK in these flies ($p<0.001$) is neuroprotective. The efficacy of KMO and TDO was also tested in *Drosophila* models of PD and AD. Transgenic fly lines expressing human αSyn (PD model) or Aβ42Arc (AD model) were used. In both models, gene silencing of TDO or KMO increased the median lifespan of flies ($p<0.001$) and improved the climbing performance ($p<0.001$). Finally, pharmacological inhibition of TDO with the inhibitor 680C91 was protective in all the above models. Taken together, these studies in flies support the concept that targeted manipulation of KP metabolism constitutes a viable therapeutic strategy in several neurodegenerative diseases.

Title: Dibutyl phthalate affects Synaptic growth and stability at the *Drosophila* NMJ

Authors: *K. M. DE LEON[1], W. AQUINO[2], B. MARIE[2];
[1]Biol., [2]Inst. of Neurobio., San Juan, Puerto Rico

Abstract: Dibutyl phthalate (DBP) is a contaminant found ubiquitously in the environment that could therefore affect multiple organisms. Nevertheless, little is known about the effects of DBP on the nervous system. Studies have shown that DBP acts as a teratogen and as an endocrine disruptor. In addition, a recent study has linked DBP to neurotoxicity in neonatal rats. In the present study, we address the effect of DBP at the neuromuscular junction (NMJ). We reared animals in contaminated food and tested the effect of DBP on the synapse structure and morphology. We expressed the concentration of DBP present in the food as a function of the maximum contaminant level (MCL) allowed in public drinking water system (defined by the Environmental Protection Agency). We characterized a variety of synaptic markers: the vesicle marker synapsin, the microtubule associated protein Futsch (MAP1B homolog), the active zone associated structural protein Bruchpilot (CAST homolog), the postsynaptic marker discs large (Dlg; PSD-95 homolog) and the presynaptic membrane marker HRP. The animals that were reared in a milieu containing 10 times the MCL for DBP, presented a reduction in synaptic growth. Indeed, synapses from contaminated milieu showed a growth that was 80% of the control synapses. In addition, the animals reared in contaminated milieu showed synaptic retractions. These retractions are defined by the presence of postsynaptic markers and the absence of a subset of presynaptic markers. In animals reared in a milieu containing 10 times MCL for DBP, 50% of the synapses showed a retraction phenotype (boutons lacking synapsin staining) and these retractions showed a severity of 6 boutons on average. We also observed that the animals exposed to DBP have boutons deficient in MAP1B and CAST, both hallmarks of synaptic retractions. This effect was found to be dose dependent. When the animals were reared in a milieu containing 5 times the MCL for DBP, the synaptic growth was normal and the frequency of the retractions was reduced to 30%. Nevertheless, at this concentration, the retractions remained as severe. When the animals were reared in a milieu containing the MCL for DBP, there was normal synaptic growth, with no retraction phenotype. In addition, it seems that only chronic exposure to DBP is deleterious to synaptic growth and stability, as acute exposure did not affect synaptic growth or retractions. We are now focusing on the consequences of chronic exposure to DBP on synaptic release and plasticity.

Title: Cytomegalovirus affects differentiation and function of neural stem cells upon infection

Authors: *H. M. GONZÁLEZ[1], A. CARRIZALES-HUERTA[2], M. JIMÉNEZ-CAPDEVILLE[1], D. NOYOLA[1], C. G. CASTILLO[1], A. MARTÍNEZ-SERRANO[3]; [1]Facultad De Medicina, U.A.S.L.P., San Luis Potosi, Mexico; [2]Facultad de Ciencias Químicas, Univ. Autónoma de San Luis Potosí, San Luis Potosí, Mexico; [3]Ctr. de Biología Mol. Severo Ochoa, Univ. Autónoma de Madrid, Madrid, Spain

Abstract: Cytomegalovirus (CMV) is the most common cause of congenital infection in developed countries and a major cause of developmental brain disorders in children, including mental retardation and hearing loss. Some *in vitro* models have demonstrated that neural precursor cells (NPCs) show the greatest susceptibility to CMV infection in developing brains. We sought to investigate the effects of CMV infection in human neural stem cells, in order to demonstrate that low virus concentrations can modify the correct function of these cells and then may have a significant impact in the developing brain. We established an *in vitro* model of CMV infection making use of an immortalized neural cell line, hNS-1 and the human CMV laboratory strain AD169. Cellular monolayers were infected at the multiplicity of infection of 0,1 and 0,01 plaque-forming units per cell. Viral infection was corroborated by detection of the CMV glycoprotein B using an indirect immunofluorescence assay. We induced infected hNS-1 to differentiate and evaluated the expression by immunocytochemistry of cellular markers of differentiation such as GFAP, MAP-2, nestin and vimentin, reflecting the presence of astrocytes, neurons and neural progenitors, respectively. Furthermore, the function of infected NPCs was assessed by measurement of the calcium influx in response to some stimuli. Our results show that NPCs are permissive to infection and the cytopathic effect was extensive. The expression of the marker for astrocytes decreased and the other proteins were unchanged. For the neural function assays, the onset time for some stimuli increased meanwhile the magnitude of the response was diminished. Our results suggest that CMV is able to produce morphological and functional changes in human neural stem cells and therefore alterations in the developing brain, even if low viral concentrations reach the central nervous system.

Abstract: Sepsis - a clinical syndrome associated with dysregulated immune responses is the most frequent cause of death in the intensive care units. Sepsis is associated with impaired brain function, which can be an independent predictor of mortality. Increased morbidity and cognitive impairment have also been reported in sepsis survivors. Providing insight into the brain alterations in sepsis survivors is important and may indicate novel therapeutic strategies. Here, we studied microglia activation and gene expression of cytokines and cholinergic system constituents in the cerebral cortex of mice - sepsis survivors, in parallel with peripheral (serum) cytokine analysis. Mice were subjected to cecal ligation and puncture (CLP) - a clinically relevant model of sepsis, which resulted in 50% mortality (vs. 100% survival in sham-operated mice) within 5 days. Murine sepsis survivors and sham controls were monitored for 9 additional days prior to utilizing them in the study. Iba1 protein immunostaining revealed marked morphological alterations in microglia - an amoeboid shape, indicative for microglia activation in mice sepsis-survivors. This microglial inflammatory phenotype was associated with significant upregulation of Iba1 gene expression. Cortex Il1b (a pro-inflammatory cytokine) mRNA expression was significantly increased ($P<0.01$) in mice sepsis-survivors. The increase in Il6 mRNA expression was not statistically significant ($P<0.08$). Ache (acetylcholine degrading enzyme) mRNA expression was increased ($P<0.03$), while Chat (acetylcholine biosynthesizing enzyme) mRNA expression was not significantly altered ($P<0.2$). In addition, nitrotyroisine protein immunostaining indicated increased nitrative stress in mice sepsis survivors. These brain alterations in mice - sepsis survivors were associated with higher serum IL-1β ($p<0.04$), IL-6 ($p<0.02$) and other cytokine levels. These results reveal a previously unrecognized persistent brain inflammatory activation in parallel with increased systemic cytokine levels in sepsis survivors. In addition, the increased brain Ache gene expression is of interest for further studying

of this enzyme (with an important role in cognition and in the regulation of inflammation) in the context of post-sepsis pathology. This study was funded in part by NIH/NIGMS

Title: The tadpole visual system as a model for assessing the effects of thyroid hormone disruption on brain development

Authors: *C. K. THOMPSON[1], M. TURKEN[2], K. D. MEDGYESY[3], H. T. CLINE[1]; [1]The Scripps Res. Inst., La Jolla, CA; [2]Univ. City High Sch., San Diego, CA; [3]UCSD, San Diego, CA

Abstract: Thyroid hormone (TH) plays an important role in brain development, and evidence shows that some compounds used in the production of industrial and consumer products can disrupt TH signaling, with severe consequences for behavior. How TH disruptors impact neural circuit development is still unclear, however. Tadpoles are useful models for better understanding endocrine disruption because they are acutely sensitive to changes in TH signaling. In addition, their external development allows for manipulation and observation of the early stages of brain development which are relatively inaccessible for study in mammalian systems. Here we show that visual system development in Xenopus laevis tadpoles is robustly affected by changes in TH signaling. Our data show that treatment with TH for 7 days induced vast changes in brain morphology, including regression of the telencephalon and expansion of the optic tectum volume. In addition, TH acts directly on the brain and the retina to significantly increase the rate of proliferation in the ventricular zone and ciliary margin, respectively. Using *in vivo* imaging, we found that TH treatment increased the rate of neuronal differentiation as well as

increased dendritic arborization. TH also increased the expression of TH sensitive genes. Triclosan, an anti-microbial agent used in a variety of consumer household products, may disrupt TH function. We are currently engaged in experiments testing the degree to which triclosan mimics TH to affect visual system development. Our preliminary data strongly suggest that triclosan does not induce TH-like changes that affect Xenopus tadpole visual system development. These experiments establish a baseline for the sensitivity of tadpole brain development to changes in TH signaling against which we will compare the effects of TH disruptors.

Title: An acute inhalation study on the effect of Hydrofluorocarbon 134a gas on the frontal cerebral cortex of albino wistar rats

Authors: *E. DIKE, M. N. WOGU, E. EKONG;
Univ. of Port-Harcourt, Port-Harcourt, Nigeria

Abstract: Incidence of accidental exposure to high concentration of refrigerant gases in factories, chemical industries and domestic houses are on the increase but the awareness on the health implications of the acute inhalation of these gases is not widespread such as its neuroanatomical basis. This study investigates the effect of acute HFC 134a gas inhalation on the weight, oxidative stress (Malondialdehyde level (MDA), Glutathione peroxidase ($GSHP_X$) level and histomorphology of the frontal cortex of cerebrum of albino wistar rats. In this study a total of 43 albino wistar rats weighing about 140-280g were used for the study. 15 out of the 43 rats were used for the Lethal Concentration 50 (LC50 test or limit study) and the remaining 28 for the test study, the LC50 for this study was found to be 44660ppm from which the test concentration was derived. The test study consists of 4 groups of 7 rats each. Group A was exposed to ½ of the LC50, Group B to 1/3 of LC50, Group C to 1/10 of LC50 and a control group. A whole body exposure system was used for the study. All groups were exposed to a single exposure to HFC 134a for 30 minutes inside an inhalation chamber except for the control group which were exposed to free air in the chamber for the same duration. The MDA, $GSHP_X$ level, body weight

and brain tissue samples were obtained from the animals immediately after exposure, 7 days after exposure and 14 days after exposure. From this study, it was noticed that there was significant weight reduction in exposed rats, serum level of MDA was significantly higher in rats immediately after exposure and 7 days after exposure which is indicative of increased oxidative stress while MDA level in day 14 was not significantly different from control group. There was profound distortion on the frontal cerebral cortex histomorphology of exposed rats especially, on the day of exposure and day 7 after exposure. There was no difference between the histomorphology of the frontal cortex of rats 14 days after exposure and in the control group. Thus it could be deduced that acute inhalation of HFC134a causes significant weight loss, oxidative stress and distortion in the histomorphology of the frontal lobe of cerebral cortex immediately after exposure and 7 days after exposure but these effects were alleviated on the 14th day after exposure. **Keywords:** HFC 134a, acute inhalation, cerebrum, Neurotoxicity.

Title: Gender differences in binge alcohol-induced brain damage

Authors: ***M. E. MAYNARD**, C. R. ROBINSON, E. A. BARTON, J. L. LEASURE; Psychology, Univ. of Houston, Houston, TX

Abstract: Binge pattern drinking is the most common alcohol use disorder (AUD) and has been linked to severe neuropathology. Mounting evidence indicates that the brains of men and women may respond differently to binge alcohol consumption. Women appear more sensitive to the neurotoxic effects of alcohol, with cognitive and structural impairments emerging faster in women than men. Additionally, women with AUDs have higher rates of medical problems and a significantly higher death rate than men with AUDs. It is alarming then that rates of binge pattern consumption have been increasing at a much faster rate in women than men in the last ten years. The current study assessed gender differences in brain damage following binge alcohol exposure using a well-established rodent model. Adult female and male Long-Evans rats were gavaged with ethanol (25% w/v) in nutritionally complete diet every 8 hours for 4 days. Control

animals received isocaloric control diet. Stereological analysis of hippocampal dentate gyrus granule cells following 4 days of binge exposure revealed a significant 13% loss in female rats but no corresponding decrement in male rats. Both female and male binged hippocampi showed a significant decrease in proliferating (Ki67+) cells, thus, a lack of cell replacement cannot account for the decrement in granule neurons in females. To probe for binge-induced differences in trophic support, we performed Western blotting for brain-derived neurotrophic factor (BDNF), its receptor (trkB) and insulin-like growth factor receptor (IGFR) in male and female rats sacrificed after 1, 2 or 4 days of binge exposure. Male, but not female hippocampi showed an increase in IGFR after 1 day of binge exposure. Female, but not male hippocampi showed a decrease in trkB receptors after 2 or 4 days of binge exposure. Females also showed an increase in BDNF protein after 4 days. Taken together, our results reflect an animal model of female brain susceptibility to binge alcohol damage. This enhanced vulnerability may be due to a decrease in available trophic support during the binge, and a delayed compensatory increase that occurs too late to attenuate damage. Ongoing studies are investigating other potential mechanisms underlying female brain susceptibility to binge alcohol, including differential inflammatory responses and oxidative stress. Finally, gender differences in binge-induced cognitive impairments are being addressed. To conclude, the present data indicate a potential mechanism underlying female brain susceptibility to alcohol-induced damage.

Title: Apomorphine attenuate ethanol-induced neurodegeneration in adult rat cortex

Authors: ***M.-H. JO**, H. BADSHSH, N. MUHAMMAD, M.-J. KIM, M.-O. KIM; Gyeongsang Natl. Univ., Jin-ju, Korea, Republic of

Abstract: Apomorphine is a dopamine D1/D2 receptor agonist, therapeutically used for Parkinson disease, has been found to be potent antioxidant and prevents free radical reaction in

rat brain mitochondrial fraction. Alcohol, being a neurotoxic agent causing neurodegeneration possibly through free radical generation. Here, we investigated apomorphine has antioxidant potential against ethanol induced neurodegeneration in cortex of adult rats. Ethanol induced apoptotic neurodegeneration was determined by the suppression of Bcl-2, induction of Bax, release of cytochrome C and activation of caspase-9 and caspase-3. Moreover, ethanol elevated level of cleaved PARP-1 indicating exaggerated neuronal DNA damage. Our results pointed out a dose dependent neuroprotective effect of apomorphine reversing the ethanol induced apoptotic trend as observed by the increased expression of Bcl-2, downregulation of Bax, inhibition of mitochondrial cytochrome C release and inhibition of activated caspase-9 and caspase-3. Immunohistochemical analysis and Nissl staining also revealed neuronal viability maintained by apomorphine after ethanol induced neuronal cell death. Furthermore, apomorphine decreased the ethanol induced neuronal damage in a dose dependent manner showing more neuronal viability at dose of 5mg/kg than that of 1mg/kg. Our finding suggest that apomorphine attenuated ethanol induced neuronal cell loss in the adult rat cortex and has a more effective neuroprotective behavior at dose of 5mg/kg than that of 1mg/kg. Finally we can conclude that apomorphine has effective therapeutic potential to protect brain against ethanol induced neurotoxicity.

Title: The potential role of Sigma-1 receptor chaperone in the genesis of autophagosome in neuronal cells

Authors: *T.-Y. WENG, T.-P. SU, S.-Y. TSAI;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The Sigma-1 receptor (Sig-1R) is an endoplasmic reticulum (ER) chaperone protein that involves in the neuronal homeostasis. Silencing of Sig-1R in primary neurons has been shown to induce ER stress, ROS production and mitochondrial dysfunctions. These cellular responses are closely related to the autophagy response when cells strive for survival. We thus test the hypothesis that Sig-1R knockout (KO) neurons are prone to an increased autophagy

response to compensate for cellular survival and that Sig-1R may relate to the genesis of autophagosome. Our preliminary data show that the preautophagosomal marker LC3-I is enhanced in the Sig-1R KO primary neurons when compared to that from wild type neurons. This result suggests that without Sig-1R the formation of autophagosome is increased in cells to compensate for survival. We next used the autophagosome inhibitor chloroquine (CQ), which accumulates in the lysosome and blocks the cellular process of autophagy, to examine the role of Sig-1R as such. We found that in the presence of CQ the autophagy marker LC3-II and its cargo protein p62 levels were reduced in Sig-1R KO primary neurons when compared to wild type neurons. Further, the reduced LC3-II was also observed in Sig-1R silenced Neuro-2a cells under serum starvation conditions. Those data suggests that the process of autophagy is hindered in the Sig-1R KO primary cortical neurons or Sig-1R silenced cells. Additionally, it is known that autophagosomes and endosomes will fuse and converge. We found that the early endosome marker EEA1 was reduced in Sig-1R KO or silenced cells in the presence of CQ, further implicating Sig-1R as a player in the initial phase of the autophagy formation. No differences in the level of autophagy-related (Atg) proteins, 5 and 12 conjugation systems, were observed. Giving that the majority of Sig1R resides in the ER-mitochondrion interface which plays pivotal roles in vesicle transport pathways to form autophagosome, we will focus on the exact functions of Sig-1R in the endosomal-autophagy pathway in the future.

Abstract: Clinical use of anti-neoplastic drugs is associated with the development of numerous adverse effects that many patients find intolerable, including peripheral neuropathy. Cisplatin, an effective anti-neoplastic agent in the treatment of solid tumors, produces a dose-limiting painful peripheral neurophathy in a clinically significant number of cancer patients. The aim of the

present study was to investigate the possible antiallodynic effect of systemic administration of dexmedetomidine and morphine either alone or in combination in an animal model of neuropathic pain evoked by cisplatin. Mechanical allodynia was measured by using von Frey filaments in the hindpaw. Male Wistar rats, weighting 180-220 g, were treated with cisplatin administered intraperitoneally three times a week (Monday, Wednesday, and Friday) at a dose of 0.1 mg/ 100 g weight. Dexmedetomidine (10, 30, 56 and 100 µg/kg), morphine (0.1, 0.3, 3 and 5.6 mg/kg) or equieffective doses of the combination in a ratio|1:1 were administered to obtain the 40% experimental effective doses (ED_{40}) for each drug and for the combination. Isobolographic analysis was performed to examine the interaction. Dexmedetomidine (ED_{40} = 33.41 +/- 3.5 µg/kg), morphine (ED_{40} = 3.2 +/- 0.7 mg/kg) and fixed-dose ratio dexmedetomidine-morphine combinations showed dose-dependently anti-allodinical effect. Theoretical ED_{40} value for the combination estimated from the isobologram was 2.05 +/- 0.3 mg/kg, whereas that experimental ED_{40} value was 1.20 +/-0.3 mg/kg. Results indicate that i.p. administration of dexmedetomidine plus morphine can interact synergistically in the neuropathic pain model and suggest the use of this combination to relieve pain evoked by anti-neoplastic agents in humans. **Keywords:** Antineoplastic drugs, Cisplatin, Neurophaty, Dexmedetomidine, Morphine.

Title: Intracerebroventricular injection of functionalized titanium dioxide nanoparticles (NBelyax®) and electroencephalographic activity in freely moving rats

Authors: *V. M. MAGDALENO-MADRIGAL[1], G. CONTRERAS-MURILLO[1], R. FERNÁNDEZ-MAS[1], P. ARTEAGA-LÓPEZ[2], G. LEÓN-GUTIÉRREZ[2], L. ALBARRÁN[2], S. LEÓN-GUTIÉRREZ[2], E. GONZÁLEZ-TRUJANO[1];

Abstract: Titanium dioxide nanoparticles (TiO2 NPs) are now in daily in a great variety of home use products, as NBelyax® a clean use home product. However, the effects of TiO2 NPs on the central nervous system are still unclear. The electroencephalographic (EEG) and background EEG power spectral analysis is a strategy to investigate and may be correlated with neurological disorders. The aim of this study was to determine if TiO2 NPs functionalized with biological molecules (NBelyax®) are able to modify the EEG activity in freely moving rats. Wistar male rats (280-320 g) were implanted with two guide-cannulas in both lateral ventricules (AP -0.5; L 1.0; H 3.0). Also both frontal, both parietal and both occipital cortices were implanted to EEG recording. Acute intracerebroventricular injection (ICV) to deliver 1 microliter/1 min of functionalized TiO2 NPs (NBelyax®) by ventricule was performed. All animals were subject to 1 h of EEG recording during five days and were compared with themselves EEG baseline obtained before of ICV of functionalized TiO2 NPs. The EEG analysis of cortical areas showed that the functionalized TiO2 NPs (NBelyax®) did not modify at 0-4, 4-10, 10-30 and 35-55 Hz bandwitdh frequencies and did not show adverse effects on the spontaneous motor activity of rats. These preliminary results suggest that functionalized with biological molecules the TiO2 NPs (NBelyax®) may not produce adverse effects on EEG activity under these conditions. In addition, more investigations are necessary to determine the chronic effects of TiO2 NPs (Nbelyax®) on EEG and spontaneous behavior of rats.

Title: H3K9 acetylation profile and behavioral changes in response to arsenic exposure

Authors: *N. F. FITZ, K. NAM, A. MOUNIER, E. L. CASTRANIO, R. KOLDAMOVA, I. LEFTEROV;
Envrn. and Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Alzheimer's disease is characterized by a complex cascade of pathological hallmarks which are affected by different genes and environmental factors, as well as gene-gene and gene-environment interactions. Dietary patterns, exposure to environmental toxicants, intellectual and physical activity, as well as cardiovascular disease and Type 2 Diabetes, display some of the highest AD association. The molecular mechanisms of these factors underlying the increased susceptibility to, earlier development or aggravated course of the disease remain poorly understood. Molecular links between certain environmental exposures/factors and AD could result in altered regulatory and metabolic pathways due to dysregulation in transcription factor binding, or epigenetic changes known to influence synaptic transmission, memory and cognitive performance. Previously we showed that Early Growth Response 1 (EGR1) transcription factor regulates the constitutive expression of genes involved in vesicular transport and synaptic transmission that may be critical for memory and cognition. Here we demonstrate changes in H3K9 acetylation profile in the proximal promoter of mouse Egr1 in response to prenatal arsenic exposure and normal diet. We also found a significant decrease in the levels of Egr1 mRNAs in the brain of offspring following in-utero exposure, as well as in 2 month old mice exposed to human relevant 100 parts/billion (100 μg/L) arsenic in drinking water. These genomic changes were related to diminished memory function as tested by contextual fear conditioning. This illustrates the potential of environmental toxicants to impact molecular mechanisms also affected by AD possibly aggravating the course of the disease.

Title: Therapeutic ionizing radiation-induced cognitive deficits: Modulation by the neurosteroid progesterone

Authors: *F. ATIF, S. YOUSUF, J. WANG, D. G. STEIN;
Emergency Med., Emory Univ., Atlanta, GA

Abstract: Despite continuous improvements, CNS toxicity of cancer treatments remains an important issue and a major cause of morbidity in cancer patients. The brain is reported to be susceptible to both high and low doses of ionizing radiation (IR), but whereas high-dose radiation exposure may lead to tissue damage, low-dose radiation exposure insidiously affects cognitive functions without causing noticeable tissue injury. We examined the neuroprotective effects of the neurosteroid progesterone (PROG) against IR-induced cognitive deficits in mice. Male C57/BL mice (non-tumor-bearing; 5-6 weeks) were exposed to two different fractionated doses of IR (3 Gy x 3 and 3 Gy x 5). PROG (16 mg/kg; single injection daily) was given as a pre-treatment (starting 3 days prior to IR treatment), concurrent treatment (during the IR treatment for 3 or 5 days), and 8 or 6 days post-IR treatment for a total of 14 days, with tapering during the last two days. Mice were tested for short- and long-term effects of IR and PROG on memory function on days 10 and 30 day after IR treatment. The spontaneous locomotor activity test revealed a significant ($P<0.001$) decrease in total distance travelled and movement time in both IR groups at both 10 and 30 days post-IR. PROG treatment showed significant ($P<0.01$) improvement at both time points. A significant ($P<0.001$) increase in resting time was observed in IR-treated groups at both 10 and 30 days post-IR. PROG treatment significantly ($P<0.01$) reduced the resting time in both IR groups at both time points. An elevated plus maze test was performed to measure anxiety-like behavior. A significant ($P<0.001$) increase in time spent in the open arms and the number of entries into the open arms was observed in both IR-treated groups at both 10 and 30 days post-IR. PROG treatment significantly ($P<0.01$) reduced the anxiety-like behavior in both IR groups at both time points. A Morris water maze test was performed between days 30-35 post-IR treatment. We observed significant ($P<0.001$) deficits in short- and long-term memory function in both IR groups. PROG treatment showed a significant ($P<0.001$) improvement in both short- and long-term memory function. There was no significant difference in the degree of deficit in any test between two doses of IR at either time point. Our data suggest that PROG could help to reduce the side effects of radiation, leading to a better quality of life for the cancer patient.

Title: Omic analyses identify lipid and bioenergetic disturbances in the brains of a GWI mouse model at 16-months post-exposure

Authors: *L. ABDULLAH[1], J. E. EVANS[1], H. MONTAGUE[2], G. CRYNEN[1], J. REED[1], T. NGUYEN[1], M. HOWLAND[1], B. MOUZON[1], Z. ZAKIROVA[1], T. EMMERICH[1], D. PARIS[1], G. AIT-GHEZALA[1], M. MULLAN[1], C. BACHMEIER[1], F. CRAWFORD[1];

Abstract: Veterans from the 1991 Gulf War (GW) suffer from Gulf War Illness (GWI), which remains untreatable due to its multi-symptom presentation. Since evidence suggests an involvement of the central nervous system (CNS) in GWI, we applied omics to identify biological disturbance within the brains of a mouse model of GWI. Barnes maze was performed to examine cognition and neuropathology to detect astroglia and microglia activation at 16-months following an acute exposure to GW agents, pyridostigmine-bromide (anti-nerve agent) and permethrin (a pesticide). Proteomics, lipidomics and metabolomics were performed on the brain tissue. Lipid transport was examined using an *in vitro* blood brain barrier (BBB) system. Protein changes corresponded with lipid transport and metabolism and bioenergetic disturbances

in exposed mice compared to controls. Phospholipid, citric acid cycle metabolites and lactate levels were reduced in GW agent exposed mice. A high ratio of arachidonic acid (AA) to docosahexaenonic acid (DHA) was detected in exposed mice. *In vitro* BBB studies suggested an imbalance in AA and DHA transport following exposure. In conclusion, lipid metabolism and transport and bioenergetic abnormalities are chronic CNS features of GWI in a mouse model, which could be targeted for the development of therapies for GWI.

Title: Neuronal and microglial cells differ in their sensitivity to glutamate toxicity

Authors: *H. O. AWWAD, S. DONG, A. EDWARDS;
Pharmaceut. Sciences, Col. of Pharm., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Excessive glutamate release in traumatic brain injury and neurodegenerative diseases like Alzheimer's disease causes cellular damage known as excitotoxicity. This toxicity in neurons has the ability to enhance phosphorylation of the tau protein, a microtubule stabilizer, and leads to the destabilization of microtubules and cell apoptosis. Microglial cells are the resident immune cells in the central nervous system and similar to astrocytes, they play a neuroprotective role by converting glutamate into glutamine. Recent reports indicate the presence of glutamate receptors on microglia. Our aim from this study was to determine whether glutamate toxicity causes tau phosphorylation in the microglia, like it does in neurons. Human neuroblastoma SH-SY5Y and microglial murine BV2 cells were treated with high concentrations of glutamate (5, 10, 15, 25 and 50mM) for 20-24 hours. Cellular morphology and cell viability were observed, and cell lysates were collected to determine tau phosphorylation at serine 404. Toxic concentrations of glutamate decreased cell viability in both cell lines using an MTT assay. However, SH-SY5Y cell lines were more sensitive, showing a significant decrease in cell

viability at both 25 and 50 mM glutamate whereas BV2 cells only showed a decrease in cell viability at 50 mM glutamate. Tau phosphorylation immunoblotting indicates that tau phosphorylation at serine 404 occurred at 5 and 10 mM Glutamate concentrations in SH-SY5Y and not in microglial BV2 cells (n=2-4). This study suggests that the lack of tau phosphorylation in microglial cells following glutamate toxicity may explain another mechanism by which microglial cells could survive harsher conditions following a brain injury than neurons. Understanding the underlying neurobiology may shed light on potential neuroprotective mechanisms and therapeutic targets against glutamate toxicity.

Title: Targeting chemobrain: a novel mechanism to prevent chemotherapy induced cognitive deficits in C57Bl/6 mice

Authors: *P. HUEHNCHEN, W. BOEHMERLE, M. ENDRES;
Charite Universitätsmedizin Berlin, Berlin, Germany

Abstract: Neurotoxicity to the peripheral and central nervous system caused by chemotherapy present a yet unsolved medical problem. Especially post-chemotherapy cognitive impairment (PCCI) or “chemobrain” has become a growing concern to cancer patients worldwide. Research on the topic is relatively scarce and the pathomechanisms involved poorly understood. The goal of this study was to characterize behavioral as well as histological changes induced by paclitaxel therapy in mice and to establish a preventive treatment based on the underlying pathophysiological processes. Adult C57Bl/6 mice were injected with a total of 12 × 20 mg/kg bodyweight paclitaxel or vehicle respectively over the course of 4 weeks 3 times a week (dose-dense therapy). The treatment was in general well tolerated with limited weight loss. Animals receiving paclitaxel developed an axonal sensory polyneuropathy as previously described. In

addition, using the Morris water maze we observed impaired spatial learning and memory after paclitaxel treatment, but no alterations regarding motor performance or changes of affective behaviors or anxiety. Histological assessment revealed a decrease in hippocampal neuroneogenesis in paclitaxel-treated animals with reduced numbers of newly generated doublecortin-positive and NeuN-positive cells. Evaluation of pharmacokinetics showed nanomolar paclitaxel concentrations in the hippocampus up to 2 hours post injection. Comparable amounts of paclitaxel induced apoptotic cell death in cultured adult mouse neural stem cells (NSCs) via a calcium and calpain mediated mechanism. The observed molecular effects were distinct from the cytostatic effect of paclitaxel and could be specifically inhibited by lithium (Li+) *in vitro*. Subsequently, we tested co-treatment of mice with Li+, which prevented paclitaxel-induced changes in spatial learning as well as peripheral neuropathy and normalized neurogenesis in the dentate gyrus. Taken together, this study uses a mouse model of dose-dense paclitaxel therapy to characterize pharmacokinetics, behavioral and histological alterations as well as a putative molecular mechanism underlying paclitaxel-induced PCCI. Based on these results, we established a strategy to prevent neurotoxic side effects of paclitaxel-therapy in the central and peripheral nervous system.

Title: Immunohistochemical study of nrf2-antioxidant response element as of oxidative stress induced by cadmium in developing rats

Authors: *M. MENDEZ-ARMENTA, S. MONTES, D. JUÁREZ-REBOLLAR, C. NAVA-RUÍZ, A. SÁNCHEZ-GARCÍA, Y. HERAS-ROMERO, C. RIOS, A. DIAZ-RUÍZ;
Natl. Inst. Neurol Neurosurg., Mexico City, Mexico

Abstract: In developing animals, Cadmium (Cd) induces toxicity to many organs including brain. Reactive oxygen species (ROS) are often implicated in Cd-inducedtoxicity and it has been clearly demonstrated that oxidative stress interferes with the expression of genes as well as transcriptional factors such asNrf2-dependent Antioxidant Response Element (Nrf2-ARE). Cd-generated oxidative stress and elevatedNrf2 activity have been reported *in vitro* and *in situ* cells. In this study we evaluated the morphological changes and the expression pattern ofNrf2 and

correlated them with the Cd concentrations in different ages of developing rats in heart, lung, kidney, liver, and brain. The Cd content in different organs of rats treated with the metal was increased in all ages assayed. Comparatively, lower Cd brain levels were found in rats intoxicated at the age of 12 days, then pups treated at 5, 10, or 15 days old, at the same metal dose. No evident changes, as a consequence of cadmium exposure, were evident in the morphological analysis in any of the ages assayed. However, Nrf2-ARE immunoreactivity was observed in 15-day-old rats exposed to Cd. Our results support that fully developed blood-brain barrier is an important protector against Cd entrance to brain and that Nrf2 increased expression is a part of protective mechanism against cadmium-induced toxicity.

Title: Chemical warfare agent-induced gene expression changes in blood and potential use as diagnostic biomarkers

Authors: *H. M. HOARD-FRUCHEY[1], C. C. ROTHWELL[1], A. A. MELBER[1], C. S. HOFMANN[1], K. D. MOTTER[1], J. W. SEKOWSKI[2];
[1]USAMRICD, Aberdeen Proving Ground, MD; [2]USAECBC, Aberdeen Proving Ground, MD

Abstract: Chemical warfare nerve agents (CWNAs) are a class of cholinesterase inhibitors that are extremely potent. The recent use of the organophosphate sarin in Syria reiterates the devastating effects that these agents can have on human health and mortality. These agents bind to and disrupt the function of acetylcholinesterase, resulting in the accumulation of the neurotransmitter acetylcholine and a variety of symptoms including miosis, excessive secretions, convulsions, seizure, and death. Point-of-care diagnostic tests to identify CWNA exposure and/or to evaluate treatment efficacy are currently unavailable. In this study, the mRNA expression changes induced by the CWNA VX in the blood were determined to initiate identification of potential biomarkers for diagnosis of CWNA exposure and indicators of treatment efficacy for

peripheral and central medical countermeasures. Adult male Sprague-Dawley rats were exposed to 0.4, 0.7, or 1.0 x LD_{50} VX (i.v.), and trunk blood was collected at 1, 2, 4, 8, or 24 hours post-exposure. Total RNA was isolated and processed for mRNA hybridization to Affymetrix GeneChip HT RG-230 PM for microarray analysis. Principal component analysis (PCA) identified VX dose and not time as the greatest source of variability within the dataset. Analysis of variance (ANOVA) was performed to identify nerve agent-induced changes in gene expression over time. Using the 1.0 x LD_{50} VX data, canonical pathways significantly affected were identified and compared across the five post-exposure time points. Six canonical pathways were common to all time points. However, 2-, 4-, and 8-hour time points displayed the largest number of common canonical pathways (26 pathways). Genes with altered expression within these common canonical pathways were identified as potential biomarkers for VX exposure. Thirty-one genes were identified as differentially expressed for at least three time points. These candidate mRNA biomarkers are being evaluated to down select an mRNA panel for further development. *Disclaimer: The views expressed are those of the author(s) and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government. Title: Insulin-like growth factor-1 accelerates recovery from botulinum neurotoxin-induced paralysis

Authors: *J. P. APLAND[1], C. H. PHUNG[1], E. J. GLOTFELTY[2], T. M. RUSSO[2], P. M. MCNUTT[2], M. ADLER[1];
[1]Neurobehavioral Toxicol, [2]Cell. and Mol. Biol., USAMRICD, Gunpowder, MD

Abstract: Recovery from paralysis induced by botulinum neurotoxin serotype A (BoNT/A) is slow, requiring >90 days for restoration of muscle function and mass in the locally injected rat extensor digitorum longus (EDL) muscle. Several years may be required for complete recovery in severely intoxicated humans. In previous studies, we investigated the effects of local intramuscular injection of insulin-like growth factor-1 (IGF) on recovery from BoNT/A-induced paralysis. IGF was injected 1, 3, and 5 days after injection of BoNT/A into left EDL (LEDL) muscles of adult male rats and 3 times/week thereafter for 7, 14, 21, and 28 days. The right EDL muscle of each rat served as an uninjected control. A control group received BoNT/A injections into LEDL muscles at the same time as the experimental group, but no IGF injections. In the latest studies we injected IGF subcutaneously to more closely resemble the human dose paradigm. At the specified times after BoNT/A injections, *in situ* muscle tension measurements were performed, rats were euthanized, and EDL muscles were removed, weighed, and fixed for assessment of atrophy. Results indicate that LEDL muscle mass in rats injected with IGF recovered more rapidly than in rats injected with BoNT/A only. Muscle tensions in LEDL muscles of IGF-injected rats were also higher at all stimulus frequencies than in BoNT/A-only rats. In histological sections, the IGF-treated muscles exhibited significantly less injury and atrophy. Immunocytochemical techniques confirmed that BoNT/A intoxication elicited significant changes in muscle fiber diameter; these changes were rescued by IGF injections. IGF treatment furthermore reduced BoNT/A-induced axonal sprouting and preserved endplate organization. These results suggest that treatment with IGF may have therapeutic value in accelerating recovery from BoNT/A-induced paralysis. The experimental protocol was approved by the Animal Care and Use Committee at the USAMRICD and all procedures were conducted in accordance with the principles stated in the Guide for the Care and Use of Laboratory Animals and the Animal Welfare Act of 1966 (P.L. 89-544), as amended. The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.

Abstract: Our previous studies show that stressful situations alone could induce breakdown of the blood-brain barrier (BBB) and neuronal damages. Thus, 8 h immobilization stress, a model of depression in rats leads to leakage of albumin in 14 brain areas that persisted even 24 h after withdrawal of the stress stimuli. This suggests that stress could induce long-term changes in the brain by breakdown of the BBB. There are evidences that long-term stress or stressful life in humans is somehow related to the development of Alzheimer's disease (AD) in their old ages as compared to their stress free counterparts, a possibility arises that breakdown of the BBB in stress could play critical roles. Thus, in present investigation we wanted to know whether AD induced brain pathology caused by amyloid beta peptide (AβP) infusion is exacerbated when the peptide is infused in rats after repeated immobilization stress enough to open the BBB to large molecules e.g., proetins. For this purpose, AβP (1-40) was administered intraventricularly (i.c.v.) in the left lateral ventricle (250 ng/10 µl) of rats (250-300 g body weight) once daily for 4 weeks in naïve animals as well as in rats that were subjected to repeated immobilization stress 2 h daily for 1 week. Control rats received identical dose of saline instead of AβP. In these control and

AβP infused rats BBB breakdown, edema formation, neuronal, glial injuries and AβP deposits in the brain was examined in a blinded fashion by at least 3 independent workers. Our observations showed that repeated 2 h stress for 1 week induced marked BBB breakdown to Evans blue albumin and radioiodine tracers in the cerebrla cortex (55 to 78 %), hippocampus (89 to 98 %), thalamus (34 to 46 %), hypothalamus (35 to 50 %), caudate nucleus (78 to 97 &), cerebellum (80 to 134 %) and brainstem (23 to 35 %) from the naive rats. Infusion of AβP in these stressed rats further enhanced the BBB breakdown to protein tracers by 3- to 5-fold and resulted in pronounced neuronal damages (+400 %), astrocytic activation (+350 %) and brain swelling (+10 %) compared to identical AβP infusion in naive rats. The number of AβP positive cells increased by 3- to 6-fold in these brain areas in stressed group as compared to naive rats. Co administration of PLGA nanoparticles (NPs) loaded cerebrolysin (2.5 ml/kg, i.v. /day from 2nd week of AβP infusion for 2 weeks) induced profound neuroprotection in stressed rats, whereas 5 ml normal cerebrolysin is needed to attenuate brain pathology after AβP infusion in these rats. Taken together our observations are the first to demonstrate that repeated stress exacerbates AD pathology in brain and nanodelivery of cerebrolysin has superior neuroprotective effects in AD.

Abstract: Gold nanoparticles (AuNPs) are now being used to delivery of drugs to treat Alzheimer's disease (AD), Parkinson's Disease, Stroke and other neurological disorders. Also AuNPs are used for therapeutic or diagnostic purposes in various diseases in clinical medicine. However, the neurotoxic effects of AuNPs are still not well known. Thus, it would b interesting to examine AuNPs neurotoxicity *in vivo* models and to study size related effects of AuNPs on brain pathology. In this investigation we examined the effects of moderate doses of AuNPs of various sizes (5 nm, 10 nm and 40 nm) administered though either intraperitoneally (10 mg/kg, i.p.), intravenously (5 mg/kg, i.v.), intracarotidly (2 mg/kg, i.c.a.) or intracerebroventricularly (20 µg in 20 µl, i.c.v.) in young healthy adult rats (Age 20 to 25 weeks). In these animals blood-brain barrier (BBB) breakdown to Evans blue albumin (EBA 3 ml/kg, i.v.) and [131]-Iodine (100 µCi/kg, i.v.) was examined 24 h after AuNPs administration in the cerebral cortex, hippocampus, thalamus, hypothalamus, cerebellum and brainstem. In these brain regions edema was measured and neuronal injury was examined by Nissl or H&E staining using histopathological techniques. The astrocytic activation was evaluated using immunohistochemistry of glial fibrillary acidic protein (GFAP). Our observations showed marked BBB breakdown (80 to 150 %) in all the above brain areas after administration of 5 to 10 nm AuNPs irrespective of the routs of administration after 24 h as compared to saline treated control group. AuNPs i.p. administration showed a mild but significant increase in BBB breakdown as compared to i.v. administration. Intracarotid administration exhibited more profound leakage of these tracers where I the injected side of the brain whereas i.c.v. administration showed leakage of tracers on the surface of the dorsal side of the brain that was most marked. The other brain areas were less intense in BBB breakdown. Brain edema and neuronal injuries were tightly correlated with BBB breakdown of EBA. Activation of astrocytes was also evident in the areas of neuronal damage and BBB leakage. Interestingly, larger sized AuNPs (40 nm) was not that effective in BBB breakdown either given through i.p., i.v., and i.c.a. or i.c.v. routes. In this group neuronal injuries and brain edema formation was also not much evident. These observations are the first to show that AuNPs induced neurotoxicity is inversely related the size. Smaller AuNPs may have most marked neurotoxic effects than the larger size of AuNPs. Whether co-administration of neuroprotective

drugs e.g., cerebrolysin could attenuate AuNPs neurotoxicity, a feature require further investigation.

Title: Cerebrolysin reduces exacerbation of nitric oxide synthase, hemeoxygenase and associated blood-brain barrier breakdown and neuropathology following heat stroke in diabetes

Authors: *D. F. MURESANU[1], A. SHARMA[2], A. NOZARI[3], R. PATNAIK[4], J. V. LAFUENTE[5], H. MOESSLER[6], A. OZKIZILCIK[7], Z. R. TIAN[7], H. S. Abstract: Nitric oxide (NO) and carbon monoxide (CO) are free radical gases. Central nervous system (CNS) contains their synthesizing enzymes within the neurons, glial and endothelial cells in forms of nitric oxide synthase (NOS) and hemeoxygenase (HO) abundantly. When these enzymes are activated by trauma, ischemia or CNS insults their activation results in formation of NO and CO from NOS and HO, respectively. Previous studies from our laboratory sowed that a focal spinal cord injury (SCI) resulted in massive expression of NOS and HO in the cord that is positively related with breakdown of the blood-brain barrier (BBB), edema formation and neuronal injuries. However, when brain derived neurotrophic factor (BDNF) or glial derived neurotrophic factor (GDNF) were given topically after SCI, these growth factors are able to thwart NOS and HO production in the cord leading to neuroprotection. This suggests that growth factors may attenuate production of these free radical gases after trauma resulting in neuroprotection. Interestingly, upregulation of NOS and HO is also seen following whole body hyperthermia (WBH) at 38° for 4 h that induces clinical symptoms of brain pathology and heat stroke (HS). When diabetic rats were subjected to identical WBH the stoke symptoms and brain pathology is exacerbated. However, upregulation of NOS and HO in diabetic rats after WBH is not well known. Thus, a possibility exists the diabetic rats after WBH may induce greater overexpression of NOS and HO and that could also be reduced by growth factors treatment. Since cerebrolysin is a balanced composition of several neurotrophic factors and active peptide fragments that reduces WBH pathology in normal and diabetic rats, in this investigation we examined the influence of nanodelivered cerebrolysin on NOS and HO upregulation in diabetic rats after WBH in relation to brain pathology in our rat model. Our observations showed that WBH in diabetic rats resulted in 90 to 130 % overexpression of neuronal NOS (nNOS) and constitutive isoform of HO (HO-2) in the cerebrla cortex, hippocampus, caudate nucleus, thalamus, hypothalamus, cerebellum and brain stem than normal animals. In these animals BBB breakdown, brain edema and neuronal injuries were also exacerbated by 50 to 140 %. Treatment with TiO2 nanodelivered cerebrolysin (2.5 ml/kg, i.v.) or normal cerebrolysin (10 ml/kg, i.v.) 1 or 2 h after a 4 h WBH session resulted in significant neuroprotection and reduction in NOS and HO expression in these brain areas. These observations are the first to show that cerebrolysin is capable to attenuate HO and NOS production in heat stroke resulting in neuroprotection, not reported earlier.

Title: Nicotine neurotoxicity in cold environment is exacerbated by alcohol and carbon nanoparticles

Authors: *S. SHARMA[1], D. F. MURESANU[2], A. NOZARI[3], J. V. LAFUENTE[4], R. PATNAIK[5], A. SHARMA[6];
[1]Uppsala Univ., Uppsala, Sweden; [2]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [3]Anesthesiol. & Intensive Care, Massachusetts Gen. Hospital, Harvard Univ., Boston, MA; [4]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [5]Biomaterials, Indian Inst. of Technology, Banaras Hindu Univ., Varanasi, India; [6]Anesthesiol. & Intensive Care Med., Uppsala Univ. Hopsital, Uppsala, Sweden

Abstract: We have shown previously that nicotine exposure for 1 week significantly increases blood-brain barrier (BBB) breakdown to proetins and induces brain edema and neuronal damages in adult rats. Since nicotine consumed by smoking is often associated with tar inhalation, it is interesting to examine the effects of carbon nanoparticles (NPs) on brain damage induced by nicotine in our model. Furthermore, nicotine consumption is also associated with alcohol intake in the society we also examined a combined effects of alcohol and nicotine on brain pathology. Our previous works showed that nicotine exposure in cold exacerbated brain pathology. Thus, in present investigation, the additional effects of carbon NPs or alcohol in combination with nicotine was also evaluated in animals exposed at cold environment. Rats were treated with nicotine (9 mg/kg/day, s.c.) at room temperature (21±1°C) or at cold environment (8±1°C in a Biological oxygen demand incubator, BOD) for 1 week. In separate group of animals exposed at 21±1°C or 8±1°C, co-administration nicotine and Ethyl alcohol (EtOH, 1.5 g/kg, i.p./day) or carbon NPs (single wall carbon nanotube SWCNT, 10 mg/kg/day, i.p.) was done for 1 week. On the 8th day the BBB permeability to protein tracers (Evans blue albumin, EBA 3 ml/kg, i.v. and [131]-I-Na 100 μCi/kg, i.v.), brain edema (water content) and brain

pathology (neuronal damage using Nissl or H&E on paraffin sections) were evaluated in all the groups in a blinded fashion. Our results show that a combination of nicotine and alcohol exacerbated BBB leakage (EBA by 240 % and radioiodine 300 %), brain edema (water content +1.5 %, volume swelling % *f* 6%) and neuronal injury in the cerebral cortex (120 %) and hippocampus (190%) from nicotine alone at room temperature. Whereas, these changes on BBB, brain edema and neuronal damage were further aggravated by 80 to 120 % at cold environment. Interestingly, the combination of nicotine and SWCNT at cold environment exacerbated brain pathology by 240 to 300 %. On the other hand, only 50 to 90% increase in brain pathology, BBB and edema formation was seen in these rats at room temperature as compared to nicotine alone. These observations are the first to show that the neurotoxicity of nicotine with alcohol combined is exacerbated in cold environment. Furthermore, neurotoxicity caused by nicotine and tar combination is more pronounced at cold environment than nicotine and alcohol combined. It remains to be seen whether a combination of nicotine, alcohol and tar could have further additive brain damaging effects, a feature that is currently being investigated in our laboratory.

Abstract: MicroRNAs (miRNAs), small noncoding RNAs, regulate the expression of more than 60% genes and thereby control many cellular processes. The canonical miRNA biogenesis pathway begins in the nucleus with the cleavage of the primary transcripts by the nuclear RNAase III enzyme Drosha. Emerging evidence suggests that the miRNA biogenic cascade may be tightly controlled. Our data show that Drosha is targeted by multiple stress signals. Under stress, p38 MAPK directly phosphorylates Drosha at its N-terminus. This reduces its interaction with DiGeorge syndrome critical region 8, promotes its nuclear export, and facilitates its degradation by calpain. This regulatory mechanism mediates stress-induced inhibition of Drosha. Reduction of Drosha activity sensitizes cells to stress and increases cellular death. Increase in Drosha attenuates stress-induced death. We further confirmed the regulation of Drosha plays a key role in neuronal stress. These findings reveal a critical regulatory mechanism by which stress engages p38 MAPK pathway to destabilize Drosha and thereby inhibit Drosha-mediated neuronal survival.

Title: Regulation of nuclear microRNA processing by MeCP2 and impact on dendritic growth

Authors: *T.-L. CHENG, Z. QIU;
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai, China

Abstract: Methyl-CpG binding protein 2 (MeCP2) is encoded by X-linked gene MECP2 and its loss- and gain-of-function mutation lead to severe neurodevelopmental disorders such as Rett syndrome and Autism spectrum disorders. MeCP2 is initially recognized as a transcriptional repressor as it recruits HDAC (Histone deacetylase)-mSin3A corepressor complex to methylated DNA sites. It has also been reported that MeCP2 could modulate gene expression post-transcriptionally by regulating microRNA expression. Here we showed that in addition to transcriptional regulation, MeCP2 could suppress nuclear microRNA processing via binding to DiGeorge syndrome critical region 8(DGCR8) directly, a critical component of the nuclear microRNA processing machinery, leading to the disrupted assembly of Drosha/DGCR8 complex. Further analysis showed that MeCP2 C-terminus is the key region for its interaction with DGCR8 but not its DNA binding domain. Protein targets of MeCP2-suppressed microRNAs include CREB, LIMK1 and Pumilio2, which are key factors of neural development. And neuronal morphogenesis such as dendritic development is impaired significantly by autism-associated gain-of-function mutations of MeCP2 and such impairment relies on the interaction of MeCP2 and DGCR8. Thus, control of microRNA processing via direct interaction with DGCR8 represents a novel mechanism for MeCP2 regulation of gene expression and neural development.

Title: Loss of Drosha underlies Abeta-induced neurotoxicity

Authors: *Z. MAO[1], W. LI[1], H. SHE[1], J. DOU[1], R. COHEN[2], G. GAO[3], Q. YANG[3];
[1]Dept Pharmacol & Neurol, [2]Dept Psychiatry, Emory Univ. Sch. Med., Atlanta, GA;
[3]Neurosurg., The Fourth Military Med. Univ., Xi'an, China

Abstract: MiRNAs (microRNAs) are a recently discovered class of non-coding small RNAs that are involved in regulating many cellular processes including stress. Its biogenesis is controlled by several tightly coupled sequential steps initiated in the nucleus by the conversion of the long primary miRNA transcripts to the precursor miRNA by the RNase III enzyme Drosha and subjected to complex regulation. Stress conditions and miRNAs are highly intertwined at several levels. Multiple lines of evidence indicate that miRNAs are especially important to the brain function, modulate pathways and key genes relevant to genetic and sporadic AD, and are themselves altered in AD. Furthermore, inhibition of miRNA biogenesis by deleting Dicer causes progressive neurodegeneration and AD-like tau hyperphosphorylation. However, how these findings translate into animal AD models and human disease remains to be tested. Recently, we have revealed a novel mechanism by which stress induces a p38 MAPK dependent phosphorylation and inhibition of Drosha and triggers cell death. Our unpublished preliminary studies indicate that neuronal stress engages this pathway. Various toxic signals activate p38 MAPK in neurons and induces a p38 MAPK dependent phosphorylation of Drosha. This results in disruption of the microprocessor complex in the neuronal nucleus, leading to Drosha export to the cytoplasm and its degradation. Aβ engages this pathway to trigger dysregulation of Drosha in model specimens. Together, these findings suggest that loss of Drosha may underlie in part Aβ toxicity and possibly the neurodegenerative process in AD.
